(21). The fetus had trisomy for group C autosomes without mosaicism. A second pregnancy in the same patient with identical therapy ended normally. In another case, a 34-year-old woman with acute lymphoblastic leukemia was treated with multiple antineoplastic agents from 22 weeks' gestation until delivery of a healthy female infant 18 weeks later (28). Cytarabine was administered only during the 27th week of gestation. Chromosomal analysis of the newborn revealed a normal karyotype (46,XX) but with gaps and a ring chromosome. The clinical significance of these findings is unknown, but because these abnormalities may persist for several years, the potential existed for an increased risk of cancer as well as for a risk of genetic damage in the next generation (28). Two women, one treated during the 1st trimester and the other treated throughout pregnancy, delivered infants with the following multiple anomalies:

Bilateral microtia and atresia of external auditory canals, right hand lobster claw with three digits, bilateral lower limb defects (29)

Two medial digits of both feet missing, distal phalanges of both thumbs missing with hypoplastic remnant of the right thumb (30)

Congenital anomalies have also been observed after paternal use of cytarabine plus other antineoplastics prior to conception (31). The investigators suggested that the antineoplastic agents may have damaged the sperm without producing infertility in the two fathers. The relationship between use of the chemotherapy in these men and the defects observed is doubtful due to the lack of experimental evidence and confirming reports. The results of these pregnancies were as follows: tetralogy of Fallot, syndactyly of first and second digits of right foot, and a stillborn with anencephaly. Cytarabine may produce reversible azoospermia (32,33). However, male fertility has been demonstrated during maintenance therapy with cytarabine (34).

Pancytopenia was observed in a 1000-g male infant exposed to cytarabine and five other antineoplastic agents during the 3rd trimester (12).

Data from one review indicated that 40% of the mothers exposed to antineoplastic drugs during pregnancy delivered low-birth-weight infants (35). This finding was not related to the timing of exposure. Except for the few cases noted above, long-term studies of growth and mental development in offspring exposed to cytarabine during the 2nd trimester, the period of neuroblast multiplication, have not been conducted (36).

Occupational exposure of the mother to antineoplastic agents during pregnancy may present a risk to the fetus. A position statement from the

National Study Commission on Cytotoxic Exposure and a research article involving some antineoplastic agents are presented in the monograph for cyclophosphamide (see Cyclophosphamide).

BREASTFEEDING SUMMARY

No reports describing the use of cytarabine during lactation have been located. Because of the potential for serious adverse effects in nursing infants, women receiving this drug should not breastfeed.

D

DABIGATRAN ETEXILATE

Anticoagulant (Thrombin Inhibitor)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of dabigatran etexilate in human pregnancy have been located. The animal data suggest moderate risk, but the absence of human pregnancy experience prevents a more complete assessment of the embryo–fetal risk. Until such data are available, other anticoagulants, such as the low-molecular-weight heparins, appear to be a better choice in pregnancy.

FETAL RISK SUMMARY

Dabigatran etexilate is a direct thrombin inhibitor that is given orally. It is indicated to reduce the risk of stroke and systemic embolism in patients with nonvalvular atrial fibrillation. After oral dosing, dabigatran etexilate is converted to dabigatran, the active agent. Dabigatran is further metabolized to four different acyl glucuronides, all of which have similar activity to dabigatran. Plasma protein binding is about 35% and the half-life is 12–17 hours (1).

Reproduction studies have been conducted in rats and rabbits. In pregnant rats, a dose that was about 2.6–3 times the human exposure from the maximum recommended dose of 300 mg/day based on AUC (MRHD) given after implantation resulted in an increase in dead offspring and caused excess vaginal/uterine bleeding close to parturition. This dose also increased the incidence of delayed or irregular ossification of fetal skull bones and vertebrae. However, the drug did not induce major malformations in the rat or rabbit (dose

in rabbits not specified). The number of implantations was decreased when dabigatran was given to male and female rats before mating and up to implantation at the above dose (1).

In 2-year studies, dabigatran was not carcinogenic in mice and rats. The drug was not mutagenic in multiple assays. No adverse effects on male and female rat fertility were observed, but, as noted above, the drug decreased the number of implantations when given up to implantation (gestation day 6) (1).

It is not known if dabigatran etexilate or dabigatran crosses the human placenta. The molecular weights of the parent compound and dabigatran (about 628 and 499 for the free bases), low plasma protein binding, and the long elimination half-life suggest that it will cross to the embryo–fetus. However, without referencing, a 2010 review of new oral anticoagulants stated that dabigatran does not cross the placenta (2).

BREASTFEEDING SUMMARY

No reports describing the use of dabigatran etexilate during human lactation have been located. The molecular weight of the parent compound (about 628 for the free base), low plasma protein binding (about 35%), and the long elimination half-life (12–17 hours) suggest that the drug and its active metabolites will be excreted into breast milk. The effect of the exposure on a nursing infant is unknown, but the drug is absorbed orally. Until such data are available, use of other anticoagulants, such as the low-molecular-weight heparins, should be considered.

DACARBAZINE

Antineoplastic

PREGNANCY RECOMMENDATION: Contraindicated—1st Trimester

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Dacarbazine is an alkylating antineoplastic agent. Other agents in this class (see also Busulfan, Chlorambucil, and Cyclophosphamide) are known to be human teratogens and, combined with the animal data, strongly suggest that dacarbazine should not be given in the 1st trimester.

FETAL RISK SUMMARY

Single intraperitoneal doses of 800 or 1000 mg/kg in pregnant rats produced skeletal reduction defects, cleft palates, and encephaloceles in their offspring (1).

Dacarbazine was used for the treatment of melanoma in the 1st trimester of one pregnancy (2). The pregnancy was electively aborted. In a second case, a woman at 21 weeks', received two cycles of chemotherapy for Hodgkin's disease (3). Each cycle consisted of dacarbazine (375 mg/m² IV, days 1 and 14), doxorubicin, bleomycin, and vinblastine. At 29 weeks', a healthy, 2400-g female infant was born, who is alive and well at 10 years of age.

No congenital malformations were observed in four live-born offspring of one male and another female treated with dacarbazine during childhood or adolescence (4). In a 2002 study, 1915 women had 4029 pregnancies after chemotherapy with or without radiation (5). No statistical differences in pregnancy outcomes (live births and spontaneous abortions) by treatment group were found, including the 170 pregnancies in women treated with dacarbazine.

Occupational exposure of the mother to antineoplastic agents during pregnancy may present a risk to the fetus. A position statement from the National Study Commission on Cytotoxic Exposure and a research article involving some antineoplastic agents are presented in the monograph for

cyclophosphamide (see Cyclophosphamide).

BREASTFEEDING SUMMARY

No reports describing the use of dacarbazine during lactation have been located. Because of the potential for severe adverse effects, such as hematopoietic depression in a nursing infant, the drug should not be used during breastfeeding.

DACLIZUMAB

Immunologic Agent (Immunosuppressant)

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >> Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of daclizumab in human pregnancy have been located. The lack of animal and human pregnancy experience prevents an assessment of the embryo–fetal risk. However, basiliximab, an antibody with a similar mechanism of action, did not cause noticeable developmental toxicity in cynomolgus monkeys. (See Basiliximab.) A 2004 review concluded that immunosuppressive antibodies have little implication for pregnancy because they are used either for induction immunosuppression or to prevent an acute rejection episode (1). If exposure does occur during pregnancy, the risk for developmental toxicity is unknown but may be low. Long-term studies of exposed offspring for functional abnormalities and other developmental toxicity are warranted. The manufacturer recommends that women of childbearing potential use effective contraception before and during therapy, and for 4 months afterward (2).

FETAL RISK SUMMARY

Daclizumab, an interleukin-2 (IL-2) receptor antagonist, is an immunosuppressive, humanized (90% human/10% murine) immunoglobulin G1 (IgG1) monoclonal antibody indicated for the prophylaxis of acute organ rejection in patients receiving renal transplants (2). Daclizumab is classified as a nondepleting (i.e., does not destroy T- or B-lymphocytes) protein immunosuppressant (3). It binds only to IL-2 receptor sites expressed on the surface of activated T-lymphocytes. This binding inhibits IL-2-mediated activation of lymphocytes. Daclizumab is used with immunosuppressive regimens that include cyclosporine and corticosteroids. The elimination half-life is about 20 days (2).

Reproduction studies have not been conducted with daclizumab (2).

It is not known if daclizumab crosses the human placenta. The molecular weight of the glycoprotein (about 144,000) may prevent transfer. However, the prolonged elimination half-life and the fact that IgG molecules are known to cross the placenta, at least in the 3rd trimester, suggest that some exposure of the embryo and/or fetus will occur.

IL-2 receptors may have an important role in the development of the immune system, but the potential effect of daclizumab on this development is unknown. While in the circulation, daclizumab impairs the response of the immune system to antigenic challenges. It is unknown if the ability to respond to these challenges returns to normal after clearance of daclizumab (2).

BREASTFEEDING SUMMARY

No reports describing the use of daclizumab during human lactation have been located. Because immunoglobulins and other large molecules are excreted into colostrum in the first 2–3 days after birth, daclizumab is also probably excreted during this time. It may not be possible to avoid exposure during this early period of lactation because of the prolonged elimination half-life (about 20 days). Excretion into mature milk also is possible. Although partial digestion of the antibody in the gastrointestinal tract is probable, the effect on a nursing infant from this exposure is unknown.

DACTINOMYCIN

Antineoplastic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest High Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

The human pregnancy experience is limited, none of which involved 1st trimester exposure. The animal data suggest high risk. If the drug must be used in pregnancy, exposure during organogenesis should be avoided.

FETAL RISK SUMMARY

Dactinomycin is an antimetabolic antineoplastic agent. It is in the same antineoplastic subclass of antibiotics as bleomycin and mitomycin.

Reproduction studies in the rat, rabbit, and hamster at IV doses 3–7 times the maximum recommended human dose has shown embryo and fetal toxicity and teratogenic effects (1).

Normal pregnancies have followed the use of this drug prior to conception (2–10). However, women were less likely to have a live birth following treatment with this drug than with other antineoplastics (6).

Eight women who were treated with dactinomycin in childhood or adolescence subsequently produced 20 liveborn offspring, 3 (15%) of whom had congenital anomalies (11). This rate was the highest among 14 antineoplastic agents studied. Another report, however, observed no major congenital malformations in 52 offspring born to 11 men and 25 women who had been treated with dactinomycin during childhood or adolescence, suggesting that the results of the initial study occurred by chance (12).

Reports on the use of dactinomycin in six pregnancies have been located (13–18). In these cases, dactinomycin was administered during the 2nd and 3rd trimesters and apparently normal infants were delivered. The infant from one of the pregnancies was continuing to do well 4 years after birth (15). Two

of the other pregnancies (16,17) are discussed in more detail in the monograph for cyclophosphamide (see Cyclophosphamide).

Data from one review indicated that 40% of the infants exposed to anticancer drugs were of low birth weight (13). This finding was not related to the timing of exposure. Long-term studies of growth and mental development in offspring exposed to dactinomycin during the 2nd trimester, the period of neuroblast multiplication, have not been conducted (19).

The long-term effects of combination chemotherapy on menstrual and reproductive function have been described in a 1988 report (20). Thirty-two of the 40 women treated for malignant ovarian germ cell tumors received dactinomycin. The results of this study are discussed in the monograph for cyclophosphamide (see Cyclophosphamide).

Occupational exposure of the mother to antineoplastic agents during pregnancy may present a risk to the fetus. A position statement from the National Study Commission on Cytotoxic Exposure and a research article involving some antineoplastic agents are presented in the monograph for cyclophosphamide (see Cyclophosphamide).

BREASTFEEDING SUMMARY

No reports describing the use of dactinomycin during human lactation have been located. Although its relatively high molecular weight (about 1255) should impede the excretion into milk, women receiving this drug should not breastfeed because of the potential risk of severe adverse reactions in the nursing infant.

DALFAMPRIDINE

Potassium Channel Blocker

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of dalfampridine in human pregnancy have been located. Although the animal data suggest risk, the complete absence of human pregnancy experience prevents an assessment of the embryo–fetal risk. If the drug is indicated in a pregnant woman, she should be advised of the absence of data.

FETAL RISK SUMMARY

Dalfampridine is a broad-spectrum potassium channel blocker that is taken as extended-release oral tablets. It is indicated to improve walking in patients with multiple sclerosis. The drug is metabolized to inactive metabolites. Plasma protein binding is very low (1%–3%) and the elimination half-life is 5.2–6.5 hours (1).

Reproduction studies have been conducted in rats and rabbits. In these species, oral doses up to about 5 times the maximum recommended human dose based on BSA (MRHD) revealed no evidence of developmental toxicity. Maternal toxicity was observed at the highest dose. When rats were given oral doses throughout pregnancy and lactation, decreased offspring survival and growth were observed. The no-effect dose for prenatal and postnatal developmental toxicity was about 0.5 times the MRHD (1).

There was no evidence of drug-induced carcinogenesis in 2-year studies in mice. However, a significant increase in uterine polyps was noted in rats at the highest dose tested (about 9 times the MRHD). In vitro and in vivo assays for mutagenesis were negative. The drug had no effect on the fertility of male and female rats (1).

It is not known if dalfampridine crosses the human placenta. The very low

molecular (about 94) and plasma protein binding combined with a moderately long elimination half-life suggest that the drug will cross to the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use of dalfampridine during human lactation have been located. The very low molecular weight (about 94) and plasma protein binding (1%–3%) combined with a moderately long elimination half-life (5.2–6.5 hours) suggest that the drug will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown. Exposed infants should be monitored for the most common adverse effects seen in adults, such as insomnia, headache, nausea, dizziness, constipation, and other reactions.

DALTEPARIN

Anticoagulant

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

The use of dalteparin during pregnancy appears to present no more fetal or newborn risk than that from standard, unfractionated heparin.

FETAL RISK SUMMARY

Dalteparin is a low-molecular-weight heparin prepared by depolymerization of heparin obtained from porcine intestinal mucosa. The molecular weight of dalteparin varies from <3000 to >8000, but 65%–78% is in the 3000–8000 range (1). Reproduction studies found no evidence of impaired fertility in male and female rats or fetal harm in rats and rabbits (1).

Because of its relatively high molecular weight, dalteparin is not expected to cross the placenta to the fetus (2). Thirty women undergoing elective pregnancy termination in the 2nd trimester (N = 15) or 3rd trimester (N = 15) for fetal malformations or chromosomal abnormalities were administered a single SC dose of 2500 IU or 5000 IU, respectively, of dalteparin immediately prior to the procedure (3). Heparin activity was not evident in fetal blood, demonstrating the lack of transplacental passage at this stage of gestation.

Dalteparin was administered as a continuous IV infusion at 36 weeks' gestation in a woman being treated for a deep vein thrombosis that had occurred during the 1st trimester (4). During the 1st trimester, she had been treated with IV heparin and then was maintained on SC doses for 4 weeks before developing an allergic reaction. Skin testing revealed immediate-type allergic reactions to heparin and some other derivatives but not to dalteparin. She was changed to warfarin therapy at 14 weeks' gestation, and this therapy was continued until the change to dalteparin at 36 weeks. Following stabilization of the anti-factor Xa plasma levels with a continuous infusion (400 anti-factor Xa U/hour), dalteparin therapy was changed to SC dosing, which was continued until delivery at 38.5 weeks of a healthy, 3010-g female infant.

No anti-factor Xa activity was detected in the cord blood.

A 1992 report described the use of dalteparin in seven women at 16–23 weeks' gestation just before undergoing therapeutic termination of pregnancy (5). SC dalteparin was given at 15 and 3 hours before pregnancy termination. Heparin activity (anti-factor Xa) was detected in all mothers but not in any of the fetuses. In the second part of the study, 11 pregnant women with a history of severe thromboembolic tendency, as evidenced by recurrent miscarriages, were treated throughout gestation with SC dalteparin (5). All of the women gave birth to healthy infants without complication. As with heparin, maternal osteoporosis may be a complication resulting from the use of low-molecular-weight heparins, including dalteparin, during pregnancy (see also Heparin and Vitamin D). However, in the 11 patients described above, all had normal mineral mass as determined by bone density scans performed shortly after delivery (5). Moreover, a study published in 1996 compared two groups of pregnant women receiving SC dalteparin, either 5000 IU daily (N = 9) or 5000 IU daily in the 1st trimester, then twice daily thereafter (N = 8), both starting in the 1st trimester, with a control group (N = 8) that did not receive heparin (6). Lumbar spine bone density fell by similar amounts in all pregnancies, and the normal physiological change of pregnancy was not increased by dalteparin.

The use of dalteparin in 184 pregnant women for thromboprophylaxis was reviewed in a brief 1994 report (7). No placental passage of the drug was found in the 9 patients investigated. Congenital malformations were observed in 3.3% of the outcomes, a rate believed to be normal for this population. Another 1994 letter reference described the use of dalteparin in five pregnant women starting between 15 and 18 weeks' gestation (8). Apparently normal infants were delivered.

Dalteparin was used for thromboembolic prophylaxis in 24 pregnant women with a risk of thromboembolic disease (9). The women received total daily doses of 2500 (16 mg) to 10,000 (32 mg) anti-factor Xa IU. Anti-factor Xa activity was demonstrated in the blood samples from the mothers but not in the normal newborns, indicating the lack of placental transfer of the drug.

A 1997 case report described the successful use of dalteparin in the 3rd trimester of a pregnant woman with iliofemoral vein thrombosis who was resistant to use unfractionated heparin (10). She was treated with 7000 IU (100 IU/kg) every 12 hours from 30 weeks' gestation until 24 hours before an uncomplicated vaginal delivery at 38 weeks'.

In a randomized 1999 trial, unfractionated heparin (N = 55; mean 20,569 IU/day) and dalteparin (N = 50; mean 4631 IU/day) were compared in 105

pregnant women with previous or current thromboembolism (11). There were no recurrences of thromboembolism or cases of thrombocytopenia in either group, but there were more bleeding complications in the patients receiving unfractionated heparin. The pregnancy outcomes in terms of blood loss at delivery, number of cesarean sections, birth weight, and Apgar scores were similar.

In a 2000 trial, a prophylactic dalteparin dose of 5000 IU/day given during pregnancy was adequate for 25 women (mean weight 70.2 kg), but the dose was decreased in 6 women (mean 58.0 kg) and increased in 2 (mean 102.5 kg) after the first anti-Xa activity measurement (12). An adjusted-weight therapeutic dose (100 IU/kg twice daily) was appropriate during pregnancy based on measured anti-Xa activity.

BREASTFEEDING SUMMARY

No reports describing the use of dalteparin during lactation have been located. Dalteparin, a low- molecular-weight heparin, still has a relatively high molecular weight (65%–78% in the range of 3000–8000) and, as such, should not be expected to be excreted into human milk. Because the drug would be inactivated in the gastrointestinal tract, the risk to a nursing infant from ingestion of dalteparin from milk appears to be negligible.

DANAPAROID

[Withdrawn from the market. See 9th edition.]

DANAZOL

Androgen

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

A number of reports have described the inadvertent use of danazol during human gestation resulting in female pseudohermaphroditism. This teratogenic condition is characterized by a normal XX karyotype and internal female reproductive organs, but ambiguous external genitalia. No adverse effects in male fetuses have been associated with danazol.

FETAL RISK SUMMARY

Danazol is a synthetic androgen derived from ethisterone that is used in the treatment of various conditions, such as endometriosis, fibrocystic breast disease, and hereditary angioedema. No fetal harm was observed in reproduction studies with pregnant rats at doses 7–15 times the human dose, but fetal development was inhibited in rabbits at doses 2–4 times the human dose (1).

Early studies with this agent had examined its potential as an oral contraceptive (2–4). This use was abandoned, however, because low doses (e.g., 50–100 mg/day) were associated with pregnancy rates $\leq 10\%$ and higher doses were unacceptable to the patient due to adverse effects (2,4).

In experimental animals, danazol crosses the placenta to the fetus, but human data are lacking. The molecular weight (about 338) suggests that it does reach the human embryo and fetus. Because danazol is used to treat endometriosis, frequently in an infertile woman, a barrier (nonhormonal) contraception method is recommended to prevent accidental use during pregnancy.

The first published report of female pseudohermaphroditism appeared in 1981 (5). A woman was treated for endometriosis with a total danazol dose of 81 g divided over 101 days. Subsequent evaluation revealed that the treatment period corresponded to approximately the first 14 weeks of pregnancy. The

female infant, whose length and weight were at the 5th percentile, had mild clitoral enlargement and a urogenital sinus evident at birth. Physical findings at 2 years of age were normal except for clitoromegaly, empty, darkened, rugated labia majora, and a complete urogenital sinus formation. Studies indicated the child had a normal vagina, cervix, fallopian tubes, and ovaries. The mother had no evidence of virilization.

A second case reported in 1981 involved a woman with endometriosis who was inadvertently treated with danazol, 800 mg/day, during the first 20 weeks of gestation (6). The mother went into premature labor at 27 weeks and delivered a female infant with a birth weight of 980 g. Ambiguous genitalia were evident at birth, consisting of marked clitoromegaly with fusion of the labia scrotal folds. A urogenital sinus, with well-developed vagina and uterus, was noted on genitogram. Bilateral inguinal hernias with palpable gonads were also present. At 4 days of age, clinical and laboratory findings compatible with a salt-losing congenital adrenal hyperplasia were observed. The infant was successfully treated for this complication, which was thought to be due to a transitory block of the steroid 21- and 11-monooxygenases (6). At 1 year of age, the infant was asymptomatic, and no signs of progressive virilization were observed.

The authors of the above report cited knowledge of 27 other pregnancies in which danazol had been accidentally used (6). Seven of these pregnancies were terminated by abortion. Of the remaining 20 pregnancies, 14 delivered female infants and 5 (36%) of these had evidence of virilization with ambiguous genitalia.

A 1982 case report described female pseudohermaphroditism in an infant exposed to a total danazol dose of 96 g administered over 120 days, corresponding to approximately the first 16 weeks of gestation (7). The infant, weighing 3100 g (5th percentile) with a length of 53.5 cm (25th–50th percentile), had fused labia with coarse rugations, mild clitoromegaly, and a urogenital sinus opening below the clitoris. An 8-cm mass, eventually shown to be a hydrometrocolpos, was surgically drained because of progressive obstructive uropathy. A balanced somatic chromosomal translocation was an incidental finding in this case, most likely inherited from the mother. Growth and development were normal at 6 months of age with no further masculinization.

Two brief 1982 communications described infants exposed in utero to danazol (8,9). In one, a 2400-g term female infant with ambiguous genitalia had been exposed to danazol (dose not specified) during the first 4 months of pregnancy (8). The infant's phallus measured 0.75 cm and complete posterior

labial fusion was observed. The second case involved a woman treated with danazol, 200 mg/day, during the first 6 weeks of gestation, who eventually delivered a female infant with normal external genitalia (9). The absence of virilization of the infant's genitalia, as evidenced by a normal clitoris and no labial fusion, indicates the drug was stopped prior to the onset of fetal sensitivity to androgens.

British investigators reported virilization of the external genitalia consisting of clitoromegaly, a fused, scrotalized labia with a prominent median raphe, and a urogenital sinus in a female infant exposed in utero to danazol, 400 mg/day, during the first 18 weeks of pregnancy (10). The mother showed no signs of virilization.

A summary of known cases of danazol exposure during pregnancy was reported in 1984 by Rosa, an investigator from the epidemiology branch of the FDA (11). A total of 44 cases of pregnancy exposure, all to 800 mg/day, were known as of this date, but this number was considered to be understated since normal outcomes were unlikely to be reported (11). Each of the cases of exposure was thought to have occurred after conception had taken place. Of the 44 cases, 7 (16%) aborted and the outcome in 14 others was unknown. Seven males and 15 females resulted from the 22 pregnancies that had been completed. Ten (67%) of the females had virilization and one male infant had multiple congenital abnormalities (details not given). No cases of virilization were observed when the drug was discontinued prior to the 8th week of gestation, the onset of androgen receptor sensitivity (11).

An Australian case of an infant with masculinized external genitalia secondary to danazol was reported in 1985 (12). The mother had been treated with 400 mg/day, without evidence of virilization, until the 19th week of gestation. The infant was developing normally at 6 months of age, except for a minimally enlarged clitoris, rugose and fused labia with a thick median raphe, and a urogenital sinus opening at the base of the phallus.

A 1985 case report described a female fetus exposed in utero to 800 mg/day of danazol until pregnancy was terminated at 20 weeks' gestation (13). A urogenital sinus was identified in the aborted fetus but the external genitalia were normal except for a single opening in the vulva. Citing a personal communication from the manufacturer, the authors noted a total of 74 cases of danazol exposure during pregnancy (13). Among these cases were 29 term females, 9 (31%) of whom had clitoromegaly and labial fusion.

A retrospective review of fetal exposure to danazol included cases gathered from multiple sources, including individual case reports, data from the Australian

Drug Reactions Advisory Committee, the FDA, and direct reports to the manufacturers (14). Of the 129 total pregnancies that were exposed to danazol, 23 were electively terminated and 12 miscarried. Among the 94 completed pregnancies, there were 37 normal males, 34 nonvirilized females, and 23 virilized females. All of the virilized female offspring were exposed beyond 8 weeks' gestation. The lowest daily dose that resulted in virilization was 200 mg.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 10 newborns had been exposed to danazol during the 1st trimester (F. Rosa, personal communication, FDA, 1993). No major birth defects were observed.

There is no conclusive evidence of fetal harm when conception occurs in a menstrual cycle shortly after cessation of danazol therapy (15–17). A 1978 publication noted 4 intrauterine fetal deaths occurring from a total of 39 pregnancies following danazol treatment, presumably after elimination of the drug from the mother (18). The stillbirths, two each in the 2nd and 3rd trimesters, occurred in women who had conceived within 0–3 cycles of stopping danazol. However, one of the fetal deaths was due to cord torsion and a second death in a twin was due to placental insufficiency, neither of which can be attributed to danazol.

No long-term follow-up studies of children exposed in utero to danazol have been located. A 1982 reference, however, did describe this type of evaluation in 12 young women, aged 16–27 years, who had been exposed to in utero synthetic androgenic progestins resulting in the virilization of the external genitalia in 11 of them (19). Despite possible virilization of early behavior with characterization as “tomboys” (e.g., increased amounts of “rough-and-tumble play” and “an avid interest in high school sports”), all of the women eventually “displayed stereotypically feminine sexual behavior” without any suggestion of behavior abnormalities (19).

BREASTFEEDING SUMMARY

No reports describing the use of danazol during lactation have been located. Because of the potential for severe adverse effects in a nursing infant, women taking this drug should not breastfeed.

DANTHRON

[Withdrawn from the market. See 9th edition.]

DANTROLENE

Muscle Relaxant

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: Hold Breastfeeding

PREGNANCY SUMMARY

Dantrolene has been used in a limited number of pregnant patients shortly before delivery. No fetal or newborn adverse effects have been observed, but a risk:benefit ratio has not yet been defined. Moreover, published 1st and 2nd trimester experience with this drug is completely lacking.

FETAL RISK SUMMARY

In obstetrics, the only documented use of dantrolene, a hydantoin derivative used as a direct-acting skeletal muscle relaxant, is to prevent or treat malignant hyperthermia. The syndrome of malignant hyperthermia is a potentially lethal complication of anesthesia induced with halogenated anesthetics and depolarizing skeletal muscle relaxants. References describing the use of dantrolene in pregnant patients for chronic spasticity or during the 1st or 2nd trimesters have not been located. The agent is embryocidal in animals and, in some species, produced minor skeletal variations at the highest dose tested (1–3).

Three studies have described the transfer of dantrolene across the human placenta to the fetus with cord:maternal serum ratios of 0.29–0.69 (4–6). Two women, who were considered to be malignant hyperthermia susceptible (MHS), were treated with oral doses of the drug prior to cesarean section (4). One woman received 100 mg twice daily for 3 days prior to elective induction of labor. The second patient received 150 mg on admission in labor and a second dose of 100 mg 6 hours later. Both women were delivered by cesarean section because of failure to progress in labor. Neither was exposed to malignant hyperthermia-triggering agents and neither developed the complication. The cord and maternal blood concentrations in the two cases were 0.40 and 1.38 mcg/mL (ratio 0.29), and 1.39 and 2.70 mcg/mL (ratio 0.51), respectively. The

timing of the doses in relationship to delivery was not specified by the author. No adverse effects of the drug exposure were noted in the infants.

A second report described the prophylactic use of dantrolene, administered as a 1-hour IV infusion (2.2 mg/kg) 7.5 hours prior to vaginal delivery, under epidural anesthesia, of a healthy, vigorous infant (5). The mother had been confirmed to be MHS by previous muscle biopsy. At the time of delivery, the cord and maternal blood dantrolene concentrations were 2.1 and 4.3 mcg/mL, respectively, a ratio of 0.48. The mother did not experience malignant hyperthermia. No respiratory depression or muscle weakness was noted in the newborn.

A study published in 1988 treated 20 pregnant women diagnosed as MHS with oral dantrolene, 100 mg/day, for 5 days prior to delivery and for 3 days following delivery (6). Three of the patients were delivered by cesarean section. Known anesthetic malignant hyperthermia-triggering agents were avoided and no cases of the syndrome were observed. All fetuses had reactive nonstress tests and normal biophysical profiles before and after the onset of dantrolene administration. The mean maternal predelivery dantrolene serum concentration was 0.99 mcg/mL compared with a mean cord blood level of 0.68 mcg/mL, a ratio of 0.69. The mean serum half-life of dantrolene in the newborns was 20 hours (6). Extensive neonatal testing up to 3 days after delivery failed to discover any adverse effects of the drug.

Prophylactic dantrolene, 600 mg given as escalating oral doses over 3 days, was administered to a woman with biopsy-proven MHS 3 days prior to a repeat cesarean section (7). The woman had experienced malignant hyperthermia during her first cesarean section but did not during this surgery. No adverse effects were noted in the newborn.

Although no dantrolene-induced complications have been observed in fetuses or newborns exposed to the drug shortly before birth, some investigators do not recommend prophylactic use of the agent because safety in pregnancy has not been sufficiently documented, and the incidence of malignant hyperthermia in the anesthetized patient is very low (8–10). (A recent reference cited incidences of 1/12,000 anesthetics in children and 1/40,000 in adults (11).) They recommend avoidance of those anesthetic agents that might trigger the syndrome, careful monitoring of the patient during delivery, and preparation to treat the complication if it occurs.

BREASTFEEDING SUMMARY

Dantrolene is excreted into human breast milk. A 37-year-old woman

undergoing an urgent cesarean section with general anesthesia (succinylcholine, thiopental, nitric oxide, oxygen, and isoflurane) developed tachycardia, respiratory acidosis, and hyperthermia (12). After delivery of the infant and cord clamping, IV dantrolene (160 mg) was administered. Over the next 3 days, she received decreasing total doses of IV dantrolene: 560 mg on day 1, 320 mg on day 2, and 80 mg on day 3. The infant was not allowed to nurse during this time. Seven breast milk samples were obtained (volume of milk samples and collection method not specified) over an 84-hour interval after the first dose. Milk concentrations of dantrolene ranged from a maximum of 1.2 mcg/mL (day 2; 36 hours after the first dose with a total dose of 720 mg at the time) to 0.05 mcg/mL on day 3 (total dose 1120 mg received at the time). The estimated elimination half-life from milk was 9.02 hours (12). Thus, waiting 2 days after the last dantrolene dose to breastfeed would assure that the exposure of the nursing infant would be negligible.

DAPSONE

Leprostatic/Antimalarial

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential
Toxicity

PREGNANCY SUMMARY

The use of dapsones during pregnancy does not appear to present a major risk to the fetus or the newborn. The agent has been used extensively for malarial treatment or chemoprophylaxis and for the treatment of leprosy and certain other dermatologic conditions without producing major fetotoxicity or causing birth defects. If used in combination with pyrimethamine (a folic acid antagonist) for malaria prophylaxis, folic acid supplements or leucovorin should be given.

FETAL RISK SUMMARY

Dapsone (DDS), a sulfone antibacterial agent, is used in the treatment of leprosy and dermatitis herpetiformis, and for various other unlabeled indications, including antimalarial prophylaxis, the treatment of *Pneumocystis carinii* pneumonia, inflammatory bowel disease, rheumatic and connective tissue disorders, and relapsing polychondritis. Because the drug is known to cause blood dyscrasias in adults, some of which have been fatal, close patient monitoring is required during use.

Although reproduction studies in animals have not been conducted (1), a 1980 reference described a study investigating carcinogenicity that was conducted in pregnant and lactating mice and rats (2). A maximum maternally tolerated dose, 100 mg/kg (usual human dose 50–300 mg/day), was administered twice in late gestation and 5 times a week during lactation and then was continued in the offspring after weaning. A small but significant increase in tumors was noted.

A number of studies have described the use of dapsones during all stages of human pregnancy. A few fetal or newborn adverse effects directly attributable

to dapsone have been reported, but no congenital anomalies thought to be due to the drug have been observed. The indications for use of dapsone during pregnancy have included dermatologic conditions, leprosy, malaria, and *P. carinii*.

A brief 1968 reference described Heinz-body hemolytic anemia in a mother and her newborn during therapy with dapsone (3). The mother had been diagnosed with herpes gestationis at 22 weeks' gestation, for which she was treated with sulfapyridine for 1 week. At 26 weeks, treatment with dapsone was begun at 400 mg/day for 1 week, 300 mg/day during weeks 2 and 3, 200 mg/day in week 4, 100 mg/day in week 5, then 200 mg/day until delivery of a male infant at 36 weeks' gestation. She developed well-compensated Heinz-body hemolytic anemia 6 days after starting dapsone. The anemia in the infant, who had a normal glucose-6-phosphate dehydrogenase (G6PD) level, completely resolved within 10 days, and he has remained hematologically normal.

In three cases, dapsone was used for the treatment of dermatitis herpetiformis or its variant, herpes gestationis (4,5). In two other reports of herpes gestationis (also referred to as pemphigoid gestationis) occurring during pregnancy, dapsone was not started until after delivery (6,7). A 26-year-old pregnant woman with recurrent herpes gestationis was treated with dapsone and other nonspecific therapy from the 24th week of gestation until delivery of a normal male infant at 38 weeks (4). A 25-year-old woman with dermatitis herpetiformis was treated with dapsone, 100–150 mg/day, during the first 3 months of pregnancy (5). The drug was discontinued briefly during the 4th month of pregnancy because of concerns of teratogenicity, then resumed at 50 mg/day because of worsening of her disease. She eventually gave birth to a full-term, normal infant who developed dapsone-induced hemolytic anemia while breastfeeding (see Breastfeeding Summary below). A 33-year-old woman, treated with dapsone, 25–50 mg/day, throughout pregnancy for dermatitis herpetiformis delivered a healthy full-term infant (8).

A 1978 paper described the clinical courses of 62 pregnancies in 26 women treated for leprosy (Hansen's disease) (9). All of the patients received therapy, with sulfone drugs (specific drugs not mentioned) being used in 58 (94%) of the pregnancies. Two (3.6%) infants (about the expected rate) among the 56 pregnancies with infants who reached an age of viability had congenital anomalies. One infant had a cleft palate, and another had a congenital hip dislocation. A review, published in 1993, discussed the adverse association of leprosy and pregnancy (10). Although dapsone was not thought to cause

adverse toxic effects or teratogenicity in the fetus, resistance to dapsone monotherapy has become a problem, and combination therapy, such as dapsone, clofazimine, and rifampin, is recommended for all forms of leprosy (10). Normal pregnancy outcomes of 15 women treated for leprosy were noted in a 1996 letter (N = 13) (11) and in a 1997 report (N = 2) (12). The patients had been treated throughout gestation with dapsone, 100 mg/day, plus rifampin, 600 mg once monthly (11), or with dapsone alone (12). In addition, two had also received clofazimine, and two had taken intermittent prednisolone (11).

Neonatal hyperbilirubinemia, suspected of being due to displacement of bilirubin from albumin-binding sites, has been attributed to the use of dapsone during gestation (13). A 25-year-old woman with leprosy was treated with dapsone, 300 mg/week, until 3 months before delivery. At that time, her dose was decreased to 50 mg/week and then was discontinued 1 week prior to a normal spontaneous vaginal delivery of a 3740-g male infant. The infant, who was not breastfed and had no evidence of ABO incompatibility, developed hyperbilirubinemia that was attributed to dapsone. In a subsequent pregnancy, dapsone therapy was stopped 1 month prior to delivery of a healthy 4070-g male infant who did not develop hyperbilirubinemia.

The combination of dapsone and pyrimethamine (Maloprim) has been frequently used during pregnancy for the chemoprophylaxis of malaria (14–21). Most consider the benefits of this combination in the prevention of maternal malaria to outweigh the risks to the fetus (16–21), but two authors classified the combination as contraindicated in pregnancy (14,15). The adverse effects of the combination were reviewed in a 1993 reference (22). Because of the potential for significant dose-related toxicity, the authors considered the drug combination to be a second-line choice for use in areas where the risk of malaria was high. Folic acid supplements should be given when pyrimethamine is used (21). (See also Pyrimethamine.)

A study published in 1990 compared chlorproguanil plus dapsone (N =44), chloroquine alone (N = 58), and pyrimethamine plus sulfadoxine (N = 54) in a group of pregnant women with falciparum malaria parasitemia (23). A single dose of chlorproguanil plus dapsone during the 3rd trimester cleared the parasitemia in all women within 1 week, compared with 84% and 94%, respectively, in the other two groups. Six weeks after treatment, the proportion of those with parasitemia in each group was 81%, 84%, and 23%, respectively. No adverse effects of the therapy in the fetuses or newborns were mentioned.

An adverse pregnancy outcome in a mother who received malarial

chemoprophylaxis with three drugs was the subject of a brief 1983 communication (24). During the 1st month of pregnancy, the 31-year-old woman had taken chloroquine (100 mg/day) and Maloprim (dapsone 100 mg plus pyrimethamine 12.5 mg) on days 10, 20, and 30 after conception. The stillborn male infant was delivered at 26 weeks' gestation with a defect of the abdominal and thoracic wall with exteriorization of most of the abdominal viscera, the heart, and the lungs (a variant of ectopia cordis?) and a missing left arm. The authors concluded that the defects were due to pyrimethamine, but others have questioned this conclusion (see Pyrimethamine).

Dapsone, either alone or in combination with pyrimethamine or trimethoprim, has been suggested as having utility in the prophylaxis of *P. carinii* during pregnancy (25,26). Although the efficacy of these therapeutic options has not been confirmed, the risks of the disease to the mother far outweigh the risks to the fetus (26).

A 1992 report described an attempted suicide with dapsone and alcohol in a 29-year-old pregnant woman (length of gestation not specified) under treatment for dermatitis herpetiformis (27). The woman had ingested 50 tablets (100 mg each) of dapsone plus six alcoholic drinks. She developed severe methemoglobinemia and hemolytic anemia, treated successfully with methylene blue (total dose about 7 mg/kg) and other therapy, and splenomegaly that resolved spontaneously. No mention was made of the pregnancy outcome.

Folic acid 5 mg/day or leucovorin 5 mg/week should be used if dapsone is combined with pyrimethamine (a folic acid antagonist) for malaria prophylaxis (21,28).

BREASTFEEDING SUMMARY

Dapsone and its primary metabolite, monoacetyldapsone, are excreted into human milk (5,29,30). A 25-year-old woman with dermatitis herpetiformis was treated with dapsone throughout most of her pregnancy and continued this therapy while breastfeeding her infant (5). During the latter two-thirds of her pregnancy and during lactation she took dapsone, 50 mg/day. Approximately 6 weeks after delivery, mild hemolytic anemia was diagnosed in the mother and her infant. Measurements of dapsone and the metabolite were conducted on the mother's serum and milk and on the infant's serum. Dapsone concentrations were 1622, 1092, and 439 ng/mL, respectively, whereas those of the metabolite were 744 ng/mL, none detected, and 204 ng/mL, respectively. The milk:plasma ratio of dapsone was 0.67. The investigators noted that the weak base properties of dapsone, its high lipid solubility, and its long serum half-life

(about 20 hours) all favored excretion and entrapment of the drug in milk (5). Moreover, both the mother and her infant appeared to be rapid acetylator phenotypes because of the relatively high ratios of metabolite to parent drug in both (0.459 in the mother, 0.465 in the infant) (5). Neither patient was tested for G6PD deficiency, although persons with this genetic defect are especially susceptible to dapsone-induced hemolytic anemia. Dose-related hemolytic anemia is the most common toxicity reported with dapsone and occurs in patients with or without G6PD deficiency (1).

A 1952 reference studied the excretion into breast milk of dapsone (diaminodiphenylsulfone) and another sulfone antibacterial agent in one and five women, respectively, with leprosy (29). Although stating that dapsone was excreted in the mother's milk and absorbed and excreted in the infant's urine, the investigator did not quantify the amount in the milk.

Three women, 2–5 days postpartum, who were not breastfeeding, were given a single dose of dapsone (100 mg) plus pyrimethamine (12.5 mg; Maloprim) and a single dose of chloroquine (300 mg base) (30). Milk and serum samples for dapsone analysis were collected at intervals up to 52, 102, and 124 hours, yielding milk:plasma ratios, based on AUC, of 0.38, 0.45, and 0.22, respectively. The authors calculated that the amounts of dapsone excreted into milk, based on 1000 mL/day, were 0.31, 0.85, and 0.59 mg, respectively, which are too small to afford malarial chemoprophylaxis to a nursing infant (30).

Although not citing the case of dapsone-induced hemolytic anemia in a nursing infant described above, the American Academy of Pediatrics classifies dapsone as compatible with breastfeeding (31).

DAPTOMYCIN

Antibiotic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Three reports describing the use of daptomycin in the 2nd and 3rd trimesters have been located. The animal reproduction data suggest low risk, but the limited human pregnancy experience prevents a better assessment of the embryo–fetal risk. However, the high molecular weight should limit exposure of the embryo–fetus. Moreover, most antibiotics can be classified as low risk in gestation. Therefore, if the antibiotic is required, it should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Daptomycin is a cyclic lipopeptide derived from the fermentation of *Streptomyces roseosporus*. It is a bactericidal antibiotic that is administered IV for the treatment of skin and skin structure infections caused by susceptible gram-positive bacteria. Daptomycin is about 92% reversibly bound to plasma proteins, primarily albumin. In patients with normal renal function, the mean elimination half-life is about 9 hours with elimination primarily via the urine. Elimination is prolonged in patients with renal impairment. For example, for patients on dialysis, the elimination half-life is about 30 hours (1).

Reproduction studies have been conducted in pregnant rats and rabbits with IV doses up to three and six times, respectively, the human dose based on BSA (HD). No evidence of fetal harm was observed in these studies (1,2). At the highest dose, maternal toxicity (decreased food consumption and weight) was observed. The no-observed-effect level for maternal toxicity was about one-fourth the maximum dose in both species (2). In male and female rats, doses up to nine times the HD had no effect on fertility (1). Carcinogenicity studies have not been conducted with daptomycin, but neither mutagenic nor

clastogenic potential were observed in a number of assays (1).

It is not known if daptomycin crosses the human placenta. The high molecular weight (about 1621) should limit passive transfer across the placenta. However, vancomycin, an antibiotic with a similar spectrum and molecular weight (about 1486), is known to cross the human placenta late in the 2nd trimester to produce detectable concentrations in amniotic fluid and cord blood. (See Vancomycin.)

A 2005 report described a woman in the 3rd trimester who was treated with a 6-week course of IV daptomycin (6 mg/kg/day) for tricuspid valve acute bacterial endocarditis (3). Other antibiotics had failed to clear the methicillin-sensitive *Staphylococcus aureus* infection that was secondary to a peripherally inserted central catheter (PICC) line for hyperalimentation. At the time of the report, the woman was still pregnant.

A case similar to the one above was reported in 2010 (4). The woman presented at 14 weeks' gestation with a history of IV drug abuse and tricuspid valve endocarditis caused by methicillin-sensitive *S. aureus*. She was treated with a 6-week course of IV daptomycin 6 mg/kg/day with resolution of the infection. A cesarean section at 37 weeks' delivered a healthy, about 3.068 kg-male infant with Apgar scores of 8 and 9 at 1 and 5 minutes, respectively (4).

Vancomycin-resistant *Enterococcus faecium* pyelonephritis occurred in a woman at 27 weeks' gestation (5). She also had positive cultures for *Ralstonia pickettii*, methicillin-resistant *S. epidermidis*, and *Enterobacter gergoviae* from blood drawn through a PICC line. The woman was successfully treated with a 14-day course of IV daptomycin 4 mg/kg/day and meropenem 1 g every 8 hours. The woman went into premature labor 1 month after completion of the therapy and delivered a baby without evidence of infection or abnormalities (no other details were provided) (5).

BREASTFEEDING SUMMARY

Daptomycin is excreted into breast milk in very low concentrations (6). A woman nursing her infant 5 months after delivery was treated with a 28-day IV course of daptomycin 6.7 mg/kg/day and ertapenem 1 g/day for a complex case of pelvic inflammatory disease (6). Serial milk concentrations were obtained on day 27. The highest measured concentration was 44.7 ng/mL 8 hours after the dose. The estimated milk:plasma ratio was 0.0012. No adverse effects were noted in the breastfeeding infant (6). A 2009 review briefly summarized this and other cases of anti-infectives used for methicillin-resistant *S. aureus* infections during lactation (7).

The very low concentrations of daptomycin in breast milk are consistent with the high molecular weight (about 1621). Confirmation is needed, however, because vancomycin, an antibiotic with a similar spectrum and molecular weight (about 1486), is excreted into breast milk with concentrations nearly identical to the mother's trough serum concentration. (See Vancomycin.) Since daptomycin must be given IV, systemic absorption by the nursing infant is not expected even if the antibiotic is excreted into milk. However, modification of the infant's bowel flora resulting in diarrhea and other gastrointestinal complaints are potential concerns. Therefore, if a lactating woman requires treatment with the antibiotic, her nursing infant should be closely observed for changes in bowel function.

DARBEPOETIN ALFA

Hematopoietic

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably
Compatible

PREGNANCY SUMMARY

Several reports have described the use of darbepoetin alfa in human pregnancy, apparently all ending in normal outcomes. The absence of major toxicity in animals and the experience with epoetin alfa (see Epoetin Alfa) suggest that darbepoetin does not represent a significant embryo or fetal risk. Because anemia and the need for frequent blood transfusions present significant risks to the mother and fetus, the benefits derived from darbepoetin probably outweigh the known risks.

FETAL RISK SUMMARY

Darbepoetin is an erythropoiesis 165-amino acid protein produced by recombinant DNA technology in Chinese hamster ovary cells. It is indicated for the treatment of anemia and is closely related to epoetin alfa. The half-life after SC administration is 49 hours (range 27–89 hours) that is reflective of its slow absorption, whereas after IV administration the terminal half-life is 21 hours.

Reproduction studies have been conducted in pregnant rats and rabbits. No evidence of direct embryotoxic, fetotoxic, or teratogenic effects was observed at IV doses up to 20 mcg/kg/day. (Note: dose is about 300 times the recommended human dose of 0.45 mcg/kg once weekly based on body weight in patients with chronic renal failure [RHD-CRF] or about 60 times the recommended human dose of 2.25 mcg/kg once weekly based on body weight in cancer patients receiving chemotherapy [RHD-C]). A slight reduction in fetal weight was observed at doses that were ≥ 1 mcg/kg/day (≥ 15 times RHD-CRF; ≥ 3 times RHD-C), but this was a maternal toxic dose. In rats, IV doses of ≥ 2.5 mcg/kg every other day (about ≥ 20 times the RHD-CRF or about ≥ 4 times the RHD-C) from day 6 of gestation through day 23 of lactation caused decreased

body weights and delayed eye opening and preputial separation. Darbepoetin had no adverse effect on uterine implantation in rats or rabbits. However, an increase in postimplantation fetal loss was observed in rats given doses ≥ 0.5 mcg/kg three times weekly (about ≥ 3 times the RHD-CRF; about ≥ 0.7 times the RHD-C) (1).

It is not known if darbepoetin alfa crosses the human placenta. The very high molecular weight (about 37,000) of this glycoprotein argues against transfer across the placenta. A closely related drug, epoetin alfa, has a lower molecular weight (about 30,000) and it does not cross to the fetus. (See Epoetin Alfa.)

A 2005 case report described the use of darbepoetin alfa in a 20-year-old woman at 28 weeks' gestation (2). Darbepoetin was given weekly. She had received a kidney transplant about 4 years earlier and had been maintained on rapamycin and iron therapy until 22 weeks' gestation, at which time the rapamycin was discontinued and replaced with cyclosporine. A cesarean section was performed at 37 weeks' because of fetal distress to deliver a healthy 6-pound (about 2.224 kg) female infant with Apgar scores of 7 and 8 at 1 and 5 minutes, respectively (2).

A 2006 report described two pregnancies that were treated with darbepoetin alfa (3). The women, a 33-year-old with chronic renal failure of unknown cause, and a 31-year-old with insulin-dependent diabetes complicated by hypertension and nephropathy, were treated with weekly doses of darbepoetin alfa from the 22nd and 20th week of gestation, respectively. The first mother gave birth at 37 weeks' to a healthy, 2.010-kg infant (sex not specified) with an Apgar score of 10, whereas the second gave birth by cesarean section at 32 weeks' to a 1.730-kg female infant with Apgar scores of 9 and 10. The status of the first infant was not specified, but the second infant was doing well (3).

A 21-year-old woman with nephrotic syndrome was treated with weekly doses of darbepoetin alfa starting at 26 weeks' (4). Because of worsening renal failure, labor was induced and she gave birth at 36 weeks'. No information of the infant was included in the report.

A 27-year-old woman with HbH disease, an intermediate clinical form of alpha thalassemia, was treated with two doses of epoetin at 15 weeks' then darbepoetin alfa 500 IU every 3 weeks from 16 weeks' until delivery by an emergency cesarean section for fetal distress (umbilical cord around the neck of the fetus) at 38 weeks'. The healthy, 3.13-kg male infant had Apgar scores of 8 and 10 (5).

BREASTFEEDING SUMMARY

No reports describing the use of darbepoetin in human lactation have been located. Darbepoetin is a 165-amino acid glycoprotein with a molecular weight of 37,000. Passage into milk is not expected, but in the event that some transfer did occur, digestion in the nursing infant's gastrointestinal tract would occur. Moreover, preterm infants have been treated with epoetin alfa, a closely related agent. (See Epoetin Alfa.) Thus, the risk to a nursing infant from ingestion of the drug via the milk appears to be nonexistent.

DARIFENACIN

Urinary Tract Agent (Antispasmodic)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of darifenacin in human pregnancy have been located. The animal reproduction data suggest low risk, but the absence of human pregnancy experience prevents an assessment of the embryo–fetal risk. Thus, the use of darifenacin during pregnancy is not recommended. However, inadvertent exposure appears to represent a low risk of embryo–fetal harm.

FETAL RISK SUMMARY

The anticholinergic agent darifenacin is a competitive muscarinic receptor antagonist available in extended-release tablets. It is indicated for the treatment of overactive bladder with symptoms of urge urinary incontinence, urgency and urinary frequency. It is in the same subclass as flavoxate, oxybutynin, solifenacin, tolterodine, and trospium. Darifenacin is extensively metabolized by the liver to inactive metabolites by the cytochrome P450 isoenzymes CYP2D6 and CYP3A4. Protein binding, primarily to α_1 -acid-glycoprotein, is about 98% and the elimination half-life is 13–19 hours (1).

Reproduction studies have been conducted in rats and rabbits. In rats, a dose about 59 times the maximum recommended human dose based on AUC (MRHD) resulted in delayed ossification of the sacral and caudal vertebrae. This effect was not observed at about 13 times the MRHD. Dystocia was observed in dams and slight developmental delay occurred in pups at about 17 times the MRHD. The no-effect dose on dams and pups was about five times the MRHD. In rabbits, a dose about 28 times the MRHD caused increased postimplantation loss, but a dose about nine times the MRHD did not. At 28 times the MRHD, dilated ureter and/or kidney pelvis were observed in offspring.

There was also one case of this effect, along with urinary bladder dilation, at nine times the MRHD, an effect consistent with the pharmacological action of darifenacin. The no-effect dose in rabbits was 2.8 times the MRHD.

No evidence of carcinogenicity was observed in studies with mice and rats. Darifenacin was neither mutagenic or clastogenic, and there was no evidence of impaired fertility in male or female rats.

It is not known if darifenacin crosses the human placenta. The molecular weight (about 508) and the long elimination half-life suggest that exposure of the embryo and/or fetus should be expected. However, the extensive metabolism and protein binding will decrease the amount of parent drug available for transfer at the maternal:fetal interface.

BREASTFEEDING SUMMARY

No reports describing the use of darifenacin during human lactation have been located. The molecular weight (about 508) and the long elimination half-life suggest that the drug will be excreted into breast milk, but the extensive metabolism and protein binding should decrease the amount of active drug in milk. The effect of exposure on a nursing infant is unknown. If a mother taking darifenacin is breastfeeding, the infant should be monitored for adverse effect, particularly those involving the gastrointestinal tract (e.g., dry mouth, constipation, abdominal pain, and nausea).

DARUNAVIR

Antiviral

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Several reports have described the use of darunavir in human pregnancy. The animal data suggest low risk, but the obtainable systemic exposures were very low. If indicated, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Darunavir is an inhibitor of HIV type 1 (HIV-1) protease. Darunavir, coadministered with 100 mg ritonavir, as well as other antiretroviral agents, is indicated for the treatment of HIV infection in antiretroviral-experienced adult patients, such as those with HIV-1 strains resistant to more than one protease inhibitor. Darunavir and ritonavir are combined because darunavir is primarily metabolized by CYP3A and ritonavir inhibits CYP3A, thereby markedly increasing the plasma concentrations of darunavir (lopinavir and tipranavir are combined with ritonavir for the same reason). The metabolites of darunavir are basically inactive, only having about 10% of the activity of darunavir. Plasma protein binding of darunavir is 95%, mainly to α 1-acid glycoprotein. The terminal elimination half-life is about 15 hours when combined with ritonavir (1).

Reproduction studies with darunavir have been conducted in mice, rats, and rabbits. No embryotoxicity or teratogenicity was observed in these species with doses producing exposures (AUC) that were about 50%, 50%, and 5%, respectively, of the human exposure obtained with the recommended clinical dose boosted with ritonavir based on AUC. The low exposures in the animals resulted from the limited oral bioavailability of darunavir and/or dosing limitations. Long-term carcinogenicity studies in rodents have not been completed. Assays for mutagenicity and chromosomal damage were negative. There was no effect on fertility in rats (1).

Darunavir crosses the human placenta (2–4). The darunavir umbilical cord plasma:maternal plasma ratios at term in two women taking 600/100 mg (darunavir/ritonavir) twice daily during pregnancy were 0.154 and 0.315 (2). The drug also was detected in cord blood at birth in two other women (3,4). The presence of the drug in fetal blood is consistent with the molecular weight (about 594) and prolonged elimination half-life.

Two case reports described the use of darunavir in two pregnancies beginning at 28 and 30 weeks' gestation (5,6). Both pregnancies ended with births of healthy infants.

The Antiretroviral Pregnancy Registry reported, for the period January 1989 through July 2009, prospective data (reported before the outcomes were known) involving 4702 live births that had been exposed during the 1st trimester to one or more antiretroviral agents (7). Congenital defects were noted in 134, a prevalence of 2.8% (95% confidence interval [CI] 2.4–3.4). In the 6100 live births with earliest exposure in the 2nd/3rd trimesters, there were 153 infants with defects (2.5%, 95% CI 2.1–2.9). The prevalence rates for the two periods did not differ significantly. There were 288 infants with birth defects among 10,803 live births with exposure anytime during pregnancy (2.7%, 95% CI 2.4–3.0). The prevalence rate did not differ significantly from the rate expected in a nonexposed population. There were 51 outcomes exposed to darunavir (31 in the 1st trimester and 20 in the 2nd/3rd trimesters) in combination with other antiretroviral agents. There were two birth defects (two in the 1st trimester and none in the 2nd/3rd trimesters). In reviewing the birth defects of prospective and retrospective (pregnancies reported after the outcomes were known) registered cases, the Registry concluded that, except for isolated cases of neural tube defects with efavirenz exposure in retrospective reports, there was no other pattern of anomalies (isolated or syndromic) (7). (See Lamivudine for required statement.)

In 1998, a public health advisory was issued by the FDA on the association between protease inhibitors and diabetes mellitus (8). Because pregnancy is a risk factor for hyperglycemia, there was concern that these antiretroviral agents would exacerbate this risk. The manufacturer's product information also notes the potential risk for new-onset diabetes, exacerbation of preexisting diabetes, and hyperglycemia in HIV-infected patients receiving protease inhibitor therapy (1). An abstract published in 2000 described the results of a study involving 34 pregnant women treated with protease inhibitors compared with 41 controls that evaluated the association with diabetes (9). No association between protease inhibitors and an increased incidence of gestational diabetes was

found.

Two reviews, one in 1996 and the other in 1997, concluded that all women currently receiving antiretroviral therapy should continue to receive therapy during pregnancy and that treatment of the mother with monotherapy should be considered inadequate therapy (10,11). The same conclusion was reached in a 2003 review with the added admonishment that therapy must be continuous to prevent emergence of resistant viral strains (12). In 2009, the updated U.S. Department of Health and Human Services guidelines for the use of antiretroviral agents in HIV-1-infected patients continued the recommendation that therapy, with the exception of efavirenz, should be continued during pregnancy (13). If indicated, therefore, protease inhibitors, including darunavir, should not be withheld in pregnancy because the expected benefit to the HIV-positive mother outweighs the unknown risk to the fetus. Pregnant women taking protease inhibitors should be monitored for hyperglycemia. Updated guidelines for the use of antiretroviral drugs to reduce perinatal HIV-1 transmission also were released in 2010 (14). Women receiving antiretroviral therapy during pregnancy should continue the therapy, but, regardless of the regimen, zidovudine administration is recommended during the intrapartum period to prevent vertical transmission of HIV to the newborn (14).

BREASTFEEDING SUMMARY

No reports describing the use of darunavir during lactation have been located. The molecular weight (about 594) and prolonged elimination half-life (about 15 hours) suggest that the drug will be excreted into breast milk. The effect on a nursing infant is unknown.

Reports on the use of darunavir during human lactation are unlikely because the antiviral agent is used in the treatment of HIV infections. HIV-1 is transmitted in milk, and in developed countries, breastfeeding is not recommended (10,11,13,15–17). In developing countries, breastfeeding is undertaken, despite the risk, because there are no affordable milk substitutes available. Until 1999, no studies had been published that examined the effect of any antiretroviral therapy on HIV-1 transmission in milk. In that year, a study involving zidovudine was published that measured a 38% reduction in vertical transmission of HIV-1 infection despite breastfeeding when compared with controls (see Zidovudine).

DASATINIB

Antineoplastic (Tyrosine Kinase Inhibitor)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

The limited human experience involves therapy that was started before conception and then discontinued when pregnancy was diagnosed. The data are too limited to assess the embryo–fetal risk. There are human pregnancy data for imatinib, a drug in the same subclass and with the same mechanism of action as dasatinib. (See Imatinib.) Agents in this subclass inhibit angiogenesis, a critical component of embryonic and fetal development. Women of childbearing potential should use adequate contraception to prevent pregnancy. However, leukemia can be fatal, so if a woman requires dasatinib and informed consent is obtained, treatment should not be withheld because of pregnancy. If an inadvertent pregnancy occurs, the woman should be advised of the potential risk for severe adverse effects in the embryo and fetus.

FETAL RISK SUMMARY

Dasatinib is an oral tyrosine kinase inhibitor that inhibits tumor growth, pathologic angiogenesis, and metastatic progression of cancer. There are several other agents in this antineoplastic subclass (see Appendix). Dasatinib is indicated for the treatment of adults with chronic, accelerated, or myeloid or lymphoid blast-phase chronic myeloid leukemia with resistance or intolerance to prior therapy including imatinib. It is extensively metabolized in the liver. One of the metabolites has activity that is equipotent to dasatinib. The exposure of the active metabolite is about 5% of the dasatinib AUC. The mean plasma elimination half-life is 3–5 hours. Elimination is primarily in the feces. The binding of dasatinib and the active metabolite by human plasma proteins is high, about 96% and 93%, respectively (1).

Reproduction studies have been conducted in rats and rabbits. In pregnant rats and rabbits, the lowest doses tested produced maternal AUCs that were

0.3 and 0.1 times, respectively, the human AUC in females at the recommended dose of 70 mg twice daily. At this dose, fetal death was observed in rats. Other embryo–fetal toxicities included skeletal malformations at multiple sites (scapula, humerus, femur, radius, ribs, and clavicle), reduced ossification (sternum; thoracic, lumbar, and sacral vertebrae; forepaw phalanges; pelvis; and hyoid body), edema, and microhepatia (1).

Studies for carcinogenicity and effects on sperm counts, function, and fertility have not been conducted. Dasatinib was not mutagenic or genotoxic in tests, but was clastogenic in one test, with and without metabolic activation (1).

It is not known if dasatinib crosses the human placenta. The molecular weight (about 486 for the nonhydrated form) is low enough, but the short plasma elimination half-life and high plasma protein binding should limit the amount crossing to the embryo–fetus. However, the drug has a very high volume of distribution, suggesting that it is extensively distributed into extravascular space (1).

A 2010 case report described a woman who was being treated with dasatinib (80 mg/day) for chronic myeloid leukemia (2). An unplanned pregnancy occurred and the drug was discontinued about 8 weeks after conception. Treatment was changed to interferon alfa (9 million IU/day). At 33 weeks' gestation, a cesarean section delivered a healthy, 2.1-kg male infant with an Apgar score of 9 at 10 minutes. No malformations were evident and the infant's growth and development were normal through 8 months of age (2).

The authors of the above report also cited a study that had been presented at a scientific meeting (3). Of eight women exposed to dasatinib during early pregnancy, two had spontaneous abortions, three had elective abortions, and three delivered apparently normal infants (3).

BREASTFEEDING SUMMARY

No reports describing the use of dasatinib during human lactation have been located. The molecular weight (about 486 for the nonhydrated form) of the parent compound is low enough, but the short plasma elimination half-lives of dasatinib and its active metabolite and the high plasma protein binding should limit the amounts excreted into breast milk. The risk to a nursing infant is unknown, but there is potential for severe toxicity affecting multiple systems.

DAUNORUBICIN

Antineoplastic

PREGNANCY RECOMMENDATION: Human and Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Human exposures to daunorubicin during organogenesis are too limited to assess the risk magnitude for congenital defects. Bone marrow suppression, a common toxicity in adults receiving the drug, is a potential fetal complication.

FETAL RISK SUMMARY

Daunorubicin is a cytotoxic antibiotic used as an antineoplastic agent. It is indicated, in combination with other approved anticancer drugs, for remission induction in acute nonlymphocytic leukemia (myelogenous, monocytic, erythroid) of adults and for remission induction in acute lymphocytic leukemia in children and adults. It is in the same antineoplastic subclass of anthracyclines as doxorubicin, epirubicin, idarubicin, and valrubicin (1).

In animal reproduction studies, exposure to daunorubicin during pregnancy produced teratogenic and toxic effects in rabbits, rats, and mice (1). In rabbits, a dose that was about 0.01 times the maximum recommended human dose based on BSA (MRHD) resulted in an increased incidence of abortions and fetal anomalies (parieto-occipital cranioschisis, umbilical hernias, or rachischisis). Malformations in rats administered doses about 0.5 times the MRHD included esophageal, cardiovascular, and urogenital malformations, as well as fused ribs. Restricted fetal and neonatal growth was observed in mice after maternal administration of daunorubicin (1).

The use of daunorubicin during pregnancy has been reported in 29 patients, four during the 1st trimester (2–19). No congenital defects were observed in the 22 (one set of twins) liveborns, but one of these infants was anemic and hypoglycemic and had multiple serum electrolyte abnormalities (8). Two infants had transient neutropenia at 2 months of age (4). Severe, transient, drug-induced bone marrow hypoplasia occurred in one newborn after in utero

exposure to daunorubicin and five other antineoplastic agents (18). The myelosuppression may have been secondary to mercaptopurine, but bone marrow suppression also is a toxic effect of daunorubicin. The infant made an uneventful recovery. Results of the remaining pregnancies were three elective abortions (one with enlarged spleen), three intrauterine deaths (one probably due to severe pregnancy-induced hypertension), one stillborn with diffuse myocardial necrosis, and one maternal death (8,9,15,17). Thirteen of the infants (including one set of twins) were studied for periods ranging from 6 months to 9 years and all showed normal growth and development (4,9–11,14,15,17–19).

Data from one review indicated that 40% of the infants exposed to anticancer drugs were of low birth weight (20). This finding was not related to timing of the exposure. Except for the infants noted above, long-term studies of growth and mental development in offspring exposed to daunorubicin during the 2nd trimester, the period of neuroblast multiplication, have not been conducted (21).

In one report, the use of daunorubicin and other antineoplastic drugs in two males was thought to be associated with congenital defects in their offspring (22). The defects observed were tetralogy of Fallot and syndactyly of the first and second digits of the right foot, and an anencephalic stillborn. Although the authors speculated that the drugs damaged the germ cells without producing infertility and thus were responsible for the defects, any relationship to paternal use of daunorubicin is doubtful due to the lack of experimental evidence and other confirming reports. In a third male, fertilization occurred during treatment with daunorubicin and resulted in the birth of a healthy infant (23). Successful pregnancies have also been reported in two women after treatment with daunorubicin (24).

Chromosomal aberrations were observed in the fetus of a 34-year-old woman with acute lymphoblastic leukemia who was treated with multiple antineoplastic agents (12). Daunorubicin was administered for approximately 3 weeks beginning at 22 weeks' gestation. A healthy female infant was delivered 18 weeks after the start of therapy. Chromosomal analysis of the newborn revealed a normal karyotype (46,XX) but with gaps and a ring chromosome. The clinical significance of these findings is unknown, but since these abnormalities may persist for several years, the potential existed for an increased risk of cancer as well as for a risk of genetic damage in the next generation (12).

Occupational exposure of the mother to antineoplastic agents during pregnancy may present a risk to the fetus. A position statement from the

National Study Commission on Cytotoxic Exposure and a research article involving some antineoplastic agents are presented in the monograph for cyclophosphamide (see Cyclophosphamide).

BREASTFEEDING SUMMARY

No reports describing the use of daunorubicin during lactation have been located. Because of the potential for severe toxicity in a nursing infant, the use of this agent is contraindicated during breastfeeding.

DECAMETHONIUM

[Withdrawn from the market. See 8th edition.]

DECITABINE

Antineoplastic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of decitabine in human pregnancy have been located. The animal reproduction data at a small fraction of the human dose suggest risk, but the absence of human pregnancy experience prevents a more complete assessment of embryo–fetal risk. Pregnant women should not be given this drug, especially in the 1st trimester. If an inadvertent pregnancy occurs, the woman should be advised of the potential risk for severe adverse effects in the embryo and fetus. In addition, because of the animal fertility studies, men should be advised not to father a child while receiving decitabine and for 2 months after treatment (1).

FETAL RISK SUMMARY

Decitabine is an analog of the natural nucleoside 2'-deoxycytidine that is administered by IV infusion every 8 hours for 3 days, and then repeated 6 weeks for at least four cycles. It is in the same antineoplastic subclass as azacitidine and nelarabine. Decitabine is indicated for the treatment of patients with myelodysplastic syndromes (MDS) including previously treated and untreated, de novo and secondary MDS of all French-American-British subtypes (refractory anemia, refractory anemia with ringed sideroblasts, refractory anemia with excess blasts, refractory anemia with excess blasts in transformation, and chronic myelomonocytic leukemia) and Intermediate-1, Intermediate-2, and High-Risk International Prognostic Scoring System groups (1). The metabolic fate of decitabine is not known, but the terminal-phase half-life is about 0.5 hours. Plasma protein binding is <1% (1).

Reproduction studies have been conducted in mice and rats. In pregnant mice, a single intraperitoneal (IP) dose, given on gestational days 8, 9, 10, or

11, that was 2% of the daily recommended clinical dose based on BSA (DRCD) was associated with reduced fetal weight and supernumerary ribs. A dose that was about 7% of the DRCD caused reduced fetal weight, fetal death, and defects (supernumerary ribs, fused vertebrae and ribs, cleft palate, vertebral defects, hindlimb defects, and digital defects of fore- and hindlimbs). Moreover, when the 7% dose was given on gestational day 10, body weights of offspring were significantly reduced at all postnatal time points. Neither the 2% nor 7% doses caused maternal toxicity (1).

In pregnant rats, single IP doses, given on gestational days 9–12, that were about 5%, 8%, or 13% of the DRCD, respectively, were not maternal toxic but did cause developmental toxicity. There were no surviving fetuses with any dose given on day 9. A dose that was $\geq 8\%$ of the DRCD given on day 10 caused a significant decrease in fetal survival and reduced fetal weight. Dose-related malformations also were observed: Increased incidences of vertebral and rib anomalies (all dose levels); fore-digit defects (doses $\geq 8\%$ of the DRCD); and exophthalmia, exencephaly, and cleft palate (13% of the DRCD). The highest dose also was associated with reduced size and ossification of the long bones in the limbs (1).

Studies for carcinogenicity have not been conducted with decitabine, but the drug was mutagenic and caused chromosomal rearrangements in larvae of fruit flies. Fertility tests have been conducted in mice. Untreated female mice, when mated with males exposed in utero had decreased fertility. No adverse effects on survival, body weight gain, or hematological measurements were observed in male mice given IP doses that were about 0.3% to 1% of the DRCD 3 times a week for 7 weeks. However, a dose about 0.7% of the DRCD was associated with reduced testes weight, abnormal histology, and significant decreases in sperm count. In female mice mated with these males, pregnancy rates were reduced and postimplantation loss was significantly increased (1).

It is not known if decitabine crosses the human placenta. The molecular weight (about 228) and lack of plasma protein binding suggest that the drug will cross, but the very short terminal phase half-life will limit the amount of drug at the maternal: fetal interface.

BREASTFEEDING SUMMARY

No reports describing the use of decitabine during human lactation have been located.

The molecular weight (about 228) and lack of plasma protein binding suggest that the drug will be excreted into breast milk, but the very short terminal-phase

half-life will limit the amount excreted. The effect of this exposure on a nursing infant is unknown, but the potential toxicity may be severe. In adults, the most common adverse effects are neutropenia, thrombocytopenia, anemia, fatigue, pyrexia, nausea, cough, petechiae, constipation, diarrhea, and hyperglycemia (1).

DEFERASIROX

Antidote/Chelating Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Three reports describing the use of deferasirox in human pregnancy have been located (1–3). Doses that were very low in comparison with the human dose were used in the animal studies, presumably because higher doses were maternally toxic. The lack of fetal harm in these studies suggests that the risk in human pregnancy is low, but the limited human pregnancy experience prevents a more complete assessment. Another iron-chelating agent, deferoxamine, has been used in pregnancy without any evidence of fetal toxicity (see Deferoxamine).

FETAL RISK SUMMARY

Deferasirox is an oral iron-chelating agent indicated for the treatment of chronic iron overload due to blood transfusions. Although the affinity for zinc and copper is much lower, deferasirox also may lower serum concentrations of these metals. The absolute oral bioavailability is 70%, and the drug accumulates after multiple doses. Protein binding, almost exclusively to albumin, is very high (99%). Elimination of deferasirox and its metabolites is primarily by excretion in the feces, with an elimination half-life of 8–16 hours (4).

Reproduction studies have been conducted in rats and rabbits. No evidence of impaired fertility or fetal harm was observed in these species with oral doses up to about 0.8 times the recommended human dose based on BSA (RHD). No effects on fertility and reproductive performance were observed in male and female rats at doses up to about 0.6 times the RHD. Studies for carcinogenicity and mutagenicity also were negative (4).

It is not known if deferasirox crosses the human placenta. The molecular weight (about 373) and long elimination half-life suggest that exposure of the

embryo and/or fetus will occur, but the very high protein binding should limit the exposure.

Three case reports have described the use of deferasirox in pregnant women with thalassemia (1–3). In each case, the drug was started before conception and continued until pregnancy was diagnosed at 22, 20, and 12 weeks'. No abnormalities related to the exposure were observed in the normal newborns (1–3).

BREASTFEEDING SUMMARY

No reports describing the use of deferasirox during human lactation have been located. The molecular weight (about 373) and long elimination half-life (8–16 hours) suggest that the drug will be excreted into breast milk. The amount of oral absorption in an infant is unknown. However, in adults, the absolute oral bioavailability is 70%, and the drug accumulates after multiple doses (4). The recommended therapy with deferasirox is very long (months), and such therapy during breastfeeding might deplete the infant's iron stores. Therefore, if the mother is taking deferasirox, the safest course is not to breastfeed.

DEFEROXAMINE

Antidote/Chelating Agent

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Deferoxamine produces toxicity and teratogenicity in various animal species. Although the number of published human pregnancy exposures to deferoxamine is limited, none of the reports have observed adverse human developmental effects. In one of the reports discussed, the authors reviewed over 65 cases of human pregnancy exposure to the agent that occurred during the management of thalassemia or iron overdose (1). No toxic or teratogenic effects were documented. A 1998 review of metal-chelating agents also failed to find any published evidence of human developmental toxicity (2).

FETAL RISK SUMMARY

Deferoxamine is used for the treatment of acute iron intoxication and chronic iron overload. Animal reproduction studies have shown delayed ossification in mice and skeletal anomalies in rabbits with daily doses up to 4.5 times the maximum daily human dose. No fetal adverse effects were observed in rats administered similar doses (3).

In another animal reproduction study, pregnant mice were administered intraperitoneal doses of deferoxamine (44, 88, 176, and 352 mg/kg/day) on gestational days 6 through 15. On a weight basis, the lower two doses are comparable to the therapeutic human dose. The no-observed-adverse-effect-level (NOAEL) for maternal toxicity (reduced body weight) was <44 mg/kg/day, whereas the NOAEL for fetal developmental toxicity was 176 mg/kg/day. The only fetal toxic effect was a decrease in the number of live fetuses that was observed at 352 mg/kg/day (4).

A number of reports have described the use of deferoxamine in human pregnancy either for acute iron overdose or for transfusion-dependent

thalassemia (1,5–9). A brief mention of three other pregnant patients treated with deferoxamine for acute overdose appeared in an earlier report, but no details were given except that all of the infants were normal (10). The authors have knowledge of a seventh patient treated in the 3rd trimester for overdose with normal outcome (S.M. Lovett, unpublished data, 1985).

In a thalassemia patient, deferoxamine was given by continuous subcutaneous infusion pump, 2 g every 12 hours, for the first 16 weeks of pregnancy (5). A cesarean section was performed at 33 weeks' gestation for vaginal bleeding and premature rupture of the membranes, with delivery of a normal preterm male infant. The neonatal period was complicated by hypoglycemia and prolonged jaundice lasting 6 weeks, but neither problem was thought to be related to deferoxamine. A 1999 report described the use of deferoxamine in an 18-year-old pregnant woman with hemoglobin E beta zero thalassemia, chronic hepatitis C, and iron overload (1). She conceived while receiving an SC dose of 40 mg/kg 4 days/week plus an additional 50-mg/kg IV every month with a transfusion. Therapy was stopped when the pregnancy was diagnosed, but then was restarted at 18 weeks' gestation because of increased iron accumulation. The dose was increased in increments in response to her high ferritin levels, eventually reaching a 50-mg/kg/day IV dose. She delivered an approximately 2298-g, normal male infant at 38 weeks' gestation. The boy was developing normally at 10 months of age and no toxic effects on bone formation, the auditory system, or the ocular system were found (1).

Several pregnant women have received deferoxamine therapy for iron overdose that occurred at 15–38 weeks' gestation (6–9). The women were treated with IM deferoxamine, and one also received the drug nasogastrically. Spontaneous labor with rupture of the membranes occurred 8 hours after iron ingestion in a 34-week gestation patient, resulting in the vaginal delivery 6 hours later of a normal male infant (6). The cord blood iron level was 121 mcg/dL (normal 106–227 mcg/dL) but fell to 21 mcg/dL at 12 hours. The infant's clinical course was normal except for low iron levels requiring iron supplementation. The authors suggested that the low neonatal iron levels were due to chelation of iron by transplacentally transferred deferoxamine. In another case, a normal-term male infant was delivered without evidence of injury from deferoxamine (6). Normal infants were delivered also in the other two cases, both at times distant from the use of deferoxamine (8,9).

BREASTFEEDING SUMMARY

No reports describing the use of deferoxamine in lactation have been located. The molecular weight (about 657) is low enough that some excretion into breast milk probably occurs. The effects, if any, on a nursing infant from this exposure are unknown.

DEHYDROEPIANDROSTERONE

Dietary Supplement

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports investigating the potential teratogenic effects from use of dehydroepiandrosterone (DHEA) in human pregnancy have been located. DHEA and its active metabolite (DHEA sulfate; DHEA-S) are weak androgens and intermediates in the biosynthesis of testosterone and estradiol. The animal reproduction data suggest that DHEA and/or DHEA-S may cause virilization of the external genitalia in female fetuses and inhibit implantation or development of the pregnancy when administered shortly after conception. However, the doses used in these studies were not compared with the human dose based on BSA or AUC, so the results might not be interpretable for estimating human risk. Moreover, DHEA-S, and probably also DHEA, crosses the human placenta. Although the intrauterine fluid DHEA-S concentrations were very low, higher levels in the embryos and fetuses may have been present. If the agent is used in pregnancy, the patient should be informed of the animal data and limited human pregnancy experience.

FETAL RISK SUMMARY

Although not approved by the FDA, DHEA is available as an over-the-counter nutritional or dietary supplement. The dose of the drug in individual products is not known. Endogenous DHEA and DHEA-S are secreted by the adrenal cortex. In the systemic circulation, most DHEA is present as DHEA-S. DHEA has been promoted for treatment of systemic lupus erythematosus, fat burn, boosting libido, as an anti-aging treatment, and for other uses, but none of these benefits has been demonstrated in controlled studies. In the plasma, DHEA is weakly bound, whereas DHEA-S is strongly bound to albumin. The

half-lives of DHEA and DHEA-S are 1–3 hours and 10–20 hours, respectively (1). The metabolic clearance rate of DHEA-S fluctuates throughout pregnancy (2).

Developmental and reproductive toxicity of DHEA has been studied in three species. In rats, DHEA was associated with failure of implantation (3) and dose-related virilization of female fetuses (increased anogenital distance) and reduced fetal weight (4). Rats exposed to DHEA on gestation days 6–17 demonstrated increased early resorptions (5). In mice, prenatal exposure to DHEA on days 11–17 was associated with increased anogenital distance but did not have a significant effect on behavior of the offspring (6). In another study, maternal weight, number, survival, and weight of pups were affected by DHEA (7). In rabbits, no effects on embryonic or fetal development were seen at various doses of DHEA during gestation days 7–20 (5).

No studies on the carcinogenic or mutagenic potential of DHEA have been located. However, a European case–control study found an association between higher serum concentrations of DHEA-S and breast cancer (8).

DHEA-S, and most likely DHEA, crosses the human placenta. This is consistent with the molecular weights of the two compounds, about 288 and 371, respectively. DHEA-S was found in intrauterine fluids only at the limit of detection in a study of 12 pregnant women at a gestational age of 8–12 weeks (9). The authors postulated that because the concentration of androgens was much lower in the intrauterine fluids compared with maternal serum, that there might be a mechanism for the protection of the embryo from higher concentrations of these hormones. Concentrations in the embryos or fetuses were not measured.

In a study of 25 women with diminished ovarian reserve, patients received 25 mg of DHEA three times daily for 16 weeks between two in vitro fertilization (IVF) cycles (10). Significant increases in fertilized oocytes, normal 3-day embryos, embryos transferred, and average embryo scores per oocyte were observed. A follow-up case–control study with 190 women undergoing IVF treatment due to diminished ovarian function demonstrated that DHEA supplementation resulted in significantly higher cumulative pregnancy rates (11).

BREASTFEEDING SUMMARY

No reports on the use of DHEA during lactation have been located. Estrogens have been associated with decreased milk production and concentrations of nitrogen and protein (see Ethinyl Estradiol). As DHEA is an intermediate in the biosynthesis of estrogen, it could decrease milk production as well (12).

Although it has not been studied, this effect should be dose-related. If used during breastfeeding, infant weight gain should be closely monitored.

DELAVIRDINE

Antiviral

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

The limited human data do not allow a prediction as to the risk of delavirdine during pregnancy. The animal data indicate that the drug may represent a risk to the developing human fetus. If indicated, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Delavirdine is a synthetic nonnucleoside reverse transcriptase inhibitor (nnRTI) that is used in the treatment of HIV type 1 (HIV-1). Because resistant viruses emerge rapidly with delavirdine monotherapy, the drug should always be used in combination with other antiretroviral agents (1). Other drugs in this class are efavirenz and nevirapine.

Reproductive studies with delavirdine have been conducted in rats and rabbits. Ventricular septal defects were produced when pregnant rats were administered the agent during organogenesis at doses producing systemic levels equal to or lower than the expected human exposure at the recommended dose (EHE) (1). Reduced pup survival on the day of birth was also noted at this dose. At doses producing 5 times the EHE, marked maternal toxicity, embryo toxicity, fetal developmental delay, and reduced pup survival were observed. Delavirdine administered during organogenesis to rabbits caused maternal toxicity, embryo toxicity, and abortions (1). The lowest dose producing these effects was about six times the EHE. No malformations were observed in the surviving rabbit offspring, but only a few were available for examination (1).

It is not known if delavirdine crosses the human placenta. The molecular weight of the free base (about 457) is low enough that passage to the fetus should be expected.

During premarketing clinical studies, seven unplanned pregnancies occurred, resulting in three ectopic pregnancies, three healthy live births, and one premature infant with a birth defect (1). The infant, exposed early in gestation to about 6 weeks of delavirdine and zidovudine, had a small muscular ventricular septal defect.

The Antiretroviral Pregnancy Registry reported, for January 1989 through July 2009, prospective data (reported before the outcomes were known) involving 4702 live births that had been exposed during the 1st trimester to one or more antiretroviral agents (2). Congenital defects were noted in 134, a prevalence of 2.8% (95% confidence interval [CI] 2.4–3.4). In the 6100 live births with earliest exposure in the 2nd/3rd trimesters, there were 153 infants with defects (2.5%, 95% CI 2.1–2.9). The prevalence rates for the two periods did not differ significantly. There were 288 infants with birth defects among 10,803 live births with exposure anytime during pregnancy (2.7%, 95% CI 2.4–3.0). The prevalence rate did not differ significantly from the rate expected in a nonexposed population. There were 14 outcomes exposed to delavirdine (11 in the 1st trimester and 3 in the 2nd/3rd trimesters) in combination with other antiretroviral agents. There were no birth defects. In reviewing the birth defects of prospective and retrospective (pregnancies reported after the outcomes were known) registered cases, the Registry concluded that, except for isolated cases of neural tube defects with efavirenz exposure in retrospective reports, there was no other pattern of anomalies (isolated or syndromic) (2). (See Lamivudine for required statement.)

Two reviews, one in 1996 and the other in 1997, concluded that all women currently receiving antiretroviral therapy should continue to receive therapy during pregnancy and that treatment of the mother with monotherapy should be considered inadequate therapy (3,4). The same conclusion was reached in a 2003 review with the added admonishment that therapy must be continuous to prevent emergence of resistant viral strains (5). In 2009, the updated U.S. Department of Health and Human Services guidelines for the use of antiretroviral agents in HIV-1-infected patients continued the recommendation that therapy, with the exception of efavirenz, should be continued during pregnancy (6). If indicated, delavirdine should not be withheld in pregnancy because the expected benefit to the HIV-positive mother outweighs the unknown risk to the fetus. Updated guidelines for the use of antiretroviral drugs to reduce perinatal HIV-1 transmission also were released in 2006 (7). Women receiving antiretroviral therapy during pregnancy should continue the therapy but, regardless of the regimen, zidovudine administration is recommended

during the intrapartum period to prevent vertical transmission of HIV to the newborn (7).

BREASTFEEDING SUMMARY

No reports describing the use of delavirdine during lactation have been located. The molecular weight of the free base (about 457) is low enough that excretion into breast milk should be expected. The effect on a nursing infant is unknown.

Reports on the use of delavirdine during human lactation are unlikely, however, because the antiviral agent is used in the treatment of HIV infections. HIV-1 is transmitted in milk, and in developed countries, breastfeeding is not recommended (3,4,6,8–10). In developing countries, breastfeeding is undertaken, despite the risk, because there are no affordable milk substitutes available. Until 1999, no studies had been published that examined the effect of any antiretroviral therapy on HIV-1 transmission in milk. In that year, a study involving zidovudine was published that measured a 38% reduction in vertical transmission of HIV-1 infection despite breastfeeding when compared with controls (see Zidovudine).

DEMECLOCYCLINE

Antibiotic (Tetracycline)

See Tetracycline.

DENILEUKIN DIFTITOX

Antineoplastic

PREGNANCY RECOMMENDATION: No Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of denileukin diftiox in human pregnancy have been located. The absence of both animal and human pregnancy experience prevents an assessment of the embryo–fetal risk. The potential for severe infusion-related toxicity is an important risk factor. Until human pregnancy experience is available, the best course is to avoid use of this agent in pregnancy. However, if a woman requires denileukin diftiox and informed consent is obtained, it should not be withheld because of pregnancy. If an inadvertent pregnancy occurs, the woman should be advised of the unknown risk to her embryo and/or fetus.

FETAL RISK SUMMARY

The biological response modifier, denileukin diftiox, is a recombinant DNA-derived cytotoxic protein composed of amino acid sequences for diphtheria toxin fragments and for interleukin-2. It is in the same antineoplastic subclass as aldesleukin. Denileukin diftiox is indicated for the treatment of patients with persistent or recurrent cutaneous T-cell lymphoma. After an IV infusion, the half-lives of the distribution phase (about 2–5 minutes) and the terminal elimination phase (about 70–80 minutes) are rapid. Denileukin diftiox is metabolized by proteolytic degradation (1).

Denileukin diftiox may cause severe, infusion-related toxicity, including hypotension and other adverse effects. Treatment with IV antihistamines, corticosteroids, and epinephrine may be required (1). Hypotension in a pregnant woman could have deleterious effects on placental perfusion, resulting in embryo and fetal harm. Moreover, the potent α -adrenergic properties of epinephrine also can cause decreased placental perfusion. IV ephedrine might

be a better choice to treat maternal hypotension.

Neither animal reproduction studies nor fertility studies have been conducted with denileukin diftitox. Studies for carcinogenicity also have not been conducted, but there was no evidence of mutagenic effects.

It is not known if denileukin diftitox crosses the human placenta. The molecular weight of the protein, about 58,000, suggests that it does not cross. However, other proteins, such as the immunoglobulins, cross the placenta. Moreover, the protein rapidly distributes into tissues (e.g., primarily into the liver and kidneys in rats). The very short distribution and elimination half-lives may limit the amount reaching the embryo and fetus.

BREASTFEEDING SUMMARY

No reports describing the use of denileukin diftitox during human lactation have been located. The molecular weight of the protein, about 58,000, suggests that it will not be excreted into breast milk. However, other proteins, such as the immunoglobulins, are excreted into milk and so may denileukin diftitox. The very short distribution (2–5 minutes) and elimination (70–80 minutes) half-lives may limit the amount in milk. Waiting about 7 hours after a dose to breastfeed should limit the potential exposure of the infant even more. The effect of exposure on a nursing infant is unknown.

DENOSUMAB

Immunologic Agent (Antiosteoporosis)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of denosumab in human pregnancy have been located. Such reports are unlikely because the monoclonal antibody is indicated only for postmenopausal women. The animal data in monkeys suggest low risk. Although exposure to denosumab during pregnancy might impair mammary gland development and subsequent lactation, the absence of human pregnancy experience prevents an accurate assessment of the maternal and embryo–fetal risk. If a woman becomes pregnant during denosumab therapy, physicians are encouraged to enroll her in the Amgen Pregnancy Surveillance Program by calling 800-77-AMGEN (800-772-6436) (1). Pregnant patients also can enroll themselves by calling the same number.

FETAL RISK SUMMARY

Denosumab is a human IgG2 monoclonal antibody that binds to a protein that is essential for bone resorption, thereby decreasing bone resorption and increasing bone mass. It is indicated for the treatment of postmenopausal women with osteoporosis at high risk for fracture or for patients who have failed or are intolerant to other available osteoporosis therapy. Denosumab is given as an SC injection every 6 months. Because hypocalcemia may occur, all patients should receive calcium (1000 mg/day) and vitamin D (at least 400 IU/day). The mean serum half-life of denosumab is about 25 days (1).

Reproduction studies have been conducted in cynomolgus monkeys. In monkeys, during organogenesis, SC doses up to 13 times the recommended human dose of 60 mg given once every 6 months based on body weight (RHD) revealed no evidence of maternal toxicity or fetal harm. However, fetal lymph nodes were not examined and the toxicity of the antibody in the 2nd and 3rd

trimesters, the periods when increasing amounts of monoclonal antibodies are expected to cross the placenta was not studied (1).

In pregnant mice lacking the protein target of denosumab (knockout mice), absence of the target led to fetal lymph node agenesis and postnatal impairment of dentition and bone growth. The mice also had altered maturation of the maternal mammary gland and impaired lactation (1).

Studies of carcinogenicity and mutagenicity have not been conducted. No effects on female fertility or male reproductive organs were observed in monkeys given doses that were 13–50 times the RHD (1).

It is not known if denosumab crosses the human placenta. The molecular weight (about 147,000) suggests that transfer will be inhibited but the long serum half-life will favor transfer. The manufacturer states that monoclonal antibodies are transported across the placenta with the highest amounts in the 3rd trimester (1).

BREASTFEEDING SUMMARY

No reports describing the use of denosumab during human lactation have been located. Such reports are unlikely because the monoclonal antibody is only indicated for postmenopausal women. The molecular weight (about 147,000) suggests that excretion into breast milk will be inhibited but the long serum half-life may favor excretion. If there is excretion, digestion in the infant's gut will probably occur.

DESFLURANE

General Anesthetic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Desflurane is not teratogenic in two animal species, but there are no reports of its use early in human gestation. The animal data are reassuring, but the absence of human data during organogenesis precludes an estimation of the risk for structural anomalies. In addition, general anesthesia usually involves the use of several pharmacological agents. Although no teratogenicity has been observed with three other halogenated general anesthetic agents (halothane, isoflurane, and methoxyflurane), only halothane has 1st trimester human exposure data (1). The use of desflurane during cesarean section does not appear to affect the newborn any differently from other general anesthetic agents. All such agents can cause depression in the newborn that may last for 24 hours or more. The potential reproductive toxicity (spontaneous abortion and infertility) of occupational exposure to desflurane has not been studied but is a concern based on the exposure concentration found in one study. In addition, occupational exposure to nitrous oxide also was measured in that study, and indicated that the nurses were exposed to both nitrous oxide and volatile anesthetic agents at the same time.

FETAL RISK SUMMARY

Desflurane, a general inhalation anesthetic agent administered via vaporizer, is indicated for the induction and/or maintenance of anesthesia during surgery. It is a nonflammable, volatile liquid that is in the same class of halogenated agents as enflurane, halothane, isoflurane, methoxyflurane, and sevoflurane. Desflurane is closely related chemically to enflurane and isoflurane. The only difference between desflurane and isoflurane is the substitution of fluorine in

desflurane for the single chlorine atom in isoflurane. This small change, however, produces marked pharmacokinetic and clinical effects. The potency of desflurane is 20% that of isoflurane, the blood–gas partition coefficient is reduced (i.e., reduced solubility in blood) (0.42 vs. 1.46) as is tissue solubility (brain–blood partition coefficient 1.3 vs. 1.6), and recovery from anesthesia is faster (2).

Three mutagenic tests with desflurane found no evidence of genotoxicity (3). No teratogenic effects were observed in reproduction tests with rats and rabbits at doses of approximately 10 and 13 cumulative minimum alveolar anesthetic concentration (MAC-hour) exposures at 1 MAC-hour/day, respectively, during organogenesis. (Note: MAC is the concentration that causes immobility in 50% of patients exposed to a noxious stimulus such as a surgical incision; it represents the ED₅₀ [4]). However, an approximately 6% decrease in the body weight of male rat pups delivered prematurely by cesarean section was noted at this dose. No treatment-related behavioral changes or other toxicity (dystocia or decreased body weight) were observed in rat offspring exposed to desflurane 1 MAC-hour/day from gestation day 15–lactation day 21 (3).

The low molecular weight (about 168) and the presence of desflurane in the brain suggest that it will cross the placenta to the fetus. Two reviews have concluded that, in general, inhalational anesthetic agents are freely transferred to fetal tissues (1,5) and, in most cases, the maternal and fetal blood concentrations are approximately equivalent (5). The relatively low human blood–gas partition coefficient and the rapid clearance from the maternal blood also suggest that desflurane will be rapidly cleared from the fetus, thus reducing the potential for neurobehavior depression of the newborn.

A brief 1993 report compared the closely related anesthetic agents, desflurane and enflurane (10 patients in each group), during cesarean delivery (6). Uterine tone increased significantly over time (a potential risk factor for maternal bleeding), but there were no differences between the groups. The mean umbilical vein:maternal artery ratios were 0.69 and 0.51, respectively. No differences between the groups were measured in the Neurological and Adaptive Capacity Scores (NACS) at 2 and 24 hours, 1 and 5 minute Apgar scores (8.0 and 8.9 vs. 7.5 and 9.0, respectively), and cord arterial blood gases or pH (6).

Two end-tidal concentrations of desflurane (3% and 6%) were compared with enflurane (0.6%) for cesarean section delivery in a 1995 study (7). The MACs for the three groups were 0.45, 0.90, and 0.40, respectively, thus

representing subanesthetic concentrations. A 50%–50% mixture of nitrous oxide and oxygen was administered with the anesthetic agents (25 patients in each group). Maternal blood loss was similar among the groups. In the newborns, the time-to-sustained-respiration was >90 seconds in one (4%), seven (28%), and five (20%), respectively. The increased incidence in the 6% desflurane group was significantly longer than in the 3% desflurane group. There were no significant differences in the NACS at 2 and 24 hours, but some depression was noted: NACS <35 at 2 hours in four (16%), seven (28%), and six (24%); and at 24 hours—one (4%), one (4%), and none, respectively. Low Apgar scores (<7) were found at 1 minute in three (12%), seven (28%), and six (24%), respectively (ns), and at 5 minutes in none, one (4%), and one (4%), respectively (ns) (7).

A 1995 study compared desflurane (1.0%–4.5%) and oxygen (N = 40) with nitrous oxide (30%–60%) in oxygen (N = 40) for analgesia during vaginal delivery (8). Maternal analgesia scores and blood loss were similar between the groups. Four (10%) of the desflurane group had an NACS < 35 at 2 hours compared with seven (18%) of those exposed to nitrous oxide (ns). At 24 hours, none of desflurane group had an NACS <35 compared with three (8%) in the nitrous oxide group (ns). Apgar scores <7 at 1 minute occurred in 13% and 8% (ns), respectively, but all Apgar scores were ≥7 at 5 minutes. However, nine patients in the desflurane group had amnesia for delivery, a potentially undesirable effect in an obstetrical patient (8).

A study published in 1998 evaluated the exposure of nine nurses in a postanesthesia care unit (PACU) to exhaled desflurane and isoflurane and compared these exposures with the National Institute of Occupational Safety and Health (NIOSH)-recommended exposure limits (9). The NIOSH recommendation for volatile anesthetics (without concomitant nitrous oxide exposure) is a maximum of 2 ppm, but it has not been adopted by the Occupational Safety and Health Administration. Moreover, the recommended limit is controversial and is thought by some to be inappropriately low. However, a potential for reproductive risk (spontaneous abortion and infertility) is thought to exist for some anesthetic agents. The study involved exposure in the PACU to exhaled anesthetic gases from 50 adult patients (desflurane N = 31, isoflurane N = 19) over an approximate 1-hour recovery time. About half the patients were extubated in the PACU. Exposure was continuously measured from the shoulders (i.e., breathing zone) of the nurses. Breathing-zone anesthetic concentrations of desflurane and isoflurane exceeded the NIOSH limits in 87% and 37% of the cases, respectively. These exposures were above

the limit 49% of the time for desflurane and 12% of the time for isoflurane. The investigators listed several limitations to their study and concluded that the results might represent a “worst-case analysis” (9).

A 2004 study found a significant association between maternal occupational exposure to waste anesthetic gases during pregnancy and developmental deficits in their children, including gross and fine motor ability, inattention/hyperactivity, and IQ performance (see Nitrous Oxide).

BREASTFEEDING SUMMARY

Although desflurane has been administered during labor and delivery, the effects of this exposure on the infant that begins nursing immediately after birth have not been described. Desflurane is probably excreted into colostrum and milk as suggested by its presence in the maternal blood and its low molecular weight (about 168), but the toxic potential of this exposure for the infant is unknown. However, the risk to a nursing infant from exposure to desflurane is probably very low (10). Moreover, the concentrations in milk should be less than other halogenated anesthetic agents because of the decreased blood and tissue solubility of desflurane and its rapid washout from the mother’s system. The manufacturer states that excretion in milk was not clinically important 24 hours after anesthesia (3). Another halogenated inhalation anesthetic, halothane, is classified as compatible with breastfeeding (see Halothane).

DESIPRAMINE

Antidepressant

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although the data are limited, desipramine does not appear to be a major human teratogen.

FETAL RISK SUMMARY

Desipramine, a tricyclic antidepressant, is an active metabolite of imipramine (see also Imipramine). No reports linking the use of desipramine with congenital defects have been located. Neonatal withdrawal symptoms, including cyanosis, tachycardia, diaphoresis, and weight loss, were observed after desipramine was taken throughout pregnancy (1).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 31 newborns had been exposed to desipramine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). One (3.2%) major birth defect was observed (one expected). No anomalies were observed in six defect categories (cardiovascular defects, oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available. The number of exposures is too small for comment.

In a 1996 descriptive case series, the European Network of the Teratology Information Services (ENTIS) prospectively examined the outcomes of 689 pregnancies exposed to antidepressants (2). Multiple drug therapy occurred in about two-thirds of the mothers. Desipramine was used in one pregnancy and the outcome was a spontaneous abortion.

In an in vitro study, desipramine was shown to be a potent inhibitor of sperm motility (3). A concentration of 27 $\mu\text{mol/L}$ produced a 50% reduction in motility.

A 2002 prospective study compared two groups of mother-child pairs: one group exposed to antidepressants throughout gestation (46 exposed to

tricyclics - 3 to desipramine; 40 to fluoxetine) and, the other group, 36 nonexposed, not depressed controls (4). Offspring between the ages 15 and 71 months were studied for effects of antidepressant exposure in terms of IQ, language, behavior, and temperament. Exposure to antidepressants did not adversely affect the measured parameters, but IQ was significantly and negatively associated with the duration of depression, and language was negatively associated with the number of depression episodes after delivery (4).

BREASTFEEDING SUMMARY

Desipramine is excreted into breast milk (5–7). No reports of adverse effects have been located. In one patient, milk:plasma ratios of 0.4–0.9 were measured with milk levels ranging between 17 and 35 mcg/mL (5). A 35-year-old mother in her 9th postpartum week took 300 mg of desipramine daily at bedtime for depression (7). One week later, simultaneous milk and serum samples were collected about 9 hours after a dose. Concentrations of desipramine in the milk and serum were 316 and 257 ng/mL (ratio 1.2), respectively, whereas levels of the metabolite, 2-hydroxydesipramine, were 381 and 234 ng/mL (ratio 1.6), respectively. The measurements were repeated 1 week later, 10.33 hours after the dose, and milk levels of the parent drug and metabolite were 328 and 327 ng/mL, respectively. No drug was detected in the infant's serum nor were any clinical signs of toxicity observed in the infant after 3 weeks of maternal treatment (7).

A 1996 review of antidepressant treatment during breastfeeding found no information that desipramine exposure during nursing resulted in quantifiable amounts in an infant or that the exposure caused adverse effects (8). The American Academy of Pediatrics classifies desipramine as a drug whose effect on the nursing infant is unknown but may be of concern (9).

DESIRUDIN

Hematological Agent (Thrombin Inhibitor)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of desirudin in human pregnancy have been located. The animal reproductive data suggest risk, but the absence of human pregnancy experience prevents an assessment of the embryo–fetal risk. Desirudin probably does not cross the placenta in clinically significant amounts but this needs study, especially in light of the teratogenicity observed in two animal species. Both unfractionated and low-molecular-weight heparin have been studied in pregnancy and probably are the preferred agents for prophylaxis against deep vein thrombus after surgery in a pregnant patient.

FETAL RISK SUMMARY

Desirudin, a specific inhibitor of human thrombin, is a single polypeptide chain with a protein structure differing slightly from that of hirudin, the anticoagulant present in the peripharyngeal glands of the medicinal leech, *Hirudo medicinalis*. Desirudin is indicated for the prophylaxis of deep vein thrombosis, which may lead to pulmonary embolism, in patients undergoing elective hip replacement surgery. It is administered as an SC injection. Desirudin is metabolized and eliminated by the kidney. The mean terminal elimination half-life is about 2 hours (1).

Reproduction studies have been conducted in rats and rabbits. In pregnant rats, daily SC doses that were 0.3–4 times the maximum recommended human dose based on BSA (MRHD) were teratogenic. Defects observed were omphalocele, asymmetric and fused sternbrae, shortened hind limbs, and other nonspecified defects. Edema also was observed. In pregnant rabbits, daily SC doses that were 0.3–3 times the MRHD were associated with spina

bifida, malrotated hindlimb, hydrocephaly, gastroschisis, and other nonspecified defects (1).

Carcinogenic studies have not been performed. Desirudin was not genotoxic in three tests but produced equivocal results in a fourth test. No effect on fertility in male and female rats was observed with doses ≤ 2.7 times the MRHD (1).

It is not known if desirudin crosses the human placenta. The animal data suggest that the drug had either a direct or an indirect effect on the embryos. However, the molecular weight, about 6964, and short elimination half-life suggest that exposure of embryo or fetus is unlikely.

BREASTFEEDING SUMMARY

No reports describing the use of desirudin during human lactation have been located. The molecular weight of this polypeptide (about 6964), and short elimination half-life (about 2 hours) suggest that excretion into breast milk is unlikely. However, even if the drug were excreted, it probably would be digested in the infant's gut because it is a protein. Thus, the risk to a nursing infant appears to be low, if it exists at all.

DESLANOSIDE

Cardiac Glycoside

See Digitalis.

DESLORATADINE

Antihistamine

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

The animal reproduction data suggest low risk, but the absence of human pregnancy experience prevents a full assessment of the risk. Although there are no reports describing the use of desloratadine in human pregnancy, there are reports for loratadine, the parent compound. (See Loratadine.) The data for loratadine are adequate to demonstrate that it is not a major human teratogen. Because desloratadine is a major metabolite of loratadine, it is reasonable to presume that desloratadine also is not a major teratogen (1). Moreover, antihistamines, in general, are not thought to cause human developmental toxicity at recommended doses. Although subjects classified as slow metabolizers will probably have greater embryo–fetal exposure to desloratadine, and possibly to its active metabolite, there is no reported evidence that such exposure will result in embryo–fetal toxicity. If an oral antihistamine is required during pregnancy, first-generation agents such as chlorpheniramine or tripeleminamine should be considered. However, if a woman has taken desloratadine during a known or unknown pregnancy, the absolute embryo–fetal risk appears to be low.

FETAL RISK SUMMARY

Desloratadine is a second-generation, peripherally selective H₁-receptor histamine antagonist that is indicated for the relief of nasal and nonnasal symptoms of allergic rhinitis. It is a major active metabolite of loratadine. (See also Loratadine.) Desloratadine itself is metabolized to an active metabolite by an enzyme that has not been identified. About 7% of the general population has decreased ability (i.e., slow metabolizers) to metabolize desloratadine, but the

incidence is about 20% in blacks. The median exposure to desloratadine, based on AUC, was about six-fold greater in subjects classified as slow metabolizers than in those with unaltered metabolism. Protein binding of desloratadine and its active metabolite is in the range of 82%–89%. In patients with unaltered metabolism, the mean elimination half-life of desloratadine is 27 hours, but it exceeds 50 hours in slow metabolizers (2).

Reproduction studies with desloratadine have been conducted in rats and rabbits. There was no evidence of teratogenicity or effect on fertility in rats at desloratadine and active metabolite exposures up to about 210 and 130 times, respectively, the AUC in humans at the recommended daily oral dose (RDOD). However, at about 120 times the RDOD, an increase in preimplantation loss and a decrease in the number of implantations and fetuses were observed. At about 50 times the RDOD, reduced body weight and slow righting reflex were noted. At about 7 times the RDOD, no effect was noted on pup development. In rabbits, there was no evidence of teratogenicity at desloratadine exposure up to about 230 times the RDOD (2).

It is not known if desloratadine (or its active metabolite) crosses the placenta. The molecular weight of desloratadine (about 311) and the prolonged elimination half-life suggest that it will cross to the embryo–fetal compartment. Moreover, patients who are slow metabolizers will have much higher plasma concentrations of desloratadine and an approximate doubling of the elimination time. Both of these properties should increase the amount of drug reaching the embryo–fetus.

BREASTFEEDING SUMMARY

Although there are no reports describing the use of desloratadine during human lactation, the parent compound (loratadine) has been studied. Both loratadine and desloratadine are excreted into human breast milk. The American Academy of Pediatrics classifies loratadine as compatible with breastfeeding. (See Loratadine.)

DESMOPRESSIN

Pituitary Hormone, Synthetic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Desmopressin is a synthetic polypeptide structurally related to vasopressin. Although the data are limited, no drug-induced toxicity related to its use in pregnancy has been reported. (See also Vasopressin.)

FETAL RISK SUMMARY

Reproduction studies with desmopressin in rats and rabbits at doses up to approximately 0.1 times and 38 times, respectively, the maximum systemic human exposure based on BSA, did not reveal fetal harm (1).

A 1997 report described five women with diabetes insipidus that were treated with desmopressin during six pregnancies (2). No desmopressin-related adverse effects were observed in the eight newborns (two sets of twins). A 1998 review cited 53 cases of desmopressin use during all stages of pregnancy for the management of diabetes insipidus (3). No adverse effects were noted in the cases. In a 1998 case report, diabetes insipidus in a woman with Sheehan's syndrome was managed with intranasal desmopressin in two pregnancies (4). No information on the status of the newborns was provided.

BREASTFEEDING SUMMARY

See Vasopressin.

DESVENLAFAXINE

Antidepressant

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 3rd Trimester

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of desvenlafaxine in human pregnancy have been located. The drug is the major active metabolite of venlafaxine that has some human pregnancy data (see also Venlafaxine). Neither the animal reproduction nor the limited human pregnancy experience with venlafaxine and other serotonin–norepinephrine reuptake inhibitors (SNRIs) suggest a major risk for structural anomalies. However, SNRIs and selective serotonin reuptake inhibitors (SSRIs) have been associated with spontaneous abortions, low birth weight, and prematurity. Exposure in the latter part of pregnancy has been associated with neonatal serotonin syndrome, neonatal behavioral syndrome (withdrawal including seizures), possible sustained abnormal neurobehavior beyond the neonatal period, and respiratory distress. These symptoms are consistent with a direct toxic effect, drug discontinuance syndrome, or a serotonin syndrome. Persistent pulmonary hypertension of the newborn (PPHN) is an additional potential risk, but confirmation is needed.

FETAL RISK SUMMARY

Desvenlafaxine, available as immediate- and extended-release formulations, is in the same antidepressant subclass of SNRIs as duloxetine, milnacipran, and venlafaxine. Desvenlafaxine is indicated for the treatment of major depressive disorder. It undergoes partial metabolism to apparently inactive metabolites. Plasma protein binding is low (30%) and the mean terminal half-life is about 11 hours (1).

Reproduction studies have been conducted in rats and rabbits. When these species were given desvenlafaxine during organogenesis, no evidence of

structural anomalies was observed with doses up to 10 and 15 times, respectively, the human dose of 100 mg/day based on BSA (HD). However, fetal weights were decreased in rats, with a no-effect dose 10 times the HD. Exposure of rats throughout gestation and lactation was associated with decreased pup weights and increased pup deaths during the first 4 days of lactation. The cause of the deaths was not known. The no-effect dose for pup mortality was 10 times the HD. Postweaning growth and reproductive performance of the offspring were not affected by maternal treatment at a dose 29 times the HD (1).

Desvenlafaxine was not carcinogenic in 2-year studies in mice and rats. Assays and studies for mutagenic and clastogenic effects also were negative. Reduced fertility was observed in male and female rats given doses about 10 times the HD. There was no effect on fertility with doses that were about 3 times the HD (1).

At term, desvenlafaxine crosses the human placenta (2). This is consistent with the molecular weight (about 381 for the nonhydrated form), low plasma protein binding, moderately long terminal half-life, and the toxicity observed in newborns. Although placental transfer of the drug has not been studied at other times, exposure of the embryo–fetus should be expected throughout gestation.

The use of desvenlafaxine late in the pregnancy may result in functional and behavioral deficits in the newborn infant. The observed toxicities with SNRIs and SSRIs include respiratory distress, cyanosis, apnea, seizures, temperature instability, feeding difficulty, vomiting, hypoglycemia, hypotonia, hypertonia, hyperreflexia, tremor, jitteriness, irritability, and constant crying. The clinical features are consistent with either a direct toxic effect or drug discontinuation syndrome and, occasionally, may resemble a serotonin syndrome. The complications may require prolonged hospitalization, respiratory support, and tube feeding (1). (See Venlafaxine for additional information.)

BREASTFEEDING SUMMARY

Consistent with the molecular weight (about 381 for the nonhydrated form), low plasma protein binding (30%), and moderately long elimination half-life (about 11 hours), desvenlafaxine is excreted into breast milk. (See also Venlafaxine.)

A 1998 study measured the excretion of venlafaxine and its active metabolite desvenlafaxine in the milk of three breastfeeding women (3). The three mothers, started on the antidepressant after delivery, had been taking a stable dose (3.04–8.18 mg/kg/day) for 0.23–5 months. The ages of the infants were 0.37–6 months. The mean milk:plasma (M:P) ratio (in two cases based on AUC

and in one on a single point) for the parent drug was 4.14 (range 3.26–5.18), whereas it was 3.06 (range 2.93–3.19) for the metabolite. The mean infant doses for venlafaxine and metabolite were 3.49% and 4.08% of the mother's weight-adjusted dose, respectively. Venlafaxine was not detected in infant plasma, but the median infant metabolite plasma concentration was 100 mcg/L (range 23–225 mcg/L). The mean total infant dose was 7.57% (range 4.74%–9.23%). No adverse effects in the infants were noted. Because of the relatively high infant dose in comparison with other antidepressants, it was recommended that close observation of the infant for short-term adverse effects (e.g., agitation, insomnia, poor feeding, or failure to thrive) was required (3).

A 2002 study determined the milk:plasma (M:P) ratios based on AUC and infant doses of venlafaxine and its metabolite desvenlafaxine in six mothers (mean age 34.5 years and weight 84.3 kg) and their seven nursing infants (mean age 7.0 months and weight 7.3 kg) (4). The median venlafaxine dose was 244 mg/day. The mean M:P ratios for the drug and its metabolite were 2.5 (range 2.0–3.2) and 2.7 (range 2.3–3.2), respectively, whereas the mean maximum milk concentrations were 1161 and 796 mcg/L, respectively. Using an estimated milk production rate of 150 mL/kg/day, the mean infant exposure expressed as a percentage of the weight-adjusted maternal dose was 3.2% (95% confidence interval [CI] 1.7–4.7) for venlafaxine and 3.2% (95% CI 1.9–4.9) for desvenlafaxine. Venlafaxine was detected in the plasma of one infant (5 mcg/L), whereas desvenlafaxine was detected in four infants (range 3–38 mcg/L). All of the infants were healthy (4).

In a 2009 report, 13 women taking venlafaxine (mean dose 194.3 mg/day) and their nursing infants (mean age about 21 weeks) were studied (5). The highest venlafaxine and desvenlafaxine concentrations in milk occurred 8 hours after maternal ingestion. For combined venlafaxine plus desvenlafaxine, the mean M:P ratio was 2.75, and the theoretical infant dose was 0.208 mg/kg/day. The relative infant dose as a percentage of the mother's weight-adjusted dose was 8.1%. The theoretical and relative infant doses for desvenlafaxine were 1.97 and 2.24 times higher than those for venlafaxine. No adverse effects were observed or reported in the infants (5).

A study of a woman taking desvenlafaxine 250 mg/day and amisulpride (an atypical antipsychotic not available in the United States) 100 mg/day for depression and nursing her 5-month-old infant was reported in 2010 (6). The absolute (theoretical) infant doses of the two drugs were 294 and 183 mcg/kg/day, respectively. The relative infant doses as a percentage of the mother's weight-adjusted doses were 7.8% and 6.1%, respectively. The infant

was achieving expected developmental progress for age and no adverse effects were noted (6).

In a 2011 study of 10 women taking desvenlafaxine (50–150 mg/day) and their nursing infants (mean age 4.3 months, range 0.9–12.7 months), 8 of whom were exclusively breastfed, no adverse effects were noted in the infants (7). The mean theoretical infant dose was 85 mcg/kg/day and the relative infant dose as a percentage of the mother's weight-adjusted dose was 6.8%.

Maternal plasma concentrations of desvenlafaxine and venlafaxine determine the amount of drug excreted into milk. In this regard, a 2009 study appears to have important implications for choosing which agent to use in a lactating woman (8). The study evaluated the effect of cytochrome P450 2D6 extensive metabolizer (EM) or poor metabolizer (PM) status on the pharmacokinetics of single doses of venlafaxine extended release and desvenlafaxine in healthy adults. The maximum plasma concentrations and AUC of desvenlafaxine were statistically similar in the two groups. In contrast, venlafaxine concentrations and AUC were significantly higher in the PM phenotype compared with the EM phenotype, whereas the desvenlafaxine concentrations and AUC were significantly lower in the PM group (8).

In summary, the available data suggest that exposure to desvenlafaxine from milk does not represent a major risk to a nursing infant. However, nursing preterm and newborn infants were not involved in the above studies and they should be closely observed for excessive sedation and appropriate weight gain if the agent is used by the mother. Additional studies, especially long-term follow-up of exposed infants, are warranted.

DEXAMETHASONE

Corticosteroid

FETAL RISK RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably
Compatible

PREGNANCY SUMMARY

Dexamethasone is a corticosteroid with potency similar to betamethasone. Use in the 1st trimester has a small absolute risk of oral clefts. However, depending on the indication, the benefit of therapy may outweigh the risk.

FETAL RISK SUMMARY

Although most sources have not linked the use of dexamethasone with congenital defects, four large epidemiologic studies have found positive associations between systemic corticosteroids and nonsyndromic orofacial clefts. Specific corticosteroids were not identified in three of these studies (see Hydrocortisone for details), but dexamethasone and other agents were listed in a 1999 study discussed below.

In a case–control study, the California Birth Defects Monitoring Program evaluated the association between selected congenital anomalies and the use of corticosteroids 1 month before to 3 months after conception (periconceptual period) (1). Case infants or fetal deaths diagnosed with orofacial clefts, conotruncal defects, neural tubal defects (NTDs), and limb anomalies were identified from a total of 552,601 births that occurred from 1987 through the end of 1989. Controls, without birth defects, were selected from the same database. Following exclusion of known genetic syndromes, mothers of case and control infants were interviewed by telephone, an average of 3.7 years (cases) or 3.8 years (controls) after delivery, to determine various exposures during the periconceptual period. The number of interviews completed were orofacial cleft case mothers (N = 662, 85% of eligible), conotruncal case mothers (N = 207, 87%), NTD case mothers (N = 265, 84%), limb anomaly case mothers (N = 165, 82%), and control mothers (N = 734,

78%) (1). Orofacial clefts were classified into four phenotypic groups: isolated cleft lip with or without cleft palate (ICLP, N = 348), isolated cleft palate (ICP, N = 141), multiple cleft lip with or without cleft palate (MCLP, N = 99), and multiple cleft palate (MCP, N = 74). A total of 13 mothers reported using corticosteroids during the periconceptional period for a wide variety of indications. Six case mothers of ICLP and 3 of ICP used corticosteroids (unspecified corticosteroid N = 1, prednisone N = 2, cortisone N = 3, triamcinolone acetonide N = 1, dexamethasone N = 1, and cortisone plus prednisone N = 1). One case mother of an infant with NTD used cortisone and an injectable unspecified corticosteroid, and three controls used corticosteroids (hydrocortisone N = 1 and prednisone N = 2). The odds ratio for corticosteroid use and ICLP was 4.3 (95% confidence interval [CI] 1.1–17.2), whereas the odds ratio for ICP and corticosteroid use was 5.3 (95% CI 1.1–26.5). No increased risks were observed for the other anomaly groups. Commenting on their results, the investigators thought that recall bias was unlikely because they did not observe increased risks for other malformations, and it was also unlikely that the mothers would have known of the suspected association between corticosteroids and orofacial clefts (1).

Maternal free estriol and cortisol are significantly depressed after dexamethasone therapy, but the effects of these changes on the fetus have not been studied (2–4).

Dexamethasone has been used in patients with premature labor at about 26–34 weeks' gestation to stimulate fetal lung maturation (5–15). Although this therapy is supported by many clinicians, its use is still controversial since the beneficial effects of steroids are greatest in singleton pregnancies with female fetuses (16–19). These benefits are as follows:

- Reduction in incidence of respiratory distress syndrome (RDS)
- Decreased severity of RDS if it occurs
- Decreased incidence of and mortality from intracranial hemorrhage
- Increased survival of premature infants

Toxicity in the fetus and newborn following the use of dexamethasone is rare.

In studies of women with premature rupture of the membranes (PROM), administration of corticosteroids does not always reduce the frequency of RDS or perinatal mortality (20–22). In addition, an increased risk of maternal infection has been observed in patients with PROM treated with corticosteroids (21,22). A recent report, however, found no difference in the incidence of maternal complications between treated and nontreated patients (23).

Dexamethasone crosses the placenta to the fetus (24,25). The drug is partially metabolized (54%) by the perfused placenta to its inactive 11-ketosteroid derivative, more so than betamethasone, but the difference is not statistically significant (25).

Leukocytosis has been observed in infants exposed antenatally to dexamethasone (26,27). The white blood cell counts returned to normal in about a week.

The use of corticosteroids, including dexamethasone, for the treatment of asthma during pregnancy has not been related to a significantly increased risk of maternal or fetal complications (28). A slight increase in the number of premature births was found, but it could not be determined whether this was an effect of the corticosteroids. An earlier study also recorded a shortening of gestation with chronic corticosteroid use (29).

In Rh-sensitized women, the use of dexamethasone may have prevented intrauterine fetal deterioration and the need for fetal transfusion (30). Five women, in the 2nd and 3rd trimesters, were treated with 24 mg of the steroid weekly for 2–7 weeks resulting, in each case, in a live newborn.

Dexamethasone, 4 mg/day for 15 days, was administered to a woman late in the 3rd trimester for the treatment of autoimmune thrombocytopenic purpura (31). Therapy was given in an unsuccessful attempt to prevent fetal/neonatal thrombocytopenia due to the placental transfer of antiplatelet antibody. Platelet counts in the newborn were 38,000–49,000/mm³, but the infant made an uneventful recovery.

The use of dexamethasone for the pharmacologic suppression of the fetal adrenal gland has been described in two women with 21-hydroxylase deficiency (32,33). This deficiency results in the overproduction of adrenal androgens and the virilization of female fetuses. Dexamethasone, in divided doses of 1 mg/day, was administered from early in the 1st trimester (5th week and 10th week) to term. Normal female infants resulted from both pregnancies.

Although human studies have usually shown a benefit, the use of corticosteroids in animals has been associated with several toxic effects (34,35):

- Reduced fetal head circumference
- Reduced fetal adrenal weight
- Increased fetal liver weight
- Reduced fetal thymus weight
- Reduced placental weight

Fortunately, none of these effects has been observed in human investigations. Long-term follow-up evaluations of children exposed in utero to dexamethasone have shown no adverse effects from this exposure (36,37).

BREASTFEEDING SUMMARY

No reports describing the use of dexamethasone during lactation have been located. The molecular weight (about 516) is low enough for passage into breast milk. Moreover, trace amounts of other corticosteroids are excreted into milk (e.g., see Hydrocortisone and Prednisone) and the excretion of dexamethasone into milk should be expected.

DEXBROMPHENIRAMINE

Antihistamine

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Dexbrompheniramine is the dextro-isomer of brompheniramine (see Brompheniramine). No reports linking its use with congenital defects have been located. In general, antihistamines are considered low risk in pregnancy. However, exposure near birth of premature infants has been associated with an increased risk of retrolental fibroplasia.

BREASTFEEDING SUMMARY

See Brompheniramine.

DEXCHLORPHENIRAMINE

Antihistamine

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

In general, antihistamines are considered low risk in pregnancy. However, exposure near birth of premature infants has been associated with an increased risk of retrolental fibroplasia.

FETAL RISK SUMMARY

Dexchlorpheniramine is the dextro-isomer of chlorpheniramine (see also Chlorpheniramine). No reports linking its use with congenital defects have been located. One study recorded 14 exposures in the 1st trimester without evidence for an association with malformations (1). Animal studies for chlorpheniramine have not shown a teratogenic effect (2).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 1080 newborns had been exposed to dexchlorpheniramine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 50 (4.6%) major birth defects were observed (43 expected). Specific data were available for six defect categories, including (observed/expected) 10/11 cardiovascular defects, 2/2 oral clefts, 0/0.5 spina bifida, 3/3 polydactyly, 0/2 limb reduction defects, and 4/3 hypospadias. These data do not support an association between the drug and congenital defects.

An association between exposure during the last 2 weeks of pregnancy to antihistamines in general and retrolental fibroplasia in premature infants has been reported. See Brompheniramine for details.

BREASTFEEDING SUMMARY

No reports describing the use of dexchlorpheniramine during human lactation have been located. (See also Chlorpheniramine.)

DEXFENFLURAMINE

[Withdrawn from the market. See 9th edition.]

DEXLANSOPRAZOLE

Gastrointestinal Drug (Antisecretory)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although there are no human data for dexlansoprazole, there are data for racemic lansoprazole (see Lansoprazole). These data, combined with the data for the other proton pump inhibitors (PPIs), suggest that the risk of developmental toxicity, including structural anomalies, is low. Human pregnancy experience with three other PPIs (see Lansoprazole, Omeprazole, and Pantoprazole) has not shown a causal relationship with congenital malformations. In some cases, malformations may have been missed because of the design and size of the studies. The carcinogenic and mutagenic data for lansoprazole and other PPIs are a potential concern, but the absence of follow-up studies prevents a risk assessment for exposed offspring. A study showing an association between in utero exposure to gastric acid-suppressing drugs and childhood allergy and asthma requires confirmation. As with all drug therapy, avoidance of dexlansoprazole during pregnancy, especially during the 1st trimester, is the safest course. If dexlansoprazole is required or if inadvertent exposure does occur early in gestation, the known risk to the embryo–fetus for congenital defects appears to be low. Long-term follow-up of offspring exposed during gestation is warranted.

FETAL RISK SUMMARY

Dexlansoprazole is a PPI that blocks gastric acid secretion by a direct inhibitory effect on the gastric parietal cell. It is indicated for healing of all grades of erosive esophagitis for up to 8 weeks, the maintenance of healed erosive esophagitis for up to 6 months, and for the treatment of heartburn associated with nonerosive gastroesophageal reflux disease (GERD) for 4 weeks.

Dexlansoprazole is the R-enantiomer of racemic lansoprazole. It is in the same drug class as esomeprazole, lansoprazole, omeprazole, pantoprazole, and rabeprazole. The drug is extensively metabolized to inactive metabolites. Plasma protein binding is about 96%–99% and the elimination half-life is about 1–2 hours (1).

Reproduction studies have been conducted in rabbits. At oral doses about 9 times the maximum recommended human dose, no evidence of fetal harm was observed (1). (See also Lansoprazole.)

Studies for carcinogenicity, mutagenicity, and impairment of fertility were conducted for lansoprazole (see Lansoprazole).

It is not known if dexlansoprazole crosses the human placenta. The molecular weight (about 369) and the elimination half-life suggest that the drug will cross to the embryo–fetus, but the high plasma protein binding might limit the exposure.

A meta-analysis of PPIs in pregnancy was reported in 2009 (2). Based on 1530 exposed compared with 133,410 not exposed pregnancies, the OR for major malformations was 1.12, 95% CI 0.86–1.45. There also was no increased risk for spontaneous abortions (OR 1.29, 95% CI 0.84–1.97) or preterm birth (OR 1.13, 95% CI 0.96–1.33) (2).

A population-based, observational, cohort study formed by linking data from three Swedish national healthcare registers over a 10-year period (1995–2004) was reported in 2009 (3). The main outcome measures were a diagnosis of allergic disease or a prescription for asthma or allergy medications. The drug types included in the study were gastric acid suppressors, including H₂-receptor antagonists, prostaglandins, PPIs, combinations for eradication of *Helicobacter pylori*, and drugs for peptic ulcer and GERD. Of 585,716 children, 29,490 (5.0%) met the diagnosis and 5645 (1%) had been exposed to gastric acid suppression therapy in pregnancy. Of these children, 405 (0.07%) were treated for allergic disease. For developing allergy, the odds ratio (OR) was 1.43, 98% confidence interval (CI) 1.29–1.59, irrespective of the drug, time of exposure during pregnancy, and maternal history of allergy. For developing childhood asthma, but not other allergic diseases, the OR was 1.51, 95% CI 1.35–1.69, irrespective of the type of acid-suppressive drug and the time of exposure in pregnancy. The authors proposed three possible mechanisms for their findings: (a) exposure to increased amounts of allergens could cause sensitization to digestion of labile antigens in the fetus; (b) maternal Th₂ cytokine pattern could promote an allergy-prone phenotype in the fetus; and (c) maternal allergen-specific immunoglobulin E could cross the placenta and

sensitize fetal immune cells to food and airborne allergens. Several limitations of the study that might have affected their findings were identified, including a general increase in childhood asthma but not necessarily an increase in allergic asthma (3). The study requires confirmation.

Several reports and reviews describing the use of PPIs during human pregnancy have observed no increased risk of developmental toxicity (see Esomeprazole, Lansoprazole, Omeprazole, Pantoprazole, and Rabeprazole).

BREASTFEEDING SUMMARY

No reports describing the use of dexlansoprazole during human lactation have been located. The molecular weight (about 369) and the elimination half-life (about 1–2 hours) suggest that the drug will be excreted into breast milk, but the high plasma protein binding (about 96%–99%) might limit the amount excreted. The effect of this exposure on a nursing infant is unknown. Because of the carcinogenicity observed in animals with lansoprazole, and the potential for suppression of gastric acid secretion in the nursing infant, the use of dexlansoprazole during lactation is best avoided.

DEXMEDETOMIDINE

Sedative

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The human pregnancy experience with dexmedetomidine is limited to short-term use immediately before or during delivery in three women. The drug crosses the human placenta at term. A 2009 editorial concluded that off-label use of dexmedetomidine might be beneficial in providing pain relief for laboring women unwilling or unable to receive neuraxial analgesia (1). However, newborn toxicity, such as hypotension and sedation, is a potential concern. Moreover, dexmedetomidine may increase uterine contractions and this property should be considered if the drug is used during pregnancy.

FETAL RISK SUMMARY

Dexmedetomidine, a relatively selective α_2 -adrenergic agonist with sedative properties, is given as an IV infusion. It is indicated for sedation of initially intubated and mechanically ventilated patients during treatment in an intensive care setting and for sedation of nonintubated patients before and/or during surgical and other procedures. At recommended doses, dexmedetomidine does not cause respiratory depression. The drug undergoes nearly complete metabolism to inactive metabolites. Plasma protein binding is 94% and the terminal elimination half-life is about 2 hours (2).

Reproduction studies have been conducted in rats and rabbits. In rats, dexmedetomidine crossed the placenta. No teratogenicity was observed in rats given SC doses during organogenesis (gestation day 5–16) up to about the maximum recommended human IV dose (MRHD) based on BSA (MRHD-BSA). However, at the highest dose, postimplantation losses and a reduced number of live pups were observed. The no-observed-effect-level (NOEL) was less

than the MRHD-BSA. In another rat study that used SC doses less than the MRHD-BSA from gestation day 16 through weaning, lower offspring weights were observed. Moreover, when offspring were allowed to mate, elevated fetal and embryocidal toxicity and delayed motor development were observed in second-generation offspring. No teratogenicity was noted in rabbits during organogenesis (day 6–18) given IV doses up to about 0.5 times the exposure at the MRHD based on AUC (2).

A study using pregnant rats evaluated the effects of chronic vs. acute exposure on fetal development and postnatal behavior (3). The rats were given either daily SC doses (gestation days 7–19) or a single SC dose on day 19. No structural anomalies were observed and there were no differences between the groups in terms of pup postnatal weight gain or behavioral performance (3). Extrapolating from the aforementioned information, all of the doses appeared to be less than the MRHD-BSA.

Studies for carcinogenicity have not been conducted. Assays for mutagenicity were negative but the drug was clastogenic in some tests. Fertility in male and female rats was not affected by SC doses that were less than the MRHD-BSA (2).

The relatively low molecular weight (about 201 for the free base) suggests that dexmedetomidine will cross the human placenta, but the plasma protein binding and short terminal elimination half-life might limit the exposure of the embryo and/or fetus, at least early in gestation. The manufacturer reported that the drug crossed the human placenta in an in vitro study but provided no other details (2). Term placentas were used in a single placental cotyledon study to measure the amount of dexmedetomidine compared with clonidine that crossed to the fetal circulation over a 2-hour period (4). Dexmedetomidine disappeared faster than clonidine from the maternal circulation, but the amount of drug appearing in the fetal circulation at 2 hours was less (12.5% vs. 22.1%). The difference was explained by greater placental retention of dexmedetomidine (48.1% vs. 11.3%). The fetal: maternal concentration ratio at 2 hours was 0.77 (4).

The sedative, analgesic, and hemodynamic controlling properties of dexmedetomidine have been reported in three pregnant women in labor (5–7). A 35-year-old woman with spinal muscular atrophy presented for cesarean section at 35 weeks' gestation (5). She was given an IV infusion of dexmedetomidine with a total dose of 1.84 mcg/kg over 38 minutes, followed by general anesthesia. A male infant (weight not specified) was delivered 68 minutes after discontinuation of the infusion. Apgar scores were 6 and 8 at 1

and 5 minutes, respectively. The initially oxygen saturation in the newborn was 88% but with treatment improved to 95% at 5 minutes. At delivery, the umbilical arterial and maternal venous concentrations were 540 and 710 pg/mL, respectively, a ratio of 0.76. The initial low Apgar score was thought to be secondary to a combination of gestational age and residual inhalational anesthetic. However, a contribution from dexmedetomidine could not be excluded. The healthy infant was discharged home with his mother 1 week later (5).

A 37-year-old woman at 38 weeks' gestation with diabetes and preeclampsia presented in labor (6). Because she refused epidural analgesia, an IV infusion of dexmedetomidine was started. Three hours later, a cesarean section under general anesthesia was conducted because of persistent late decelerations in the fetal heart rate. A healthy, 3.7-kg female infant was delivered with Apgar scores of 8 and 9. The mother and infant were doing well and discharged home after 7 days (6).

In another 2009 report, a morbidly obese 31-year-old woman with spina bifida occulta and a tethered spinal cord at L5-S1 presented at 40 weeks' for elective induction of labor (7). Patient-controlled analgesia with IV fentanyl was started but was unsuccessful in controlling pain from her contractions. An IV infusion of dexmedetomidine was added, which immediately resulted in a marked decrease in her pain. Because of prolonged labor and the diagnosis of chorioamnionitis, a cesarean section was conducted under general anesthesia. The dexmedetomidine infusion was continued during the procedure. A healthy male infant (weight not specified) was delivered with Apgar scores of 7 and 8. The infant did well and was discharged 4 days later (7).

A 2005 in vitro study described the effects of dexmedetomidine on human myometrium (8). At simulated clinical plasma concentrations, the drug enhanced the frequency and amplitude of contractions.

BREASTFEEDING SUMMARY

No reports describing the use of dexmedetomidine during human lactation have been located.

The relatively low molecular weight (about 201 for the free base) suggests that the drug will be excreted into breast milk, but the plasma protein binding (94%) and short terminal elimination half-life (2 hours) should limit the amount in milk. However, as with other weak bases, accumulation in the relatively acidic milk may occur. The oral absorption of the drug is unknown, as is the effect, if any, of exposure in a nursing infant. Nevertheless, the sedative properties of

the drug in the mother will limit the opportunities for breastfeeding.

DEXMETHYLPHENIDATE

Central Stimulant

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of dexamethylphenidate in human pregnancy have been located. No teratogenicity was observed in two animal species, but the maximum maternal systemic exposures obtained were very close to those measured in humans clinically. Reported pregnancy exposures to methylphenidate, a closely related agent, are limited, but have not shown a major risk for embryo–fetal harm (see also Methylphenidate). Until human data are available for dexamethylphenidate, the safest course is to avoid the drug in pregnancy. If the mother's condition requires the drug, the lowest effective dose, avoiding the 1st trimester if possible, should be used. Long-term follow-up of exposed offspring may be warranted.

FETAL RISK SUMMARY

Dexamethylphenidate is a CNS stimulant that is indicated for the treatment of attention deficit/hyperactivity disorder (ADHD). There are no active metabolites. The mean plasma elimination half-life is about 2.2 hours (1).

Reproduction studies have been conducted in rats and rabbits. No evidence of teratogenicity was observed in rats treated during organogenesis with doses resulting in maternal plasma levels (AUC) up to five times the levels (AUC) obtained in adult humans taking the recommended dose of 20 mg/day (RHD). However, at the highest dose, delayed skeletal ossification was seen. When doses resulting in plasma levels up to five times the RHD were given throughout gestation and lactation, the highest dose resulted in decreased postweaning body weight in male offspring. In rabbits, no evidence of teratogenicity was observed at plasma levels up to one time the RHD (1).

It is not known if dexamethylphenidate crosses the human placenta. The

molecular weight (about 234 for the free base) suggests that the drug will cross to the embryo and/or the fetus. The relatively short half-life, however, should limit the amount crossing the placenta.

BREASTFEEDING SUMMARY

No reports describing the use dexamethylphenidate during human lactation have been located. The molecular weight (about 234 for the free base) is low enough that excretion into breast milk should be expected. However, the relatively short plasma elimination half-life should limit the amount of the drug in milk. The effect of this exposure on a nursing infant is unknown. If a mother chooses to breastfeed while taking dexamethylphenidate, the infant should be monitored for adverse effects observed in children and adults (e.g., abdominal pain, fever, anorexia, and nausea).

DEXPANTHENOL

Vitamin/Gastrointestinal Agent (Stimulant)

PREGNANCY RECOMMENDATION: No Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of dexpanthenol in human pregnancy have been located. The absence of animal and human pregnancy experience prevents an assessment of the embryo–fetal risk. The potential dose over a 24-hour period for postoperative adynamic ileus (500—2500 mg) ranges from 50 to 250 times the U.S. recommended daily allowance in pregnancy (10 mg) for pantothenic acid. Although a 1982 review (1) recommended dexpanthenol for functional constipation in pregnant women, without providing any data in pregnancy, the safest course is to avoid the drug in pregnancy and certainly in the 1st trimester. Increased fluid intake and a high fiber diet are still the best way to decrease constipation in pregnancy (2).

FETAL RISK SUMMARY

Dexpanthenol is administered by IM or IV injection to prevent paralytic ileus, for the treatment of intestinal atony causing abdominal distention, and for postoperative or postpartum retention of flatus, or delay in resumption of intestinal motility. It also is used topically for the treatment of minor skin disorders. Dexpanthenol, the alcoholic analogue of d-pantothenic acid, is a prodrug that is converted in vivo to pantothenic acid, a B complex vitamin. (See Pantothenic Acid.) The vitamin is a precursor of coenzyme A, the cofactor for enzyme-catalyzed reactions involving the transfer of acetyl groups. The plasma elimination half-life and protein binding have not been reported (3).

Animal reproduction studies have not been conducted with dexpanthenol. Neither have animal studies been performed for carcinogenicity, mutagenicity, or impairment of fertility (3).

Studies describing the placental crossing of dexpanthenol have not been located. The molecular weight (about 205) is low enough that exposure of the embryo and fetus should be expected. Moreover, the active metabolite, pantothenic acid, is required for good health and crosses the placenta to the fetus (see Pantothenic Acid).

BREASTFEEDING SUMMARY

No studies describing the use of dexpanthenol during human lactation have been located. The molecular weight (about 205) is low enough that excretion into breast milk should be expected. The active metabolite, pantothenic acid, is excreted into milk. (See Pantothenic Acid.) The U.S. recommended daily allowance during lactation has not been established for pantothenic acid, but the potential dose of dexpanthenol is very high. (See Pregnancy Summary.). Although most of the dexpanthenol dose should be converted to the B vitamin, excretion of unmetabolized prodrug could potentially cause colic and diarrhea in a nursing infant.

DEXRAZOXANE

Antineoplastic Cytoprotectant

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably
Compatible

PREGNANCY SUMMARY

No reports describing the use of dexrazoxane in human pregnancy have been located. Developmental toxicity was observed in two animal species, but the doses studied were greater than the dose causing maternal toxicity. Nevertheless, the absence of human pregnancy experience prevents a more complete assessment of the embryo–fetal risk. However, dexrazoxane is intended to protect the patient from doxorubicin-induced cardiomyopathy. Thus, if a pregnant woman requires dexrazoxane and gives informed consent, the maternal benefit from the drug appears to outweigh the potential embryo–fetal risk. If inadvertent exposure occurs during pregnancy, the woman should be advised of the potential risk for adverse effects in the embryo and fetus.

FETAL RISK SUMMARY

Dexrazoxane, a cyclic derivative of ethylenediaminetetraacetic acid (EDTA) that readily penetrates cell membranes, is given as an IV dose immediately prior to a dose of doxorubicin. It is indicated for reducing the incidence and severity of cardiomyopathy associated with doxorubicin in women with metastatic breast cancer who have received a cumulative doxorubicin dose of 300 mg/m² and who will continue to receive doxorubicin therapy to maintain tumor control. Dexrazoxane is partially metabolized to inactive metabolites and is not bound to plasma proteins. The mean dose-related plasma elimination half-lives were 2.1 and 2.5 hours (1).

Reproduction studies have been conducted in rats and rabbits, but the route of administration was not specified in either species. Maternal toxicity was observed in pregnant rats given a dose that was about 0.025 times the human

dose based on BSA (HD). When given daily to rats during organogenesis, a dose that was about 0.1 times the HD was embryotoxic and teratogenic. Teratogenic effects were imperforate anus, microphthalmia, and anophthalmia. In rabbits, a daily dose during organogenesis that was about 0.1 times the HD caused maternal toxicity. A higher dose, about 0.5 times the HD, was embryotoxic and teratogenic, including skeletal malformations (short tail, rib, and thoracic defects), soft tissue variations (subcutaneous, eye, and cardiac hemorrhagic areas), and agenesis of the gallbladder and of the intermediate lobe of the lung (1).

Long-term studies for carcinogenic potential have been conducted. Dexrazoxane was not mutagenic in one test but was clastogenic in two other tests. Fertility was impaired in mature male and female rats exposed in utero during organogenesis to doses that were about 0.1 times the HD. Testicular atrophy was observed in rats given a dose that was about 0.33 times the HD for 6 weeks, and in dogs given a dose about equal to the HD for 13 weeks (route of administration not specified) (1).

It is not known if dexrazoxane crosses the human placenta. The molecular weight (about 268), lack of plasma protein binding, and elimination half-life suggest that the drug will cross to the embryo and/or fetus.

BREASTFEEDING SUMMARY

No reports describing the use dexrazoxane during human lactation have been located.

The molecular weight (about 268), lack of plasma protein binding, and elimination half-life (2.1 or 2.5 hours) suggest that the drug will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown. However, because the drug is given as a short IV infusion immediately before doxorubicin, and breastfeeding would be unlikely at this time, the risk of exposing an infant to dexrazoxane when nursing is later resumed appears to be nil.

DEXTROAMPHETAMINE

Central Stimulant

See Amphetamine.

DEXTROMETHORPHAN

Respiratory Drug (Antitussive)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

The available human data on the reproductive effects of dextromethorphan do not demonstrate a major teratogenic risk. Except for one study involving chick embryos, there are no published animal reproductive studies. Unpublished pregnant rat and rabbit data have been cited, though, that indicated there was no embryo or fetal harm with the doses used. Extrapolation of the chick embryo data to humans is not possible because of the lethal dose used and the absence of maternal and placental metabolizing systems. Moreover, prior teratology studies have not shown agreement between the chick and mammalian models (1). Fetuses of women with the phenotype for slow dextromethorphan metabolism should have higher concentrations of the drug than fetuses of mothers with normal metabolism, but this may not be clinically significant in the absence of a demonstrated dose–effect. Use of liquid preparations of dextromethorphan that contain ethanol, however, should be avoided during pregnancy because ethanol is a known teratogen.

Many authors consider dextromethorphan to be safe for consumption during pregnancy. This opinion appears to have been based on the low incidence of congenital defects reported in surveillance studies and its wide appeal as a cough suppressant, rather than on evidence derived from human pregnancy research with dextromethorphan or from studies in any animal model. The latest data, however, provide more assurance that dextromethorphan is not a major teratogen.

FETAL RISK SUMMARY

Dextromethorphan, a derivative of the narcotic analgesic levorphanol (see also Levorphanol) that is widely used as a cough suppressant in over-the-counter (OTC) preparations, produces little or no CNS depression. Although it is an

antitussive without expectorant, analgesic, or addictive characteristics, abuse of the liquid product, possibly because of the ethanol vehicle used in some proprietary mixtures, is a potential complication (see case below). The agent is available either alone (as capsules, lozenges, or oral solutions) or in combination with a large variety of other compounds used for upper respiratory tract symptoms. Combination products containing ethanol should be avoided during pregnancy (see also Ethanol).

No information is available on the placental transfer of dextromethorphan. The molecular weight (about 271) is low enough that transfer to the fetus should be expected.

Only one published animal reproduction study involving dextromethorphan has been located (see reference 2 for unpublished data). A 1998 report examined the effects of dextromethorphan on chick embryos (3). The authors hypothesized that N-methyl-D-aspartate (NMDA) receptor antagonists, such as ethanol and dextromethorphan, induced neural crest (craniofacial and cardiac septal defects) and neural tube defects (NTDs). Dextromethorphan, an NMDA receptor antagonist that acts as a channel blocker at the receptor, was injected into chick embryos in ovo for 3 consecutive days at doses of 0.5, 5, 50, and 500 nmol/embryo/day. The embryos were examined 24 hours after the third dose (none of the embryos were allowed to hatch). Dextromethorphan caused a dose-related increase in embryo mortality with rates of 14.1% with the 50-nmol dose ($p < 0.05$ vs. controls) and 56.7% with the 500-nmol dose ($p < 0.001$ vs. controls). Seven (1.2%) of the 595 control embryos injected only with the vehicle (normal saline) had anomalies (spinal defect [N = 1], craniofacial defects [N = 4], and multiple defects [N = 2]), whereas 30 (8.0%) of all dextromethorphan-treated embryos had anomalies (spinal defect [N = 1], craniofacial defects [N = 12], multiple defects [N = 16], and other defects [N = 1]). Only the number of defects (about 15%) in the 500-nmol group, however, was significantly increased ($p < 0.001$) over the number in the control group. The authors cited published evidence that the receptors blocked by dextromethorphan in the chick embryos are analogous to receptors in other animals, including humans, during early development and that the drug would also block these receptors, resulting in similar malformations (3).

Interpretation of the results of the above study have been criticized (1,2,4) and defended (5). The primary concerns raised were the inappropriateness of the chick embryo model for determining human teratogenicity and the design of the study (1,4). Of particular concern, no embryos were allowed to hatch (the doses used were lethal) so it could not be determined if dextromethorphan was

actually teratogenic. In addition, one author cited unpublished animal reproduction data from a drug manufacturer showing that in pregnant rats and rabbits, daily doses up to 20 and 100 times the human therapeutic dose on a body weight basis, respectively, caused no embryo or fetal harm in comparison with controls (1).

Metabolism of dextromethorphan has been shown to be primarily a result of O-demethylation to dextrorphan (6). The ability to metabolize many drugs, including O-demethylation of dextromethorphan, is genetically determined in adults. In this study of 155 adult volunteers, 144 (93%) metabolized dextromethorphan rapidly, and 11 (7%) were poor metabolizers, but the poor (slow) drug metabolizer phenotype has been reported in 5%–10% of whites (6). In poor metabolizers, unmetabolized drug was the main excretion product, implying that these individuals had much higher and more prolonged plasma concentrations of dextromethorphan than did those who were extensive metabolizers. Moreover, using microsomal preparations obtained from aborted 10- to 30-week-old human fetuses and live newborn infants, the average activity of O-demethylation was less than 1% of the adult value and did not begin to rise until after birth (6). Thus, accumulation of unmetabolized dextromethorphan in the fetal compartment is a potential result of maternal ingestion of the drug during pregnancy (6).

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 300 of whom took dextromethorphan during the 1st trimester (7, p. 378). Twenty-four of the infants exposed in utero had a congenital malformation, a standardized relative risk (SRR) of 1.18. When only malformations showing uniform rates by hospital were considered, 17 (SRR 1.21) infants had a congenital defect (7, p. 379). Of these 17, 9 had major defects (SRR 1.10) and 8 had minor defects (SRR 1.30) (7, p. 382). For use anytime during pregnancy, 580 exposures were recorded, 15 of which had a malformation (SRR 1.39) (7, pp. 438, 442). Ten of these defects were inguinal hernias (7, p. 496). The SSRs do not support a relationship between the drug and congenital malformations.

A case report published in 1981 described a woman who consumed 480–840 mL/day of a cough syrup throughout pregnancy (8). The potential maximum daily doses based on 840 mL of syrup were 1.68 g of dextromethorphan, 16.8 g of guaifenesin, 5.0 g of pseudoephedrine, and 79.8 mL of ethanol. The infant had facial features of the fetal alcohol syndrome (bilateral epicanthal folds; short palpebral fissures; short, upturned nose; hypoplastic philtrum and upper lip with thinned vermilion; and a flattened midface [8]). (See also Ethanol.)

Other defects noted were an umbilical hernia and labia that appeared hypoplastic. The infant displayed irritability, tremors, and hypertonicity. It is not known if dextromethorphan or the drugs other than ethanol were associated with the adverse effects observed in the infant.

The use of dextromethorphan in four of five cases of a rare and distinct malformation complex was reported in 1984 (9). The complex of defects included absence of external genitalia, urinary, genital, and anal orifices, and persistence of the cloaca (9).

Chromosome analysis in four of the cases was normal and genetics did not appear to be a cause of the defects. Although a causative relationship could not be determined, the authors noted that three of the pregnancies, possibly all five, were exposed to doxylamine during the first 50 days of pregnancy (9). Dextromethorphan, however, was not thought to be related to the outcomes because only four of the mothers had symptoms of respiratory infection or took dextromethorphan during the critical period.

A surveillance study published in 1985 examined the prevalence of certain major birth defects among liveborn infants of 6509 mothers (10). Dextromethorphan was assumed to have been used by 59 of the mothers, only one of whom gave birth to an infant with a major anomaly. This study found no strong association between any of the commonly used drugs and the congenital malformations surveyed (10).

Data from the Spanish Collaborative Study of Congenital Malformations (ECEMC) evaluating prenatal exposure to cough medicines containing dextromethorphan were published in 2001 (11). Using standardized methods, all newborn infants born in more than 77 hospitals throughout Spain were examined during the first 3 days of life for major and/or minor congenital defects. The case-control study was conducted between 1976 and 1998 and included 1,575,388 liveborn infants, 27,864 of whom had congenital defects detected during the first 3 days. Each case infant (those with defects) and its control (the next nonmalformed, same sex-infant born) were obtained from the same hospital. Among the case and control mothers, 0.26% (N = 70) and 0.18% (N = 48), respectively, had taken cough medicines containing dextromethorphan during the 1st trimester. The data were primarily analyzed for NTD and cardiac defects to test the hypothesis raised in the chick embryo study cited above (reference 3), but about 600 different categories of defects were also examined. Most of these categories, however, had no cases or controls. The adjusted (for maternal age, fever, drugs other than dextromethorphan, flu/cold, first-degree relatives with the same defects) odds

ratio and 95% confidence intervals for selected anomalies were NTD 0.67 (0.09–4.94), CNS defects 1.36 (0.39–4.72), hydrocephaly 3.39 (0.38–30.35), congenital heart defects 0.92 (0.13–6.61), oral clefts 4.72 (0.55–40.24), and cleft palate 3.26 (0.35–30.34). When data on the amount consumed were available, the estimated total dextromethorphan dose and duration for cases and controls was about 101 mg/2.69 days and 117 mg/3.96 days, respectively. The investigators concluded that the use of dextromethorphan during the 1st trimester was not associated with an increase in congenital defects (11).

A 1984 review on the effect of OTC drugs on human pregnancy concluded that dextromethorphan was safe to use during this period (12). Other reference sources (13–16) have also concluded that this antitussive does not pose a risk to the human fetus, and a 1998 source states that dextromethorphan is one of the drugs of choice during pregnancy for cough (17). Two of these references recommended a combination of guaifenesin plus dextromethorphan as the preferred antitussive in pregnant asthmatic patients (15,16).

A study published in 2001 described the outcomes of 184 pregnancies exposed to dextromethorphan, 128 of which were exposed in the 1st trimester, compared with 184 matched controls (18). The subjects were women who had called a teratogen information service concerning their use of dextromethorphan during pregnancy. There were six major birth defects (type not specified) in the subject group. One was a chromosomal abnormality and two were born to women who had used the antitussive after the 1st trimester. Among controls, there were five major birth defects (type not specified), one of which was a chromosomal abnormality. There were also no statistical differences between all subjects and controls in other outcomes: live births (172 vs. 174), spontaneous abortions (10 vs. 8), therapeutic abortions (1 vs. 2), stillbirths (1 vs. 0), minor malformations (10 vs. 8), and birth weight (3381 g vs. 3446 g) (18).

BREASTFEEDING SUMMARY

No reports describing the use of dextromethorphan during human lactation or measuring the amount, if any, excreted into milk have been located. The relatively low molecular weight of dextromethorphan (about 271) suggests that passage into milk probably occurs. Many preparations containing dextromethorphan also contain ethanol. These products should be avoided during nursing (see Ethanol). Preparations without ethanol, however, are probably safe to use during breastfeeding.

DEXTROTHYROXINE

Antilipemic

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Although formerly used to treat hypothyroidism, the drug is now used exclusively for the therapy of hyperlipidemia. Except for the one report below, no mention of its use in human pregnancy has been located.

FETAL RISK SUMMARY

Dextrothyroxine is the dextro-isomer of levothyroxine (see also Levothyroxine). In a study of placental passage of dextrothyroxine, approximately 9% of a radiolabeled dose given 2–8 hours before delivery was found in the cord blood (1).

BREASTFEEDING SUMMARY

No reports describing the use of dextrothyroxine during human lactation have been located.

Reference

DIATRIZOATE

Diagnostic

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Diatrizoate is available as diatrizoate sodium for IV use (1) and as diatrizoate meglumine for instillation into the bladder (retrograde cystourethrography) (2). When administered alone, neither form of diatrizoate has been associated with suppression of the fetal thyroid. The guidelines of the Contrast Media Safety Committee of the European Society of Urogenital Radiology recommend that iodinated contrast media may be used in pregnancy if such use is essential. However, neonatal thyroid function should be checked during the 1st week (3).

FETAL RISK SUMMARY

Diatrizoate sodium is a water-soluble organic iodide contrast medium that is given IV. It is indicated for excretory urography, cerebral and peripheral angiography, aortography, intraosseous venography, direct cholangiography, hysterosalpingography, splenoportography, and contrast enhancement of computed tomographic head imaging. It is not metabolized but excreted unchanged in the urine. The alpha and beta half-lives are 30 and 120 minutes, respectively, but, in patients with renal impairment, the beta half-life can be up to several days (1).

Diatrizoate meglumine is a water-soluble contrast medium of organically bound iodine that is instilled directly into the bladder. It is indicated for retrograde cystourethrography.

Studies of reproduction, carcinogenicity, mutagenicity, or fertility have not been conducted with either salt form of diatrizoate.

The use of diatrizoate (both salt forms) for amniography has been described in several studies (4–13). Except for inadvertent injection of the contrast media

into the fetus during amniocentesis, the use of diatrizoate was not thought to result in fetal harm. More recent studies have examined the effect of the drug on fetal thyroid function.

All of the various preparations of diatrizoate contain a high concentration of organically bound iodine. Twenty-eight pregnant women received intra-amniotic injections (50 mL) of diatrizoate meglumine for diagnostic indications (14). When compared with nontreated controls, no effect was observed on cord blood levothyroxine (T4) or liothyronine resin uptake values regardless of the time interval between injection and delivery. The authors concluded that the iodine remained organically bound until it was eliminated in 2–4 days from the amniotic fluid (14).

In another report, seven patients within 13 days or less of term were injected intra-amniotically with a mixture of ethiodized oil (12 mL) and diatrizoate meglumine (30 mL) (15). Thyrotropin (TSH) levels were determined in the cord blood of five newborns and in the serum of all seven infants on the 5th day of life. TSH was markedly elevated in three of five cord samples and six of seven neonatal samples. Three of the infants had signs and symptoms of hypothyroidism:

- Elevated TSH/normal T4; apathy and jaundice clearing immediately with thyroid therapy (1 infant)

- Elevated TSH/decreased T4 (1 infant)

- Elevated TSH/decreased T4 with goiter (1 infant)

In contrast to the initial report, the severity of thyroid suppression seemed greater when the time interval between injection and delivery was longer. The explanation offered for these different results was the use of the more sensitive TSH serum test and the use of only water-soluble contrast media in the first study (15).

BREASTFEEDING SUMMARY

Diatrizoate was not detected in breast milk in one study. A woman, 7 weeks postpartum, received the contrast medium (a mixture of sodium and meglumine salts) for urography (16). Nine hours after the dose, no measurable drug was identified by spectrophotometer. Based on this report, the American Academy of Pediatrics classifies diatrizoate as compatible with breastfeeding (17). In addition, a 2005 review concluded that breastfeeding may be continued normally when iodinated agents are given to the mother (3).

DIAZEPAM

Sedative

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 1st and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

The effects of benzodiazepines, including diazepam, on the human embryo and fetus are controversial. Although a number of studies have reported an association with various types of congenital defects, other studies have not found such associations. Maternal denial of exposure, as reported in one study, and the concurrent exposure to other toxic drugs and substances (e.g., alcohol and smoking) may be confounding factors. If the drug does cause birth defects, the risk appears to be low. Continuous use during gestation has resulted in neonatal withdrawal and a dose-related syndrome is apparent if diazepam is used close to delivery. Consequently, if the maternal condition requires the use of diazepam during pregnancy, the lowest possible dose should be taken. Moreover, abrupt discontinuance of diazepam should be avoided.

FETAL RISK SUMMARY

Shepard (1) reviewed six studies of the reproductive effects of the benzodiazepine, diazepam in rats and mice in 1989. Cleft palates in mice and delayed neurobehavioral development and postnatal malignancies in rats were the only adverse effects noted (1).

Diazepam and its metabolite, desmethyldiazepam, freely cross the placenta and accumulate in the fetal circulation with newborn levels about 1–3 times greater than maternal serum levels (2–13). Transfer across the placenta has been demonstrated as early as 6 weeks' gestation (12). Of interest, fetal drug levels were independent of maternal serum concentrations and time from drug administration to sampling. These data suggest that diazepam accumulates in the fetal circulation and tissues during organogenesis (12). At term, equilibrium

between mother and fetus occurs in 5–10 minutes after IV administration (11). The maternal and fetal serum binding capacity for diazepam is reduced in pregnancy and is not correlated with albumin (14,15). The plasma half-life in newborns is significantly increased due to a decreased clearance of the drug. Because the transplacental passage is rapid at term, timing of the IV administration with uterine contractions will greatly reduce the amount of drug transferred to the fetus (7).

In a case of gross overdose, a mother who took 580 mg of diazepam as a single dose on about the 43rd day of gestation delivered an infant with cleft lip and palate, craniofacial asymmetry, ocular hypertelorism, and bilateral periauricular tags (16). The authors concluded that the drug ingestion was responsible for the defects. An association between diazepam and an increased risk of cleft lip or palate has been suggested by several studies (17–20). The findings indicated that 1st or 2nd trimester use of diazepam, and selected other drugs, is significantly greater among mothers of children born with oral clefts. However, a review of these studies, published in 1976, concluded that a causal relationship between diazepam and oral clefts had not yet been established, but even if it had, the actual risk was only 0.2% for cleft palate and only 0.4% for cleft lip with or without cleft palate (21). In addition, large retrospective studies showing no association between diazepam and cleft lip/palate have been published (22–25). The results of one of these studies has been criticized and defended (26,27). Although no association was found with cleft lip/palate, a statistically significant association was discovered between diazepam and inguinal hernia (27). This same association, along with others, was found in another investigation (28).

In 1427 malformed newborns compared with 3001 controls, 1st trimester use of tranquilizers (diazepam most common) was associated with inguinal hernia, cardiac defects, and pyloric stenosis (28). Second trimester exposure was associated with hemangiomas and cardiac and circulatory defects. The combination of cigarette smoking and tranquilizer use increased the risk of delivering a malformed infant by 3.7-fold as compared with those who smoked but did not use tranquilizers (28). A survey of 390 infants with congenital heart disease matched with 1254 normal infants found a higher rate of exposure to several drugs, including diazepam, in the offspring with defects (29). Other congenital anomalies reported in infants exposed to diazepam include absence of both thumbs (two cases), spina bifida (one case), and absence of left forearm and syndactyly (one case) (30–32). Any relationship between diazepam and these defects is unknown.

A 1989 report described dysmorphic features, growth restriction, and central nervous system defects in eight infants exposed either to diazepam, 30 mg/day or more, or oxazepam, 75 mg/day or more throughout gestation (33). Three of the mothers denied use of drugs during pregnancy, but diazepam and its metabolite were demonstrated in their plasma in early pregnancy. The mothers did not use alcohol or street drugs, had regular prenatal care, and had no record of criminality or prostitution. The mean birth weight of the infants was 1.2 standard deviations below the Swedish average, only one having a weight above the mean, and one was small for gestational age. Six of the newborns had low Apgar scores primarily due to apnea, five needed resuscitation, all were hypotonic at birth, and all had neonatal drug withdrawal with episodes of opisthotonos and convulsions. Seven of the eight infants had feeding difficulties caused by a lack of rooting and sucking reflexes. Craniofacial defects observed in the infants (number of infants with defect shown in parenthesis) were short nose with low nasal bridge (six), upturned nose (six), slanted eyes (eight), epicanthic folds (eight), telecanthus (two), long eyelashes (three), highly arched palate (four), cleft hard palate and bifid uvula (two), low-set/abnormal ears (four), webbed neck (three), flat upper lip (five), full lips (four), hypoplastic mandible (five), and microcephaly (two). Other defects present were small, wide-spaced nipples (two), renal defect (one), inguinal hernia (two), and cryptorchidism (two). An infant with severe psychomotor retardation died of possible sudden infant death syndrome at 11 weeks of age. Microscopic examination of the brain demonstrated slight cortical dysplasia and an increased number of single-cell neuronal heterotopias in the white matter. Six other children had varying degrees of mental retardation, some had severely disturbed visual perception, all had gross motor disability, and hyperactivity and attention deficits were common. Extensive special examinations were conducted to identify other possible etiologies, but the only common factor in the eight cases was maternal consumption of benzodiazepines (33). Based on the apparent lack of other causes, the investigators concluded that the clinical characteristics observed in the infants probably represented a teratogenic syndrome due to benzodiazepines.

A 1992 study reported on heavy benzodiazepine exposure during pregnancy from Michigan Medicaid data collected during 1980–1983 (34). Of the 2048 women, from a total sample of 104,339, who had received benzodiazepines, 80 had received 10 or more prescriptions for these agents. The records of these 80 women indicated frequent alcohol and substance abuse. Their pregnancy outcomes were three intrauterine deaths, two neonatal deaths in infants with

congenital malformations, and 64 survivors. The outcome for 11 infants was unknown. Six of the 64 surviving infants had diagnoses consistent with congenital defects and neurological abnormalities. No cases of oral clefts were found in 1354 1st trimester benzodiazepine exposures. The investigators concluded that the high rate of congenital anomalies was suggestive of multiple alcohol and substance abuse and may not have been related to benzodiazepine exposure. However, subtle defects, developmental abnormalities, and retardations may not have been included in the records (34).

A 1992 letter correspondence suggested that the Möbius' syndrome observed in a 3-week-old infant was the result of in utero exposure to benzodiazepines (diazepam and oxazepam) (35). The mother had been treated for hypertension starting at 16 weeks' gestation with methyldopa. Diazepam (20 mg/day) was added at 25 weeks', and shortly thereafter, hyoscine butylbromide, oxazepam (20 mg/day), and ritodrine were added. The infant had normal weight, length, and head circumference but was markedly hypotonic at birth. In addition to an expressionless face, malformations observed were epicanthal folds, short palpebral fissures, convergent strabismus, low nasal bridge, short upturned nose, hypertelorism, and high arched palate (35). An electromyogram confirmed bilateral cranial nerve VII palsy. The authors speculated that the Möbius' syndrome and the strabismus were caused by the benzodiazepine therapy based on previous reports. At least one mechanism of Möbius' syndrome (VI and VII nerve palsy), however, was thought to be a result of mechanical trauma induced by uterine contractions early in gestation that results in ischemia in the cranial nuclei VI and VII (see Shepard, 1995, in Misoprostol).

The pregnancy outcomes of five women who had attempted suicide with diazepam combined with other drugs early in gestation were described in a 1997 report (36). The gestational ages when the overdoses occurred were 3–4 weeks and the diazepam doses ranged from 90 mg to 200 mg. All five of the infants were delivered at term and, except for an infant with bilateral undescended testes, were normal. The undescended testes were not thought to have been related to the self-poisoning (36).

A meta-analysis of cohort and case–control studies involving the association of 1st trimester exposure to benzodiazepines and major malformations was published in 1998 (37). Analysis of nine cohort studies (nonepileptic patients) showed no relationship to major malformations (odds ratio [OR] 0.90, 95% confidence interval [CI] 0.61–1.35) or to oral clefts (OR 1.19, 95% CI 0.34–4.15). Two cohort studies involving epileptic patients were also negative. In

contrast, pooled data from nine case–control studies showed an association with major defects (OR 3.01, 95% CI 1.32–6.84) or to oral clefts alone (OR 1.79, 95% CI 1.13–2.82) (37). In correspondence concerning this study, objections were raised as to the exclusion of certain studies and to the statistical methods used (38–40).

Another 1998 study described the outcomes of 460 pregnancies (subjects) exposed to benzodiazepines, 98% during the 1st trimester, compared with 424 control pregnancies (41). Subjects and controls had called the Israeli Teratogen Information Service concerning exposure to either benzodiazepines (subjects) or various other nonteratogenic exposures (controls). Diazepam was used by 89 women, but several subjects in the total group used more than one type of benzodiazepine. Subjects were older (31.7 vs. 29.4 years, $p = 0.001$) and called earlier in pregnancy (10.3 vs. 12.9 weeks', $p = 0.001$) than controls. There were also more spontaneous and induced abortions in subjects, 8.7% vs. 5.2% $p = 0.047$ and 14.1% vs. 4.7% $p = 0.001$, respectively. None of the induced abortions involved major congenital defects. The higher rates of spontaneous and induced abortions were thought to be related to the lower gestational ages at calling and to the counseling of the callers, respectively (41). The gestational ages and birth weights of the two groups were similar. Major malformations were observed in 11 of the 355 subject live births (3.1%) and in 10 of 382 control live births (2.6%) (ns). The birth defects in infants of subjects were four cases of congenital heart disease (ventricular septal defect, pulmonic stenosis, and two unspecified with one neonatal death; carbamazepine used in two cases), two cases of polydactyly, two cases of hydronephrosis, and one each of esophageal atresia, cerebral palsy, and Down's syndrome (41).

Several investigators have observed that the use of diazepam during labor is not harmful to the mother or her infant (42–49). A dose response is likely as the frequency of newborn complications rises when doses exceed 30–40 mg or when diazepam is taken for extended periods, allowing accumulation to occur (50–56). Two major syndromes of neonatal complications have been observed:

Floppy infant syndrome:

Hypotonia

Lethargy

Sucking difficulties

Withdrawal syndrome:

Intrauterine growth restriction

Tremors
Irritability
Hypertonicity
Diarrhea/vomiting
Vigorous sucking

Under miscellaneous effects, diazepam may alter thermogenesis, cause loss of beat-to-beat variability in the fetal heart rate, and decrease fetal movements (33,57–62).

Abrupt discontinuance of benzodiazepines should be avoided because severe withdrawal symptoms (physical and psychological) may occur in the mother and could result in the substitution of other substances (e.g., alcohol) to treat the symptoms (63). Fetal withdrawal, such as that observed with narcotics, has not been reported, but should be considered.

BREASTFEEDING SUMMARY

Diazepam and its metabolite, n-demethyldiazepam, enter breast milk (61,62,64–69). Lethargy and loss of weight have been reported (67,69). Milk:plasma ratios varied between 0.2 and 2.7 (66).

A mother who took 6–10 mg daily throughout pregnancy delivered a full-term, normally developed male infant (69). The infant was breastfed and the mother continued to take her diazepam. Sedation was noted in the infant if nursing occurred less than 8 hours after taking a dose. Paired samples of maternal serum and breast milk were obtained on five occasions between 1 and 4 months after delivery. Milk concentrations of diazepam and desmethyldiazepam varied between 7.5 and 87 ng/mL and 19.2 and 77 ng/mL, respectively. The milk:serum ratios for diazepam varied between 0.14 and 0.21 in four samples but was 1.0 in one sample. The ratio for desmethyldiazepam varied from 0.10 to 0.18 in four samples and was 0.53 in the sample with the high diazepam ratio. A serum level was drawn from the infant on one occasion, revealing levels of diazepam and the metabolite of 0.7 and 46 ng/mL, respectively (69).

Diazepam may accumulate in breastfed infants, and its use in lactating women is not recommended. The American Academy of Pediatrics classifies the effects of diazepam on the nursing infant as unknown but may be of concern (70).

DIAZOXIDE

Antihypertensive

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 3rd Trimester

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Because other antihypertensive drugs are available for severe maternal hypertension and the long-term effects on the infant have not been evaluated, diazoxide should be used with caution, if at all, during pregnancy. If diazoxide is needed after other therapies have failed, small doses are recommended.

FETAL RISK SUMMARY

Diazoxide readily crosses the placenta and reaches fetal plasma concentrations similar to maternal levels (1). The drug has been used for the treatment of severe hypertension associated with pregnancy (1–12). Daily doses of 30, 21, and 10 mg/kg in rats, rabbits, and dogs, respectively, were associated with reduced fetal and pup survival, and reduced fetal growth (13).

Some investigators have cautioned against the use of diazoxide in pregnancy (14,15). In one study, the decrease in maternal blood pressure was sufficient to produce a state of clinical shock and endanger placental perfusion (14). Transient fetal bradycardia has been reported in other studies following a rapid, marked decrease in maternal blood pressure (7,16). Fatal maternal hypotension has been reported in one patient after diazoxide therapy (17). Recommendations have been made that the infusion technique, rather than rapid IV boluses, is preferred to prevent maternal and fetal complications (18). However, small IV boluses at frequent intervals (30 mg every 1–2 minutes) have successfully controlled maternal hypertension without producing fetal toxicity (19).

Diazoxide is a potent relaxant of uterine smooth muscle and may inhibit uterine contractions if given during labor (2,3,5–7,20–22). The degree and

duration of uterine inhibition are dose dependent (21). Augmentation of labor with oxytocin may be required in patients receiving diazoxide.

Hyperglycemia in the newborn (glucose 500–700 mg/dL) secondary to IV diazoxide therapy in a mother just prior to delivery has been observed to persist for up to 3 days (23). In some series, all of the mothers and newborns had hyperglycemia without ketoacidosis (14). The glucose levels returned to near normal within 24 hours.

The use of oral diazoxide for the last 19–69 days of pregnancy has been associated with alopecia, hypertrichosis lanuginosa, and decreased ossification of the wrist (1). However, long-term oral therapy has not caused similar problems in other newborns exposed in utero (4).

BREASTFEEDING SUMMARY

No reports describing the use of diazoxide during lactation have been located. The molecular weight (about 231), however, suggests that the drug will be excreted into breast milk.

DIBENZEPIN

[Withdrawn from the market. See 9th edition.]

DICHLORALPHENAZONE

Sedative

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

There is limited information on the use of dichloralphenazone during human pregnancy. The lack of developmental toxicity in one animal species and the absence of human reports describing embryo–fetal toxicity suggest that the risk, if any, is low.

FETAL RISK SUMMARY

Dichloralphenazone is a sedative hypnotic composed of two molecules of chloral hydrate (a sedative/hypnotic) (see also Chloral Hydrate) bound together with the analgesic/antipyretic, phenazone (see also Antipyrine) (1). Antipyrine and chloral hydrate are derived from dichloralphenazone and the latter drug is metabolized to the active agent, trichloroethanol. Little information is available on the reproductive effects of antipyrine, chloral hydrate, or the prodrug, dichloralphenazone, a component, along with isometheptene and acetaminophen, of several proprietary mixtures commonly used for tension and vascular (migraine) headaches (see also Isometheptene and Acetaminophen).

Two studies have been located that examined the effect of dichloralphenazone in pregnant rats (1,2). No teratogenic or other adverse fetal effects were observed when doses ranging from 50 to 500 mg/kg/day were fed to rats throughout gestation.

No published reports describing the use of dichloralphenazone in human pregnancy have been located, although one reference commented that the drug has been “widely used” during pregnancy (3). The Collaborative Perinatal Project recorded 71 1st trimester exposures to chloral hydrate (4, pp. 336–344), one of the drugs derived from dichloralphenazone. From this group, eight infants with congenital defects were observed (standardized relative risk (SRR)

1.68). When only malformations with uniform rates by hospital were examined, the SRR was 2.19. Neither of these relative risks reached statistical significance. Moreover, when chloral hydrate was combined with all tranquilizers and nonbarbiturate sedatives, no association with congenital malformations was found (SRR 1.13; 95% confidence interval [CI] 0.88–1.44). For use anytime during pregnancy, 358 exposures to chloral hydrate were discovered (4, p. 438). The nine infants with anomalies yielded an SRR of 0.98 (95% CI 0.45–1.84). (See also Antipyrine for additional information.)

BREASTFEEDING SUMMARY

Dichloralphenazone is a prodrug composed of the sedative/hypnotic, chloral hydrate, bound together with the analgesic/antipyretic, phenazone. Trichlorethanol, an active metabolite of chloral hydrate, is excreted into human breast milk as is phenazone (see Antipyrine).

Mild morning drowsiness was observed in a nursing infant of a woman taking 1300 mg (13 times the dose per capsule in the proprietary headache products mentioned above) of dichloralphenazone at bedtime (5). The mother was also taking chlorpromazine, 100 mg 3 times daily. Milk concentrations of trichloroethanol were 60% to 80% of the maternal serum levels. The metabolite was not detected in the infant's plasma 20 hours after a dose. Infant growth and development remained normal during the exposure and at follow-up 3 months after the drug was stopped. Apparently, no attempt was made in this study to determine the milk concentration of phenazone, the other component of dichloralphenazone. The American Academy of Pediatrics classifies chloral hydrate as compatible with breastfeeding (see Chloral Hydrate).

DICHLORPHENAMIDE

Diuretic (Carbonic Anhydrase Inhibitor)

PREGNANCY RECOMMENDATION: No Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports of human use of dichlorphenamide during pregnancy have been located. The drug is best avoided during organogenesis.

FETAL RISK SUMMARY

Dichlorphenamide is a carbonic anhydrase inhibitor used in the treatment of glaucoma. Its mechanism of action is similar to, but much more potent than, acetazolamide or methazolamide (see also Acetazolamide and Methazolamide). The drug is teratogenic in chicks, mice, and rats, producing otolith deficits and forelimb deformities in the fetuses of the latter two species, respectively (1). Skeletal anomalies were observed in rats at a dose 100 times the human dose (2).

It is not known if dichlorphenamide crosses the human placenta. The molecular weight (about 305) is low enough, however, that passage to the embryo or fetus should be expected.

BREASTFEEDING SUMMARY

No reports describing the use of dichlorphenamide during lactation have been located. The molecular weight (about 305) is low enough that excretion into milk should be expected.

DICLOFENAC

Nonsteroidal Anti-inflammatory

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 1st and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Constriction of the ductus arteriosus in utero is a pharmacologic consequence arising from the use of prostaglandin synthesis inhibitors during pregnancy, as is inhibition of labor, prolongation of pregnancy, and suppression of fetal renal function (see also Indomethacin) (1). As indicated above and published cases with other nonsteroidal anti-inflammatory drugs (NSAIDs), persistent pulmonary hypertension of the newborn may occur if these agents are used in the 3rd trimester close to delivery (1,2). Women attempting to conceive should not use any prostaglandin synthesis inhibitor, including diclofenac, because of the findings in a variety of animal models that indicate these agents block blastocyst implantation (3,4). Moreover, as noted below, NSAIDs have been associated with spontaneous abortions (SABs) and congenital malformations (see also Ibuprofen). The risk for these defects, however, appears to be low.

FETAL RISK SUMMARY

Diclofenac is an NSAID used for the treatment of arthritis, acute and chronic pain, and primary dysmenorrhea. Similar to other agents in this class, it also has antipyretic activity. Diclofenac is in the same subclass (acetic acids) as three other NSAIDs (indomethacin, sulindac, and tolmetin).

In reproduction studies in mice, rats, and rabbits, the drug was not teratogenic with doses up to those that produced maternal and fetal toxicity. Maternal toxic doses, however, were associated with dystocia, prolonged gestation, decreased fetal survival (5), and intrauterine growth restriction (5,6).

A 1990 report described an investigation on the effects of several nonsteroidal anti-inflammatory agents on mouse palatal fusion both in vivo and

in vitro (7). The compounds, including diclofenac, were found to induce cleft palate. In the rat, diclofenac, presumably by inhibiting prostaglandin synthesis, has been shown to inhibit implantation and placentation.

The tocolytic effect of diclofenac was demonstrated in a study that used mifepristone (RU 486) to induce preterm labor in rats (8). Diclofenac inhibited preterm delivery but had no effect on mifepristone-induced cervical maturation.

Diclofenac crosses the human placenta. In a 2000 study, 30 women undergoing termination of pregnancy at a mean gestational age of 10.2 weeks (range 8–12 weeks) were given two 50-mg oral doses at a mean 13.5 and 2.5 hours before the procedure (9). Diclofenac was detected in all maternal serum (mean 183.9 ng/mL) and fetal tissue (mean 279.2 ng/mL) samples, producing a mean maternal serum:fetal tissue ratio of 0.95 (range 0.05–4.26). Only 7 of the 30 amniotic fluid samples contained detectable diclofenac (range 0.6–3.5 ng/mL), whereas 17 of 30 coelomic fluid samples contained the drug (range 1.1–33.4 ng/mL) (9).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 51 newborns had been exposed to diclofenac during the 1st trimester (F. Rosa, personal communication, FDA, 1993). One unspecified major birth defect was observed (two expected). No anomalies were observed in six defect categories (cardiovascular defects, oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available. Although the number of exposures is small, these data do not support an association between the drug and congenital defects.

A 29-year-old woman at 33 weeks' gestation was diagnosed by clinical symptoms and ultrasound as having a spontaneous rupture of the right renal pelvis with a small amount of perinephric extravasation of urine (10). She was treated conservatively with diclofenac while hospitalized (50 mg twice daily; duration not specified) and delivered a healthy female infant 5 weeks later. A follow-up examination of her kidney by ultrasonography 5 days postpartum was normal (10).

A combined 2001 population-based, observational cohort study and a case–control study estimated the risk of adverse pregnancy outcome from the use of NSAIDs (11). The use of NSAIDs during pregnancy was not associated with congenital malformations, preterm delivery, or low birth weight, but a positive association was discovered with SABs. A similar study, also published in 2001, failed to find a relationship, in general, between NSAIDs and congenital malformations, but did find a significant association with cardiac defects and

orofacial clefts (12). In addition, a 2003 study found a significant association between exposure to NSAIDs in early pregnancy and SABs (13). (See Ibuprofen for details on these three studies.)

A brief 2003 editorial on the potential for NSAID-induced developmental toxicity concluded that NSAIDs, and specifically those with greater cyclooxygenase 2 (COX-2) affinity, had a lower risk of this toxicity in humans than aspirin (14).

A 2003 case–control study was conducted to identify drug use in early pregnancy that was associated with cardiac defects (15). Cases (cardiovascular defects without known chromosome anomalies) were drawn from three Swedish health registers (N = 5015) and controls consisting of all infants born in Sweden (1995–2001) (N = 577,730). Among the NSAIDs, only naproxen had a positive association with the defects (see Naproxen). For diclofenac, there were 1362 pregnant women exposed and 15 cases of cardiac defects (odds ratio 1.30, 95% confidence interval [OR] 0.78–2.16) (15).

A 2006 case–control study found a significant association between congenital anomalies, specifically cardiac septal defects, and the use of NSAIDs in the 1st trimester (16). A population-based pregnancy registry (N = 36,387) was developed by linking three databases in Quebec. (See Naprosyn for other study details.) Case infants were those with any congenital anomaly diagnosed in the first year of life and were compared with matched controls. There were 93 infants (8.8%) with congenital defects from 1056 mothers who had filled prescriptions for NSAIDs in the 1st trimester. In controls, there were 2478 infants (7%) with anomalies from 35,331 mothers who had not filled such a prescription. The adjusted OR was 2.21 (95% CI 1.72–2.85). The adjusted OR for cardiac septal closure was 3.34 (95% CI 1.87–5.98). There also was a significant association for anomalies of the respiratory system OR 9.55 (95% CI 3.08–29.63), but this association disappeared when cases coded as “unspecified anomaly of the respiratory system” were excluded. For the cases involving septal closure, 61% were atrial septal defects and 31% were ventricular septal defects. There were no significant associations for oral clefts or defects involving other major organ systems. The five most common NSAIDs were naproxen (35%), ibuprofen (26%), rofecoxib (15%), diclofenac (9%), and celecoxib (9%). Among these agents, the only significant association was for ibuprofen prescriptions in the 1st trimester and congenital defects (p <0.01) (16).

Premature closure of the ductus arteriosus in a fetus who was exposed to diclofenac, 50 mg twice daily, for 2 weeks from the 34th week of gestation was

reported in 1998 (17). The mother had taken the drug for musculoskeletal back pain and carpal tunnel syndrome. At 41 weeks' gestation, a fetal echocardiogram revealed the ductus defect, enlargement of the right side of the heart, and early cardiac failure. An emergency cesarean section was performed and the baby was successfully resuscitated (17). Another 1998 case described the effects of diclofenac in late gestation (18). The woman, in the 35th week of pregnancy, was treated for thrombophlebitis with a 5-day course of diclofenac (75 mg twice daily) and heparin. Thirteen days after completion of therapy, she delivered a 3200-g female infant with Apgar scores of 6 and 2 at 1 and 5 minutes, respectively. The infant was treated for severe pulmonary hypertension secondary to intrauterine ductal closure. Normal motor and mental development was noted at 2 years of age, but the infant still had cardiac dysfunction (18).

A 1999 report described constriction of the fetal ductus following a single 75-mg IM dose of diclofenac administered at 36 weeks' gestation (19). The constriction resolved within 24 hours and, 32 hours after the dose, the mother delivered 2780-g female infant with an Apgar score of 9 at 1 minute.

In another 1999 case, a woman took diclofenac (50 mg twice daily) for severe arthritis of the hands for 10 days during gestational weeks 34 and 35 (20). She also was occasionally taking Chinese herbs in what was thought to be homeopathic doses. Fetal distress was noted at 41 weeks' gestation and an ultrasound revealed hydrops fetalis with cardiomegaly and right atrial and right ventricular dilatation. An emergency cesarean section delivered a 3980-g female infant with Apgar scores of 6, 7, and 9, at 1, 5, and 10 minutes, respectively. The infant was flaccid with profound bradycardia requiring resuscitation. An echocardiogram within 30 minutes of birth revealed a severely dilated, poorly contractile right ventricle, dilated right atrium, a patent foramen ovale with right to left shunt, moderate tricuspid regurgitation, and a closed ductus arteriosus. The findings were compatible with pulmonary hypertension. The infant markedly improved over the next 4 weeks and was asymptomatic with normal growth and intellectual development at 18 months of age (20).

A 2004 case report described severe pulmonary hypertension in a newborn exposed in utero to diclofenac near delivery (21). The mother, at about 38 weeks' gestation, had been prescribed diclofenac (25 mg three times daily for 3 days) for flu-like symptoms. Immediately after completion of the prescribed course, fetal bradycardia was detected and the mother was delivered of a 3.4-kg male infant by cesarean section. The nonhydropic infant was cyanotic with respiratory distress and required mechanical ventilation. An echocardiogram

was consistent with severe neonatal pulmonary hypertension and transient right-sided hypertrophic cardiomyopathy caused by premature closure of the ductus arteriosus. The condition was thought to have resulted from diclofenac. By 40 days of age, the pulmonary hypertension had resolved and the right ventricular hypertrophy had markedly regressed (21).

BREASTFEEDING SUMMARY

No reports describing the use of diclofenac during lactation have been located. The manufacturer states that diclofenac is excreted into the milk of nursing mothers but does not cite quantitative data (5). One reviewer classified diclofenac as one of several low-risk alternatives, because of its short adult serum half-life (1.1 hours) and toxicity profile compared with other similar agents, if an NSAID was required while nursing (22). Other reviewers have also stated that diclofenac can be safely used during breastfeeding (23,24). Another NSAID in the same subclass as diclofenac is classified as compatible with breastfeeding by the American Academy of Pediatrics (see Indomethacin).

DICLOXACILLIN

Antibiotic (Penicillin)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Although the reported pregnancy experience with dicloxacillin is limited, all penicillins are considered low risk in pregnancy.

FETAL RISK SUMMARY

Dicloxacillin is a penicillin antibiotic (see also Penicillin G). The drug crosses the placenta into the fetal circulation and amniotic fluid. Levels are low compared with other penicillins due to the high degree of maternal protein binding (1,2). Following a 500-mg IV dose, the fetal peak serum level of 3.4 mcg/mL occurred at 2 hours (8% of maternal peak) (2). A peak of 1.8 mcg/mL was obtained at 6 hours in the amniotic fluid.

No reports linking the use of dicloxacillin with congenital defects have been located. The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 3546 of whom had 1st trimester exposure to penicillin derivatives (3, pp. 297–313). For use anytime in pregnancy, 7171 exposures were recorded (3, p. 435). In neither case was evidence found to suggest a relationship to large categories of major or minor malformations or to individual defects.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 46 newborns had been exposed to dicloxacillin during the 1st trimester (F. Rosa, personal communication, FDA, 1993). One (2.2%) major birth defect was observed (two expected). No anomalies were observed in six defect categories (cardiovascular defects, oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available. Although the number of exposures is small, these data do not support an association between the drug and congenital defects.

BREASTFEEDING SUMMARY

No reports describing the use of dicloxacillin during lactation have been located. Because other penicillins are excreted into breast milk in low concentrations (e.g., see Ampicillin and Penicillin G) the presence of dicloxacillin should also be expected. Although adverse effects from other penicillins in breast milk are rare, three potential problems exist for the nursing infant: modification of bowel flora, direct effects on the infant (e.g., allergic response), and interference with the interpretation of culture results if a fever workup is required.

DICUMAROL

[Withdrawn from the market. See 9th edition.]

DICYCLOMINE

Parasympatholytic

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

The use of dicyclomine during human pregnancy does not appear to represent a risk to the fetus or newborn. A 1990 review on the teratogenic risk of commonly used drugs categorized the risk from dicyclomine as “none” (1).

FETAL RISK SUMMARY

This anticholinergic/antispasmodic agent was a component of a proprietary mixture (Bendectin, others) used for the treatment and prevention of pregnancy-induced nausea and vomiting from 1956 until 1976, when the product was reformulated. Dicyclomine was removed at that time because it was discovered that it did not contribute to the effectiveness of the mixture as an antiemetic (see also Doxylamine).

Animal studies conducted with dicyclomine alone, and in combination with doxylamine and pyridoxine (i.e., Bendectin), have found no evidence of impaired fertility or adverse fetal effects (2,3).

In the Collaborative Perinatal Project, 1024 mother–child pairs of the 50,282 studied were exposed to dicyclomine during the 1st trimester (4, pp. 346–356). It was the most common parasympatholytic agent consumed by the women studied. A statistically significant association (standardized relative risk (SRR) 1.46) was discovered for minor malformations with 21 malformed children (4, p. 353). Other defects with an SRR greater than 1.5, and the number of affected newborns, were polydactyly in blacks (SRR 1.89; N = 6; 277 black mothers), macrocephaly (SRR 8.8; N = 3), diaphragmatic hernia (SRR 12.0; N = 3), and clubfoot (SRR 1.8; N = 7) (3, pp. 353, 477). For use anytime during pregnancy, 1593 women consumed dicyclomine and an increased SRR was measured for macrocephaly (6.2; N = 3) and pectus excavatum (1.8; N = 9) (4, p. 492). The

authors of this study, however, strongly cautioned that a causal relationship could not be inferred from any of these data, especially when the drug was used after the 1st trimester, and that independent confirmation was required with other studies.

A retrospective study published in 1971, involving more than 1200 mothers, examined the relationship between drugs and congenital malformations (5). This investigation found that significantly fewer mothers of infants with major anomalies, as compared with normal controls, took antiemetics during the first 56 days of pregnancy. Dicyclomine was the fourth most frequently ingested antiemetic.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 642 newborns had been exposed to dicyclomine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 31 (4.8%) major birth defects were observed (27 expected). Specific data were available for six defect categories, including (observed/expected) 5/6 cardiovascular defects, 1/1 oral clefts, 0/0.5 spina bifida, 0/1 limb reduction defects, 0/2 hypospadias, and 3/1 polydactyly. Only with the latter defect is there a suggestion of a possible association, but other factors, including the mother's disease, concurrent drug use, and chance may be involved.

BREASTFEEDING SUMMARY

No published reports on the excretion of dicyclomine into breast milk have been located. The manufacturer has received a case report of apnea in a breastfed 12-day-old infant whose mother was receiving dicyclomine (personal communication, N.G. Dahl, Marion Merrell Dow, Inc., 1992). Following the adverse event, the mother was administered a single, 20-mg dose of the drug and breastfeeding was suspended for 24 hours. Plasma and milk concentrations of dicyclomine 2 hours after the dose were 59 ng/mL and 131 ng/mL (milk:plasma ratio 2.2), respectively. Although a causal relationship between dicyclomine and apnea was not established, similar adverse reactions have occurred when the drug was administered directly to infants (1). Consequently, the safest course is to avoid dicyclomine during nursing.

DIDANOSINE

Antiviral

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit
>>Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

An increased risk of congenital defects after 1st trimester exposure to didanosine was reported by the Antiretroviral Pregnancy Registry, but the rate has decreased as the number of exposures has increased. Theoretically, exposure to didanosine at the time of implantation could result in impaired fertility due to embryonic cytotoxicity, but this has not been studied in humans. Mitochondrial dysfunction in offspring exposed in utero or postnatally to nucleoside reverse transcriptase inhibitors (NRTIs) has been reported (see Lamivudine and Zidovudine). However, if indicated, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Didanosine (2',3'-dideoxyinosine; ddi) inhibits viral reverse transcriptase and DNA synthesis. It is classified as an NRTI used for the treatment of HIV infections. Its mechanism of action is similar to that of five other nucleoside analogues: abacavir, lamivudine, stavudine, zalcitabine, and zidovudine. Didanosine is converted by intracellular enzymes to the active metabolite, dideoxyadenosine triphosphate (ddATP).

No evidence of teratogenicity or toxicity was observed in pregnant rats and rabbits administered doses of didanosine up to 12 and 14.2 times the human dose, respectively (1). In another report, didanosine was given to pregnant mice in doses ranging from 10 to 300 mg/kg/day, through all or part of gestation, without resulting in teratogenic effects or other toxicity (2).

The reproductive toxicity of 2',3'-dideoxyadenosine (ddA; the unphosphorylated active metabolite of didanosine) in rats was compared in a combined in vitro/in vivo experiment with four other nucleoside analogs (vidarabine phosphate, ganciclovir, zalcitabine, and zidovudine), and these

results were then compared with previous data obtained under identical conditions with acyclovir (3). Utilizing various concentrations of the drug in a whole-embryo culture system and direct administration to pregnant females (200 mg/kg subcutaneously every 4 hours for three doses) during organogenesis, *in vitro* vidarabine showed the highest potential to interfere with embryonic development, whereas *in vivo* acyclovir had the highest teratogenic potential. In this study, the *in vitro* reproductive toxicity of ddA was less than that of the other agents, except for zidovudine. The *in vivo* toxicity was less than that of acyclovir, vidarabine, and ganciclovir, and equal to that observed with zalcitabine and zidovudine.

Antiretroviral nucleosides have been shown to have a direct dose-related cytotoxic effect on preimplantation mouse embryos. A 1994 report compared this toxicity among zidovudine and three newer compounds, didanosine, stavudine, and zalcitabine (4). Whereas significant inhibition of blastocyst formation occurred with a 1 $\mu\text{mol/L}$ concentration of zidovudine, stavudine, and zalcitabine toxicity was not detected until 100 $\mu\text{mol/L}$, and no toxicity was observed with didanosine up to 100 $\mu\text{mol/L}$. Moreover, postblastocyst development was severely inhibited in those embryos that did survive exposure to 1 $\mu\text{mol/L}$ zidovudine. As for the other compounds, stavudine, at a concentration of 10 $\mu\text{mol/L}$ (2.24 mcg/mL), inhibited postblastocyst development, but no effect was observed with concentrations up to 100 $\mu\text{mol/L}$ of didanosine or zalcitabine. An earlier study found no cytotoxicity in preimplantation mouse embryos exposed to didanosine concentrations ≤ 500 $\mu\text{mol/L}$ (2). Although there are no human data, the authors of the 1994 study concluded that the three newer agents may be safer than zidovudine to use in early pregnancy (4).

A 1995 report described the effect of exposure to a relatively high concentration of didanosine (20 $\mu\text{mol/L}$ vs. recommended therapeutic concentrations of 3–5 $\mu\text{mol/L}$) for prolonged periods (2–11 days) on trophoblasts from term and 1st trimester placentas (5). No significant effects on trophoblast function, as measured by human chorionic gonadotropin (hCG) secretion, protein synthesis, progesterone synthesis, and glucose consumption, were observed.

A 1999 study also investigated the effects of a single 24-hour exposure of zidovudine (AZT) or didanosine on human trophoblast cells using a human choriocarcinoma cell line that exhibited many characteristics of the early placenta (6). Two drug concentrations (7.6 mM or 0.076 mM) were studied for their effects on trophoblast cell proliferation and hormone production (hCG,

estradiol (E_2) and progesterone (P_4)). The higher concentrations of AZT or ddI resulted in significant decreases in cell numbers and growth rate (38% and 51% of control values, respectively), but increased production of hCG, E_2 , and P_4 . The decrease in trophoblast cell proliferation may have been the mechanism for the increased incidence of rodent embryo loss observed with AZT (6). In contrast, the lower concentrations of AZT and ddI did not cause changes in cell numbers, producing only significant increases in E_2 production. Because of these findings, the researchers concluded that high therapeutic doses of either AZT or ddI during early human gestation were potentially embryo toxic (6).

Didanosine crosses the placenta to the fetus in both animals and humans (1,7–13). In pregnant macaques, didanosine was administered by constant infusion at a dose of either 42.5 or 425 mcg/minute/kg (7). The compound crossed the placenta by simple diffusion, resulting in fetal:maternal concentration ratios for both doses of approximately 0.5. In near-term rhesus monkeys, a single IV bolus (2.0 mg/kg) of didanosine resulted in mean fetal concentrations of unmetabolized drug of 33% of the maternal plasma concentrations (8). Concentrations of didanosine were 20% of those in the fetal plasma by 3 hours. However, ddATP was not found in any fetal tissue.

Using a perfused term human placenta, investigators concluded in a 1992 publication that the placental transfer of didanosine was most likely due to passive diffusion (9). Two other studies, again using perfused human placenta, found that only about 50% of the drug would be passively transferred to the fetal circulation (10), and at approximately half the rate of zidovudine (11). In contrast to zidovudine (see Zidovudine), no metabolite was detected in the placenta (10).

Two HIV-positive women, at 21 and 24 weeks' gestation, respectively, were given a single 375-mg oral dose of didanosine immediately prior to pregnancy termination (12). Drug concentrations in the maternal blood, fetal blood, and amniotic fluid at slightly more than 1 hour after the dose were 295, 42, and <5 ng/mL, respectively, in the first patient, and 629, 121, and 135 ng/mL, respectively, in the second woman. The fetal:maternal blood ratios were 0.14 and 0.19, respectively. Although single-drug-level determinations are difficult to interpret, a study published in 1993 found that human placental first-pass metabolism was not the reason for these low fetal and amniotic fluid levels (13).

Three experimental in vitro models using perfused human placentas to predict the placental transfer of NRTIs (didanosine, stavudine, zalcitabine, and

zidovudine) were described in a 1999 publication (14). For each drug, the predicted fetal:maternal plasma drug concentration ratios at steady state with each of the three models were close to those actually observed in pregnant macaques. Based on these results, the authors concluded that their models would accurately predict the mechanism, relative rate, and the extent of in vivo human placental transfer of NRTIs (14).

The pharmacokinetics of IV (1.6 mg/kg/hr) and oral (200 mg twice daily) didanosine have been studied in pregnant women with HIV infection at 31 weeks' gestation, during labor, and 6 weeks postpartum (15). This study also described the pharmacokinetics of oral didanosine (60 mg/m²) in infants at day 1 and at week 6 after birth.

The Antiretroviral Pregnancy Registry reported, for January 1989 through July 2009, prospective data (reported before the outcomes were known) involving 4702 live births that had been exposed during the 1st trimester to one or more antiretroviral agents (16). Congenital defects were noted in 134, a prevalence of 2.8% (95% confidence interval [CI] 2.4–3.4). In the 6100 live births with earliest exposure in the 2nd/3rd trimesters, there were 153 infants with defects (2.5%, 95% CI 2.1–2.9). The prevalence rates for the two periods did not differ significantly. There were 288 infants with birth defects among 10,803 live births with exposure anytime during pregnancy (2.7%, 95% CI 2.4–3.0). The prevalence rate did not differ significantly from the rate expected in a nonexposed population. There were 627 outcomes exposed to didanosine (370 in the 1st trimester and 257 in the 2nd/3rd trimesters) in combination with other antiretroviral agents. There were 22 birth defects (17 in the 1st trimester and 5 in the 2nd/3rd trimesters). In reviewing the birth defects of prospective and retrospective (pregnancies reported after the outcomes were known) registered cases, the Registry concluded that, except for isolated cases of neural tube defects with efavirenz exposure in retrospective reports, there was no other pattern of anomalies (isolated or syndromic) (16). (See Lamivudine for required statement.)

A case of life-threatening anemia following in utero exposure to antiretroviral agents was described in 1998 (17). A 30-year-old woman with HIV infection was treated with zidovudine, didanosine, and trimethoprim/sulfamethoxazole (three times weekly) during the 1st trimester. Vitamin supplementation was also given. Because of an inadequate response, didanosine was discontinued and lamivudine and zalcitabine were started in the 3rd trimester. Two weeks before delivery the HIV viral load was undetectable. At term, a pale, male infant was delivered, who developed respiratory distress shortly after birth. Examination

revealed a hyperactive precordium and hepatomegaly without evidence of hydrops. The hematocrit was 11% with a reticulocyte count of zero. An extensive work-up of the mother and infant failed to determine the cause of the anemia. Bacterial and viral infections, including HIV, parvovirus B19, cytomegalovirus, and others, were excluded. The infant received a transfusion and was apparently doing well at 10 weeks of age. Because no other cause of the anemia could be found, the authors attributed the condition to bone marrow suppression, most likely to zidovudine (17). A contribution of the other agents to the condition, however, could not be excluded.

A 2000 case report described the adverse pregnancy outcomes, including NTD, of two pregnant women with HIV infection who were treated with the anti-infective combination, trimethoprim/sulfamethoxazole, for prophylaxis against *Pneumocystis carinii*, concurrently with antiretroviral agents (18). Exposure to didanosine occurred in one of these cases. A 31-year-old woman presented at 15 weeks' gestation. She was receiving trimethoprim/sulfamethoxazole, didanosine, stavudine, nevirapine, and vitamin B supplements (specific vitamins and dosage not given) that had been started before conception. A fetal ultrasound at 19 weeks' gestation revealed spina bifida and ventriculomegaly. The patient elected to terminate her pregnancy. The fetus did not have HIV infection. Defects observed at autopsy included ventriculomegaly, an Arnold–Chiari malformation, sacral spina bifida, and a lumbosacral meningocele. The authors attributed the NTDs in both cases to the antifolate activity of trimethoprim (18).

No data are available on the advisability of treating pregnant women who have been exposed to HIV via occupational exposure, but one author discourages this use (19).

Two reviews, one in 1996 and the other in 1997, concluded that all women currently receiving antiretroviral therapy should continue to receive therapy during pregnancy and that treatment of the mother with monotherapy should be considered inadequate therapy (20,21). The same conclusion was reached in a 2003 review with the added admonishment that therapy must be continuous to prevent emergence of resistant viral strains (22). In 2009, the updated U.S. Department of Health and Human Services guidelines for the use of antiretroviral agents in HIV type 1 (HIV-1)-infected patients continued the recommendation that therapy, with the exception of efavirenz, should be continued during pregnancy (23). If indicated, didanosine should not be withheld in pregnancy because the expected benefit to the HIV-positive mother outweighs the unknown risk to the fetus. The updated guidelines for the use of

antiretroviral drugs to reduce perinatal HIV-1 transmission also were released in 2010 (24). Women receiving antiretroviral therapy during pregnancy should continue the therapy, but, regardless of the regimen, zidovudine administration is recommended during the intrapartum period to prevent vertical transmission of HIV to the newborn (24).

BREASTFEEDING SUMMARY

No reports describing the use of didanosine during lactation have been located. The molecular weight (about 236) is low enough that excretion into milk should be expected. The effect on a nursing infant is unknown.

Reports on the use of didanosine during human lactation are unlikely because the antiviral agent is used in the treatment of HIV infections. HIV-1 is transmitted in milk, and in developed countries, breastfeeding is not recommended (20,21,23,25–27). In developing countries, breastfeeding is undertaken, despite the risk, because there are no affordable milk substitutes available. Until 1999, no studies had been published that examined the effect of any antiretroviral therapy on HIV-1 transmission in milk. In that year, a study involving zidovudine was published that measured a 38% reduction in vertical transmission of HIV-1 infection despite breastfeeding when compared with controls (see Zidovudine).

DIENESTROL

[Withdrawn from the market. See 9th edition.]

DIETHYLPROPION

Central Stimulant/Anorexiant

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports, in humans or animals, linking the use of diethylpropion with congenital defects have been located.

FETAL RISK SUMMARY

Diethylpropion has been studied as an appetite suppressant in 28 pregnant patients and, although adverse effects were common in the women, no problems were observed in their offspring (1). A retrospective survey of 1232 patients exposed to diethylpropion during pregnancy found no difference in the incidence of defects (0.9%) when compared with a matched control group (1.1%) (2). No impairment of fertility, teratogenicity, or fetotoxicity was observed in animal studies with doses up to nine times those used in humans (3,4).

BREASTFEEDING SUMMARY

Diethylpropion and its metabolites are excreted into breast milk (4). No reports of adverse effects in a nursing infant have been located.

DIETHYLSTILBESTROL

Estrogenic Hormone

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Diethylstilbestrol (DES) is a known human teratogen. It causes developmental toxicity in both female and male offspring. It is contraindicated in pregnancy.

FETAL RISK SUMMARY

Between 1940 and 1971, an estimated 6 million mothers and their fetuses were exposed to DES to prevent reproductive problems such as miscarriage, premature delivery, intrauterine fetal death, and toxemia (1–4). Controlled studies have since proven that DES was not successful in preventing these disorders (5,6). This use has resulted, however, in significant complications of the reproductive system in both female and male offspring (1–12). Two large groups have been established to monitor these complications: the Registry for Research on Hormonal Transplacental Carcinogenesis and the Diethylstilbestrol Adenosis (DESAD) Project (4). The published findings and recommendations of the DESAD project through 1980 plus a number of other studies including the Registry were reviewed in a 1981 National Institutes of Health booklet available from the National Cancer Institute (4). This information was also reprinted in a 1983 journal article (13). The complications identified in female and male children exposed in utero to DES are as follows:

Female

- Lower müllerian tract
- Vaginal adenosis
- Vaginal and cervical clear cell adenocarcinoma
- Cervical and vaginal fornix defects (10)
- Cock's comb (hood, transverse ridge of cervix)
- Collar (rim, hood, transverse ridge of cervix)
- Pseudopolyp

- Hypoplastic cervix (immature cervix)
- Altered fornix of vagina
- Vaginal defects (exclusive of fornix) (10)
- Incomplete transverse septum
- Incomplete longitudinal septum
- Upper müllerian tract
- Uterine structural defects
- Fallopian tube structural defects

Male

- Reproductive dysfunction
- Altered semen analysis
- Infertility

The Registry was established in 1971 to study the epidemiologic, clinical, and pathologic aspects of clear cell adenocarcinoma of the vagina and cervix in DES-exposed women (2). More than 400 cases of clear cell adenocarcinoma have been reported to the Registry. Additional reports continue to appear in the literature (14). The risk of carcinoma is apparently higher when DES treatment was given before the 12th week of gestation and is estimated to be 0.14–1.4/1000 for women younger than 25 years (2,4).

The first-known case of adenosquamous carcinoma of the cervix in an exposed patient was described in 1983 (15). In a second case, a fatal malignant teratoma of the ovary developed in a 12-year-old exposed girl (16). The relationship between these tumors and DES is unknown.

The frequency of dysplasia and carcinoma in situ (CIS) of the cervix and vagina in 3980 DESAD Project patients was significantly increased over controls with an approximately 2- to 4-fold increase in risk (11). These results were different from earlier studies of these same women, which had indicated no increased risk for dysplasia and CIS (17,18). Researchers speculated that the increased incidence now observed was related to the greater amount of squamous metaplasia found in DES-exposed women (11). Scanning electron microscopy of the cervicovaginal transformation zone has indicated that maturation of epithelium is slowed or arrested at the stage of immature squamous epithelium in some DES-exposed women (19). This process may produce greater susceptibility to factors such as herpes and papillomavirus obtained through early coitus with multiple partners and result in the observed increased rates of dysplasia/CIS (11). Of interest in this regard, a 1983 article reported detectable papillomavirus antigen in the cervical–vaginal biopsies of 16

(43%) of 37 DES-exposed women (20).

The incidence of cervical or vaginal structural changes has been reported to occur in up to 85% of exposed women, although most studies place the incidence in the 22%–58% range (2,3,5,7,12,21–24). The structural changes are outlined earlier. The DESAD Project reported an incidence of approximately 25% in 1655 women (10). Selection bias was eliminated by analyzing only those patients identified by record review. Patients referred by physicians and self-referrals had much higher rates of defects, about 49% and 43%, respectively. Almost all of the defects were confined to the cervical–vaginal fornix area, with only 14 patients having vaginal changes exclusive of the fornix and nearly all of these being incomplete transverse septums (10).

Reports linking the use of DES with major congenital anomalies have not been located. The Collaborative Perinatal Project monitored 614 mother–child pairs with 1st trimester exposure to estrogens, including 164 with exposure to DES (25, pp. 389, 391). Evidence for an increase in the expected frequency for cardiovascular defects, eye and ear anomalies, and Down’s syndrome was found for estrogens as a group, but not for DES (25, pp. 389, 391, 395). Reevaluation of these data in terms of timing of exposure, vaginal bleeding in early pregnancy, and previous maternal obstetric history, however, failed to support an association between estrogens and cardiac malformations (26). An earlier study also failed to find any relationship with nongenital malformations (27).

Alterations in the body of the uterus have led to concern regarding increased pregnancy wastage and premature births (8,22,28–31). Increased rates of spontaneous abortions, premature births, and ectopic pregnancies are well established by these latter reports, although the relationship to the abnormal changes of the cervix and/or vagina is still unclear (8). Serial observations of vaginal epithelial changes indicate that the frequency of such changes decreases with age (4,17,24).

Spontaneous rupture of a term uterus has been described in a 25-year-old primigravid with DES-type changes in her vagina, cervix, and uterus (32). Other reports of this type have not been located.

In a 1984 study, DES exposure had no effect on the age at menarche, first coitus, pregnancy, or live birth, or on a woman’s ability to conceive (33). One group of investigators found that although anomalies in the upper genital tract increased the risk for poor pregnancy outcome, they could not relate specific changes to specific types of outcomes (34).

Hirsutism and irregular menses were found in 72% and 50%, respectively, of

32 DES-exposed women (35). The degree of hirsutism was age related, with the mean ages of severely and mildly hirsute women being 28.8 and 24.7 years, respectively. Based on various hormone level measurements, the authors concluded that in utero DES exposure might result in hypothalamic–pituitary–ovarian dysfunction (35). However, other studies in much larger exposed populations have not observed disturbances of menstruation or excessive hair growth (36).

Data on DES-exposed women who had undergone major gynecologic surgical procedures, excluding cesarean section, were reported in a 1982 study (37). Of 309 exposed women, 33 (11%) had a total of 43 procedures. The authors suggested that DES exposure resulted in an increased incidence of adnexal disease involving adhesions, benign ovarian cysts, and ectopic pregnancies (37). Surgical manipulation of the cervix (cryocautery or conization) in DES-exposed patients results in a high incidence of cervical stenosis and possible development of endometriosis (38,39). Both studies concluded, however, that the causes of infertility in these patients were comparable to those in a non–DES-exposed population.

Adverse effects in male offspring attributable to in utero DES exposure have been reported (1,5,40–46). Abnormalities thought to occur at greater frequencies include the following:

- Epididymal cysts

- Hypotrophic testis

- Microphallus

- Varicocele

- Capsular induration

- Altered semen (decreased count, concentration, motility, and morphology)

An increase in problems with passing urine and urogenital tract infections has also been observed (40).

DES exposure has been proposed as a possible cause of infertility in male offspring (1). However, in a controlled in vitro study, no association was found between exposure to DES and reduced sperm penetration of zona-free hamster eggs (46). In addition, a study of 828 exposed males found no increase over controls for risk of genitourinary abnormalities, infertility, or testicular cancer (47). Based on their data, the authors proposed that previous studies showing a positive relationship might have had selection biases, differences in DES use, or both.

Testicular tumors have been reported in three DES-exposed patients (6,48).

In one case, a teratoma was discovered in a 23-year-old male (6). Two patients, 27 and 28 years of age, were included in the second report (48). Both had left-sided anaplastic seminomas, and one had epididymal cysts. A male sibling of one of the patients, also exposed to DES, had severe oligospermia, and two exposed sisters had vaginal adenosis and vaginal adenocarcinoma.

Changes in the psychosexual performance of young boys have been attributed to in utero exposure to DES and progesterone (49,50). The mothers received estrogen/progestogen regimens for diabetes. A trend to less heterosexual experience and fewer masculine interests than controls was shown. A 2-fold increase in psychiatric disease, especially depression and anxiety, has been observed in both male and female exposed offspring (6).

BREASTFEEDING SUMMARY

No data are available. Decreased milk volume and nitrogen–protein content may occur if DES is used during lactation (see Mestranol and Ethinyl Estradiol).

DIFLUNISAL

Nonsteroidal Anti-inflammatory

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 1st and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Constriction of the ductus arteriosus in utero is a pharmacologic consequence arising from the use of prostaglandin synthesis inhibitors during pregnancy (see also Indomethacin) (1). Persistent pulmonary hypertension of the newborn may occur if these agents are used in the 3rd trimester close to delivery (1,2). These drugs also have been shown to inhibit labor and prolong pregnancy, both in humans (3) (see also Indomethacin) and in animals (4). Women attempting to conceive should not use any prostaglandin synthesis inhibitor, including diflunisal, because of the findings in a variety of animal models that indicate these agents block blastocyst implantation (5,6). Moreover, nonsteroidal anti-inflammatory drugs (NSAIDs) have been associated with spontaneous abortions (SABs) and congenital malformations. The absolute risk for these defects, however, appears to be low.

FETAL RISK SUMMARY

Diflunisal is an NSAID used in the treatment of mild-to-moderate pain, osteoarthritis, and rheumatoid arthritis. The drug is teratogenic and embryotoxic in rabbits administered 40–60 mg/kg/day, the highest dose equivalent to 2 times the maximum human dose (7). Similar results were not observed in mice and rats treated with 45–100 mg/kg/day (7,8) or in monkeys treated with 80 mg/kg during organogenesis (9). No published reports describing the use of this drug in human pregnancy have been located.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 258 newborns had been exposed to diflunisal during the 1st trimester (F. Rosa, personal

communication, FDA, 1993). A total of 19 (7.4%) major birth defects were observed (10 expected). Specific data were available for six defect categories, including (observed/expected) 1/3 cardiovascular defects, 1/0.4 oral clefts, 0/0 spina bifida, 1/1 polydactyly, 0/0 limb reduction defects, and 1/1 hypospadias. It remains to be investigated whether an unusual frequency distribution of the other 15 defects is in the overall excess of birth defects.

A combined 2001 population-based, observational cohort study and a case–control study estimated the risk of adverse pregnancy outcome from the use of NSAIDs (10). The use of NSAIDs during pregnancy was not associated with congenital malformations, preterm delivery, or low birth weight, but a positive association was discovered with SABs. A similar study, also published in 2001, failed to find a relationship, in general, between NSAID and congenital malformations, but did find a significant association with cardiac defects and orofacial clefts (11). In addition, a 2003 study found a significant association between exposure to NSAIDs in early pregnancy and SABs (12). (See Ibuprofen for details on these three studies.)

A brief 2003 editorial on the potential for NSAID-induced developmental toxicity concluded that NSAIDs, and specifically those with cyclooxygenase 2 (COX-2) affinity, had a lower risk of this toxicity in humans than aspirin (13).

BREASTFEEDING SUMMARY

Diflunisal is excreted into human milk. Milk concentrations range from 2% to 7% of the levels in the mother's plasma (7). No reports describing the use of this agent during lactation have been located.

DIGITALIS

Cardiac Glycoside

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No reports linking digitalis or the various digitalis glycosides with congenital defects have been located. Animal studies have not shown a teratogenic effect (1).

FETAL RISK SUMMARY

Rapid passage to the fetus has been observed after administration of digoxin and digitoxin (2–9). One group of investigators found that the amount of digitoxin recovered from the fetus depended on the length of gestation (2). In the late 1st trimester, only 0.05%–0.10% of the injected dose was recovered from three fetuses. Digitoxin metabolites accounted for 0.18%–0.33%. At 34 weeks' gestation, digitoxin recovery was 0.85% and metabolite recovery was 3.49% from one fetus. Average cord concentrations of digoxin in three reports were 50%, 81%, and 83% of the maternal serum (3,4,9). The highest fetal concentrations of digoxin in the second half of pregnancy were found in the heart (5). The fetal heart has only a limited binding capacity for digoxin in the first half of pregnancy (5). In animals, amniotic fluid acts as a reservoir for digoxin, but no data are available in humans after prolonged treatment (5). The pharmacokinetics of digoxin in pregnant women have been reported (10,11).

Digoxin has been used for both maternal and fetal indications (e.g., congestive heart failure and supraventricular tachycardia) during all stages of gestation without causing fetal harm (12–25). Direct administration of digoxin to the fetus by periodic IM injections has been used to treat supraventricular tachycardia when indirect therapy via the mother failed to control the arrhythmia (26).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 34 newborns had been exposed to digoxin during the 1st trimester (F. Rosa, personal

communication, FDA, 1993). One (2.9%) major birth defect was observed (one expected), an oral cleft. Although the number of exposures is small, these data are supportive of previous experience for a lack of association between the drug and congenital defects.

Fetal toxicity resulting in neonatal death has been reported after maternal overdose (27). The mother, in her 8th month of pregnancy, took an estimated 8.9 mg of digitoxin as a single dose. Delivery occurred 4 days later. The baby demonstrated digitalis cardiac effects until death at age 3 days from prolonged intrauterine anoxia.

In a series of 22 multiparous patients maintained on digitalis, spontaneous labor occurred more than 1 week earlier than in 64 matched controls (28). The first stage of labor in the treated patients averaged 4.3 hours vs. 8 hours in the control group. In contrast, others found no effect on duration of pregnancy or labor in 122 patients with heart disease (29).

BREASTFEEDING SUMMARY

Digoxin is excreted into breast milk. Data for other cardiac glycosides have not been located. Digoxin milk:plasma ratios have varied from 0.6 to 0.9 (4,7,30,31). Although these amounts seem high, they represent very small amounts of digoxin due to significant maternal protein binding. No adverse effects in the nursing infant have been reported. The American Academy of Pediatrics classifies digoxin as compatible with breastfeeding (32).

DIGOXIN IMMUNE FAB (OVINE)

Antidote

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Several reports have described the use of digoxin immune Fab (ovine) in pregnancy, but all involved patients who had preeclampsia. Although no fetal harm related to digoxin immune Fab (ovine) was observed, none of the cases involved exposure during organogenesis. Nevertheless, in cases of digoxin overdose, the maternal benefits of therapy should take priority over the embryo–fetus. Thus, if indicated, therapy with this product should not be withheld because of pregnancy (1).

FETAL RISK SUMMARY

Digoxin immune Fab (ovine) is given IV. It is indicated for the treatment of patients with life-threatening or potentially life-threatening digoxin toxicity or overdose. Digoxin immune Fab (ovine) binds digoxin, thereby preventing the cardiac agent from binding to cells. The Fab-digoxin complex is then excreted in the urine. The elimination half-life is approximately 15–20 hours. Reproduction studies in animals have not been conducted (2).

It is not known if digoxin immune Fab (ovine) can cross the human placenta to the embryo–fetus. The antibody fragments probably do not cross, at least early in pregnancy, because of their high molecular weight (about 46,000), but some antibodies are able to cross the placenta in the 3rd trimester (e.g., see Immune Globulin Intravenous).

A 1988 case report described the use of digoxin immune Fab (ovine) in a woman with severe preeclampsia (3). In five additional reports involving 56 women, 13 in the immediate postpartum period (4) and 44 in the 2nd and 3rd trimesters (5–8), the drug was used for the same indication. No drug-induced adverse effects were observed in the fetuses or newborns.

BREASTFEEDING SUMMARY

No reports describing the use of digoxin immune Fab (ovine) during lactation have been located. It is doubtful that clinically significant amounts are excreted into breast milk. Even if some excretion did occur, it would be digested in the nursing infant's stomach. Therefore, the risk to a nursing infant appears to be nil. In addition, the maternal benefits of therapy in cases of digoxin overdose should outweigh the unknown risk to a nursing infant.

DIHYDROCODEINE

Narcotic Agonist Analgesic

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 3rd Trimester

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports linking the use of dihydrocodeine with congenital defects have been located. Usage in pregnancy is primarily confined to labor. Respiratory depression in the newborn has been reported to be less than that with meperidine, but depression is probably similar when equianalgesic doses are compared (1–4). If dihydrocodeine is used in pregnancy, healthcare professionals are encouraged to call the toll-free number (800-670-6126) for information about patient enrollment in the Motherisk study.

BREASTFEEDING SUMMARY

No reports describing the use of dihydrocodeine bitartrate during lactation have been located. Because other opiates are excreted into milk (e.g., see Morphine) and the molecular weight (about 452) of dihydrocodeine bitartrate is low enough, the presence of the narcotic in milk should be expected. The long-term effects on neurobehavior and development in a nursing infant are unknown but warrant study.

DIHYDROERGOTAMINE

Sympatholytic (Antimigraine)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Dihydroergotamine is a potent semi-synthetic ergot alkaloid that has oxytocic and sympatholytic properties. The animal data suggest a risk of intrauterine growth restriction probably resulting from reduced uteroplacental blood flow and/or increased myometrial tone. Although there is no evidence that it is a teratogen, dihydroergotamine is contraindicated in pregnancy, especially near term. Inadvertent exposure early in gestation, however, does not appear to represent a major risk.

FETAL RISK SUMMARY

Dihydroergotamine is the hydrogenated derivative of ergotamine (see also Ergotamine). It is available only in formulations for injection and nasal spray because oral absorption is poor. Both preparations are indicated for the acute treatment of migraine headaches with or without aura. In addition, the injectable formulation is indicated for the acute treatment of cluster headaches. The mean bioavailability of the nasal spray is 32% relative to the injectable administration. Plasma protein binding is 93% and the elimination half-life is about 9 hours (1,2). Another source, however, states that elimination is biphasic with half-lives of about 1–2 hours and 22–32 hours, respectively (3).

The oxytocic properties of ergotamine have been known since the early 1900s, producing a prolonged and marked increase in uterine tone that may lead to fetal hypoxia (4). The pharmacologic properties of dihydroergotamine are different from ergotamine, as the former is a much more potent sympatholytic (4). In a 1952 study, the oxytocic and toxic effects of dihydroergotamine were demonstrated (5). Twenty women at term were given 1 mg of dihydroergotamine in 500 mL distilled water IV over a period of 2–4 hours to induce labor. Labor induction was successful in eight women (40%), but in six other women the outcomes were four stillborns, one neonatal death

1.25 hours after delivery, and one severely depressed infant that developed seizures 3 days after delivery (progressing satisfactorily at 3 months of age with no abnormal neurological signs). The investigators concluded that dihydroergotamine should not be used to induce labor (5).

Reproduction studies have been conducted in rats and rabbits. In rats, intranasal administration throughout the period of organogenesis at doses producing maternal plasma exposures (AUC) about 0.4–1.2 times the human exposure (AUC) from the maximum recommended daily dose of ≥ 4 mg (MRDD) resulted in decreased fetal body weights and/or skeletal ossification. Administration of the dose throughout pregnancy and lactation resulted in reduced body weights and impaired reproductive function in the offspring. The no-effect level for rat embryo–fetal toxicity was not established. In rabbits administered the nasal spray during organogenesis, maternal exposures at about 7 times the MRDD also resulted in delayed skeletal ossification. The no-effect dose for rabbit embryo–fetal toxicity was about 2.5 times the MRDD. The embryo–fetal toxic doses in both species did not cause maternal toxicity. The in utero growth restriction in the animal studies was thought to have resulted from reduced uteroplacental blood flow and/or increased myometrial tone (1,2).

A study in guinea pigs quantified the effect of dihydroergotamine on uteroplacental blood flow (6). Pregnant guinea pigs were given the drug (14 mcg/kg/day) from day 30 to 60 of pregnancy (gestational length for guinea pigs is 64–68 days). At term, placental blood flow was decreased by 51% and, fetal weight and fetal weight/placental weight ratio were significantly decreased compared with controls (6).

It is not known if dihydroergotamine crosses the human placenta. The molecular weight of the free base (about 584) and long elimination half-life suggest that the drug will cross the placenta, but the extensive protein binding will limit passage.

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 32 of whom were exposed to ergot derivatives (three to dihydroergotamine) other than ergotamine during the 1st trimester (7). Three malformed children were observed from this group, but the numbers are too small to draw any conclusion.

A brief 1993 report described a 31-year-old woman with depression, panic disorder, and migraine headaches who was exposed to a number of drugs in the first 6 weeks of pregnancy, including dihydroergotamine, citalopram, buspirone, thioridazine, and etilefrine (a sympathomimetic agent) (8). An

elective abortion was performed at 12 weeks' gestation. A thorough macroscopic and microscopic examination of the male fetus revealed no evidence of malformation. A detailed neuropathological examination and chromosome analysis (46,XY karyotype) was normal (8).

BREASTFEEDING SUMMARY

No reports describing the use of dihydroergotamine during human lactation have been located. The molecular weight of the free base (about 584) and long elimination half-life (may be as long as 22 hours) suggest that the drug will be excreted into breast milk, but the high protein binding (about 93%) will limit this excretion. The closely related agent ergotamine is excreted into milk (see Ergotamine). An ergot product has been associated with symptoms of ergotism (vomiting, diarrhea, and convulsions) in nursing infants of mothers taking the agent for the treatment of migraine (see Ergotamine). Moreover, dihydroergotamine is a member of the same chemical family as bromocriptine, an agent that is used to suppress lactation. Although no specific information has been located relating to the effects of dihydroergotamine on lactation, ergot alkaloids may hinder lactation by inhibiting maternal pituitary prolactin secretion (9).

DIHYDROTACHYSTEROL

Vitamin

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Dihydrotachysterol is a synthetic analog of vitamin D. It is converted in the liver to 25-hydroxydihydrotachysterol, an active metabolite. See Vitamin D.

BREASTFEEDING SUMMARY

See Vitamin D.

DILTIAZEM

Calcium Channel Blocker

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

The animal reproductive data suggest high risk, but it is based on body weight comparison, not on BSA or AUC. The limited human pregnancy data suggest that the risk is low, if it exists at all.

FETAL RISK SUMMARY

Diltiazem is a calcium channel inhibitor used for the treatment of angina. Reproductive studies in mice, rats, and rabbits at doses ≤ 5 –10 times (on a body weight basis) the daily recommended human dose found increased mortality in embryos and fetuses. These doses also produced abnormalities of the skeletal system. An increased incidence of stillbirths was observed in perinatal animal studies at ≥ 20 times the human dose (1). In fetal sheep, diltiazem, like ritodrine and magnesium sulfate, inhibited bladder contractions, resulting in residual urine (2).

A 34-year-old woman, in her 1st month of pregnancy, was treated with diltiazem, 60 mg 4 times/day, and isosorbide dinitrate, 20 mg 4 times/day, for symptomatic myocardial ischemia (3). Both medications were continued throughout the remainder of gestation. Normal twins were delivered by repeat cesarean section at 37 weeks' gestation. Both infants were alive and well at 6 months of age.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 27 newborns had been exposed to diltiazem during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Four (14.8%) major birth defects were observed (one expected), two of which were cardiovascular defects (0.3 expected). No anomalies were observed in five other categories of defects (oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias) for which data

were available. Although the number of exposures is small, the total number of defects and the number of cardiovascular defects are suggestive of an association, but other factors, including the mother's disease, concurrent drug use, and chance may be involved.

A prospective, multicenter cohort study of 78 women (81 outcomes; 3 sets of twins) who had 1st trimester exposure to calcium channel blockers, including 13% to diltiazem, was reported in 1996 (4). Compared with controls, no increase in the risk of major congenital malformations was found.

A 22-year-old woman with Eisenmenger syndrome that was managed with sildenafil 50 mg/day was diagnosed with an atrial septal defect that was closed surgically (5). Eight days after surgery, the patient reported 7 weeks of amenorrhea and a pregnancy test was positive. Sildenafil 150 mg/day and diltiazem 60 mg/day were started. Two weeks later sildenafil was discontinued because of its high cost and the dose of diltiazem was increased to 180 mg/day. Because of worsening pulmonary hypertension at 31 weeks, sildenafil 150 mg/day was restarted and diltiazem was discontinued. The fetal weight was estimated to be in the 15th percentile. At 32 weeks, L-arginine (a nitric oxide donor) 3 g/day was started. During the next 2 weeks, the estimated fetal weight increased to the 35th percentile. Because of superimposed preeclampsia, a cesarean section was performed at 36 weeks to deliver a 2.290-kg male infant with Apgar scores of 9 and 9. No additional information on the infant was provided (5).

Diltiazem has been used as a tocolytic agent (6). In a prospective randomized trial, 22 women treated with the agent were compared with 23 treated with nifedipine. No differences between the groups in outcomes or maternal effects were observed.

BREASTFEEDING SUMMARY

Diltiazem is excreted into human milk (7). A 40-year-old woman, 14 days postpartum, was unsuccessfully treated with diltiazem, 60 mg 4 times/day, for resistant premature ventricular contractions. Her infant was not allowed to breastfeed during the treatment period. Simultaneous serum and milk levels were drawn at several times on the 4th day of therapy. The peak level in milk was approximately 200 ng/mL, almost the same as the peak serum concentration. Milk and serum concentrations were nearly the same during the measurement interval, with changes in the concentrations closely paralleling each other. The data indicated that diltiazem freely diffuses into milk (7). In a separate case described earlier, a mother nursed twins for at least 6 months

while being treated with diltiazem and isosorbide dinitrate (3). Milk concentrations were not determined, but both infants were alive and well at 6 months of age. The American Academy of Pediatrics classifies diltiazem as compatible with breastfeeding (8).

DIMENHYDRINATE

Antihistamine/Antiemetic

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

In general, antihistamines are considered low risk in pregnancy. However, exposure near birth of premature infants has been associated with an increased risk of retrolental fibroplasia.

FETAL RISK SUMMARY

Dimenhydrinate is the chlorotheophylline salt of the antihistamine diphenhydramine. A prospective study in 1963 compared dimenhydrinate usage in three groups of patients: 266 with malformed infants and two groups of 266 each without malformed infants (1). No difference in usage of the drug was found between the three groups.

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 319 of whom had 1st trimester exposure to dimenhydrinate (2, pp. 367–370). For use anytime in pregnancy, 697 exposures were recorded (2, p. 440). In neither case was evidence found to suggest a relationship to large categories of major or minor malformations. Two possible associations with individual malformations were found: cardiovascular defects (five cases) and inguinal hernia (eight cases). Independent confirmation is required to determine the actual risk for these anomalies (2, p. 440).

A number of reports have described the oxytocic effect of IV dimenhydrinate (3–13). When used either alone or with oxytocin, most studies found a smoother, shorter labor. However, in one study of 30 patients who received a 100-mg dose during 3.5 minutes, some (at least two, but exact number not specified) also showed evidence of uterine hyperstimulation and fetal distress (e.g., bradycardia and loss of beat-to-beat variability) (13). Owing to these effects, dimenhydrinate should not be used for this purpose.

Dimenhydrinate has been used for the treatment of hyperemesis gravidarum

(14). In 64 women presenting with the condition prior to 13 weeks' gestation, all were treated with dimenhydrinate followed by various other antiemetics. Three of the newborns had integumentary abnormalities consisting of one case of webbed toes with an extra finger, and two cases of skin tags (one preauricular and one sacral). The defects were not thought to be related to the drug therapy (14).

An association between exposure during the last 2 weeks of pregnancy to antihistamines in general and retrolental fibroplasia in premature infants has been reported. See Brompheniramine for details.

BREASTFEEDING SUMMARY

No reports describing the use of dimenhydrinate during lactation have been located. The molecular weight (about 470) is low enough that excretion into milk should be expected. For a closely related product, see Diphenhydramine.

DIMERCAPROL

Antidote

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Although the limited animal data suggest low embryo–fetal risk, there are no reports of dimercaprol use during organogenesis in humans. This absence of data prevents an assessment of the human embryo risk. However, the maternal benefit, and indirect embryo–fetal benefit, appears to far outweigh the unknown embryo–fetal risk. Therefore, if indicated, dimercaprol should not be withheld because of pregnancy (1).

FETAL RISK SUMMARY

Dimercaprol is a chelating agent indicated in the treatment of arsenic, gold, and acute mercury poisoning, and for lead poisoning when used concomitantly with edetate calcium disodium. It is not very effective for chronic mercury poisoning. Dimercaprol is administered by IM injection. The mechanism of action involves dimercaprol sulfhydryl groups forming complexes with certain heavy metals, thereby preventing or reversing the metal from binding sulfhydryl-containing enzymes (2).

A 1998 review cited five studies that evaluated the reproductive toxicity of dimercaprol in animals (3). The antidote was given to pregnant mice in doses of 15–60 mg/kg/day for 4 days to protect against methylmercury-induced developmental toxicity. Similar single or multiple doses given to mice daily did not alleviate arsenate-induced fetal toxicity, but no dimercaprol-induced developmental toxicity was noted. In another study, SC dimercaprol (125 mg/kg/day) in mice on gestational days 9–12 resulted in embryotoxicity (growth restriction, increased mortality) and teratogenicity (digits with abnormal direction and situation, cleft palate, and cerebral hernia) (3). (Note: the human IM dose, depending on the type of poisoning, varies from 2.5 mg/kg/day to 18 mg/kg/day with up to 13-day courses.)

It is not known if dimercaprol can cross the human placenta. The low molecular weight (about 124) suggests that the drug does cross to the embryo–fetal compartment.

The first reported case of dimercaprol in a human pregnancy appeared in 1948 (4). An 18-year-old woman at about 26 weeks' gestation was given dimercaprol for arsenical encephalopathy. The woman had received several arsenic-containing injections for vaginal and perineal warts 10 days earlier. She was given a total dose of 5440 mg over 13 days. Labor was induced at about 36 weeks' gestation because of eclampsia, and she delivered a 5.5-lb male infant who required resuscitation but was otherwise healthy. Long-term follow-up of the infant was not reported (4).

A 1969 case report detailed the pregnancy outcome of a 17-year-old patient at 30 weeks' gestation who had ingested approximately 30 mL of arsenic trioxide containing 1.32% of total elemental arsenic (5). About 24 hours after ingestion, she was treated with 150 mg of IM dimercaprol but developed renal failure over the next 72 hours. Spontaneous labor occurred, and she delivered a 1.1-kg female infant with an Apgar score of 4 at 1 minute. A qualitative test for arsenic on the baby's plasma was negative. The infant died 11 hours later of respiratory distress syndrome. At autopsy, toxicologic analysis for arsenic (reported as arsenic trioxide per 100 g of wet tissue) revealed that the metal had crossed the placenta to the fetus with the following concentrations: 0.740 mg (liver), 0.150 mg (kidneys), and 0.0218 mg (brain). The arsenic levels in the infant were all significantly higher than those measured in adult autopsy material. The authors could locate only one other similar case of inorganic arsenic poisoning in pregnancy. In that case, published in 1928 in a French journal, both the mother and infant died. Arsenic levels for the infant were not reported, but the level in the maternal liver was 0.56 g/100 g, less than the level found in the current infant (5).

A 2002 report described the use of IV edetate and IM dimercaprol (dose not specified) in a woman at 30 weeks' gestation with a high blood lead concentration (5.2 $\mu\text{mol/L}$; goal $\leq 0.48 \mu\text{mol/L}$) (6). Twenty-four hours after initiation of chelation therapy, her lead level was 2.3 $\mu\text{mol/L}$. Twelve hours later, labor was induced because of uterine hemorrhage and she gave birth to a 1.6-kg (75th percentile) female infant. Lead concentration in the cord blood was 7.6 $\mu\text{mol/L}$. The Apgar scores were 4 and 6 (presumably at 1 and 5 minutes, respectively). The newborn was flaccid with absent reflexes, no movement to noxious stimuli, and no gag reflex, but she did have spontaneous eye movement. Bilateral diaphragmatic palsy was confirmed by fluoroscopy. During

her 7 months of hospitalization, the infant received multiple courses of chelation to treat the intrauterine lead intoxication. In spite of this therapy, she had right sensorineural deafness and neurodevelopment delay at discharge. Oral succimer was continued at home because the blood lead level was still elevated (0.95 $\mu\text{mol/L}$). The mother's lead source was identified as herbal tablets that had been prescribed for a gastrointestinal complaint. She had taken the tablets periodically over the past 9 years and throughout her pregnancy. Mercury also was present in some of the tablets. The lead intake during pregnancy was estimated to be 50 times the average weekly intake of Western populations (6). In a 2003 case report and review of severe lead poisoning in pregnancy, seven new cases and eight from the literature were identified (7). Ten of the women admitted to intentional ingestion of pica. Among the 15 cases, five underwent chelation while they were pregnant, four with edetate calcium disodium, including one who also received IM dimercaprol, and one who received succimer. No lead-induced congenital defects were noted in the infants, but all received chelation therapy in the neonatal period (7).

BREASTFEEDING SUMMARY

No reports describing the use of dimercaprol during human lactation have been located. The molecular weight (about 124) and the typical prolonged therapy (13 days) suggest that the antidote will be excreted into breast milk. The effect, if any, of this exposure on a nursing infant is unknown. Because the use of dimercaprol implies poisoning with arsenic, gold, mercury, or lead, these metals also will be excreted into milk and are toxic to a nursing infant. Therefore, breastfeeding is contraindicated in women receiving dimercaprol.

DIMETHINDENE

[Withdrawn from the market. See 9th edition.]

DIMETHOTHIAZINE

[Withdrawn from the market. See 9th edition.]

DINOPROSTONE

Endocrine/Metabolic Agent (Prostaglandin)

PREGNANCY RECOMMENDATION: First 28 Weeks of Pregnancy—Contraindicated Unless for Termination/Evacuation of Pregnancy Near or At Term—Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing human pregnancy outcomes following use of dinoprostone in failed medical abortions have been located. In animals, prostaglandin E₂ exposure has resulted in embryotoxicity and an increase in skeletal anomalies. Another prostaglandin analog, misoprostol, when used unsuccessfully in the 1st trimester as an abortifacient, has been associated with cranial nerve defects in the fetus. Use of dinoprostone for cervical ripening near term has not been associated with an excess of adverse outcomes for the infant.

FETAL RISK SUMMARY

Dinoprostone is a naturally occurring prostaglandin E₂ that is available in vaginal suppository form and is used for induced abortion between 12 and 20 weeks' gestation, for evacuation of uterine contents in the case of missed abortion or intrauterine death up to 28 weeks' gestation, and in the management of benign hydatidiform mole. Dinoprostone is also available as a controlled-release vaginal insert and in gel form, and is used for cervical ripening in term or near-term pregnancies. Dinoprostone, when given as a vaginal suppository, functions to stimulate the myometrium of the uterus to contract. Dinoprostone has a short half-life of 2.5–5 minutes (1,2).

Reproductive studies have been conducted with prostaglandin E₂ in rats and rabbits. In both species given the agent during organogenesis, embryotoxicity and fetal skeletal variations were observed (1,2).

No carcinogenicity or fertility studies have been conducted for dinoprostone. No evidence of mutagenicity was observed in the various assays (1,2).

It is not known if prostaglandin E2 crosses the placenta. The molecular weight (about 352) suggests that exogenous prostaglandin E2 will cross the placenta. However, the indicated uses for the drug and the very short elimination half-life (2.5–5 minutes) suggest that little drug may actually cross to the embryo–fetus (1,2).

No reports describing the outcomes of human pregnancies following the use of dinoprostone in failed medical abortions have been located. Although a failed attempted abortion would typically be followed by completion of the procedure by some other means, in rare cases a woman may wish to maintain the pregnancy. Isolated case reports suggest that the failed procedure(s) themselves may result in damage to the placenta and therefore damage to the fetus (3). First trimester exposure to another prostaglandin, misoprostol, in failed induced abortion, has been associated with an increased risk for 6th and 7th cranial nerve damage leading to Möbius' syndrome (see Misoprostol). However, in the case of dinoprostone, the most common use of the product would be after the first trimester.

BREASTFEEDING SUMMARY

No reports describing the use of dinoprostone during human lactation have been located. The molecular weight of dinoprostone (about 352) suggests that it will be excreted in breast milk. However, the local use of the product and the very short elimination half-life (2.5–5 minutes) suggest that clinically significant amounts will not be present in milk (1,2).

DIPHENHYDRAMINE

Antihistamine

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Both the animal data and the published human experience suggest that diphenhydramine is safe for use in human pregnancy. The exception is the case-control study discussed below that showed an association with cleft palate. In addition, premature infants exposed within 2 weeks of birth may be at risk for toxicity. At least one review has concluded that diphenhydramine is the drug of choice if parenteral antihistamines are indicated in pregnancy (1).

FETAL RISK SUMMARY

Diphenhydramine is a first-generation antihistamine agent. Reproductive studies with diphenhydramine in rats and rabbits at doses up to 5 times the human dose revealed no evidence of impaired fertility or fetal harm (2). Rapid placental transfer of diphenhydramine has been demonstrated in pregnant sheep with a fetal:maternal ratio of 0.85 (3). Peak fetal concentrations occurred within 5 minutes of a 100-mg IV dose.

The Collaborative Perinatal Project monitored 50,282 mother-child pairs, 595 of whom had 1st trimester exposure to diphenhydramine (4, pp. 323-337). For use anytime during pregnancy, 2948 exposures were recorded (4, p. 437). In neither case was evidence found to suggest a relationship to large categories of major or minor malformations. Several possible associations with individual malformations were found, but independent confirmation is required to determine the actual risk: genitourinary (other than hypospadias) (5 cases); hypospadias (3 cases); eye and ear defects (3 cases); syndromes (other than Down's syndrome) (3 cases); inguinal hernia (13 cases); clubfoot (5 cases); any ventricular septal defect (open or closing) (5 cases); and malformations of diaphragm (3 cases) (4, pp. 323-337, 437, 475).

Cleft palate and diphenhydramine usage in the 1st trimester were statistically associated in a 1974 case–control study (5). A group of 599 children with oral clefts was compared with 590 controls without clefts. In utero exposures to diphenhydramine in the groups were 20 and 6, respectively, a significant difference. However, in a 1971 report significantly fewer infants with malformations were exposed to antihistamines in the 1st trimester as compared with controls (6). Diphenhydramine was the second most commonly used antihistamine. In addition, a 1985 study reported 1st trimester use of diphenhydramine in 270 women from a total group of 6509 (7). No association between the use of the drug and congenital abnormalities was found.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 1461 newborns had been exposed to diphenhydramine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 80 (5.5%) major birth defects were observed (62 expected). Specific data were available for six defect categories, including (observed/expected) 14/14 cardiovascular defects, 3/2 oral clefts, 0/1 spina bifida, 9/4 polydactyly, 1/2 limb reduction defects, and 3/4 hypospadias. Possible associations with congenital defects are suggested for the total number of anomalies and for polydactyly, but other factors, including the mother's disease, concurrent drug use, and chance may be involved.

Diphenhydramine withdrawal was reported in a newborn infant whose mother had taken 150 mg/day during pregnancy (8). Generalized tremulousness and diarrhea began on the 5th day of life. Treatment with phenobarbital resulted in the gradual disappearance of the symptoms.

A stillborn, full-term, 1000-g female infant was exposed during gestation to high doses of diphenhydramine, theophylline, ephedrine, and phenobarbital, all used for maternal asthma (9). Except for a ventricular septal defect, no other macroscopic internal or external anomalies were observed. However, complete triploidy was found in lymphocyte cultures, which is unusual because very few such infants survive until term (9). No relationship between the chromosome abnormality or the congenital defect and the drug therapy can be inferred from this case.

A 1996 report described the use of diphenhydramine, droperidol, metoclopramide, and hydroxyzine in 80 women with hyperemesis gravidarum (10). The mean gestational age at the start of treatment was 10.9 weeks. The patients received 200 mg/day IV of diphenhydramine for 2–3 days and 12 (15%) required a second course of therapy when their symptoms recurred. Three of the mothers (all treated in the 2nd trimester) delivered offspring with

congenital defects: Poland's syndrome, fetal alcohol syndrome, and hydrocephalus and hypoplasia of the right cerebral hemisphere. Only the latter anomaly is a potential drug effect, but the most likely cause was thought to be the result of an in utero fetal vascular accident or infection (10).

A 2001 study, using a treatment method similar to the above study, described the use of droperidol and diphenhydramine in 28 women hospitalized for hyperemesis gravidarum (11). Pregnancy outcomes in the study group were compared with a historical control of 54 women who had received conventional antiemetic therapy. Oral metoclopramide and hydroxyzine were used after discharge from the hospital. Therapy was started in the study and control groups at mean gestational ages of 9.9 and 11.1 weeks', respectively. The study group appeared to have more severe disease than controls as suggested by a greater mean loss from the prepregnancy weight, 2.07 vs. 0.81 kg (ns.), and a slightly lower serum potassium level, 3.4 vs. 3.5 mmol/L (ns.). Compared with controls, the droperidol group had a shorter duration of hospitalization (3.53 vs. 2.82 days, $p = 0.023$), fewer readmissions (38.9% vs. 14.3%, $p = 0.025$), and lower average daily nausea and vomiting scores (both $p < 0.001$). There were no statistical differences ($p > 0.05$) in outcomes (study vs. controls) in terms of spontaneous abortions (N = 0 vs. N = 2 [4.3%]), elective abortions (N = 3 [12.0%] vs. N = 3 [6.5%]), Apgar scores at 1, 5, and 10 minutes, age at birth (37.3 vs. 37.9 weeks'), and birth weight (3114 vs. 3347 g). In controls, there was one (2.4%) major malformation of unknown cause, an acardiac fetus in a set of triplets, and one newborn with a genetic defect (Turner's syndrome). There was also one unexplained major birth defect (4.4%) in the droperidol group (bilateral hydronephrosis), and two genetic defects (translocation of chromosomes 3 and 7; tyrosinemia) (11).

A potential drug interaction between diphenhydramine and temazepam resulting in the stillbirth of a term female infant has been reported (12). The mother had taken diphenhydramine 50 mg for mild itching of the skin and approximately 1.5 hours later, had taken 30 mg of temazepam for sleep. Three hours later she awoke with violent intrauterine fetal movements, which lasted several minutes and then abruptly stopped. The stillborn infant was delivered approximately 4 hours later. Autopsy revealed no gross or microscopic anomalies. In an experiment with pregnant rabbits, neither of the drugs alone caused fetal mortality, but when combined, 51 (81%) of 63 fetuses were stillborn or died shortly after birth (12). No definite mechanism could be established for the suggested interaction.

A 1980 report described the oxytocic properties of diphenhydramine when

used in labor (13). Fifty women were given 50 mg IV over 3.5 minutes in a study designed to compare its effect with dimenhydrinate (see also Dimenhydrinate). The effects on the uterus were similar to those of dimenhydrinate but not as pronounced. Although no uterine hyperstimulation or fetal distress was observed, the drug should not be used for this purpose due to these potential complications (13).

Regular (every 1–2 minutes with intervening uterine relaxation), painful uterine contractions were observed in a 19-year-old woman at 26 week's gestation, following ingestion of about 35 capsules of diphenhydramine and an unknown amount of acetaminophen in a suicide attempt (14). The uterine contractions responded promptly to IV magnesium sulfate tocolysis and 5 hours later, after treatment with oral activated charcoal for the overdose, no further contractions were observed. The eventual outcome of the pregnancy was not mentioned.

An association between exposure during the last 2 weeks of pregnancy to antihistamines in general and retrolental fibroplasia in premature infants has been reported. See Brompheniramine for details.

BREASTFEEDING SUMMARY

Diphenhydramine is excreted into human breast milk, but levels have not been reported (15). Although the levels are not thought to be sufficiently high to affect the infant after therapeutic doses, the manufacturer considers the drug contraindicated in nursing mothers (2). The reason given for this is the increased sensitivity of newborn or premature infants to antihistamines.

DIPHENOXYLATE

Antidiarrheal

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Neither the animal data, although based on body weight, nor the limited human pregnancy data suggest that the combination of diphenoxylate and atropine causes developmental toxicity.

FETAL RISK SUMMARY

Diphenoxylate is a narcotic related to meperidine. It is available only in combination with atropine (to discourage overdose) for the treatment of diarrhea. Diphenoxylate is rapidly metabolized to diphenoxylate acid (difenoxin), a biologically active metabolite (1).

Reproduction studies have been conducted in mice, rats, and rabbits with oral doses of 0.4–20 mg/kg/day (1). Because of the experimental design and small numbers of litters, embryotoxic, fetotoxic, and teratogenic effects could not be adequately assessed, but examination of the available fetuses did not reveal any evidence of teratogenicity (1).

No reports describing the placental transfer of diphenoxylate to the fetus have been located. The molecular weight of the active, major metabolite difenoxin (425 for the free base) is low enough that the presence of this agent in the fetus should be expected.

In one study, no malformed infants were observed after 1st trimester exposure in seven patients (2). A single case of a female infant born at 36 weeks' gestation with multiple defects, including Ebstein's anomaly, was described in a 1989 report (3). In addition to the cardiac defect, other abnormalities noted were hypertelorism, epicanthal folds, low-set posteriorly rotated ears, a cleft uvula, medially rotated hands, deafness, and blindness. The mother had taken Lomotil (diphenoxylate and atropine) for diarrhea during

the 10th week of gestation. Since exposure was beyond the susceptible stages of development for these defects, the drug combination was not considered causative. A possible viremia in the mother as a cause of the diarrhea and the defects could not be excluded.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 179 newborns had been exposed to diphenoxylate (presumably combined with atropine) during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Nine (5.0%) major birth defects were observed (seven expected). Specific data were available for six defect categories, including (observed/expected) 3/2 cardiovascular defects, 0/0.3 oral clefts, 1/0 spina bifida, 1/0.5 polydactyly, 1/0.3 limb reduction defects, and 1/0.4 hypospadias. These data do not support an association between the drug and congenital defects.

BREASTFEEDING SUMMARY

The manufacturer reports that the active metabolite, diphenoxylate (difenoxin), is probably excreted into breast milk, and the effects of that drug and atropine may be evident in the nursing infant (1). One source recommends that the drug should not be used in lactating mothers (4). However, the American Academy of Pediatrics classifies atropine (diphenoxylate was not listed) as compatible with breastfeeding (5).

DIPHTHERIA/TETANUS TOXOIDS (ADULT)

Toxoid

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably
Compatible

PREGNANCY SUMMARY

Diphtheria and tetanus produce severe morbidity in the mother with mortality rates of 10% and 30%, respectively (1). In neonates, the tetanus mortality rate is 60%. The risk to the fetus from diphtheria/tetanus toxoids (Td) is unknown, but there is no evidence of teratogenicity (1,2). The CDC and the American College of Obstetricians and Gynecologists (ACOG) recommend Td booster vaccination in pregnancy if ≥ 10 years have elapsed since a previous Td booster or if booster protection against diphtheria is needed (3,4). If tetanus or diphtheria protection is needed during pregnancy, the diphtheria and reduced tetanus toxoids/acellular pertussis vaccine (Tdap; see Vaccine, Pertussis [Acellular]), instead of Td, may be considered in the 2nd or 3rd trimesters, or earlier if protection is needed urgently. Tdap should only be given once during a lifetime.

FETAL RISK SUMMARY

Diphtheria/tetanus toxoids (Td) for adult use are the specific toxoids of *Corynebacterium diphtheriae* and *Clostridium tetani* adsorbed onto aluminum compounds. Reproduction studies in animals have not been conducted with this product (2).

In a 1999 study using the Hungarian Case-Control Surveillance of Congenital Abnormalities, 1980–1994, database, exposure to tetanus toxoid during pregnancy was examined in 21,563 women who had offspring with congenital defects (5). The control group consisted of 35,727 women who had infants without defects. Exposure to tetanus toxoid occurred in 25 (0.12%) case women (13 in the 1st trimester) compared with 33 (0.09%) control women (17 in the 1st trimester). The difference was not significant (5).

BREASTFEEDING SUMMARY

No reports describing the use of Td during human lactation have been located. The CDC and ACOG recommend Tdap in breastfeeding women who have not received the vaccine previously or 2 years or more have elapsed since the most recent Td administration (3,4).

DIPHThERIA/TETANUS TOXOIDS/ACELLULAR PERTUSSIS VACCINE ADSORBED

Vaccine/Toxoid

See Vaccine, Pertussis (Acellular)

DIPYRIDAMOLE

Hematological Agent (Antiplatelet)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Neither the animal nor the limited human pregnancy data suggest that dipyridamole causes developmental toxicity.

FETAL RISK SUMMARY

Dipyridamole is a platelet inhibitor that is indicated as an adjunct to coumarin anticoagulants in the prevention of postoperative thromboembolic complications of cardiac valve replacement. The drug has a terminal elimination half-life of about 10 hours and is highly bound to plasma proteins (1).

Reproduction studies have been conducted in mice, rats, and rabbits at doses up to 1.3, 20, and 1.6 times the maximum recommended daily human dose based on BSA, respectively. No evidence of fetal harm was found in these studies (1).

No reports linking the use of dipyridamole with congenital defects have been located. The drug has been used in pregnancy (2–9). A single IV 30-mg dose of dipyridamole was shown to increase uterine perfusion in the 3rd trimester in 10 patients (10). In one pregnancy, a malformed infant was delivered, but the mother was also taking warfarin (2). The multiple defects in the infant were consistent with the fetal warfarin syndrome (see Coumarin Derivatives).

In a randomized, nonblinded study to prevent preeclampsia, 52 high-risk patients treated from the 13th week of gestation through delivery with daily doses of 300 mg of dipyridamole plus 150 mg of aspirin were compared with 50 high-risk controls (11). Four treated patients were excluded from analysis (spontaneous abortions before 16 weeks) vs. five controls (two lost to follow-up plus three spontaneous abortions). Hypertension occurred in 41 patients—19 treated and 22 controls. The outcome of pregnancy was significantly better

in treated patients in three areas: preeclampsia (0 vs. 6), fetal and neonatal loss (0 vs. 5), and severe intrauterine growth restriction (0 vs. 4). No fetal malformations were observed in either group. Other reports and reviews have documented the benefits of this therapy, namely a reduction in the incidence of stillbirth, placental infarction, and intrauterine growth restriction (12–18).

BREASTFEEDING SUMMARY

Dipyridamole is excreted into breast milk (1). The effect of this exposure on a nursing infant is unknown.

DIRITHROMYCIN

[Withdrawn from the market. See 9th edition.]

DISOPYRAMIDE

Antiarrhythmic

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 3rd Trimester

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports linking the use of disopyramide with congenital defects in humans or animals have been located. The drug is indicated for the treatment of cardiac arrhythmias. There is evidence that disopyramide has oxytocic effects.

FETAL RISK SUMMARY

Reproduction studies of disopyramide have been conducted in rats and rabbits. Maternal toxicity (decreased food consumption and weight gain), embryotoxicity (decreased number of implantation sites), and fetotoxicity (decreased growth and pup survival) were observed in pregnant rats dosed at ≥ 20 times the recommended human dose of 12 mg/kg/day, assuming a patient weighing at least 50 kg (RHD) (1). Increased resorption rates occurred in rabbits dosed at doses ≥ 5 times the RHD, but implantation rates, fetal growth, and offspring survival were not evaluated.

At term, a cord blood level of 0.9 mcg/mL (39% of maternal serum) was measured 6 hours after a maternal 200-mg dose (2). A 27-year-old woman took disopyramide throughout a full-term gestation, 1350 mg/day for the last 16 days, and delivered a healthy, 2920-g female infant (2). Concentrations of disopyramide and the metabolite N-monodesalkyl disopyramide in the cord and maternal serum were 0.7 and 0.9 mcg/mL, and 2.7 and 2.1 mcg/mL, respectively. The cord:maternal ratios for the parent drug and metabolite were 0.26 and 0.43, respectively (3). In a separate study, the mean fetal:maternal total plasma ratio was 0.78 when the mother's plasma concentration was within the therapeutic range of 2.0–5.0 mcg/mL (4).

Disopyramide has been used throughout other pregnancies without evidence

of congenital abnormalities or growth restriction (2,5,6) (M.S. Anderson, personal communication, G.D. Searle and Company, 1981). Early onset of labor has been reported in one patient (7). The mother, in her 32nd week of gestation, was given 300 mg orally, followed by 100 or 150 mg every 6 hours for posterior mitral leaflet prolapse. Uterine contractions, without vaginal bleeding or cervical changes, and abdominal pain occurred 1–2 hours after each dose. When disopyramide was stopped, symptoms subsided over the next 4 hours. Oxytocin induction 1 week later resulted in the delivery of a healthy infant.

The oxytocic effect of disopyramide was studied in 10 women at term (8). Eight of the 10 women, treated with 150 mg every 6 hours for 48 hours, delivered within 48 hours, compared with none in a placebo group. In one patient, use of 200 mg twice daily during the 18th and 19th weeks of pregnancy was not associated with uterine contractions or other observable adverse effects in the mother or fetus (9). Most reviews of antiarrhythmic drug therapy consider the drug probably safe during pregnancy (5,10), but one does not recommend it for routine therapy (11), and one warns of its oxytocic effects (12).

BREASTFEEDING SUMMARY

Disopyramide is excreted into breast milk (3,6,13,14). In a woman taking 200 mg 3 times daily, samples obtained on the 5th–8th days of treatment revealed a mean milk:plasma ratio of 0.9 for disopyramide and 5.6 for the active metabolite (13). Neither drug was detected in the infant's plasma. In a second case, a mother was taking 450 mg of disopyramide every 8 hours 2 weeks postpartum (3). Milk and serum samples were obtained at 0, 2, 4, and 8 hours after the dose following an overnight fast. Milk concentrations of disopyramide and its metabolite, N-monodesalkyl disopyramide, ranged from 2.6 to 4.4 mcg/mL and from 9.6 to 12.3 mcg/mL, respectively. In both cases, the lowest levels occurred at the 8-hour sampling time. The mean milk:plasma ratios for the two were 1.06 and 6.24, respectively. Disopyramide was not detected in the infant's serum (test sensitivity 0.45 mcg/mL), but both disopyramide and the metabolite were found in the infant's urine, 3.3 and 3.7 mcg/mL, respectively. A brief 1985 report described a woman taking 100 mg five times a day throughout pregnancy who delivered a normal female infant (6). On the 2nd postpartum day and 2 hours after a dose, paired milk and serum sample were obtained. The concentrations of disopyramide in the aqueous phase of the milk and the serum were 4.0 and 10.3 $\mu\text{mol/L}$, respectively, a milk:serum ratio of

0.4. The same ratio was obtained 2 weeks later with samples drawn 3 hours after a dose and levels of 5.0 and 11.5 $\mu\text{mol/L}$, respectively. No disopyramide was found in the infant's serum (limit of test accuracy 1.5 $\mu\text{mol/L}$) during the second sampling. A woman taking 200 mg twice daily had milk and serum samples drawn before and 3.5 hours after a dose (14). The concentrations in the serum were 3.7 and 5.5 $\mu\text{mol/L}$, and those in the milk were 1.7 and 2.9 $\mu\text{mol/L}$, respectively. The milk:serum ratios were 0.46 before and 0.53 after the dose. No adverse effects were noted in the nursing infants in any of the above cases. The American Academy of Pediatrics classifies disopyramide as compatible with breastfeeding (15).

DISULFIRAM

Antialcoholic Agent

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

The lack of teratogenicity in animals and the absence of a clustering of similar birth defects in human pregnancies exposed to disulfiram suggest that this drug is not a major human teratogen. Obviously, women taking disulfiram should not drink alcohol, but this is occasionally the case because of the findings of fetal alcohol syndrome and defects that are suggestive of fetal alcohol exposure.

FETAL RISK SUMMARY

Disulfiram is used to prevent alcohol consumption in patients with a history of alcohol abuse. In animals, disulfiram is embryotoxic, possibly due to copper chelation, but it is not teratogenic (1).

No reports describing the placental transfer of disulfiram have been located. The molecular weight (about 297) is low enough that transfer to the fetus probably occurs.

Published reports describing the use of disulfiram in gestation involve 36 pregnancies (2–9). Eleven of the 38 exposed fetuses (two sets of twins) had congenital defects, 6 pregnancies were terminated electively, a spontaneous abortion occurred in 1 case, 1 was stillborn, 5 were lost to follow-up, and 14 newborns were normal. No congenital malformations were observed in autopsies conducted on three of the elective terminations (4). The malformations observed, some of which were or may have been related to alcohol exposure or other causes, were as follows:

Clubfoot (two cases) (2)

Multiple anomalies with VACTERL syndrome (radial aplasia, vertebral fusion, tracheoesophageal fistula) (twin) (3)

- Phocomelia of lower extremities (one case) (3)
- Microcephaly, mental retardation (possible fetal alcohol syndrome) (one case) (5)
- Pierre–Robin sequence, pulmonary atresia (one case) (6)
- Cleft soft palate, short palpebral fissure (twin) (8)
- Limb reduction right forearm (radius and ulna), 2 rudimentary fingers without nails, short palpebral fissure (twin) (8)
- Fetal alcohol syndrome (two cases; both mothers continued to drink) (9)
- Fetal hydantoin syndrome (mother also took phenytoin) (one case) (9)

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 25 newborns had been exposed to disulfiram during the 1st trimester (F. Rosa, personal communication, FDA, 1993). One (4.0%) major birth defect was observed (one expected), a cardiovascular defect.

BREASTFEEDING SUMMARY

No reports describing the use of disulfiram during lactation have been located. Because of the relatively low molecular weight (about 297), excretion into milk should be expected. The potential effect of this exposure on a nursing infant is unknown.

DOBUTAMINE

Sympathomimetic (Adrenergic)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Although the animal data suggest low risk, the limited human pregnancy experience prevents an assessment of the embryo–fetal risk.

FETAL RISK SUMMARY

Dobutamine, an inotropic agent, is structurally related to dopamine. Reproduction studies in rats (at doses up to the normal human dose of 10 mcg/kg/min for 24 hours for a total daily dose of 14.4 mg/kg [NHD]) and rabbits (at doses up to 2 times the NHD) did not reveal any evidence of fetal harm (1).

No reports describing the placental transfer of dobutamine or studying its effects during human pregnancy have been located (see also Dopamine). The relatively low molecular weight (about 301) suggests that exposure of the embryo and fetus probably occurs. Short-term use in one patient with a myocardial infarction at 18 weeks' gestation was not associated with any known fetal adverse effects (2).

In a 1996 abstract, eight women with severe preeclampsia who required pulmonary artery catheter monitoring were given an IV infusion of dobutamine (3). The drug was effective in improving oxygen delivery in patients with depressed left ventricular function. No mention was made of fetal effects.

A 2009 report described a pregnant woman with dilated cardiomyopathy who was treated with dobutamine starting at 22 weeks' (4). She underwent a cesarean section at 28 weeks' and the 830-g infant was in stable condition.

BREASTFEEDING SUMMARY

No reports describing the use of dobutamine during human lactation have been located. The relatively low molecular weight (about 301) suggests that the drug

will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown.

DOCETAXEL

Antineoplastic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Docetaxel, always in combination with other antineoplastics, has been reported in eight pregnancies, two of which involved the 1st trimester but only one during organogenesis. Both of the 1st trimester exposures had normal infant outcomes. Mild hydrocephalus, which resolved spontaneously, was observed in one fetus exposed in the 2nd and 3rd trimesters; the cause is unknown. In another case, multiple anomalies were identified before chemotherapy was started and the infant died shortly after birth. The animal reproduction data suggest risk at doses that were a small fraction of the human dose, but maternal toxicity also was evident. Based on the very limited human pregnancy experience, docetaxel, if indicated, should not be withheld because of pregnancy, but avoiding organogenesis should be considered.

FETAL RISK SUMMARY

Docetaxel is an antineoplastic with antimetabolic activity. It is in the same antineoplastic subgroup of taxoids as cabazitaxel and paclitaxel. Docetaxel is indicated either alone or in combination with other antineoplastics for the treatment of breast cancer, non-small-cell lung cancer, prostate cancer, gastric adenocarcinoma, and head and neck cancer. Plasma protein binding of the highly lipophilic drug is about 94%, mainly to α_1 -acid glycoprotein, albumin, and lipoproteins. The terminal half-life is 11.1 hours (1).

Reproduction studies have been conducted in rats and rabbits. In these species, doses given during organogenesis, which were 1/50 and 1/300 the daily maximum recommended human dose based on BSA, were embryotoxic and fetotoxic, manifested as intrauterine death, increased resorption, reduced fetal weight, and fetal ossification delay. These doses also caused maternal

toxicity (1).

Long-term studies for carcinogenic potential have not been conducted. The drug was clastogenic in several tests but did not induce mutagenicity in assays. No impairment of fertility was noted in rats, but decreased testicular weights did occur. In a 10-cycle toxicity study (dosing once every 21 days for 6 months) in rats and dogs, testicular atrophy or degeneration was observed (1).

It is not known if docetaxel crosses the human placenta. The molecular weight (about 862), highly lipophilic nature, and the long terminal half-life suggest that the drug will cross to the embryo–fetus. However, the plasma protein binding might limit the transfer.

The first case of docetaxel use in pregnancy was reported in 2000 (2). A 34-year-old woman presented at 15 weeks' gestation with recurrent breast cancer. Approximately 1 year before presentation, she had undergone a modified radical mastectomy followed by chemotherapy for treatment of breast cancer. Chemotherapy at that time had been epirubicin, cyclophosphamide, fluorouracil, and methotrexate. At 19 weeks', vinorelbine was given, but, because of rapid disease progress, that agent was discontinued and docetaxel was given every 3 weeks for 3 cycles. A planned cesarean section was performed at 32 weeks' that delivered a normal, 1620-g female infant with Apgar scores of 8 and 9 presumably at 1 and 5 minutes, respectively. The infant did well and her psychophysical development was normal at 20 months of age.

In a 2006 report, a 35-year-old woman at 13 weeks' gestation with breast cancer was treated with four 21-day cycles of fluorouracil, doxorubicin, and cyclophosphamide (3). No response was noted and at 25 weeks' her therapy was changed to 21-day cycles of docetaxel. She gave birth at 39 weeks to a healthy, 3.09-kg, length 51-cm male infant with normal Apgar scores and blood counts (3). No other information on the infant was provided.

A second 2006 report described two cases of docetaxel exposure in pregnancy (4). In the first case, a 29-year-old woman at 12 weeks' gestation was diagnosed with breast cancer. Treatment with doxorubicin and cyclophosphamide every 2 weeks for four cycles was started at 14 weeks'. At 17 weeks', a fetal ultrasound revealed hydrocephalus (dilated lateral and third ventricle). A modified radical mastectomy and axillary node dissection was conducted at 24 weeks', followed by docetaxel every 2 weeks between 26 and 32 weeks' gestation for four cycles. At 34 weeks', she gave birth to an infant with mild hydrocephalus that regressed spontaneously over several months. The child's development at 28 months was normal (no other details of the infant

were provided). The second case involved a 38-year-old woman who was diagnosed with breast cancer at 10 weeks' gestation. At 14 weeks', docetaxel and doxorubicin every 3 weeks for six cycles was started. She developed preeclampsia and a cesarean section was conducted at 35 weeks' to deliver a healthy infant with no detectable malformations. The infant was developing normally at 9 months of age (no additional details were provided) (4).

A brief case report described a 44-year-old woman with advanced-stage breast cancer (5). She was treated with fluorouracil, epirubicin, and cyclophosphamide before undergoing a mastectomy before she became pregnant. During pregnancy, she was treated with five weekly doses of docetaxel because of symptomatic bone metastases starting at about 35 weeks' gestation. She gave birth at 40 weeks to a normal male infant who was doing well and developing normally at 15 months of age (5).

A 2007 case report described a 28-year-old woman with a history of radical mastectomy, chemotherapy, and radiotherapy 1 year before pregnancy (6). Because of metastases, she was treated with docetaxel and trastuzumab at 23 and 26 weeks' gestation, trastuzumab alone at 27 weeks', and docetaxel alone at 30 weeks'. Trastuzumab was omitted at 30 weeks' because an ultrasound revealed anhydramnios and fetal growth at the fifth percentile. The anhydramnios was thought to be due to trastuzumab. At 33 weeks', oligohydramnios was noted. An elective cesarean section was conducted at 36 weeks' to deliver a 2.23-kg male infant with Apgar scores of 7 and 9 at 1 and 5 minutes, respectively. No evidence of positional deformations or respiratory abnormalities from the prolonged low amniotic fluid was noted and the neonatal urine output was normal. The development of the infant also was normal (6).

A 35-year-old woman with metastatic non-small-cell lung cancer was treated in the 1st and 2nd trimesters with chemotherapy of an unknown pregnancy (7). After undergoing a craniotomy to remove the metastatic tumor and whole brain irradiation early in pregnancy, she was treated with docetaxel and cisplatin on days 1 and 8 every 21 days for four cycles (gestational weeks 9–18). Because of lack of response, treatment was changed to two cycles of gemcitabine and cisplatin (gestational weeks 19 and 22). About 2 months after the last dose her pregnancy was diagnosed. At 33 weeks', a cesarean section delivered a normal 1490-g female infant (normal karyotype 46,XX) with Apgar scores of 8, 9, and 10 at 1, 5, and 10 minutes, respectively, and normal blood counts. An extensive examination of the infant failed to find any abnormalities. The infant was developing normally at 10 months of age (7).

A 32-year-old woman underwent surgery at 20 weeks' gestation (from in

vitro fertilization) for a ruptured ovarian cyst (8). Ovarian cancer was diagnosed and she was given four cycles of docetaxel and cisplatin before a cesarean section at 34 weeks. The 2245-g female infant had Apgar scores of 3 and 6 at 1 and 10 minutes, respectively. The infant died at 5 days of age from multiple congenital anomalies that had been diagnosed before starting chemotherapy (8).

BREASTFEEDING SUMMARY

No reports describing the use of docetaxel during human lactation have been reported. The molecular weight (about 862), highly lipophilic nature, and the long terminal half-life (11.1 hours) suggest that the drug will be excreted into breast milk, although the plasma protein binding (about 94%) might limit the excretion. The effect of this exposure on a nursing infant is unknown, but serious toxicities (e.g., bone marrow depression, allergic reactions, nausea, vomiting, and diarrhea) have been reported in adults and are a potential complication. If a mother is receiving this drug, she should not breastfeed.

DOCUSATE CALCIUM

Laxative

See Docusate Sodium.

DOCUSATE POTASSIUM

Laxative

See Docusate Sodium.

DOCUSATE SODIUM

Laxative

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No reports linking the use of docusate sodium (DSS) with congenital defects have been located. DSS is a common ingredient in many over-the-counter laxative preparations.

FETAL RISK SUMMARY

In a large prospective study, 116 patients were exposed to this drug during pregnancy (1). No evidence for an association with malformations was found. Similarly, no evidence of fetal toxicity was noted in 35 women treated with a combination of docusate sodium and dihydroxyanthraquinone (2).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 232 newborns had been exposed to a docusate salt during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Nine (3.9%) major birth defects were observed (nine expected), including one cardiovascular defect (two expected) and one polydactyly (one expected). No anomalies were observed in four other categories of defects (oral clefts, spina bifida, limb reduction defects, and hypospadias) for which specific data were available. These data do not support an association between the drug and congenital defects.

Chronic use of 150–250 mg/day or more of docusate sodium throughout pregnancy was suspected of causing hypomagnesemia in a mother and her newborn (3). At 12 hours of age, the neonate exhibited jitteriness, which resolved spontaneously. Neonatal serum magnesium levels ranged from 0.9 to 1.1 mg/dL between 22 and 48 hours of age with a maternal level of 1.2 mg/dL on the 3rd postpartum day. All other laboratory parameters were normal.

BREASTFEEDING SUMMARY

A combination of docusate sodium and dihydroxyanthraquinone was given to 35

postpartum women in a 1973 study (2). One infant developed diarrhea, but the relationship between the symptom and the laxative is unknown.

DOFETILIDE

Antiarrhythmic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of dofetilide during human pregnancy have been located. Although the antiarrhythmic is teratogenic and toxic in animals at exposures slightly above those expected in humans, the lack of human data prevents an assessment of the potential embryo–fetal risk. However, if dofetilide therapy is required in a pregnant woman, the benefits appear to outweigh the unknown risk.

FETAL RISK SUMMARY

Dofetilide is an antiarrhythmic agent with Class III (cardiac action potential duration prolongation) properties that is indicated for the maintenance of normal sinus rhythm in patients with atrial fibrillation/flutter. Only about 20% of the drug is metabolized.

In reproduction studies in mice and rats, oral doses of dofetilide equal to or greater than 4 and 2 times, respectively, the maximum likely human exposure based on AUC (MHE), caused sternebral and vertebral anomalies in both species (1). In addition, an increased incidence of unossified calcaneum was noted in mice. In rats given doses approximately equal to the MHE, an increased incidence of unossified metacarpals and the occurrence of hydroureter and hydronephroses were observed. When the dose was doubled (twice the MHE) in rats, additional defects noted were cleft palate, adactyly, levocardia, and dilation of cerebral ventricles. The no-effect adverse-effect dose in mice was approximately equal to the MHE, whereas in rats it was about half the MHE (1).

Dofetilide had no effect on mating and fertility in rats at doses up to three times the MHE (1). It was also not mutagenic in various assays nor was it

carcinogenic in tests with mice and rats. Chronic administration of dofetilide did cause testicular atrophy, decreased testicular weight, and/or epididymal oligospermia in mice, rats, and dogs at doses greater than 3, 4, and 1.3 times, respectively, the MHE (1).

In a 1996 study, the embryo toxicity and teratogenicity of dofetilide in rats were shown to be gestational age related and resulted from dose-dependent bradycardia in in vitro (rat embryo culture) and in vivo (pregnant rat) experiments (2). In the embryo cultures, the minimum effective concentration for significant bradycardia (22 ng/mL) was about six times the human peak plasma concentration achieved after an oral dose of 12 mcg/kg (3.5 ng/mL) (2). An embryo culture dose twice the minimum effective dose caused an almost complete cessation of the heartbeat. In pregnant rats, single oral doses of various concentrations were given on different gestational days. On gestational day (GD) 10, a high incidence of resorptions occurred, but no malformations except one fetus with a short tail. Defects and/or toxicity seen on other days included GD 11 (right-sided cleft lip), GD 12 (small number of defects; 100% lethality at highest dose), and GD 13 (most sensitive day; hindlimb defects; resorptions at higher doses). The defects were preceded by hemorrhage, but the investigators could not determine if the hemorrhage caused the defect or if the hemorrhage and defect were caused by the bradycardia-induced hypoxia (2).

It is not known if dofetilide crosses the human placenta. The molecular weight (about 442) is low enough that transfer to the fetus should be expected.

BREASTFEEDING SUMMARY

No reports describing the use of dofetilide in human lactation have been located. The molecular weight (about 442) is low enough that excretion in breast milk should be expected. The effect of this exposure on a nursing infant is unknown. Until the effects on a nursing infant from exposure to the drug in milk have been clarified, women receiving this agent should probably not breastfeed.

2. Webster WS, Brown-Woodman PDC, Snow MD, Danielsson BRG. Teratogenic potential of almokalant, dofetilide, and d-sotalol: drugs with potassium channel blocking activity. *Teratology* 1996;53:168–75.

DOLASETRON

Antiemetic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Summary: No reports describing the use of dolasetron during human pregnancy have been located. Among other agents with similar mechanisms of actions and indications (see Granisetron and Ondansetron), only ondansetron has published human pregnancy experience. Based on this experience and the lack of embryo–fetal toxicity in two animal species, dolasetron appears to represent minimal, if any, risk to a human fetus.

FETAL RISK SUMMARY

Dolasetron is a specific and selective serotonin subtype 3 (5-HT₃) receptor antagonist that is used for the treatment and prevention of nausea and vomiting in the postoperative period and after chemotherapy. The drug has no effect on plasma prolactin levels (1).

Dolasetron had no effect on fertility and reproductive performance in female rats at doses up to 8 times the recommended human dose based on BSA (RHD) or in male rats at doses up to 32 times the RHD. No evidence of impaired fertility or fetal harm was observed in pregnant rats and rabbits at oral doses up to 8 and 16 times, respectively, the RHD (1). In 24-month carcinogenicity studies, there was a dose-related significant increase in combined hepatocellular adenomas and carcinomas in male mice, but not in female mice or in male and female rats. No mutagenicity was observed in various tests (1).

It is not known if dolasetron crosses the human placenta. The molecular weight of the free base (about 325 for the free base) is low enough that transfer to the fetus should be expected.

BREASTFEEDING SUMMARY

No reports describing the use of dolasetron in human lactation have been located. The molecular weight (about 325 for the free base) is low enough that excretion into breast milk should be expected. The effect of this exposure on a nursing infant is unknown.

DONEPEZIL

Cholinesterase Inhibitor (CNS Agent)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of donepezil in human pregnancy have been located. Because of its indication, such reports should be rare. Moreover, the animal data suggest that the risk to the embryo and/or fetus is low. Therefore, inadvertent exposure to donepezil during pregnancy should not be a reason for pregnancy termination.

FETAL RISK SUMMARY

Donepezil (known previously as E2020) is a reversible cholinesterase inhibitor that is indicated for the treatment of mild-to-moderate dementia of the Alzheimer's type. Two metabolites of donepezil are known to be active. The drug is extensively protein bound (about 96%) in the plasma, primarily to albumin (about 75%) and α_1 -acid glycoprotein. The plasma elimination half-life is about 70 hours (1,2).

Reproduction studies have been conducted in rats and rabbits. In rats, doses up to about 13 times the maximum recommended human dose based on BSA (MRHD) were not teratogenic. At 8 times the MRHD given from gestational day 17 through postpartum day 20, there was a slight increase in stillbirths and a slight decrease in pup survival through postpartum day 4. Donepezil had no effect on rat fertility at doses up to about 8 times the MRHD. In rabbits, no teratogenic effects were observed at a dose 16 times the MRHD (1,2).

It is not known if donepezil or its active metabolites cross the human placenta. The molecular weight of the parent compound (about 416) and its long plasma elimination half-life suggest that the drug will cross to the embryo–fetus, but the extensive protein binding will limit this transfer.

BREASTFEEDING SUMMARY

No reports describing the use of donepezil during human lactation have been located. Because of its indication, such reports should be rare. Donepezil has two active metabolites. The molecular weight of the parent compound (about 416) and its long plasma elimination half-life (about 70 hours) suggest that donepezil, and possibly the active metabolites, will be excreted into breast milk. The extensive protein binding (about 96%), however, should limit this excretion. The effects of this exposure on a nursing infant are unknown.

DOPAMINE

Sympathomimetic (Adrenergic)

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo-Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably
Compatible

PREGNANCY SUMMARY

Experience with dopamine in human pregnancy is limited. No reports of embryo–fetal harm have been located. Since dopamine is indicated only for life-threatening situations, chronic use would not be expected.

FETAL RISK SUMMARY

Animal studies have shown both increases and decreases in uterine blood flow (1,2). In a study in pregnant baboons, dopamine infusion increased uterine vascular resistance and thus impaired uteroplacental perfusion (1). Because of this effect, the investigators concluded that the drug should not be used in patients with severe preeclampsia or eclampsia (1).

However, although human studies on uterine perfusion have not been conducted, the use in women with severe toxemia has not been associated with fetal harm. The drug has been used to prevent or treat renal failure in 10 oliguric or anuric eclamptic patients by reestablishing diuresis (3,4).

In another study of six women with severe preeclampsia and oliguria, low-dose dopamine infusion produced a significant rise in urine and cardiac output (5). No significant changes in blood pressure, central venous pressure, or pulmonary capillary wedge pressure occurred. In another case, low-dose dopamine was successful in treating oliguria due to severe maternal pulmonary hypertension (6).

Dopamine has been used to treat hypotension in 26 patients undergoing cesarean section (2). No adverse effects attributable to dopamine were observed in the fetuses or newborns of the mothers in these studies.

BREASTFEEDING SUMMARY

No reports describing the use of dopamine during lactation have been located. Because it is only indicated for life-threatening situations, it is doubtful if such reports will occur.

DORIPENEM

Antibiotic

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of doripenem in human pregnancy have been located. In two animal species, the low exposures were not associated with teratogenicity or other developmental toxicity. Moreover, there is no evidence that β -lactam antibiotics (e.g., penicillins and cephalosporins) cause developmental toxicity in humans at therapeutic doses. Therefore, if the maternal condition requires the use of doripenem, the antibiotic should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Doripenem, an antibiotic that is structurally related to β -lactam antibiotics, has activity against aerobic and anaerobic gram-positive and gram-negative bacteria. It is given as an IV infusion. It was approved by the FDA in 2007. Doripenem is classified as a carbapenem in the same class as ertapenem, imipenem–cilastatin, and meropenem. Both plasma protein binding (about 8.1%) and metabolism (about 18%) are low. The mean terminal plasma elimination half-life is about 1 hour (1).

Reproduction studies have been conducted in rats and rabbits. In these species, IV doses producing exposures that were at least 2.4 and 0.8 times, respectively, the human exposure based on AUC from a 500-mg dose every 8 hours (HE) were not teratogenic and did not produce effects on ossification, developmental delays, or fetal weight (1).

It is not known if doripenem crosses the human placenta. The molecular weight (about 421), low metabolism, and minimal plasma protein binding suggest that exposure of the embryo–fetus probably occurs, but the short elimination half-life should limit the amount of exposure.

BREASTFEEDING SUMMARY

No reports describing the use of doripenem during human lactation have been located. It is not known if doripenem is excreted into breast milk. The molecular weight (about 421), low metabolism (18%), and minimal plasma protein binding (about 8.1%) suggest that it will be excreted into milk. However, the short elimination half-life (about 1 hour) should limit the amount of exposure. The effect on a nursing infant from this exposure is unknown but of doubtful clinical significance. Most antibiotics are excreted into breast milk in low concentrations, and adverse effects are rare. Potential problems for the nursing infant are modification of bowel flora, direct effects on the infant (e.g., allergic response), and interference with the interpretation of culture results if a fever workup is required.

DORNASE ALFA

Respiratory Agent (Mucolytic)

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of dornase alfa in human pregnancy have been located. The animal data suggest low risk for developmental toxicity. Moreover, inhalation of dornase alfa does not result in higher concentrations of endogenous DNase in the maternal circulation. These data suggest that the risk of using dornase alfa during pregnancy is negligible.

FETAL RISK SUMMARY

Dornase alfa is recombinant human deoxyribonuclease I (rhDNase), an enzyme that selectively cleaves DNA. Dornase alfa is produced from Chinese hamster ovary cells. It is a glycoprotein containing 260 amino acids with a molecular weight of about 37,000. The primary amino acid sequence is identical to that of the native human enzyme. Dornase alfa is administered by inhalation of an aerosol mist to improve pulmonary function in the management of cystic fibrosis patients (1).

Reproduction studies have been conducted in rats and rabbits. There was no evidence of impaired fertility, fetal harm, or effects on development with IV doses that were >600 times the systemic exposures expected with the recommended human dose (1).

It is not known if dornase alfa crosses the human placenta. Cynomolgus monkeys were given IV dornase alfa at term in a study to determine if the enzyme crosses the monkey placenta (2). Consistent with the high molecular weight, dornase alfa was not detected in either the fetus or the amniotic fluid. Native human DNase is an endogenous enzyme in the maternal circulation. In humans, inhaled dornase alfa does not produce serum levels of DNase

significantly higher than normal endogenous levels, and no accumulation has been noted after prolonged use (1). Because the monkey and human placentas are similar (both are hemomonochorial), the absence of transfer in the former suggests that the agent is not transferred to the fetal compartment in the latter.

BREASTFEEDING SUMMARY

No reports describing the use of dornase alfa during lactation have been located. Inhaled dornase alfa does not result in a significant increase in the serum concentrations of endogenous DNase. Therefore, it would not be expected in the milk (1). Because the enzyme is a natural constituent of the mother's circulation, the risk to a nursing infant from the mother's use of dornase alfa is negligible.

DOTHIEPIN

[Withdrawn from the market. See 9th edition.]

DOXAPRAM

Central Stimulant

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of doxapram in human pregnancy have been located. The animal data are limited but do not suggest a major risk for the embryo and/or fetus. Moreover, although the elimination half-life of the drug is unknown, the duration of effect is very short and the agent is extensively metabolized. Thus, the embryo and/or fetal exposure are probably limited except when continuous infusions are administered. The commercial product contains 0.9% benzyl alcohol as a preservative. Since benzyl alcohol can cross the placenta, the use of doxapram near term, especially continuous infusions, should be avoided because of the potential for toxicity in the newborn. However, if indicated, the maternal benefit from single injections of doxapram at any time in pregnancy appears to outweigh the unknown embryo–fetal risk.

FETAL RISK SUMMARY

Doxapram is a short-acting respiratory stimulant. It is administered IV to stimulate respiration in acute situations such as postanesthesia, mild-to-moderate respiratory and central nervous system depression due to drug overdose, and hypercapnia in patients with chronic obstructive pulmonary disease. The duration of effect varies from 5 to 12 minutes (1). Doxapram is extensively metabolized by the liver after IV injection (2).

Reproduction studies have been conducted in mice and rats. In rats, doses up to 1.6 times the human dose revealed no evidence of impaired fertility or fetal harm. The dose, assumed to be based on weight, was given by the IM and oral routes, but the human dose (either a single dose of 1–2 mg/kg, or an IV infusion of 1–3 mg/kg/hr) are given IV (1). In another study, no teratogenicity

was observed in rats (3). In pregnant mice, a dose of 144 mg/kg/day was given intraperitoneal during organogenesis (4). No gross defects were observed, but fetal death and growth restriction were noted. In addition, minor skeletal defects occurred in the fetuses of one pregnancy (4).

Doxapram crosses the sheep placenta and stimulates fetal breathing (5). Doxapram was infused into a maternal vein over 2–5 minutes and peak fetal plasma levels occurred between 0.08 and 0.17 hours after the start of the infusion. The increase in fetal breathing, up to about 41% during the infusion, was dose related (5).

It is not known if doxapram crosses the human placenta. The drug does cross the placenta in dogs (1) and sheep (5). The molecular weight of the free base (about 379) is low enough for transfer, but the very short duration of action suggests that limited amounts will be available at the maternal:fetal interface after single injections. However, continuous infusions of doxapram probably allows for placental passage to the embryo–fetus.

In an in vitro study, doxapram was shown to undergo substantial metabolism by the human fetal liver (6). The fetal livers were obtained from elective abortions conducted at 10–20 weeks' gestation.

BREASTFEEDING SUMMARY

No reports describing the use of doxapram during human lactation have been located. In addition, the indications for the drug suggest that such reports will be rare. However, doxapram has been given to newborns at risk for respiratory depression when narcotic analgesics or general anesthetics were used during delivery (7). No adverse effects attributable to doxapram were observed. The molecular weight of the free base (about 379) suggests that the drug will be excreted into breast milk. The maternal plasma elimination half-life is unknown, but the relatively short duration of effect combined with the extensive hepatic metabolism, probably indicates a short half-life, at least for the parent compound. Of note though, doxapram is a basic drug and accumulation in the relatively acidic breast milk by ion trapping is a potential concern, especially if continuous infusions are used. An additional concern involves benzyl alcohol, the preservative used in the commercial preparation that is known to be toxic in newborns.

DOXAZOSIN

Sympatholytic (Antiadrenergic)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

One report describing the use of doxazosin in human pregnancy has been located.

FETAL RISK SUMMARY

Doxazosin is a peripherally acting α_1 -adrenergic blocking agent used in the treatment of hypertension.

No adverse fetal effects were observed when pregnant rats and rabbits were given oral doses 4 and 10 times the human serum levels achieved with a 12 mg/day therapeutic dose (HD), respectively. However, reduced fetal survival occurred in rabbits dosed at 20 times the HD and delayed postnatal development was observed in rat pups whose mothers were given doses 8 times the HD during the perinatal and postnatal periods. Doxazosin crosses the placenta in rats (1).

It is not known if doxazosin crosses the human placenta. The molecular weight (about 548) suggests that the drug will cross to the embryo and/or fetus.

In a 2012 report, a 36-year-old pregnant woman developed pheochromocytoma at 26 weeks' (2). She was initially treated with proroxan (an alpha adrenergic blocker not available in the United States) (15 mg three times daily). Eleven days after treatment started, her condition worsened and doxazosin (dose not specified), a calcium channel blocker (name and dose not specified), and an ACE inhibitor (name and dose not specified) were added. The four-drug combination was continued until a cesarean section was performed at 30 4/7 weeks' gestation to deliver a 1.700-kg male infant. A simultaneous laparatomic right-sided adrenalectomy also was performed.

Apgar scores were 6 and 8 at 1 and 5 minutes, respectively. No further details on the premature infant were provided. The woman underwent a hysterectomy for placenta increta (2).

BREASTFEEDING SUMMARY

No reports describing the use of doxazosin during human lactation have been located.

DOXEPIN

Antidepressant

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Doxepin was not teratogenic in four animal species. One large database reported a possible association with birth defects, but no confirming reports have been located. In general, tricyclic antidepressants are not thought to cause structural anomalies.

FETAL RISK SUMMARY

Doxepin is a tricyclic antidepressant in the same class as amitriptyline, clomipramine, imipramine, and trimipramine. It was not teratogenic in rats, rabbits, monkeys, and dogs (1–3). At the highest doses used, however, an increase in neonatal death was observed in rats and rabbits (1,2). Because of the relatively low molecular weight (280 for the free base), placental transfer of the drug to the fetus should be expected.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 118 newborns had been exposed to doxepin during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 12 (10.2%) major birth defects were observed (4.5 expected), including (observed/expected) cardiovascular defects (2/1), oral clefts (2/0.2), and polydactyly (2/0.3). No anomalies were observed in three other categories of malformations (spina bifida, limb reduction defects, and hypospadias) for which specific data were available. The total number of major birth defects and the cases of polydactyly are suggestive of an association, but other factors, including concurrent drug use and chance, may be involved.

In a 1996 descriptive case series, the European Network of the Teratology Information Services (ENTIS) prospectively examined the outcomes of 689 pregnancies exposed to antidepressants (4). Multiple drug therapy occurred in

about two-thirds of the mothers. Doxepin was used in 14 pregnancies. The outcomes of these pregnancies were four elective abortions, one spontaneous abortion, one stillbirth, and eight normal newborns.

Paralytic ileus has been observed in an infant exposed to doxepin at term (5). The condition was thought to be primarily due to chlorpromazine, but the authors speculated that the anticholinergic effects of doxepin worked synergistically with the phenothiazine.

A 2002 prospective study compared two groups of mother–child pairs exposed to antidepressants throughout gestation, 46 exposed to tricyclics (2 to doxepin) and 40 exposed to fluoxetine, with 36 nonexposed, nondepressed controls (6). Offspring were studied between the ages 15 and 71 months for effects of antidepressant exposure in terms of IQ, language, behavior, and temperament. Exposure to antidepressants did not adversely affect the measured parameters, but IQ was significantly and negatively associated with the duration of depression, and language was negatively associated with the number of depression episodes after delivery (6).

BREASTFEEDING SUMMARY

Doxepin and its active metabolite, N-desmethyldoxepin, are excreted into breast milk (7–9). A 36-year-old woman was treated with doxepin, 10 mg daily, for approximately 5 weeks starting 2 weeks after the birth of her daughter (7). The dose was increased to 25 mg 3 times daily 4 days before the wholly breastfed 8-week-old infant was found pale, limp, and near respiratory arrest. Although drowsiness and shallow respirations continued on admission to the hospital, the baby made a rapid recovery and was normal in 24 hours. A peak milk concentration of doxepin, 29 ng/mL, was measured 4–5 hours after a dose, whereas two levels obtained just prior to a dose (12 hours after the last dose in each case) were 7 and 10 ng/mL, respectively. Milk concentrations of the metabolite ranged from “not detectable” (lower limit of detection 7 ng/mL) to 11 ng/mL. The averages of nine determinations for doxepin and the metabolite in the milk were 18 and 9 ng/mL, respectively. Maternal serum doxepin and N-desmethyldoxepin levels ranged from trace to 21 ng/mL (average 15 ng/mL) and 33 to 66 ng/mL (average 57 ng/mL), respectively. The milk:serum ratio for doxepin on two determinations was 0.9, whereas ratios for the metabolite were 0.12 and 0.17. Doxepin was almost undetectable (estimated to be 3 ng/mL) in the infant’s serum, but the levels of the metabolite on two occasions were 58 and 66 ng/mL, demonstrating marked accumulation in the infant’s serum. The initial infant urine sample contained 39 ng/mL of the

metabolite (7).

A 26-year-old woman, 30 days postpartum, was treated with doxepin (150 mg/day) (8). Blood samples were obtained a mean 18 hours after a dose on days 7, 14, 22, 28, 36, 43, 50, and 99 days of treatment. On the same days that blood specimens were drawn, milk samples were collected at the start of feeding (17.2 hours after the last dose) and at the end of feeding (17.7 hours after the last dose). Plasma concentrations of doxepin varied between 35 and 68 ng/mL, with a mean value of 46 ng/mL. Levels for the metabolite, N-desmethyldoxepin, ranged from 65 to 131 ng/mL, with a mean of 90 ng/mL. Mean pre- and postfeed milk:plasma ratios for doxepin were 1.08 (range 0.51–1.44) and 1.66 (range 0.79–2.39), respectively, and for the metabolite, 1.02 (range 0.54–1.45) and 1.53 (range 0.85–2.35), respectively. A plasma sample drawn from the infant on day 43 showed no detectable doxepin (sensitivity 5 ng/mL) and 15 ng/mL of the metabolite. No adverse effects of the exposure to doxepin were observed in the infant (8).

Muscle hypotonia, drowsiness, poor sucking and swallowing, and vomiting were reported in a 9-day-old breastfed, 2950-g male baby whose mother was taking doxepin 35 mg/day (9). The mother had started doxepin in the 3rd trimester and continued it postpartum. The normal, full-term, 3030-g infant had Apgar scores of 10 and 10 at 1 and 5 minutes, respectively. Breastfeeding began 8 hours after birth. Hyperbilirubinemia (indirect bilirubin 17 mg/dL) was diagnosed at age 3 days. He was discharged at age 5 days with a bilirubin of 9 mg/dL and a weight of 3100 g. At presentation 9 days after birth, jaundice was again present (indirect bilirubin 18 mg/dL) and was treated with 24 hours of phototherapy. The concentrations of doxepin and metabolite in the infant's serum at 11 days of age, 2 hours after breastfeeding, were about 10 ng/mL and <10 ng/mL, respectively. The milk:plasma ratio, 13–15 hours after the last dose, was estimated to be 1.0–1.7 (doxepin plus metabolite). The calculated infant dose, based on 150–200 mL milk/kg/day, was 10–20 mcg/kg/day, or about 2.5% of the weight-adjusted maternal dose. Breastfeeding was stopped at age 14 days because of persistent drowsiness and vomiting and, about 24 hours later, his symptoms resolved. He was asymptomatic when discharged home 2 days later (9).

Adverse effects were observed in two of the three cases cited above and were potentially lethal to one infant. Based on these reports, doxepin should be avoided during lactation. The American Academy of Pediatrics classifies doxepin as an agent whose effect on the nursing infant is unknown but may be of concern (10).

DOXORUBICIN

Antineoplastic

PREGNANCY RECOMMENDATION: Contraindicated—1st Trimester

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Doxorubicin caused structural anomalies and death in two animal species, and has been associated with similar outcomes in humans after exposure during organogenesis. Exposure during the 1st trimester should be avoided. [See Rituximab for additional data.]

FETAL RISK SUMMARY

Doxorubicin is an antineoplastic agent used for the treatment of various types of cancer. It is in the same antineoplastic subclass of anthracyclines as daunorubicin, epirubicin, idarubicin, and valrubicin. The drug is embryotoxic and teratogenic in rats and embryotoxic and abortifacient in rabbits (1).

Several reports have described the use of doxorubicin in pregnancy, including three during the 1st trimester (2–21). One of the fetuses exposed during the 1st trimester to doxorubicin, cyclophosphamide, and unshielded radiation was born with an imperforate anus and rectovaginal fistula (15). At about 3 months of age, the infant was small with a head circumference of 46 cm (<5th percentile) but was doing well after two corrective surgeries (15). A 1983 report described the use of doxorubicin and other antineoplastic agents in two pregnancies, one of which ended in fetal death 36 hours after treatment had begun (18). Other than maceration, no other fetal abnormalities were observed. The investigators could not determine the exact cause of the outcome but concluded that the chemotherapy was probably not responsible. The only other complication observed in exposed infants was transient polycythemia and hyperbilirubinemia in one subject. Infants who have been evaluated have shown normal growth and development.

A 1999 report from France described the outcomes of pregnancies in 20 women with breast cancer who were treated with antineoplastic agents (18). The first cycle of chemotherapy occurred at a mean gestational age of 26

weeks with delivery occurring at a mean 34.7 weeks. A total of 38 cycles were administered during pregnancy with a median of two cycles per woman. None of the women received radiation therapy during pregnancy. The pregnancy outcomes included two spontaneous abortions (both exposed in the 1st trimester), one intrauterine death (exposed in the 2nd trimester), and 17 live births, one of whom died at 8 days of age without apparent cause. The 16 surviving children were developing normally at a mean follow-up of 42.3 months (18). Doxorubicin (D), in combination with cyclophosphamide (C), fluorouracil (F), or vincristine (V), was administered to four of the women at a mean dose of 68.7 mg/m² (range 50–100 mg/m²). The outcomes were four surviving liveborn infants (two exposed to DCF and one each to DF and DV in the 2nd or 3rd trimesters).

Three studies have investigated the placental passage of doxorubicin (2,19,20). In one, the drug was not detected in the amniotic fluid at 20 weeks' gestation, which suggested that the drug was not transferred in measurable amounts to the fetus (2). Placental transfer was demonstrated in a 17-week-old aborted fetus, however, using high-performance liquid chromatography (HPLC) (20). High concentrations were found in fetal liver, kidney, and lung. The drug was not detected in amniotic fluid (<1.66 ng/mL), brain, intestine, or gastrocnemius muscle. A third study examined the placental passage of doxorubicin in two pregnancies, one resulting in the birth of a healthy infant at 34 weeks' gestation and one ending with a stillborn fetus at 31 weeks' gestation (19). Using HPLC, doxorubicin was demonstrated in the first case, 48 hours after a 45-mg/m² dose (total cumulative dose, 214 mg/m²), on both sides of the placenta and in the umbilical cord but not in cord blood plasma. In the stillborn, doxorubicin was not detected in any fetal tissue, 36 hours after a single dose of 45 mg/m². However, a substance was detected in all fetal tissues analyzed that the investigators concluded may have represented an unknown doxorubicin metabolite (19).

In a 2004 case report, a 17-year-old woman at 22 weeks' gestation was diagnosed with an extraskelatal Ewing's sarcoma (21). She was treated with doxorubicin 50 mg/m² by 48-hour continuous infusion and ifosfamide 2 g/m² as a single injection, both given at 25, 28, and 30 weeks'. Mild fetal growth restriction was noted from the 29th week of gestation. An elective cesarean section delivered a 1.245-kg male infant with Apgar scores of 7 and 9 at 1 and 5 minutes, respectively. Based on weight and length (38 cm), the infant was small for gestational age. The infant had no congenital anomalies and no respiratory distress syndrome, but did have mild hyperbilirubinemia. He was

growing well at 8 months of age (21).

A 2006 case report described the pregnancy outcome of a 21-year-old woman with Burkitt's lymphoma who was treated with intensive chemotherapy (22). Beginning at 26 weeks', she was treated with two cycles of chemotherapy that included ifosfamide, cyclophosphamide, vincristine, doxorubicin, cytarabine, etoposide, cytarabine, and mesna. At 32 weeks', a cesarean section delivered a 1.731-kg male infant with Apgar scores of 8 and 9 at 1 and 5 minutes, respectively. His weight, length, and head circumference were within normal limits for gestational age. No anomalies were noted but respiratory distress was evident. At 9 months of age, his weight was 6.36 kg. He had mild delayed motor skills that were thought to result from his premature birth. Otherwise he was healthy (22).

Long-term studies of growth and mental development of offspring exposed to doxorubicin and other antineoplastic agents in the 2nd trimester, the period of neuroblast multiplication, have not been conducted (23).

Doxorubicin may cause reversible testicular dysfunction (24,25). Similarly, normal pregnancies have occurred in women treated before conception with doxorubicin (26). In 436 long-term survivors treated with chemotherapy for gestational trophoblastic tumors between 1958 and 1978, 33 (8%) received doxorubicin as part of their treatment regimens (26). Of the 33 women, five (15%) had at least one live birth (data given in parentheses refer to mean/maximum doxorubicin dose in milligrams) (100/100), two (6%) had no live births (150/200), one (3%) failed to conceive (100/100), and 25 (76%) did not try to conceive (140/400). Additional details, including congenital anomalies observed, are described in the monograph for methotrexate (see Methotrexate).

The long-term effects of combination chemotherapy on menstrual and reproductive function have been described in a 1988 report (27). Only one of the 40 women treated for malignant ovarian germ cell tumors received doxorubicin. The results of this study are discussed in the monograph for cyclophosphamide (see Cyclophosphamide).

Occupational exposure of the mother to antineoplastic agents during pregnancy may present a risk to the fetus. A position statement from the National Study Commission on Cytotoxic Exposure and a research article involving some antineoplastic agents, including doxorubicin, are presented in the monograph for cyclophosphamide (see Cyclophosphamide).

BREASTFEEDING SUMMARY

Doxorubicin is excreted into human milk. A 31-year-old woman, 7 months postpartum, was given doxorubicin (70 mg/m²), infused over 15 minutes, for the treatment of ovarian cancer (28). Both doxorubicin and the metabolite, doxorubicinol, were detected in the plasma and the milk. Peak concentrations of the two substances in the plasma occurred at the first sampling time (0.5 hour) and were 805 and 82 ng/mL, respectively. In the milk, the peak concentrations occurred at 24 hours with levels of 128 and 111 ng/mL, respectively. The AUC of the parent compound and metabolite in the plasma were 8.3 and 1.7 $\mu\text{mol/L} \times \text{hours}$, respectively, while the AUC in the milk were 9.9 and 16.5 $\mu\text{mol/L} \times \text{hours}$, respectively. The highest milk:plasma ratio, 4.43, was measured at 24 hours. Although milk concentrations often exceeded those in the plasma, the total amount of active drug available in the milk was only 0.24 mcg/mL (28). If the infant consumed 150 mL/kg/day, the estimated dose would be 0.036 mg/kg/day

Although the above amounts might be considered negligible, the American Academy of Pediatrics classifies doxorubicin as a drug that may interfere with the cellular metabolism of the nursing infant (29).

DOXYCYCLINE

Antibiotic (Tetracycline)

PREGNANCY RECOMMENDATION: Contraindicated in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

See Tetracycline.

BREASTFEEDING SUMMARY

Doxycycline is excreted into breast milk. Oral doxycycline, 200 mg, followed after 24 hours by 100 mg, was given to 15 nursing mothers (1). Milk:plasma ratios determined at 3 and 24 hours after the second dose were 0.3 and 0.4, respectively. Mean milk concentrations were 0.77 and 0.38 mcg/mL.

Theoretically, dental staining and inhibition of bone growth could occur in breastfed infants whose mothers were consuming doxycycline. However, this theoretical possibility seems remote, because in infants exposed to a closely related antibiotic, tetracycline, serum levels were undetectable (less than 0.05 mcg/mL) (2).

The American Academy of Pediatrics classifies tetracycline as compatible with breastfeeding (3). Three potential problems may exist for the nursing infant even though there are no reports in this regard: modification of bowel flora, direct effects on the infant, and interference with the interpretation of culture results if a fever workup is required.

DOXYLAMINE

Antihistamine/Antiemetic

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The preponderance of data supports the assessment that the fixed combination of doxylamine–pyridoxine is safe in human pregnancy, including the 1st trimester. Positive associations with congenital malformations have been observed but probably reflect outcomes that have occurred by chance or are the consequences of nausea and vomiting itself. Moreover, these reports do not consistently describe a specific syndrome or group of malformations. Therefore, pregnant women who request medication for nausea and vomiting can be offered this drug combination, but, as with any treatment during pregnancy, the available evidence should be reviewed with them to obtain their informed consent before initiating therapy.

FETAL RISK SUMMARY

Doxylamine, an antihistamine of the ethanolamine class, is approved for use as a sedative, either alone or in combination with other agents in cough and cold preparations. It is not used in the United States for the symptomatic relief of hypersensitivity reactions, most likely because of its pronounced sedative effects.

The antihistamine was a component of the proprietary product, Bendectin, which contained equal concentrations of doxylamine, pyridoxine (vitamin B6), and dicyclomine (an antispasmodic). Bendectin was marketed in 1956 for the prevention and treatment of nausea and vomiting during pregnancy. The product was reformulated in 1976 to eliminate dicyclomine because that component was not found to contribute to the antiemetic effectiveness. A similar Canadian two-drug formulation (doxylamine and pyridoxine), Diclectin, was marketed in 1978. More than 30 million women have taken this product during pregnancy, making it one of the most heavily prescribed drugs for this

condition. The US manufacturer ceased producing the drug combination in 1983 because of litigation and adverse media coverage over its alleged association with congenital limb defects. The fixed two-drug combination, although no longer available in the United States, continues to be produced in Canada and the individual components are marketed worldwide by various manufacturers.

Six studies in rodents and nonhuman primates have not observed teratogenic effects with Bendectin or its components (1–6), but dose-related toxicity was observed in three studies. In a 1968 publication, the reproductive effects of dicyclomine, doxylamine, and Bendectin (the three-drug combination of doxylamine [10 mg], dicyclomine [10 mg], and pyridoxine [10 mg]) in rats and rabbits were reported (1). Dicyclomine and doxylamine were given as pure compounds, whereas Bendectin was administered as pulverized tablets. In rats, dicyclomine and doxylamine (10–100 mg/kg/day) (15–150 times the maximum recommended human dose [four tablets] for a 60-kg human [MRHD]) were given orally for 80 days or more before pregnancy and continued during one (dicyclomine) or two (doxylamine) successive litters. The Bendectin group received 3–60 mg/kg/day (5–90 times the MRHD) orally beginning on the first day of gestation and continued throughout the remainder of the study. First-generation male and female offspring from the control and 60 mg/kg/day groups were then bred (nonsibling matings) and their progeny examined. Compared with nonexposed controls, no increase in congenital malformations or other adverse effects were noted in the pregnancy outcomes of the three drug groups. The one exception appeared to be a small dose-related decrease in fetal weight that was observed in the dicyclomine and doxylamine groups. Pregnant rabbits were administered 10–100 mg/kg/day (15–150 times the MRHD) orally of dicyclomine or doxylamine, or 3–30 mg/kg/day (5–45 times the MRHD) orally of Bendectin on days 9 through 16 of gestation (1). Similar to the study with rats, no adverse effects in pregnancy outcomes were noted when compared with controls except when toxic (100 mg/kg/day) doses were used in the pure drug groups (1).

A 1993 reference studied the effects of three antiemetic histamine H₁ antagonists, doxylamine, chlorcyclizine, and promethazine, on the skeletons of rat fetuses exposed during organogenesis (days 7–13) (2). Doxylamine was given orally at doses of 500 and 750 mg/kg (750 and 1125 times the MRHD). Compared with controls, a dose-dependent loss of skeletal integrity and marked fragility occurred with each antihistamine (2). The investigators concluded that the fragility was due to a defect in joint development rather than to intrauterine growth restriction.

No increase in malformations was observed in rats given Bendectin (two-drug combination) during organogenesis in doses of 0, 200, 500, and 800 mg/kg/day (3). Both maternal and fetal toxicity were evident at the two highest doses. The developmental toxicity observed was reduced prenatal viability (800 mg/kg/day) and reduced fetal body weight/litter (500 and 800 mg/kg/day).

Three of the reproduction studies involved nonhuman primates (4–6). In an unpublished study, rhesus monkeys were given a dose of 7 mg/kg/day (10 times the MRHD) without producing malformations (4). A second study, published in 1985, administered pulverized Bendectin (10 mg doxylamine plus 10 mg pyridoxine) to pregnant cynomolgus monkeys, rhesus monkeys, and baboons (5). A commercial preparation of doxylamine (Decapryn) was used in some baboons to reduce the total amount of drug if they would not take Bendectin. Nonexposed controls were used in each species. Most animals received the study drugs daily from gestation day 22–50, the major period of organogenesis (5). Cynomolgus and rhesus monkeys were given doses 10–40 times the MRHD, whereas baboons received doses 1–10 times the MRHD of Bendectin or 10 times the MRHD of doxylamine. A few cynomolgus monkeys (short-term exposure group) received Bendectin doses 20 times the MRHD for 4 consecutive days on gestation days 22–25, 26–29, 30–33, 34–37, or 38–41. Some of the long-term exposure monkey groups, all of the short-term exposure groups, and all of the baboon fetuses were removed by hysterotomy prenatally at day 100 of gestation. The remaining monkey fetuses were delivered at term (150–160 days). In the offspring examined prenatally, the incidence of ventricular septal defect (VSD) was 40% (6 of 15) in cynomolgus monkeys, 0% (0 of 8) in cynomolgus monkey short-term exposure groups, 18% (2 of 11) in rhesus monkeys, 23% (3 of 13) in Bendectin-exposed baboons, and 20% (1 of 5) in doxylamine-exposed baboons. The VSD was restricted to the muscular portion of the septum in 91% (11 of 12). No other defects were observed in the monkeys and no dose response was evident among the long-term-treated groups. In addition to the VSD, one baboon fetus (drug group not specified) had exophthalmia, micrognathia, reduction of first and fifth digits on both hands, facial hemangioma, and ambiguous genitalia, and was small for gestational age. The cause of the multiple defects was unknown, but a genetic basis for the anomalies could not be excluded. (Karyotyping was not available at that time.) (5). At term, no cases of VSD were found in nine cynomolgus and four rhesus monkey offspring, but one cynomolgus monkey had a mitral valve defect. Data from the author's laboratory indicated a very low incidence of spontaneous VSD in the three species: 0.3% (1 of 297) cynomolgus monkeys;

0% (0 of 1692) rhesus monkeys; 1.6% (1 of 61) baboons (5). The authors concluded, therefore, that the results suggested a delay in closure of the ventricular septum but that closure would occur before birth (5).

In the second part of the above investigation, daily Bendectin (doxylamine plus pyridoxine) doses 2, 5, and 20 times the MRHD were administered double-blind to cynomolgus monkeys (N = 69) from gestational days 22 through 50 (6). A control group (N = 21) received placebo tablets containing inert excipients and coatings similar to those in Bendectin. The doses for the four groups (three active, one placebo) were prepared by the manufacturer, and their identity was unknown to the researchers. Delivery occurred at term (approximately 155 days of gestation). No congenital malformations were noted, and no evidence of embryo, fetal, or maternal toxicity was observed.

More than 160 cases of congenital defects have been reported in the literature or to the FDA as either “Bendectin-induced” or associated with use of the drug in the 1st trimester (7–12). Defects observed included skeletal, limb, and cardiac anomalies as well as cleft lip or palate. A 1983 study found an association between Debendox (three-drug formulation) and clefts of the lip, palate, or both, although the authors stated that the association may have been due to chance alone (13).

In a 1989 study, the association between maternal use of marijuana and childhood acute nonlymphoblastic leukemia (ANLL) was investigated (see Marijuana) (14). An incidental finding was that the relative risk (RR) for ANLL in offspring of case mothers who used anti-nauseant medication was 1.75 (95% confidence interval [CI] 0.98–3.20) ($p = 0.06$). A statistically significant dose–response relationship was observed when the RR increased to 2.81 if the use of anti-nauseant medication continued for more than 10 weeks. Although not all of the mothers used Bendectin, most of them specifically named the product (14). However, several factors make a causal relationship between Bendectin and ANLL unlikely, including the possibility of recall bias between cases and controls, the absence of biological plausibility, the likelier possibility that the leukemia was induced by other toxins (e.g., marijuana, herbicides, or pesticides), and the lack of other reports of such an association.

A possible association between doxylamine–pyridoxine and diaphragmatic hernia was reported in 1983 and was assumed to reflect earlier findings of a large prospective study (12). Authors of the latter study, however, cautioned that their results could not be interpreted, even when apparently strong associations existed, without independent confirmation (15,16). In a large case–control study, infants exposed to the combination in utero had a slightly

greater RR of 1.40 for congenital defects (17). The risk was more than doubled (RR 2.91) if the mother also smoked. An increased risk for heart valve anomalies (RR 2.99) was also found. A minimal relationship was found between congenital heart disease and doxylamine (Bendectin) use in early pregnancy in another 1985 report comparing 298 cases with 738 controls (18). The authors went to great efforts to establish that their drug histories were accurate. Their findings provided evidence that if an association existed, it was very small.

In one of the above studies, an association was discovered between Bendectin and pyloric stenosis (RR 4.33–5.24), representing about a 4-fold increase in risk for this anomaly (17). Similarly, the Boston Collaborative Drug Surveillance Programs reported preliminary findings to the FDA indicating a 2.7-fold increase in risk (19). A 1983 case–control study, however, found no association between Bendectin use and the anomaly (20). In evaluating these three reports, the FDA considered them the best available information on the topic but concluded that no definite causal relationship had been shown between Bendectin and pyloric stenosis (19). In addition, the FDA commented that even if there were evidence for an association between the drug and the defect, it did not necessarily constitute evidence of a causal relationship since the nausea and vomiting themselves, or the underlying disease causing the condition, could be responsible for the increased risk (19). A 1984 study, which was not included in the above FDA evaluation, found a possible association with pyloric stenosis but could not eliminate the possibility that it was due to other factors (21). Compared with a control group, the odds ratio (OR) for pyloric stenosis in the offspring of mothers using Bendectin was 2.5 (95% CI 1.2–5.2). However, the authors stated that a conclusion supporting a causal association was not warranted because of the absence of a plausible biologic basis for the defect and conflicting results from other studies (21). Of interest, the Birth Defects Encyclopedia describes the etiology of pyloric stenosis (i.e., congenital hypertrophic pyloric stenosis) as probably polygenic and sex-modified, with an occurrence rate of 1/250 births (1200 males; 1/1000 females) (22).

The evidence indicating that doxylamine–pyridoxine is safe in pregnancy is impressive. A number of large studies, many reviewed in a 1983 article (23), have discovered no relationship between the drug combination and birth weight or length, head circumference, gestational age, congenital malformations, or other adverse fetal outcomes (24–40). An editorial accompanying the review article pointed out that Bendectin met none of the criteria for judging that a drug was a teratogen (41). One study was unable to observe chromosomal

abnormalities associated with the drug combination, whereas a second study found that use of the drugs was not related to the Poland anomaly (unilateral absence of the pectoralis major muscle with or without ipsilateral hand defect) (42,43).

The Northern California Kaiser Permanente Birth Defects Study, published in 1989, prospectively studied the occurrence of 58 categories of major congenital defects in 31,564 newborns in relation to maternal Bendectin use (44). The OR for any major anomaly and Bendectin was 1.0 (95% CI 0.8–1.4). Three categories of defects were statistically associated with the drug: microcephaly (OR 5.3, 95% CI 1.8–15.6); congenital cataract (OR 5.3, 95% CI 1.2–24.3); and lung malformations (OR 4.6, 95% CI 1.9–10.9). However, this was the exact number of associations that would have been expected by chance alone (44). The authors then reviewed an earlier independent study that did not involve Bendectin and found strong positive associations of microcephaly and congenital cataract with vomiting in pregnancy (44). They concluded, therefore, that Bendectin use during the 1st trimester was not associated with an increase in congenital malformations and that the associations found were unlikely to be causal (44).

A meta-analysis of 17 studies involving the use of Bendectin in pregnancy was published in 1988 (45). The OR 1.01 (95% CI 0.66–1.55) for all studies indicated that Bendectin was not related to congenital defects. The studies were then separated by study type (cohort and case–control studies), and again, no relationship to birth defect outcomes was found (45). Another meta-analysis, published in 1994, examined 16 cohort and 11 case–control studies that had reported birth defects in pregnancies exposed to Bendectin during the 1st trimester (46). The RR of any birth defect in association with exposure to Bendectin was 0.95 (95% CI 0.88–1.04). The RR and 95% CI intervals for specific defects were cardiac (0.90, 0.77–1.05), central nervous system (1.00, 0.83–1.20), neural tube (0.99, 0.76–1.29), limb reduction (1.12, 0.83–1.48), genital tract (0.98, 0.79–1.22), oral clefts (0.81, 0.64–1.03), and pyloric stenosis (1.04, 0.85–1.29). These results indicate that the use of Bendectin during the 1st trimester is unlikely to be associated with congenital malformations (46).

A five-part analysis of the medical literature involving Bendectin and pregnancy outcomes, published in 1995, was used as a demonstration of methodology to determine if a drug presented a human reproductive hazard (47). Some of the legal history surrounding Bendectin's alleged reproductive hazards was also reviewed. The analysis included: (a) analysis of human

epidemiologic studies, (b) the relationship between the secular trend of birth defects and the population exposure to drugs, (c) the ability to develop an animal model, (d) analysis of dose–response relationships and pharmacokinetics of the drug in animals and humans, and (e) the biological plausibility for the alleged teratogenicity (47). The author reviewed eight in vitro studies that examined the toxicity, mutagenicity, teratogenicity, and other toxicities of doxylamine. None of these studies found toxicity at serum concentrations obtainable in humans. Moreover, the author emphasized the fact that in vitro studies, by themselves, cannot establish human teratogenicity (47). Based on the total data presented in this analysis, a strong case was made for the contention that Bendectin has no measurable teratogenic effects. In response to this and other publications, however, an intense debate in the scientific literature has developed between some who contend that Bendectin is safe and a proponent of the view that Bendectin induces limb reduction defects (48–53).

Interestingly, a population-based case–control study conducted in 1982–1983 by the Atlanta Birth Defects Case–Control Study and published in 1999 found a protective effect from Bendectin for congenital heart defects (54). The use of antiemetic medication, particularly Bendectin (two- and three-drug combinations), in early moderate to severe nausea during pregnancy was associated with a lower risk for heart defects compared with the absence of nausea (OR 0.67, 95% CI 0.50–0.92), and nausea without medication use (OR 0.70, 95% CI 0.50–0.94). The authors concluded that the results suggested that pregnancy hormones, other factors, or a component of Bendectin (most likely pyridoxine) may be important for normal heart development (54).

In spite of the abundant evidence supporting the safety of doxylamine–pyridoxine in pregnancy, the adverse media publicity and litigation proceedings surrounding Bendectin have affected the use of the combination in other countries. A 1995 article briefly reviewed the history of Bendectin in the United States and compared it with a similar Canadian product, Diclectin (55). Diclectin is the drug of choice for the treatment of emesis in pregnancy as specified by a Canadian Department of Health and Welfare task force, and is labeled for this indication. It is used less frequently, however, than another antihistamine, dimenhydrinate (Gravol; Dramamine in the United States), that is not specifically labeled for pregnancy use. The reason for this appears to be a fear of possible teratogenicity and subsequent litigation (55).

A 2003 ecological analysis of Bendectin found no evidence of a teratogenic effect (56). This study was accompanied by a historical review of the drug and

a recommendation that the combination be reintroduced in the American market (57).

A double-blind, placebo-controlled trial published in 2010 was designed to evaluate the effectiveness of a delayed release formulation of doxylamine and pyridoxine (Diclectin), similar to Bendectin, for the treatment of nausea and vomiting of pregnancy (58). Pregnant women were randomized to a 14-day treatment regimen of either the drug combination (N = 131) or placebo (N = 125). The drug combination was significantly better in controlling nausea and vomiting and significantly more women (48.9% vs. 32.8%) wanted to continue the combination at the end of the study (58).

BREASTFEEDING SUMMARY

No reports describing the use of doxylamine or the fixed combination of doxylamine–pyridoxine during human lactation have been located. Both components of the fixed combination, however, are available as single agents. Pyridoxine is excreted into breast milk but presents no risk to a nursing infant (see Pyridoxine). Doxylamine is an antihistamine that is used not only as an antiemetic, but also as a hypnotic and in cough and common cold preparations. The molecular weight of doxylamine succinate, about 389, is low enough that passage into breast milk should be expected. The effect on a nursing infant is unknown, but sedative and other antihistamine actions are a potential concern. The manufacturer of at least one doxylamine preparation states that the drug is contraindicated during nursing (59).

DRONABINOL

Antiemetic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Only one report has described the use of dronabinol in human pregnancy. Studies in animals revealed no teratogenicity, but dose-related maternal toxicity resulting in embryo–fetal death was observed. The human data are too limited to assess the risk to the embryo–fetus. Marijuana is contraindicated in pregnancy (see Marijuana) but that product is usually smoked, whereas dronabinol is taken orally. Nevertheless, the use of dronabinol in a pregnant woman should be classified as a “last resort” option.

FETAL RISK SUMMARY

Dronabinol (delta-9-tetrahydrocannabinol [delta-9-THC, THC]) is a synthetic formulation of the naturally occurring component of marijuana. It is indicated for the treatment of anorexia associated with weight loss in patients with AIDS and nausea and vomiting associated with cancer chemotherapy in patients who have failed to respond adequately to conventional antiemetic treatments. Dronabinol undergoes extensive hepatic metabolism to both active and inactive metabolites. Dronabinol and its principal active metabolite, 11-OH-delta-9-THC, are present in approximately equal concentrations in the plasma. Plasma protein binding of dronabinol and its metabolites is about 97% and the terminal elimination half-life is 25–36 hours (1).

Reproduction studies have been conducted in mice and rats. Pregnant mice were given doses that were 0.2–5 times the maximum recommended human dose based on BSA (MRHD) in patients with cancer (MRHD-C) or 1–30 times the MRHD in patients with AIDS (MRHD-A), whereas rats received doses that were 0.8–3 times the MRHD-C or 5–20 times the MRHD-A. No evidence of teratogenicity was observed in these studies. However, dose-dependent

maternal toxicity was observed, resulting in decreased maternal weight gain and number of viable pups, and increased fetal mortality and early resorptions (1).

In 2-year carcinogenicity studies, no evidence of carcinogenic effects was observed in rats. In mice, similar studies produced thyroid follicular cell adenoma in males and females but the tumors were not observed at higher doses. Three assays for mutagenicity were negative, whereas one assay produced a weak positive response. Fertility studies were conducted in rats with doses that were 0.3–1.5 times the MRHD-C or 2–10 times the MRHD-A. At these doses, reduced ventral prostate, seminal vesicle, and epididymal weights were observed, as well as decreases in seminal volume, spermatogenesis, number of developing germ cells, and number of Leydig cells in the testis. However, sperm count, mating success, and testosterone concentrations were not affected (1).

THC and one of its metabolites, 9-carboxy-THC, cross the human placenta at term. Data for other periods of gestation and for other metabolites are not available (see Marijuana).

A 2009 case report described the use of dronabinol in pregnancy (2). A 26-year-old woman who had been treated for 2 years with dronabinol (5 mg three times daily) for a complex hyperkinetic movement disorder became pregnant. Because the drug had improved her condition, treatment was continued during pregnancy. No signs of tolerance or need for dose escalation were noted. Her appetite was stimulated and she gained a total of 21 kg weight and her BMI increased to 31. She gave birth vaginally to a healthy baby (additional details not provided) (2).

BREASTFEEDING SUMMARY

No reports describing the use of dronabinol during human lactation have been located. THC is excreted and concentrated in breast milk (see Marijuana).

A 1990 report studied 68 breastfed infants exposed to marijuana in the mother's milk in the first month postpartum and compared their development at 1 year with 68 infants not exposed (3). The exposure appeared to be associated with a decrease in infant motor development at 1 year of age. On the basis of this report, additional research is warranted to confirm or refute these effects. Until such data are available, mothers taking dronabinol should not breastfeed.

DRONEDARONE

Antiarrhythmic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of dronedarone in human pregnancy have been located. Major structural anomalies in two animal species and embryo–fetal death in one species were caused by doses equal to or less than the human dose based on BSA. These data strongly suggest that dronedarone should not be used in the 1st trimester of human pregnancy. The manufacturer states that women of childbearing potential must use effective contraception while taking dronedarone (1). The effects of exposure later in pregnancy are completely unknown.

FETAL RISK SUMMARY

Dronedarone is an oral benzofuran derivative that has antiarrhythmic properties belonging to all four Vaughan–Williams classes. It is indicated to reduce the risk of cardiovascular hospitalization in patients with paroxysmal atrial fibrillation (AF) or atrial flutter (AFL), with a recent episode of AF/AFL and associated cardiovascular risk factors (i.e., age >70, hypertension, diabetes, prior cerebrovascular accident, left atrial diameter ≥ 50 mm, or left ventricular ejection fraction <40%), who are in sinus rhythm or who will be cardioverted. Dronedarone is extensively metabolized to a less potent but active metabolite. Further metabolism results in a large number of inactive metabolites. Plasma protein binding of dronedarone and the active metabolite is >98%. The elimination half-life of the parent compound is 13–19 hours (1).

Reproduction studies have been conducted in rats and rabbits. In pregnant rats, doses equal to or greater than the maximum recommended human dose based on BSA (MRHD) resulted in increased rates of external, visceral, and skeletal malformations (cranioschisis, cleft palate, incomplete evagination of

pineal body, brachygnathia, partially fused carotid arteries, truncus arteriosus, abnormal lobation of the liver, partially duplicated inferior vena cava, brachydactyly, ectrodactyly, syndactyly, and anterior and/or posterior club feet). In pregnant rabbits, a dose that was about half the MRHD (the lowest dose tested) caused an increased rate of skeletal abnormalities (anomalous ribcage and vertebrae, pelvic asymmetry) (1).

In 2-year studies for carcinogenicity, an increased incidence of histiocytic sarcomas in male mice, mammary adenocarcinomas in female mice, and hemangiomas in male rats were observed. No genotoxic potential was noted in multiple assays. In fertility studies with female rats, a dose 0.12 times the MRHD given before breeding and implantation caused an increase in irregular estrus cycles and cessation of cycling. Doses that were 1.2 times the MRHD were associated with decreased corpora lutea, implantations, and live fetuses. However, doses up to 1.2 times the MRHD had no effect on the mating behavior or fertility of male rats (1).

It is not known if dronedarone and its active metabolite cross the human placenta. The molecular weight of the parent drug (about 557 for the free base) and long elimination half-life suggest that it will cross to the embryo–fetus, although the high plasma protein binding might limit the exposure.

BREASTFEEDING SUMMARY

No reports describing the use of dronedarone during human lactation have been located. The molecular weight of the parent drug (about 457 for the free base) and long elimination half-life (13–19 hours) suggest that it will cross to the embryo–fetus, although the high plasma protein binding (>98%) of dronedarone and its active metabolite might limit the exposure. The effect of this exposure on a nursing infant is unknown. Adverse reactions that were most common in patients treated with the drug included diarrhea, nausea, abdominal pain, vomiting, dyspeptic signs and symptoms, weakness, and bradycardia (1). If a nursing mother chooses to breastfeed while taking this drug, her infant should be closely observed for these effects.

DROPERIDOL

Antiemetic/Antipsychotic

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

The limited animal and human data suggest that droperidol does not represent a significant risk to the fetus for major anomalies. The drug is a potent antiemetic that is effective for the treatment of severe nausea and vomiting of pregnancy.

FETAL RISK SUMMARY

Droperidol is a butyrophenone derivative structurally related to haloperidol (see also Haloperidol). The agent is not teratogenic in animals, but has produced a slight increase in the mortality of newborn rats (1). After IM administration, the increased pup mortality was attributed to CNS depression of the dams resulting in their failure to remove the placentae from the offspring (1).

The relatively low molecular weight of droperidol (about 379) suggests that the drug crosses the placenta to the fetus. In humans, the placental transfer of droperidol is slow (2).

Droperidol promotes analgesia for patients undergoing cesarean section without affecting the respiration of the newborn (2,3). The drug was also administered during labor as a sedative in a study comparing 48 women treated with droperidol with 52 women receiving promethazine (4). These investigators noted eight other reports in which the drug was used in a similar manner. No serious maternal or fetal adverse effects were observed.

Droperidol has been used for the treatment of severe nausea and vomiting occurring during pregnancy (5,6). A 1996 report described the use of droperidol and other drugs (diphenhydramine, metoclopramide, and hydroxyzine) in 80 women with hyperemesis gravidarum (6). The mean gestational age at the start of treatment was 10.9 weeks and the mean total dose received for the approximately 2 days of therapy was 49.6 mg. Twelve

(15%) of the women required a second hospitalization and were again treated with the same therapy. Three of the mothers (all treated in the 2nd trimester) delivered offspring with congenital defects: Poland's syndrome, fetal alcohol syndrome, and hydrocephalus and hypoplasia of the right cerebral hemisphere. Only the latter anomaly is a potential drug effect, but the most likely cause was thought to be the result of an in utero fetal vascular accident or infection (6).

A 2001 study, using a treatment method similar to the above study, described the use of droperidol and diphenhydramine in 28 women hospitalized for hyperemesis gravidarum (7). Pregnancy outcomes in the study group were compared with a historical control of 54 women who had received conventional antiemetic therapy. Oral metoclopramide and hydroxyzine were used after discharge from the hospital. Therapy was started in the study and control groups at mean gestational ages of 9.9 and 11.1 weeks', respectively. The study group appeared to have more severe disease than controls, as suggested by a greater mean loss from the prepregnancy weight, 2.07 vs. 0.81 kg (ns), and a slightly lower serum potassium level, 3.4 vs. 3.5 mmol/L (ns). Compared with controls, the droperidol group had a shorter duration of hospitalization (3.53 vs. 2.82 days, $p = 0.023$), fewer readmissions (38.9% vs. 14.3%, $p = 0.025$), and lower average daily nausea and vomiting scores (both $p < 0.001$). There were no statistical differences ($p > 0.05$) in outcomes (study vs. controls) in terms of spontaneous abortions (N = 0 vs. N = 2 [4.3%]), elective abortions (N = 3 [12.0%] vs. N = 3 [6.5%]), Apgar scores at 1, 5, and 10 minutes, age at birth (37.3 vs. 37.9 weeks'), and birth weight (3114 vs. 3347 g) (7). In controls, there was one (2.4%) major malformation of unknown cause, an acardiac fetus in a set of triplets, and one newborn with a genetic defect (Turner's syndrome). There was also one unexplained major birth defect (4.4%) in the droperidol group (bilateral hydronephrosis), and two genetic defects (translocation of chromosomes 3 and 7; tyrosinemia) (7).

In a nonrandomized, prospective study, two doses (0.5 and 1.0 mg/hr) of droperidol plus diphenhydramine for hyperemesis gravidarum were compared with historical controls (8). The number of patients in each group was 34, 67, and 54, respectively. Data were available for major anomalies in 26, 53, and 21 infants, respectively. Major anomalies, excluding those that were obviously not drug-induced (i.e., genetic, chromosomal, or amniotic bands), observed in the study were one (clubfoot—possible genetic defect), one (bilateral hydronephrosis), and none, respectively (8).

BREASTFEEDING SUMMARY

No reports describing the use of droperidol during lactation have been located. The molecular weight (about 379) is low enough that excretion into human milk should be expected. Because the drug is only available as an injectable formulation, the opportunity for exposure of a nursing infant appears to be limited. The effect of exposure on a nursing infant is unknown.

DROTRECOGIN ALFA (ACTIVATED)

Hematologic Agent (Thrombolytic)

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably
Compatible

PREGNANCY SUMMARY

The lack of animal reproductive studies and the near absence of human pregnancy experience prevent an assessment of the embryo–fetal risk. The drug does not appear to cross the placenta so that a direct risk to the embryo or fetus seems unlikely. However, drotrecogin alfa (activated) has been associated with a nonsignificant trend to more maternal hemorrhage and this would be a major risk to both the mother and fetus (1). Nevertheless, as demonstrated by the two case reports below, if the drug is indicated, it should not be withheld because of pregnancy (2,3).

FETAL RISK SUMMARY

Drotrecogin alfa (activated), a serine protease, is a recombinant (from a human cell line) form of human activated protein C. This glycoprotein is indicated for the reduction of mortality in adult patients with severe sepsis who have a high risk of death. It is administered as a continuous IV infusion because of its very short elimination half-life. The antithrombotic action of drotrecogin alfa (activated) is a result of inhibition of Factors Va and VIIIa. The agent is inactivated by endogenous plasma protease inhibitors. Animal reproduction studies have not been conducted with drotrecogin alfa (activated) (4).

It is not known if drotrecogin alfa (activated) crosses the human placenta to the embryo or fetus, but the molecular weight (about 55,000) of this glycoprotein should inhibit transfer. In addition, because the fetus can synthesize coagulation factors from early in gestation, there are no known physiologic processes in which endogenous maternal activated protein C would be actively transported across the placenta (1). Further, in vitro studies have found no evidence that endogenous protein C crosses the placenta or that it is

metabolized by the placenta (1). However, the effect on these processes from high maternal plasma concentrations of activated protein C resulting from infusion of the drug has not been studied.

Drotrecogin alfa (activated) has been recommended for the treatment of preeclampsia because this disease is similar in some ways to severe sepsis: diffuse effects on the maternal vascular endothelium resulting in multiple organ dysfunctions (1,5). A 2002 publication reviewed previous reports on the pathogenesis of preeclampsia to determine whether administration of drotrecogin alfa (activated) could be beneficial in the treatment of this disease (1). The authors of this in-depth assessment concluded that, although the data were limited, there was adequate evidence to support phase II clinical studies in women with early-onset preeclampsia (before 33 weeks' gestation) or severe or worsening postpartum disease (1).

A preliminary report of a phase II study describing the use of human activated protein C for the treatment of disseminated intravascular coagulation (DIC) was published in 1999. A total of 16 women with moderate-to-severe placental abruption were treated over a 2-day period (4). The activated protein C was prepared by extracting protein C from human plasma and activating it with human thrombin. Clinical signs were markedly improved and all coagulation/fibrinolysis parameters, except for the number of platelets, demonstrated significant changes toward normal values. No adverse effects attributable to the treatment were observed (6).

Two case reports described the successful use of drotrecogin alfa (activated) in the 2nd and 3rd trimesters of two women with severe sepsis (2,3). Use of the drug in these cases was indicated because severe sepsis is characterized, among other problems, by dysregulation of coagulation. The women received a continuous infusion of drotrecogin alfa (activated) for 96 hours and their conditions significantly improved. Both eventually gave birth to normal infants (2,3).

BREASTFEEDING SUMMARY

No reports describing the use of drotrecogin alfa (activated) during human lactation have been located. It is doubtful if a nursing infant would have access to the breast milk of a woman treated with this drug because of its indication for severe, life-threatening disease. The very high molecular weight of this glycoprotein (about 55,000) should inhibit excretion into milk, but even if such excretion occurred, the drug would most likely be digested in the infant's gut.

DULOXETINE

Antidepressant

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 3rd Trimester

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Duloxetine causes developmental toxicity in animals (growth restriction in rats and rabbits; behavior deficits and death in rats) at doses <10 times the maximum recommended human dose of 60 mg/day based on BSA (MRHD). No structural anomalies were observed in these species. The human data for duloxetine are limited and incomplete. However, the pharmacologic action of duloxetine is similar to that of venlafaxine and selective serotonin reuptake inhibitors (SSRIs). SSRIs and venlafaxine have been associated with developmental toxicities, including spontaneous abortions, low birth weight, prematurity, neonatal serotonin syndrome, neonatal behavioral syndrome (withdrawal), possible sustained abnormal neurobehavior beyond the neonatal period, respiratory distress, and persistent pulmonary hypertension of the newborn (PPHN). Some of these symptoms are thought to be consistent with a direct toxic effect, drug discontinuance syndrome, or a serotonin syndrome. If duloxetine is used in pregnancy, healthcare professionals are encouraged to call the toll-free number (800-670-6126) for information about patient enrollment in the Motherisk study.

FETAL RISK SUMMARY

Duloxetine is a selective serotonin and norepinephrine reuptake inhibitor (SNRI). It has both antidepressant and central pain inhibitory action. Other drugs in the same class are desvenlafaxine, milnacipran, and venlafaxine. Duloxetine is extensively metabolized to inactive metabolites. The parent compound is highly bound (>90%) to plasma albumin and α_1 -acid glycoprotein. The elimination half-life is about 12 hours (range 8–17 hours) (1).

Reproduction studies have been conducted in rats and rabbits. In pregnant rats, there was no evidence of fetal structural defects at doses up to seven times the MRHD administered during organogenesis. However, fetal weights were decreased at this dose. The no-effect dose was twice the MRHD. When duloxetine was administered throughout gestation and lactation, pup survival to 1 day postpartum and pup body weights at birth and during lactation were decreased at a dose five times the MRHD. In addition, pup behavior was adversely affected as shown by increased reactivity (e.g., increased startle response to noise and decreased habituation of locomotor activity). No adverse effects were observed on postweaning growth and reproductive performance. In pregnant rabbits, no evidence of fetal structural defects was observed at doses up to 15 times the MRHD during organogenesis, but fetal growth restriction was noted. The no-effect dose was three times the MRHD (1).

Duloxetine crosses the human placenta, at least at term. In a 2009 case report, the cord blood duloxetine concentration about 14 hours after a 60-mg extended release dose was 65 mcg/L (2). This is consistent with the molecular weight (about 298 for the free base) and the long elimination half-life of the drug.

Approximately 10 women became pregnant in a study of duloxetine in the treatment of depression (3). Treatment was discontinued and no additional information was provided.

A 2007 review conducted a literature search to determine the risk of major congenital malformations after 1st trimester exposure to SSRIs and SNRIs (4). Fifteen controlled studies were analyzed. The data were adequate to suggest that citalopram, fluoxetine, sertraline, and venlafaxine were not associated with an increased risk of congenital defects. In contrast, the analysis did suggest an increased risk with paroxetine. The data were inadequate to determine the risk for the other SSRIs and SNRIs (4).

A case–control study, published in 2006, found that exposure to SSRIs in late pregnancy was associated with persistent pulmonary hypertension of the newborn (PPHN) (5) (see Paroxetine or other SSRIs). Although there were no exposures to duloxetine in this study, the action of duloxetine is similar enough to the SSRIs that it might cause the same effect.

A brief report in 2008 described a case of poor neonatal behavioral syndrome due to duloxetine (6). The 36-year-old mother had been treated with monotherapy duloxetine 90 mg/day during pregnancy. Her female infant was born at 38 weeks' with Apgar scores of 7 and 9 (birth weight not provided). At delivery, the infant was blue, with minimal respiratory effort and oxygen

saturation was in the 80s. Laboratory and other tests to determine the cause of the infant's condition were normal. "Jerky rhythmic movements" or "twitchiness" and episodes of shaking began on day 3. The initial electroencephalogram (EEG) showed nonspecific encephalopathy, but a repeat test at 7 days was suggestive of subclinical seizures. The infant was treated with phenobarbital but continued occasional twitching. At 7 weeks, the EEG was normal and phenobarbital was discontinued. At age 2 years, the child is healthy with normal neurobehavioral development (6).

A 2009 report described the use of duloxetine during the second half of pregnancy (2). The 20-year-old woman, treated for depression, was taking 60 mg once daily (868 mcg/kg/day or 34 mg/m²). She gave birth to a healthy, 2.916-kg female infant at 38 weeks'. The Apgar scores were 8 and 9 at 1 and 5 minutes, respectively. The concentration of duloxetine in the cord blood (see above) was greater than the mother's peak plasma concentration obtained 6 hours after a dose 32 days after birth (see Breastfeeding Summary below). No evidence of developmental toxicity or other toxicity was observed in the infant (2).

Using the Lilly Safety System, a database for the collection, storage, and reporting of adverse events involving Lilly products, investigators identified 400 pregnancies (233 prospective; 167 retrospective) with known outcomes (7). The data collection period was from 2004 (drug approval) through October 2011. Of the prospectively reported cases, 170 (73%) were spontaneous reports, 58 (25%) were from clinical trials, and 5 (2%) involved post-marketing studies. In addition, 176 reports involving duloxetine from the FDA Adverse Events Reporting System through September 2011 were also examined. Analysis of the two data sources suggested that the frequency of abnormal outcomes were generally consistent with historic control rates in the general population (7).

BREASTFEEDING SUMMARY

Duloxetine is excreted into breast milk (2,8). A 2008 study conducted by the manufacturer described the use of duloxetine 40 mg every 12 hours for 3.5 days in six healthy women, at least 12 weeks postpartum, who had stopped nursing when the study was started (8). Seven paired milk and blood samples were collected on day 4 (probably at steady state). The mean milk:plasma ratio was 0.25 (90% confidence interval 0.18–0.35). The theoretical infant dose (TID) was 1.72 mcg/kg/day (range 0.59–3.05) and the mean maternal weight-adjusted dose was 1210 mcg/kg/day, resulting in a relative infant dose (RID) of

0.14% (range 0.068–0.249) (8).

In the case described in the Fetal Risk Summary, the mother exclusively breastfed her infant and, on day 32, milk and plasma samples (peak and trough) and a peak infant plasma sample were obtained (2). The milk:plasma ratios for the peak and trough collections were 1.2 and 1.3, respectively, whereas the drug was not detected in the infant plasma. The TID was 7.1 mcg/kg/day, whereas the mother's weight-adjusted dose was 868 mcg/kg/day. This yielded an RID of 0.82%. No signs of toxicity were noted in the infant at any time (2).

A 2010 study using human and animal models found that drugs that disturb serotonin balance such as SSRIs and SNRIs can impair lactation (9). The authors concluded that mothers taking these drugs may need additional support to achieve breastfeeding goals.

The presence of duloxetine in milk is consistent with the molecular weight (about 298 for the free base) and long elimination half-life (12 hours). Moreover, because milk is relatively acidic compared with blood, the milk:plasma ratio that was >1 also is consistent. Although no toxicity was observed in the above case, the long-term effects of exposure to duloxetine and similar antidepressants have not been adequately studied. The long-term effects on neurobehavior and cognitive development from exposure to potent SNRIs and SSRIs during a period of rapid CNS development have not been adequately studied. Therefore, the best course is to avoid duloxetine, if possible, during nursing. The American Academy of Pediatrics classifies antidepressants as drugs for which the effect on nursing infants is unknown but may be of concern (10).

DYPHYLLINE

Respiratory Drug (Bronchodilator)

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

The absence of animal reproductive data and the very limited human pregnancy experience prevent a complete assessment of the embryo–fetal risk. However, this xanthine derivative is closely related to theophylline, an agent considered compatible in pregnancy. (See also Theophylline.)

FETAL RISK SUMMARY

No published reports describing the use of dyphylline in human pregnancy have been located. In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 97 newborns had been exposed to dyphylline during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Seven (7.2%) major birth defects were observed (four expected), including (observed/expected) cardiovascular defects (3/1), and polydactyly (1/0.3). No anomalies were observed in four other categories of defects (oral clefts, spina bifida, limb reduction defects, and hypospadias) for which specific data were available. Only with cardiovascular defects is there a suggestion of a possible association, but other factors, including the mother's disease, concurrent drug use, and chance may be involved.

BREASTFEEDING SUMMARY

Dyphylline is excreted into breast milk. In 20 normal lactating women, a single 5 mg/kg IM dose produced an average milk:plasma ratio of 2.08 (1). The milk and serum elimination rates were equivalent. Although the drug accumulates in milk, the American Academy of Pediatrics classifies dyphylline as compatible with breastfeeding (2).

E

ECALLANTIDE

Hematological Agent (Kallikrein Inhibitor)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of ecallantide in human pregnancy have been located. The protein caused developmental toxicity (death) in one animal species, but the dose comparison was based on body weight, not BSA or AUC, and maternal toxicity was present. Although a rare genetic disorder, acute episodic attacks of hereditary angioedema can cause localized swelling, inflammation, and pain. If a pregnant woman requires ecallantide, consideration should be given to avoiding early gestation. She should be informed of the lack of human pregnancy experience and the potential risk of embryo death. Moreover, the woman should be informed of the risk of anaphylaxis that has occurred in 3.9% of treated patients (1).

FETAL RISK SUMMARY

Ecallantide, a small protein, is a human plasma kallikrein inhibitor. There are no other agents in this class. It is indicated for the treatment of acute attacks of hereditary angioedema in patients 16 years of age and older. After a single SC dose in healthy subjects, the mean elimination half-life was 2 hours. No information was provided for metabolism and plasma protein binding (1).

Reproduction studies have been conducted in rats and rabbits. In rats, an IV dose that was about 13 times the maximum recommended human dose (MRHD) based on body weight (MRHD-BW) caused increased numbers of early resorptions and percentages of resorbed conceptuses in the presence of

mild maternal toxicity. No developmental toxicity was observed with IV doses that were about eight times the MRHD-BW. There were no adverse effects on rat embryo–fetal development with SC doses resulting in exposures up to about 2.4 times the MRHD based on AUC (MRHD-AUC). In rabbits, IV doses resulting in exposures up to about six times the MRHD-AUC were not associated with adverse effects on embryo–fetal development (1).

Studies for carcinogenic or mutagenic potential have not been conducted. SC doses up to about 21 times the MRHD-BW had no effect on fertility and reproductive performance in rats (1).

It is not known if ecallantide crosses the human placenta. The drug is a small protein with a molecular weight of 7054 and a short elimination half-life. These characteristics suggest that clinically significant amounts of the drug will not reach the embryo or fetus.

BREASTFEEDING SUMMARY

No reports describing the use of ecallantide during human lactation have been located. The drug is a small protein with a molecular weight of 7054 and a short 2-hour elimination half-life. These characteristics suggest that clinically significant amounts of the drug will not be excreted into breast milk. The risks to a nursing infant from exposure to the protein appear to be low, if they exist at all.

ECHINACEA

Herb

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Echinacea is an ancient preparation that has recently undergone resurgence in use. Use during pregnancy creates the potential for exposure of the embryo and fetus to multiple chemical compounds that have not undergone reproductive toxicity testing in animals or humans. Moreover, standardization of any herbal product as to its constituents, concentrations, and the presence of contaminants are generally lacking. Two sources recommend that parenteral administration of the herb (a product form not available in the United States) should not be used in pregnancy (1,2). Another source states that echinacea should be avoided during pregnancy because of the lack of information (3). There is only one published report describing human pregnancy exposure. Although this study found no increased risk for major malformations, it was limited by its small sample size, the self-selection of the study group, and the lack of dose standardization (4). Thus, the safety of echinacea products during pregnancy remains to be established and, until such additional evidence is published, pregnant women should be counseled of such.

FETAL RISK SUMMARY

The traditional uses of echinacea are topically to enhance wound healing and systemically as an immunostimulant (5). It was used by the Native Americans before colonization of the continent and was a common medicine in the United States in the late 19th and early 20th centuries (6). The herb is available orally as capsules, as expressed, fresh juice, and as tinctures. In Germany, an intravenous preparation is also available (7). Specific indications for systemic echinacea listed in one publication are prophylaxis and treatment of viral upper

respiratory tract infections and combined with conventional anti-infective agents in the treatment of more severe infections (6). Specific topical indications listed are the treatment of eczema, psoriasis, and herpes simplex. Another publication lists antiseptic and antiviral indications (8).

Echinacea angustifolia, the plant most commonly used for medicinal purposes, is a perennial herb of the Compositae family that grows to a height of 3 feet, terminating in a single colorful flower head. The plant is indigenous to the central United States. Related species that have been used in traditional medicine include *E. purpurea* and *E. pallida* (5,9). Because *E. angustifolia* and *E. pallida* closely resemble each other, preparations of echinacea may be mislabeled or contain mixtures of the two species. German authors recommend the use of the above-ground parts (not the roots) of *E. purpurea* or the roots of *E. angustifolia* for medicinal purposes (9).

The principal anti-inflammatory and immunostimulant compounds are found in the hydrophilic and lipophilic fractions of the root, leaves, and flowers (5,6). The specific active ingredients accounting for the medicinal effects of the herb have not been identified. The water-soluble polysaccharides in the roots, however, appear to be a major component of the anti-inflammatory and immune-stimulating properties (6). Essential oil from the root also contains unsaturated alkyl ketones and isobutylamides. Although not all components from the various parts of the plant have been identified, the chemical compounds that have been isolated include echinacoside (a caffeic acid glycoside), a volatile germacrene alcohol (not usually found in dried plant material), echinacein (an isobutylamide responsible for the pungent odor), echinacin B, chicoric acid, cyanrine, chlorogenic acid, caftaric acid, (z)-1,8-pentadecadiene (also known as Z-pentadeca-1,8-diene), and arabinogalactan (5,6).

No animal studies examining the reproductive effects of any of the species of echinacea or their components have been located. One prospective report, however, described the use of this herb in human pregnancies (4). Between 1996 and 1998, 206 women contacted a teratogen information service regarding their exposure to echinacea products (primarily *E. angustifolia* and *E. purpurea*) during gestation. Of these, 112 used echinacea during the 1st trimester. The total cohort was disease matched to 206 women exposed to nonteratogenic agents by maternal age, alcohol, and cigarette use. There were three sets of twins in the study group and none in the control group. Both groups were followed prospectively to determine pregnancy outcomes. No statistically significant differences between the study and control women were found for the following outcomes: live birth (94.7% vs. 96.1%), spontaneous

abortion (6.3% vs. 3.4%), induced abortion (0.5% vs. 0.5%), vaginal delivery (83.1% vs. 81.3%), maternal weight gain (15.2 vs. 14.4 kg), gestational age at delivery (39.2 vs. 39.2 weeks), birth weight (3466 vs. 3451 g) (excluding twins), fetal distress (23.6% vs. 21.1%), major malformations (in total group) (3.6% vs. 3.5%), and minor malformations (3.6% vs. 3.5%). Among the 98 newborns exposed during the 1st trimester, there were four (4.1%) major defects: left inguinal hernia requiring surgical repair; bilateral hydronephrosis; syndactyly of the second and third toes; and duplicate left renal pelvis. The authors concluded that there was no increased risk for major anomalies (4).

An in vitro study using *E. purpurea* reported adverse effects in human sperm (10). In a sperm penetration assay, zona-free hamster oocytes were incubated for 1 hour with two concentrations of *E. purpurea*, 0.8 and 8 mg/mL, dissolved in HEPES-buffered synthetic human tubal fluid (modified HTF). Fresh human donor sperm was suspended in the modified HTF and then mixed with the oocytes for 3 hours. Modified HTF served as the control. At the 0.8 mg/mL concentration, 5 of 9 (56%) of the oocytes were penetrated, whereas at 8 mg/mL, only 1 of 8 (13%) of oocytes was penetrated. The decrease in penetration was not associated with a decrease in sperm motility. In the second part of the study, sperm were incubated with the herbal solutions for 7 days. Both concentrations caused significant sperm DNA denaturation concomitant with decreases in sperm viability compared with controls. Extrapolation of these data to the reproductive risk of echinacea in males is difficult, in part because the concentration of echinacea in semen or sperm has not been studied (10). Moreover, although the doses used in this study are small fractions of the actual recommended human dose, there is no published evidence that the adverse effects observed have occurred in vivo.

BREASTFEEDING SUMMARY

No reports describing the use of echinacea during lactation have been located. For the reasons discussed above, and because of the immaturity of an infant's metabolic and elimination systems, use of this herb should probably be avoided during nursing.

ECHOTHIOPHATE

Parasympathomimetic (Cholinergic)

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Echothiophate is a long-acting, relatively irreversible organophosphate that is used in the eye for its anticholinesterase activity. One report of its use in pregnancy has been located.

FETAL RISK SUMMARY

As a quaternary ammonium compound, echothiophate is ionized at physiologic pH and transplacental passage in significant amounts would not be expected (see also Neostigmine). However, 1968 case report suggested otherwise. A 22-year-old woman was treated with echothiophate iodide 0.125% instilled daily into both eyes and acetazolamide 1 g/day (1). She became pregnant shortly after starting this treatment, which was continued until 32 weeks' at which time the therapy was changed to pilocarpine and betamethasone eye drops. Two months later, a normal, full-term female infant was born. Pseudocholinesterase activity was measured in the mother and infant at 10 days, 28 days, and 3 months after birth. Increasing activity with time was shown in both mother and infant. The authors concluded that the drug had crossed the placenta to lower the enzyme activity in the fetus (1).

BREASTFEEDING SUMMARY

No reports describing the use of echothiophate during human lactation have been located.

ECONAZOLE

Antifungal

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Topical econazole does not appear to represent a risk to the human fetus. No teratogenic effects were observed in three animal species following oral and SC dosing that produced systemic exposures far greater than those obtained in humans. The very low systemic bioavailability of this antifungal agent after topical or vaginal application prevents clinically significant amounts from reaching the maternal circulation. Although details of the available human pregnancy experience are incomplete, the risk to an embryo or fetus from the maternal use of econazole appears to be nil. However, one study speculated that antifungals that inhibit placental aromatase, such as econazole, have a potential to cause spontaneous abortions. Until additional data are available on this potential association, the best course is to avoid the use of econazole for vaginitis treatment in the 1st trimester or the application of the antifungal to large areas of skin at any time in pregnancy.

FETAL RISK SUMMARY

Econazole is available only in a topical cream formulation. Vaginal suppositories, spray powder, lotion, and spray solution are available outside of the United States. Econazole is in the same antifungal class of imidazole derivatives as butoconazole, clotrimazole, ketoconazole, miconazole, oxiconazole, sertaconazole, sulconazole, and tioconazole. It is indicated for the treatment of dermatologic fungal infections including candidiasis. Systemic absorption from the skin or vagina is minimal, with less than 1% of a dose absorbed and recovered in the urine and feces (1–3).

In reproduction studies with oral econazole, no evidence of teratogenicity was observed in mice, rats, or rabbits. Oral doses 10–80 times the human

dermal dose, however, did cause embryo and fetal toxicity in some or all members of these species. In addition, prolonged gestation was observed in rats (1). SC doses have also been studied in pregnant mice and rabbits (4). Although no teratogenicity was observed, prolonged gestation and/or fetal death were noted.

It is not known if econazole nitrate crosses the human placenta. The molecular weight (about 445) is low enough, but the amount of drug in the systemic circulation is very low. It is doubtful that clinically significant amounts of the antifungal agent reach the embryo or fetus.

A 1979 report described the use of econazole vaginal suppositories (150 mg at bedtime for 3 days) for the treatment of vaginal candidiasis (5). Some patients required a second course of therapy. Among the patients treated, 24 were pregnant, but the gestational timing of the treatment and pregnancy outcomes were not provided. In a 1981 study, 33 women in various phases of gestation used the same dose and route of administration (6). A second 3-day course of treatment was given to nine of these patients. No details on pregnancy outcomes were reported.

Pregnancy outcome after treatment with a 3-day regimen of econazole vaginal suppositories for vaginal candidiasis was detailed in a 1985 open study (7). Treated were 117 pregnant women with a mean gestational age of 30 weeks (range 10–42 weeks), 44.4% at or after the 36th week of gestation. The number of patients in each trimester was not specified. In 106 pregnancies for which outcome data were available (107 infants, including one set of twins), 13 deliveries were premature. No prolongation of gestation was observed. There were three stillbirths among the 107 infants: one twin; one after intrauterine infection (no fungus recovered); and one death in utero. No congenital defects were observed in the 104 healthy newborns. The mean weight and height were 3301 g and 50.3 cm, respectively. One newborn developed oral thrush, but the mother was still infected at delivery (7).

A 2002 study evaluated azole antifungals commonly used in pregnancy for their potential to inhibit placental aromatase, an enzyme that is critical for the production of estrogen and for the maintenance of pregnancy (8). The authors speculated that the embryotoxicity observed in animals and humans (see also Clotrimazole, Miconazole, and Sulconazole) might be explained by inhibition of aromatase. They found that the most potent inhibitors of aromatase were (shown in order of decreasing potency) econazole, bifonazole (not available in the United States), sulconazole, clotrimazole, and miconazole. However, an earlier study reported a pregnancy that was maintained even when there was

severe fetal and placental aromatase deficiency (<0.3% of that of controls) caused by a rare genetic defect (9). In this case, both the fetus and mother were virilized because of diminished conversion of androgens to estrogen. Because the pregnancy was maintained and the virilization, the case suggested that the main function of placental aromatase was to protect the mother and fetus from exposure to adrenal androgens (9).

A population-based case–control study of vaginal econazole in pregnancy was conducted using the Hungarian Case–Control Surveillance of Congenital Abnormalities (10). The study compared 22,843 case women who had newborn infants with a congenital defect with 38,151 controls. Vaginal econazole treatment was used in 68 cases and 122 controls. The crude prevalence odds ratio was 0.9, 95% confidence interval 0.7–1.3 (ns). There also was no evidence that econazole use in the 2nd and 3rd month of pregnancy was associated with teratogenicity (10).

BREASTFEEDING SUMMARY

Although no reports describing the use of topical or vaginal econazole during lactation have been located, the very low systemic bioavailability after topical use suggests that little, if any, of this antifungal will be excreted into breast milk. Therefore, the risk of this exposure to a nursing infant appears to be nil.

ECSTASY

Central Stimulant

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

The use of amphetamines under controlled conditions, such as 3,4-methylenedioxymethamphetamine (MDMA) in the animal studies above and as amphetamines in the treatment of human disease (see Amphetamine), suggests that these agents are not teratogenic when used alone and do not cause clinically significant fetal toxicity. Other abuse drugs (e.g., lysergic acid diethylamide [LSD] and marijuana) are also not teratogenic (see Lysergic Acid Diethylamide and Marijuana), but alcohol and cocaine are well-known teratogens and/or fetal toxins (see Cocaine and Ethanol). However, ecstasy is not used under controlled conditions. Neither the dosage nor the actual chemical consumed is usually known and, in many cases, the product is taken with other abuse drugs. Because both human studies involved voluntary reporting, a true incidence of major congenital defects cannot be determined, but there does not appear to be a clustering of similar anomalies.

FETAL RISK SUMMARY

In the United States, ecstasy (“Adam”), a central stimulant, is an illicit substance of abuse that is used for its mind-altering properties. It has been associated with dance events known as “raves” (1). Chemically, ecstasy is a member of the amphetamine (3,4-methylenedioxymethamphetamine; MDMA) class of drugs (see also Amphetamine) (1,2).

A brief 2000 publication reported the results of a chemical analysis of 107 pills of ecstasy that were voluntarily and anonymously donated to the authors for analysis after a nationwide solicitation (1). However, because the donors were required to pay a fee for the analysis, the findings may not represent what is actually available. Of the total, only 67 pills (63%) contained some MDMA or a closely related analog (either 3,4-methylenedioxy-ethyl-

amphetamine or 3,4-methylenedioxyamphetamine) (1). Forty (37%) contained no MDMA or related amphetamine. Of these, 23 (58%) contained the antitussive dextromethorphan (see also Dextromethorphan) and 9 (23%) contained no identifiable drug. Other substances identified were caffeine, ephedrine, pseudoephedrine, and salicylates (1).

MDMA was not teratogenic in pregnant rats at oral doses of 2.5 or 10 mg/kg/day administered on alternate days from gestational day 6 to day 18 (3). The drug had no effect on gestational duration, litter sizes, or birth weights. Although most pup neurobehavior parameters were unaffected, olfactory discrimination was enhanced in both males and females, and negative geotaxis was delayed in females. However, the density of brain serotonin-uptake sites and levels of brain serotonin and 5-hydroxyindoleacetic acid (5-HIAA; metabolite of serotonin) were not affected. There was a significant reduction of maternal weight and a dose-dependent decrease in maternal brain serotonin (5-HT) (3).

In another study with pregnant rats, MDMA 20 mg/kg SC was administered twice daily on days 14–17 of gestation (4). Marked, long-lasting maternal hyperthermia was observed after the first dose, but the response was attenuated with further doses. The body weight of the dams decreased during treatment and there was a 20% decrease in litter size. There was a slight reduction in pup weights on postnatal day 7, but the difference was not statistically significant compared with controls. In the dams, a significant decrease in the concentration of 5-HT and 5-HIAA in the hippocampus, striatum, and cortex of the brain were measured 1 week after parturition (i.e., nearly 2 weeks after the last dose). In contrast, neither the 5-HT nor 5-HIAA level in the dorsal telencephalon of the pups was different from that of controls. The lack of MDMA-induced toxicity in the fetal brains suggested that either MDMA was not being metabolized to free radical-producing entities or the fetal brains were more efficient than adult brains in eliminating the toxic free radical metabolites (4).

Although there is no information on the placental passage of MDMA, other amphetamines rapidly cross the human placenta (see Amphetamine). Moreover, the relatively low molecular weight of MDMA (about 179, compared with about 135 for amphetamine) suggests that it also rapidly crosses to the fetus.

An abstract published in 1998 described the pregnancy outcomes of 49 women who had called a teratology information service (TIS) in Holland concerning their exposure to pure MDMA or to closely related amphetamines

(methylene dioxyamphetamine [MDA]; methylene dioxyethylamphetamine [MDEA]; or other) (5). In 47 cases, the exposure occurred during the 1st trimester; the other 2 were in the 2nd trimester. The mean age of the women was 26 (range 17–44). Other abuse drugs, usually cocaine or marijuana, were taken by 43%, 34% of the women drank alcohol, and 63% of the women smoked cigarettes. Eleven pregnancies were still ongoing. The outcomes of the remaining 38 pregnancies were 2 spontaneous abortions, 2 elective abortions (1 fetus with a defect suggestive of an omphalocele), and 36 liveborn infants (6 premature including one set of triplets). One term newborn, exposed in utero to ecstasy alone, had a congenital heart defect and died a few hours after birth (5).

A 1999 report from the United Kingdom National TIS cited 302 inquiries from pregnant women concerning ecstasy from January 1989 to June 1998 (6). Of the total, 31 pregnancies were ongoing and 135 were lost to follow-up. Outcome data were available for 136 pregnancies (1 set of twins). Among this group, 74 women took only ecstasy, and 62 took ecstasy with other drugs, including amphetamines (N = 37), cocaine (N = 20), marijuana (N = 16), alcohol (N = 13), and/or LSD (N = 9). Exposure to ecstasy was limited to the 1st trimester in 127 pregnancies (71 to ecstasy alone, 56 to ecstasy plus other drugs of abuse), to the 1st and 2nd trimesters in 2, to the 2nd trimester in 2, to the 3rd trimester in 1, and throughout gestation in 4. Thus, 133 of the pregnancies (98%) were exposed to ecstasy in the 1st trimester. The outcomes included 11 spontaneous abortions (8%) and 48 elective abortions (35%). One elective abortion occurred at 22 weeks' gestation because of a fetus with absent upper limbs, left scapula, clavicles, and hypoplasticity of the first rib pair. The mother said she had taken only ecstasy during the 1st trimester. No data were available on the other aborted fetuses. There were 12 infants with congenital defects among the 78 born live infants (15.4%, 95% confidence interval [CI] 8.2–25.4). One newborn (without apparent birth defects), who was exposed in utero to ecstasy, heroin, and methadone throughout pregnancy died from an unknown cause. The birth defects and drug exposures (all in the 1st trimester except 1 case) were ecstasy only (6 cases): left 4th toe underlying 3rd toe, right-sided plagiocephaly, 2 with unilateral talipes, bilateral talipes, pyloric stenosis; ecstasy and amphetamine (2 cases): clicking hips, intrauterine growth restriction, ambiguous sex (1 of twins born at 25 weeks'); ecstasy, amphetamine, and gamma hydroxybutyric acid (1 case): ventricular septal defect (VSD) (possibly atrial and ventricular), bilateral hydronephrosis, bilateral clinodactyly; ecstasy and alcohol (3 cases): VSD,

pigmentation of the right thigh, ptosis of left eye (exposed in 2nd trimester). There were three female infants with talipes (3.8%, 95% CI 8–109) compared with the expected rate of 0.1% (6). In addition, in Great Britain, there is a 3:1 male predominance of idiopathic talipes equinovarus (6). Neither the sex ratio nor birth weights of term infants (specific data not provided) were adversely affected by the exposures (6).

BREASTFEEDING SUMMARY

No reports describing the use of ecstasy or MDMA during human lactation have been located. The molecular weight (about 179) is low enough, however, that excretion into milk should be expected. The closely related drug amphetamine is concentrated in breast milk with milk:plasma ratios ranging from 2.8 to 7.5 (see Amphetamine). The American Academy of Pediatrics classifies amphetamines as contraindicated during breastfeeding (7).

ECULIZUMAB

Immunologic Agent (Antihemolysis)

PREGNANCY RECOMMENDATION: Maternal Benefit >> Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The human pregnancy experience with eculizumab is very limited. The animal data from one species, using a murine version of the antibody, suggest risk. However, eculizumab is indicated for paroxysmal nocturnal hemoglobinuria (PNH), a high-risk complication in pregnancy manifested by hemolytic anemia, bone marrow failure, and thrombosis (1–3). Significant morbidity and mortality have occurred from PNH-induced venous thromboembolism with maternal and perinatal mortality up to 20% and 10%, respectively (1). Supportive therapy (red blood cells and platelet transfusions) and routine prophylactic anticoagulation are recommended. Moreover, there also is a need for additional iron and folic acid supplements because of the hemolysis. In nonpregnant and the limited number of pregnant patients, the use of eculizumab, usually in combination with low-molecular-weight heparin (LMWH), has reduced the need for transfusions and the rate of hemolytic episodes and thrombosis (1–3). Thus, if indicated, the maternal benefit appears to far outweigh the unknown embryo–fetal risk.

FETAL RISK SUMMARY

Eculizumab, an anti-C5 antibody, is a recombinant humanized monoclonal IgG_{2/4K} antibody that contains human constant regions from IgG2 and IgG4 sequences. It is given as an IV infusion once weekly for 5 weeks and then every 2 weeks. The antibody binds to the complement protein C5 to inhibit its cleavage thereby preventing terminal complement mediated intravascular hemolysis. Eculizumab is indicated for the treatment of patients with PNH to reduce hemolysis. Eculizumab increases a patient's susceptibility to serious

meningococcal infections (septicemia and/or meningitis), so all patients must be given meningococcal vaccine at least 2 weeks before starting eculizumab therapy and revaccinated according to current medical guidelines. The half-life of the antibody is 272 hours (4).

Reproduction studies have been conducted in mice using a murine anti-C5 antibody. Mice were given doses that were about 2–4 times (low dose) or 4–8 times (high dose) the recommended human dose based on body weight (RHD). When maternal exposure occurred during organogenesis, two cases of retinal dysplasia and one case of umbilical hernia were observed in the high-dose group among 230 offspring. There was no increase in fetal loss or neonatal death. When the antibody was given from implantation through weaning, male offspring had an increased risk of death (1/25 controls, 2/25 low-dose group, and 5/25 high-dose group). Surviving offspring had normal development and reproductive performance (4).

Carcinogenic and mutagenic studies have not been conducted with eculizumab. No effects on reproductive performance or fertility were observed in male and female mice given IV doses of the murine anti-C5 antibody up to 4–8 times the RHD (4).

Although the molecular weight (about 148,000) is very high, the manufacturer states that the antibody is expected to cross the human placenta (4). There are data suggesting that all IgG subtypes can potentially cross the placenta but the IgG2 sequence having the least transfer of the subtypes (3). However, in two newborns (one at term and the other at 28 weeks'), the antibody was not detected in cord blood; in two others (twins at 35 weeks'), low levels within the background level for the assay were found (see reference 8). These cases suggest that the fetus will not be exposed to clinically significant concentrations of eculizumab.

In a 2006 correspondence, brief mention was made of a woman who became pregnant during a study of eculizumab in PNH, even though pregnancy was a study exclusion (5). Eculizumab therapy was discontinued and the woman had a successful full-term birth without complications.

A 34-year-old woman with PNH was treated with eculizumab in a twin pregnancy resulting from in vitro fertilization (6). Her first pregnancy 2 years earlier had ended with a spontaneous abortion (SAB) at 6 weeks' despite anticoagulation with LMWH. Ongoing active hemolysis before and during the current pregnancy was documented and the patient was treated with therapeutic LMWH. At 30 weeks', eculizumab was started with the recommended induction dose of 600 mg weekly for 4 weeks, followed by 900

mg every other week and LMWH was continued. At 35 weeks', thrombocytopenia (60,000/ μ L) and increasing peripheral edema were observed. One week later, a cesarean section was conducted to deliver a 2919-g male infant and a 2199-g female infant with Apgar scores of 9 and 10 and 8 and 9, respectively. The female twin had an obstructed duplicated kidney that had been diagnosed early in the pregnancy. No additional information was provided on the status of the twins (6).

A 2010 reference described the pregnancy outcomes of seven women exposed to eculizumab for the treatment of PNH (7). All of the patients were initially on the standard maintenance dose of 900 mg every 2 weeks unless specified otherwise. Five of these cases were from the 106 women enrolled in clinical trials of the antibody in PNH. In one case, the woman underwent an elective abortion (EAB) and continued on eculizumab. In three cases, eculizumab was discontinued at 4, 5, and 14 weeks' gestation, respectively. All delivered healthy newborns without any adverse effects. The fifth patient conceived after having been on eculizumab for 5 years. She withdrew from the trial and continued the antibody combined with LMWH throughout pregnancy. Because of breakthrough hemolysis, the eculizumab dosing interval was reduced to 12 days. She gave birth vaginally at term to a healthy, 4-kg male infant. The mother had a therapeutic eculizumab concentration (116.1 mcg/mL; time from last dose not specified) at delivery but the antibody was not detected in cord blood. The sixth patient, with twins, was treated with eculizumab for 2 years before stopping therapy for embryo implantation. She was maintained on therapeutic LMWH. At 27 weeks', eculizumab was restarted with the recommended induction regime (600 mg every week for 4 weeks, then 900 mg every 2 weeks) but, because of continued intravascular hemolysis and hemoglobinuria, the 900 mg maintenance dosing interval was shortened to once weekly. An elective cesarean section at 35 weeks' delivered two healthy infants (sex not specified) weighing 2.4 kg and 2 kg, respectively. At delivery, the mother had a therapeutic antibody concentration (80.5 mcg/mL; time from last dose not specified). The cord blood samples from the twins had subtherapeutic eculizumab concentrations (19.2 and 14.4 mcg/mL) that were within the background level for the assay. Patient number 7 had been receiving eculizumab and warfarin for PNH before conception. She also had chronic hypertension. At 5 weeks' gestation, warfarin was discontinued and replaced with LMWH. At 28 weeks', preeclampsia developed and a cesarean section delivered a 900-g infant (sex not specified). The mother had a therapeutic eculizumab concentration (63.2 mcg/mL; time from last dose not specified) at

delivery but the antibody was not detected in cord blood. The mother and baby were doing well (7,8).

Another 2010 report described the pregnancy outcome of a 29-year-old woman with PNH who had been treated with eculizumab for 3 years before conception (9). Although the patient had never had thrombotic complications, LMWH was added when her pregnancy was discovered. Eculizumab and LMWH were continued throughout an uneventful pregnancy. At 38 weeks', she vaginally delivered a healthy 3.43-kg male infant with Apgar scores of 9 and 10 at 1 and 5 minutes, respectively. At 9 months of age, the infant was developing normally (9).

In a 2013 case report, a 26-year-old white woman at 17 weeks' had a recurrence of atypical hemolytic uremic syndrome that was initially controlled with multiple plasma exchanges with fresh-frozen plasma (10). The disease recurred at 26 weeks' and she was treated with IV eculizumab 900 mg every 14 days until a cesarean section at 38 weeks'. The healthy, 3650-g female infant had Apgar scores of 9 and 10 at 1 and 5 minutes, respectively. The infant had normal laboratory values and was discharged home after 1 week (10).

BREASTFEEDING SUMMARY

No reports describing the use of eculizumab during human lactation have been located. In a case described above where the mother received eculizumab (900 mg) at 12-day intervals and had a therapeutic serum concentration (116.1 mcg/mL) at delivery, the antibody was not detected in milk samples obtained on postpartum days 1, 2, 3, 9, and 10 (8). Neither the time of the last dose nor the detection limit of the assay was specified. Nevertheless, the findings are compatible with the high molecular weight (about 148,000) of eculizumab. However, because human IgG is found in milk, additional reports are required to confirm that eculizumab is not excreted in detectable amounts.

The manufacturer states that published data suggest that breast milk antibodies are not systemically absorbed by nursing infants in substantial amounts (4). Consequently, breastfeeding by women receiving eculizumab is probably compatible, but meningococcal infections are a serious potential risk. Moreover, nursing infants should be closely observed for the most common (>10%) adverse effects observed in adults: headache, nasopharyngitis, back pain, nausea, fatigue, and cough.

EDETATE CALCIUM DISODIUM

Antidote

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Only two reports of human pregnancy experience with edetate, both involving a short course in late gestation, have been located. Moreover, interpretation of the rat study is hindered by the presumed oral administration of edetate, a drug that is poorly absorbed from the gastrointestinal (GI) tract. That study did suggest, however, that the observed fetal malformations were induced by zinc deficiency. The human cases and limited animal data are insufficient to assess the risk for the human embryo and fetus. Dietary zinc supplementation might be an option if prolonged treatment with edetate calcium disodium was required during pregnancy, but this has not been studied. In addition, hypotension is a reported adverse effect in adults, and in a pregnant patient, this could jeopardize placental perfusion and the fetus. However, lead is a well-known reproductive toxicant that has significant associations with preterm birth, reduced birth weight and postnatal growth, minor congenital anomalies, and deficits in postnatal neurological or neurobehavioral status (1). Therefore, if indicated, the maternal, and possibly the embryo–fetal, benefit of therapy appear to outweigh any unknown direct or indirect risks (2).

FETAL RISK SUMMARY

The chelating agent edetate calcium disodium (edetate) is the calcium chelate of disodium ethylenediaminetetraacetate. It is indicated for the reduction of blood levels and depot stores of lead in acute or chronic lead poisoning and lead encephalopathy. Edetate also forms stable chelates with other divalent or trivalent metals that can displace calcium, such as cadmium, iron, manganese, mercury, and zinc, but not copper. However, insignificant amounts of iron and manganese are chelated, and mercury is either too tightly bound to be chelated

or is stored in inaccessible body compartments. In contrast, the excretion of zinc is significantly increased. Edetate must be given by injection (IM preferred but also by IV) because it is poorly absorbed from the GI tract. The drug is not metabolized and is excreted by the kidneys with an elimination half-life of 20–60 minutes (3).

Reproduction studies have been conducted in pregnant rats. In one study, doses up to 13 times the human dose (presumed to be based on body weight) revealed no evidence of impaired fertility or fetal harm. In a second study, doses up to about 25–40 times the human dose caused fetal malformations, but the anomalies were prevented by simultaneous supplementation of dietary zinc (3).

A 1998 review summarized the developmental toxicity of metal chelating agents, including ethylenediaminetetraacetic acid (EDTA) and its salts (disodium, trisodium, calcium disodium, and tetrasodium edetate) (4). The author cited several animal studies showing teratogenicity that was proven to be secondary to EDTA-induced zinc deficiency. Different incidences of teratogenicity were observed depending on the route of administration (IV, SC, gavage, or diet) and dose. In one study, oral administration of EDTA and its salts, even at maternally toxic doses, had little or no teratogenic effects in rats. The different outcomes were thought to be partially due to poor absorption of the compounds after oral administration (4).

It is not known if edetate crosses the human placenta to the embryo or fetus. The molecular weight (about 374) is low enough for transfer to the fetus. In addition, small amounts of the drug cross the blood–brain barrier as about 5% of the plasma concentration can be found in spinal fluid. However, the very short elimination half-life will limit the amount of drug at the maternal–fetal interface.

The first known case of lead poisoning treated with edetate in a pregnant woman was reported in 1964 (5). A family of six (father, mother, and four male siblings) was diagnosed with lead poisoning caused by using battery cases as fuel in the living room stove for several months. The mother, who was 8 months pregnant, had a blood lead level of 0.24 mg/dL. She was treated with a 7-day course of edetate (75 mg/kg/day). Four weeks later, she delivered an apparently healthy 3.2-kg male infant. The cord blood lead level was undetectable (<0.06 mg/dL). At follow-up, the physical and neurologic examination and developmental assessment were normal at 4.25 years (5).

An unusual case of lead poisoning in a 17-year-old pregnant woman was apparently reported by two different groups of authors from the same New

York hospital (6,7). The patient had eaten paint from the walls of her apartment for several months during pregnancy. She was hospitalized at about 38 weeks' gestation because of abdominal pain, paresthesias in her feet, and calf pain. A blood sample yielded a lead level of 86 mcg/mL, whereas the amniotic fluid lead level was 90 mcg/mL. She was treated with IV edetate 1 g twice daily for 3 days. Two days after chelation therapy, her blood level was 41 mcg/mL. Six days later, she delivered a 2665-g female infant spontaneously. The cord blood lead concentration was 60 mcg/mL, whereas the maternal level at discharge was 26 mcg/mL. The small-for-date infant's head circumference was 32 cm (10th percentile), and the length was 45 cm (25th percentile). Radiographs revealed a dense skull with delayed deciduous dental development and abnormal long bones. At about 2 years of age, the girl's growth and development were normal (6,7).

A 2002 report described the use of IV edetate (dose not specified) and IM dimercaprol in a woman at 30 weeks' gestation with a high blood lead concentration (5.2 $\mu\text{mol/L}$; goal $\leq 0.48 \mu\text{mol/L}$) (8). Twenty-four hours after initiation of chelation therapy, her lead level was 2.3 $\mu\text{mol/L}$. Twelve hours later, labor was induced because of uterine hemorrhage, and she gave birth to a 1.6-kg (75th percentile) female infant. Lead concentration in the cord blood was 7.6 $\mu\text{mol/L}$. The Apgar scores were 4 and 6 (presumably at 1 and 5 minutes, respectively). The newborn was flaccid with absent reflexes, no movement to noxious stimuli, and no gag reflex, but she did have spontaneous eye movement. Bilateral diaphragmatic palsy was confirmed by fluoroscopy. During her 7 months of hospitalization, the infant received multiple courses of chelation to treat the intrauterine lead intoxication. In spite of this therapy, she had right sensorineural deafness and neurodevelopment delay at discharge. Oral succimer was continued at home because the blood lead level was still elevated (0.95 $\mu\text{mol/L}$). The mother's lead source was identified as herbal tablets that had been prescribed for a GI complaint. She had taken the tablets periodically over the last 9 years and throughout pregnancy. Mercury also was present in some of the tablets. The lead intake during pregnancy was estimated to be 50 times the average weekly intake of Western populations (8).

In a 2003 report, four women with severe lead poisoning were treated with IV edetate during the 3rd trimester, including one also treated with dimercaprol. The source of the lead in most cases was the ingestion of pica (soil/clay-based substances). No lead-induced congenital defects were noted in the infants, but all received chelation therapy in the neonatal period (9).

BREASTFEEDING SUMMARY

No reports describing the use of edetate calcium disodium (edetate) during lactation have been located. The molecular weight (about 374) suggests that the drug will be excreted into breast milk, but the very short elimination half-life will limit the amount excreted. Moreover, edetate is poorly absorbed after oral dosing, at least from the adult GI tract. The risk to a nursing infant from exposure to the drug in milk is unknown but appears to be very low or nonexistent. However, because the use of edetate implies poisoning with lead, this metal also will be excreted into milk and is toxic to a nursing infant. Therefore, breastfeeding is contraindicated in women receiving edetate.

EDROPHONIUM

Parasympathomimetic (Cholinergic)

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 3rd Trimester

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Edrophonium is a short-acting quaternary ammonium chloride with anticholinesterase activity used in the diagnosis of myasthenia gravis. The drug has been used in pregnancy without producing fetal malformations (1–7).

FETAL RISK SUMMARY

Because it is ionized at physiologic pH, significant amounts of edrophonium would not be expected to cross the placenta. The molecular weight (about 202 for edrophonium chloride) is low enough that placental transfer of the nonionized fraction probably occurs.

Caution has been advised against the use during pregnancy of IV anticholinesterases because they may cause premature labor (1,3). This effect on the pregnant uterus increases near term. IM neostigmine has been recommended as an alternative to IV edrophonium if diagnosis of myasthenia gravis is required in a pregnant patient (3). However, vaginal bleeding and abortion have occurred with IM neostigmine and are potential complications (see Neostigmine). In one report, IV edrophonium was given to a woman in the 2nd trimester in an unsuccessful attempt to treat tachycardia secondary to Wolff–Parkinson–White syndrome (6). No effect on the uterus was mentioned and she continued with an uneventful full-term pregnancy.

Transient muscular weakness has been observed in about 20% of newborns of mothers with myasthenia gravis (8). The neonatal myasthenia is caused by transplacental passage of anti-acetylcholine receptor immunoglobulin G antibodies (8).

BREASTFEEDING SUMMARY

No reports describing the use of edrophonium during lactation have been located. Edrophonium is ionized at physiologic pH and is not expected to be excreted into breast milk (9). The molecular weight (about 202 for edrophonium chloride) is low enough that excretion of the nonionized fraction into milk may occur. The effects, if any, on a nursing infant from this exposure are unknown (9).

EFALIZUMAB

Immunologic Agent (Immunosuppressant)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of efalizumab in human pregnancy have been located. The animal data suggest that the human embryo and fetal risk are low, but the absence of human pregnancy experience prevents a full assessment of the risk. Because psoriasis is common in women of childbearing potential, the long elimination half-life of efalizumab suggests that exposure of inadvertent pregnancies is highly probable. Based on the animal data, suppression of the antibody response in infants exposed in utero late in gestation is a potential complication.

FETAL RISK SUMMARY

Efalizumab is an immunosuppressant recombinant humanized immunoglobulin (IgG1) kappa isotype monoclonal antibody. It is indicated for the treatment of chronic moderate to severe plaque psoriasis in patients who are candidates for systemic therapy or phototherapy. It is administered by SC injection. After the last steady-state dose, the mean time to eliminate efalizumab was 25 days (range 13–35 days) (1). (Note: This corresponds to a mean elimination half-life of about 5 days.)

Animal reproduction studies with efalizumab have not been conducted. However, a study was conducted in mice during organogenesis using an antimouse CD11a antibody with SC doses up to 30 times the equivalent of the recommended clinical dose of efalizumab (ERCD). In this study, no evidence of maternal toxicity, embryotoxicity, or teratogenicity was observed. When doses 3–30 times the ERCD were administered in late gestation and during lactation, no adverse effects on behavior, reproduction, or growth were noted. However, at 11 weeks of age, offspring exhibited a significant reduction in their ability to

mount an antibody response. There was evidence at 25 weeks of age that this effect was partially reversible.

The transplacental passage of efalizumab in humans has not been studied. However, immunoglobulin G is known to cross the human placenta. Thus, exposure of the human embryo or fetus should be expected.

BREASTFEEDING SUMMARY

No reports describing the use of efalizumab during human lactation have been located. As an immune globulin, efalizumab is probably excreted into breast milk. Because of the long elimination time (about 25 days), holding breastfeeding after a dose to allow clearance from the mother's system does not appear to be practical. The effect of this exposure on a nursing infant is unknown, but the immune globulin would most likely undergo some degree of digestion in the infant's gut. However, suppression of the infant's antibody response is a potential complication. Until data are available, avoiding nursing during use of efalizumab is the safest course.

EFAVIRENZ

Antiviral

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

The human data are too limited to allow a prediction as to the risk of efavirenz during pregnancy. The teratogenicity observed in cynomolgus monkeys and the embryo toxicity in rats suggests that there is a potential for risk in the developing human. Exposure of the human embryo–fetus is likely to occur because the agent was found to easily cross the placenta of all animal species tested. Moreover, the case report of a myelomeningocele was considered to be consistent with the toxicity observed in monkeys. Taken in sum, however, the total data do not support the concept that efavirenz is a major teratogen. If indicated, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Efavirenz is an orally active, nonnucleoside reverse transcriptase inhibitor (nnRTI) that is specific for HIV-1. It is indicated, in combination with other antiretroviral agents, for the treatment of HIV-1 infections. Efavirenz has a terminal half-life of 52–76 hours after a single dose and 40–55 hours after multiple dosing (1). The shorter elimination time after chronic dosing is a result of cytochrome P450 enzyme induction that induces its own metabolism.

In reproduction studies, cynomolgus monkeys were administered oral efavirenz (60 mg/kg/day) throughout pregnancy (postcoital days 20–150). This dose produced plasma drug concentrations similar to those achieved in humans given 600 mg/day. Three of 20 exposed newborns had major congenital malformations, compared with 0 of 20 in nonexposed control monkeys. The defects observed were one case each of anencephaly and unilateral anophthalmia, microphthalmia, and cleft palate. In pregnant rats, doses producing plasma concentrations similar to those in humans resulted in an

increase in fetal resorptions. Neither mating nor fertility was impaired in rats at these doses. No teratogenic or toxic effects were observed in rabbits given doses producing plasma concentrations similar to those in humans (1).

It is not known if efavirenz crosses the human placenta to the fetus. The relatively low molecular weight (about 316) suggests that the drug is transferred to the fetus. Placental transfer of efavirenz has been documented in cynomolgus monkeys, rats, and rabbits, with fetal blood concentrations approximately the same as maternal plasma concentrations (1).

A 2002 case report described the pregnancy outcome of a 34-year-old woman with asymptomatic HIV infection (2). The woman was taking zidovudine, stavudine, efavirenz, and folic acid before and during the first 24 weeks of gestation, at which time pregnancy was diagnosed. Therapy was then changed to lamivudine, stavudine, and nelfinavir. At 38 weeks' gestation, a 3450-g male infant was born with length 49 cm and head circumference 34.5 cm. The infant had a large sacral myelomeningocele lesion (10 cm diameter) and a triventricular hydrocephalus. The serologic test for HIV was positive. Surgical repair of the neural tube defect was performed along with ventriculoperitoneal shunting. Because of the reproduction studies in monkeys, the authors attributed the infant's defect to efavirenz (2).

The Antiretroviral Pregnancy Registry reported, for the period January 1989 through July 2009, prospective data (reported before the outcomes were known) involving 4702 liveborn infants who had been exposed during the 1st trimester to one or more antiretroviral agents (3). Congenital defects were noted in 134, a prevalence of 2.8% (95% confidence interval [CI] 2.4–3.4). In the 6100 live births with earliest exposure in the 2nd/3rd trimesters, there were 153 infants with defects (2.5%, 95% CI 2.1–2.9). The prevalence rates for the two periods did not differ significantly. There were 288 infants with birth defects among 10,803 live births with exposure anytime during pregnancy (2.7%, 95% CI 2.4–3.0). The prevalence rate did not differ significantly from the rate expected in a nonexposed population. There were 556 outcomes exposed to efavirenz (501 in the 1st trimester and 55 in the 2nd/3rd trimesters) in combination with other antiretroviral agents. There were 16 birth defects (14 exposures in the 1st trimester and 2 in the 2nd/3rd trimesters). One of the defects from a 1st trimester exposure was a neural tube defect. In reviewing the birth defects of prospective and retrospective (pregnancies reported after the outcomes were known) registered cases, the Registry concluded that, except for isolated cases of neural tube defects with efavirenz exposure in retrospective reports, there was no other pattern of anomalies (isolated or

syndromic) (3). (See Lamivudine for required statement.)

Two reviews, one in 1996 and the other in 1997, concluded that all women receiving antiretroviral therapy should continue to receive therapy during pregnancy and that treatment of the mother with monotherapy should be considered inadequate (4,5). The same conclusion was reached in a 2003 review with the added admonishment that therapy must be continuous to prevent emergence of resistant viral strains (6). In 2009, the updated U.S. Department of Health and Human Services guidelines for the use of antiretroviral agents in HIV-1 infected patients continued the recommendation that therapy, with the exception of efavirenz, should be continued during pregnancy (7). The guidelines recommended avoiding efavirenz in pregnancy, particularly during the 1st trimester, because of the teratogenic effects observed in primates and the report of a neural tube defect in a newborn (7). Updated guidelines for the use of antiretroviral drugs to reduce perinatal HIV-1 transmission also were released in 2010 (8). Women receiving antiretroviral therapy during pregnancy should continue the therapy but, regardless of the regimen, zidovudine administration is recommended during the intrapartum period to prevent vertical transmission of HIV to the newborn (8).

BREASTFEEDING SUMMARY

No reports describing the use of efavirenz during human lactation have been located. The molecular weight (about 316) is low enough that excretion into breast milk should be expected. The effect on a nursing infant is unknown.

Reports on the use of efavirenz during human lactation are unlikely because the antiviral agent is used in the treatment of HIV infection. HIV-1 is transmitted in milk, and in developed countries, breastfeeding is not recommended (4,5,7,9–11). In developing countries, breastfeeding is undertaken, despite the risk, because there are no affordable milk substitutes available. Until 1999, no studies had been published that examined the effect of any antiretroviral therapy on HIV-1 transmission in milk. In that year, a study involving zidovudine was published that measured a 38% reduction in vertical transmission of HIV-1 infection despite breastfeeding when compared with controls (see Zidovudine).

ELECTRICITY

Miscellaneous

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity (Mother)

PREGNANCY SUMMARY

Exposure of the pregnant woman to electric current may produce dramatically different fetal outcomes depending on the source and type of current. Based on published reports previous to 1997, otherwise harmless maternal exposure to household alternating current was usually fatal to the fetus. In contrast, a 1997 prospective controlled cohort study cited below described live births in 94% of their cases (1,2); the difference between this report and the previous published experience is most likely due to selective reporting of adverse outcomes, the level of voltage involved (110 vs. 220 V), and whether the current passed through the uterus. Although the new data should lessen a woman's concern for her fetus after electric shock, pregnant women who have experienced this type of injury, even when deemed to be minor, should be advised to consult their health care provider. Oligohydramnios, intrauterine growth restriction, and fetal death may be late effects of exposure to alternating current (3). Lightning strikes of any human are often fatal, but in those rare cases in which the victim is pregnant and survives, about half of the fetuses will also survive. Electroconvulsive therapy (ECT) and direct-current cardioversion do not seem to pose a significant risk to the fetus. The most frequent adverse effect of ECT in the mother was premature contractions and labor, whereas in the fetus it was bradyarrhythmias. Based on one report, the use of a Taser weapon on a pregnant woman may result in spontaneous abortion.

FETAL RISK SUMMARY

Published reports have described the exposure of pregnant women to electric currents through five different means: accidental electric injury in the home,

lightning strikes, ECT, antiarrhythmic direct-current cardioversion, and from a Taser weapon. Dramatically different fetal outcomes have occurred based on the type of exposure.

Four reports involving 14 women described accidental electric shock with alternating current, either 110 or 220 V, from appliances or wiring in the home (3–6). In each of the cases, the electric current took a presumed hand-to-foot pattern through the body and, thus, probably through the uterus. Gestational ages varied from 12 to 40 weeks. Although none of the mothers was injured or even lost consciousness, in these otherwise harmless events, fetal death occurred in 10 (71%). In at least five of the cases, immediate cessation of fetal movements was noted. One mother, who received the shock at about 28 weeks' gestation, subsequently developed hydramnios and delivered an infant 4 weeks later (4). Burn marks were evident on the newborn, who died 3 days after birth. A second growth-restricted infant was stillborn at 33 weeks' gestation, 12 weeks after the electrical injury (3). In most cases, no specific clinical or pathologic signs could be noted (3). However, oligohydramnios was observed in two cases in which the fetuses survived. The accidents occurred at 20 and 32 weeks' gestation, with injury-to-delivery intervals of 6 and 21 weeks, respectively. The specific cause of fetal damage has not been determined. It may be due to changes in fetal heart conduction resulting in cardiac arrest (4,5) or by lesions in the uteroplacental bed (3).

A 1997 paper described 20 cases from the literature of electric shock during pregnancy with healthy newborn outcomes occurring in only 5 cases (1). An abstract of their preliminary findings was published in 1995 (2). The authors of this report then described the outcomes of 31 women studied prospectively after exposure to home appliances with 110 V (N = 26) or 220 V (N = 2), or to high voltage (2000 and 8000 V) from electrified fences (N = 2), or to a low-voltage (12 V) telephone line (N = 1). An additional 16 women who had received electric shocks during pregnancy were either lost to follow-up (N = 10) or had not yet given birth (N = 6). Of the 31 outcomes, there were 2 spontaneous abortions, one of which may have been caused by the electric shock. In that case, the abortion occurred 2 weeks after the mother had received the shock. One of the live newborns had a ventricular septal defect that eventually closed spontaneously. In comparison to the group of 20 cases from the literature, there were significant differences discovered in the number of live births (94% vs. 25%), voltage involved (77% to 110 V vs. 76% to 220 V), and current crossing the uterus (i.e., hand-to-foot transmission suggesting that the current crossed the uterus) (10% vs. 62%) (1).

Lightning strikes of pregnant women are rare, with only 12 cases described since 1833 (4,7–11). All mothers survived the event, but 6 (50%) of the fetuses died. A 1965 reference reported a lightning strike of a woman in approximately the 11th week of gestation (4). The woman briefly lost consciousness, but other than transient nausea and anxiety that decreased as the pregnancy progressed, she was unhurt. She subsequently delivered a healthy term infant who was developing normally at 5 months of age. This report also described five other cases of lightning strikes of pregnant women that occurred between 1833 and 1959 with two fetal deaths. In one of the latter cases, the electrical injury caused uterine rupture in a mother at 6 months' gestation requiring an immediate cesarean section that was unable to save the fetus. Two cases of lightning strikes in term pregnant women were reported in 1972 (7). Both women were in labor when examined shortly after the events. One infant was delivered 12.5 hours after the maternal injury but died 15.5 hours after birth apparently secondary to congestive heart failure. In the other case, a healthy infant was delivered 14 hours after the lightning strike. A 1979 report described a near-fatal lightning strike in the chest of a 21-year-old woman at 34 weeks' gestation (8). Successful cardiopulmonary resuscitation was performed on the mother, but fetal heart tones were absent on initial examination. A stillborn fetus was delivered 48 hours after admission while the mother was still comatose. No fetal movements were felt by a 12-year-old mother at term after awakening from a lightning strike (9). She went into labor 9 days after the accident and delivered a macerated male fetus. Both the fetus and the placenta appeared grossly normal. A case of a woman in her 7th month of pregnancy who was struck in the right arm by lightning was published in 1982 (10). She apparently did not lose consciousness. Examination revealed minimal maternal injury and normal fetal heart tones. A healthy infant was delivered 10 weeks later who is developing normally at 19 months of age. Finally, the picture and brief description of a 41-year-old woman, in her 26th week of pregnancy, who was struck by lightning, was presented in 1994 (11). The woman, but not the fetus, survived. Interestingly, the direction of the lightning strike in the mother was discussed in later correspondence (12,13).

ECT for depression and psychosis in pregnant patients has been the subject of a large number of references (14–45). The procedure has been used in all trimesters of pregnancy and has been considered safe for the fetus. However, the published data suggest that a better assessment is low risk.

General guidelines for ECT established by the National Institutes of Health (NIH) were published in 1985 (34). The NIH report recommended that ECT,

instead of drug therapy, be considered for pregnant patients with severe depression or psychosis in their 1st trimester but did not mention use in the other phases of gestation. Guidelines for the use of ECT in pregnant women were first proposed in 1978 (29) and then later expanded in 1984 (33). The combined guidelines from these two sources are (a) thorough physical examination, including a pelvic examination, if not completed earlier; (b) the presence of an obstetrician; (c) endotracheal intubation; (d) low-voltage, nondominant ECT with EEG monitoring; (e) ECG monitoring of the mother; (f) evaluation of arterial blood gases during and immediately after ECT; (g) Doppler ultrasonography of fetal heart rate (FHR); (h) tocodynamometer recording of uterine tone; (i) administration of glycopyrrolate (see Glycopyrrolate) as the anticholinergic of choice during anesthesia; and (j) weekly nonstress tests.

One report described mental retardation in a 32-month-old child whose mother had received 12 ECT treatments in the 2nd and 3rd trimesters for schizophrenia, but the investigators did not believe the treatments were responsible (37). A 1955 reference examined 16 children who had been exposed in utero to maternal ECT between the 9th and 21st weeks of pregnancy (38). The age of the children at examination ranged from 14 to 81 months and all exhibited normal mental and physical development. Transient (2.5 minutes) fetal heart rate deceleration was observed in a twin pregnancy in which the mother was receiving ECT under general anesthesia (39). A total of eight ECT treatments were given, two before the observed deceleration and five afterwards.

Only one report has been located that described arterial blood gas analyses during ECT in a pregnant patient (28). As observed in previous studies, maternal blood pressure (average systolic blood pressure increase 10 mmHg) and heart rate (average pulse increase 15 beats/minute) rose slightly immediately after the shock, but no maternal hypoxia was measured. A fetal arrhythmia lasting about 15 minutes occurred that was apparently unrelated to oxygen changes in the mother (28).

Transient maternal hypotension after ECT was described in a 1984 case report (32). The adverse effect was attributed to decreased intravascular volume. IV hydration preceded subsequent ECT treatments in the patient, and no further episodes of hypotension were observed (32).

A 1991 report noted mild, bright red vaginal bleeding and uterine contractions after each of seven weekly ECT treatments between 30 and 36 weeks' gestation (35). A cesarean section, performed at 37 weeks' gestation because

of bleeding, confirmed a diagnosis of abruptio placentae. The authors attributed the complication to the transient marked hypertension caused by the ECT. Only one other report, however, has described vaginal bleeding after ECT (26). Three women, all in the 8th or 9th month of pregnancy, complained either of severe recurrent abdominal pain (N = 2) or vaginal bleeding (N = 1) after ECT. Therapy was stopped in these cases, and normal infants were eventually delivered.

A 2007 case report described the pregnancy outcome of woman that had received ECT every 2 weeks throughout pregnancy (40). Labor was induced at 36 weeks' because of preeclampsia to deliver a 2.550-kg male infant with Apgar scores of 4 and 7. The infant had multiple brain infarcts that were attributed to the ECT. An accompanying editorial, however, thought that the infarcts were unlikely to have been caused by the ECT (41). Multiple ECT sessions were associated with premature labor in two reports (42,43).

A 2009 review cited 339 cases of ECT in pregnancy that had been reported over a 65-year interval (1941–2007) (44). Of the 25 fetal or neonatal complications that occurred in these cases, the authors thought that 11, which included 2 deaths, were likely related to ECT. The 11 cases included 8 cases of transient fetal arrhythmias, 1 fetal death due to maternal status epilepticus, 1 miscarriage in the 1st trimester, and 1 case of multiple brain infarcts (same case as reference 40). The review did not cite the above editorial (reference 41). The most frequent adverse effect of ECT in the mother was premature contractions and labor, whereas in the fetus it was bradyarrhythmias (44).

Antiarrhythmic, direct-current cardioversion is considered a safe procedure during gestation (45–48). Cardioversion has been used in the 2nd trimester in a woman with atrial fibrillation after mitral valvulotomy (45), in the 1st trimester in a patient with atrial flutter in 1:1 atrioventricular conduction (46), seven times during three pregnancies in one patient for atrial tachycardia resistant to drug therapy (47), and twice in a single patient in two pregnancies for atrial fibrillation (48). No fetal harm was noted from the procedure in any of these cases. Two review articles on cardiac arrhythmias during pregnancy considered cardioversion (with energies of 10–50 J (49)) to be safe and usually effective in this patient population (49,50).

A 1992 reference described the effect from using a Taser (an electronic immobilization and defense weapon) on a pregnant woman at an estimated 8–10 weeks' gestation (51). The subject, in custody at the time because of drug abuse, was struck by one dart above the uterus and by a second dart in the left thigh, thereby establishing a current path through the uterus. Vaginal spotting

began the next day and heavy vaginal bleeding began 7 days after the Taser incident. Uterine curettage performed 7 days later confirmed the presence of an incomplete spontaneous abortion (51).

BREASTFEEDING SUMMARY

No data are available.

ELETRIPTAN

Antimigraine

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No reports describing the use of eletriptan in human pregnancy have been located. The animal data suggest moderate risk, but an assessment of the actual risk cannot be determined until human pregnancy experience is available. Although a 2008 review of triptans in pregnancy found no evidence for teratogenicity, the data did suggest a possible increase in the rate of preterm birth (1).

FETAL RISK SUMMARY

Eletriptan is an oral selective serotonin (5-hydroxytryptamine; 5HT_{1B/1D}) receptor agonist that has high affinity for 5HT_{1B}, 5HT_{1D}, and 5HT_{1F} receptors. The drug is closely related to almotriptan, frovatriptan, naratriptan, rizatriptan, sumatriptan, and zolmitriptan. It is indicated for the acute treatment of migraine with or without aura in adults. Protein binding is moderate (about 85%). One active metabolite has been identified. The elimination half-life of eletriptan is about 4 hours, whereas the half-life of the active metabolite is about 13 hours (2).

Reproduction studies have been conducted in rats and rabbits. In rats, eletriptan was given during organogenesis at doses ranging from about 1.2 to 12 times the maximum recommended human daily dose of 80 mg based on BSA (MRHDD). At 12 times the MRHDD, fetal weights were decreased and the incidence of vertebral and sternebral variations were increased, but this dose was also maternal toxic (decreased body weight gain). The no-effect-dose for developmental toxicity in rats was about four times the MRHDD. When rabbits were administered doses ranging from about 1.2 to 12 times the MRHDD throughout organogenesis, fetal weights were reduced at the highest dose. All doses were associated with increased incidences of fused sternebrae

and vena cava deviations. Maternal toxicity was not observed with the doses used. A no-effect-dose for development toxicity in rabbits was not determined (2).

It is not known if eletriptan or its active metabolite crosses the human placenta to the fetus. The molecular weight of the parent compound (about 382 for the free base) is low enough that passage to the fetus should be expected. In addition, the moderate protein binding and elimination half-life suggest that the drug will be available for transfer at the maternal–fetal interface.

BREASTFEEDING SUMMARY

Eletriptan is excreted into human breast milk. In a study conducted by the manufacturer, eight women were given a single oral dose of 80 mg (2). The mean amount of drug recovered from milk over a 24-hour period was approximately 0.02% of the maternal dose. The mean milk:plasma ratio was 1:4, but there was great variability. At 18–24 hours after the dose, the drug was still present in milk in low concentrations (mean 1.7 ng/mL). The active metabolite was not measured in the milk (2).

The effect of this exposure on a nursing infant is unknown. However, the very low concentrations measured in milk suggest that eletriptan is compatible with breastfeeding.

ELTROMBOPAG

Hematological Agent (Hematopoietic)

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential
Toxicity

PREGNANCY SUMMARY

Eltrombopag is in a pharmacologic class by itself. Only one report describing the use of eltrombopag in human pregnancy has been located. The animal reproduction data suggest low risk, but the doses tested were very low. A more complete assessment of the potential for human embryo–fetal risk cannot be made until human data are available. Nevertheless, if eltrombopag is indicated, the maternal benefit appears to outweigh the unknown embryo–fetal risk, and the drug should not be withheld because of pregnancy. Health care professionals are encouraged to enroll exposed patients in the Promacta Pregnancy Registry by calling 888-825-5249.

FETAL RISK SUMMARY

Eltrombopag is a hematopoietic agent that is in the subclass of thrombopoietin receptor agonists. There are no other agents in the subclass. Because of the risk of hepatotoxicity and other risks, the drug only is available through a restricted distribution program. Eltrombopag is indicated for the treatment of thrombocytopenia in patients with chronic immune (idiopathic) thrombocytopenic purpura (ITP) who have had an insufficient response to corticosteroids, immunoglobulins, or splenectomy. Moreover, it should only be given if the patient's degree of thrombocytopenia and clinical condition increase the risk of bleeding (1). Eltrombopag is extensively metabolized. The drug is highly bound to plasma proteins (>99%). Elimination is primarily via feces with a half-life of 21–32 hours in healthy subjects and 26–35 hours in ITP patients. Systemic concentrations approximately 40% higher in healthy African-American subjects were noted in one clinical study (1).

Reproduction studies have been conducted in rats and rabbits. In pregnant

rats, a dose that was seven times the human clinical exposure based on AUC (HCE) was maternal toxic (decreases in body weight gain and food consumption). At this dose, fetal weights were significantly reduced and there was a slight increase in the presence of cervical ribs. No maternal or fetal adverse effects were observed in rats at a dose that was twice the HCE. In pregnant rabbits, no evidence of fetotoxicity, embryoletality, or teratogenicity was observed with doses up to 0.6 times the HCE (1).

Carcinogenicity studies have been conducted in mice and rats. No carcinogenic effect was observed with doses up to 4–5 times the HCE. The drug was not mutagenic or clastogenic in various assays, but was marginally positive (more than threefold increase in mutation frequency) in a mouse lymphoma assay. Eltrombopag had no effect on the fertility of female and male rats at doses that were two and five times the HCE, respectively (1).

It is not known if eltrombopag crosses the human placenta. The molecular weight (about 443 for the free acid) and the long elimination half-life suggest that the drug will cross the placenta, but the high-protein binding should limit the amount crossing the placenta. The drug was detected in the plasma of rat offspring exposed during gestation (1).

A 2012 case report described the pregnancy of a 34-year-old woman at 27 weeks' with systemic lupus erythematosus who developed severe thrombocytopenia (2). She was treated with high-dose corticosteroids, IV immunoglobulin, rituximab (weekly for four doses), one dose of cyclophosphamide, and anti-D immunoglobulin. At about 32 weeks', she received eltrombopag, 50–75 mg/day for about 3 days, but the thrombocytopenia was resistant to all of these agents. Romiplostim (weekly for three doses) was then given and the platelet count rose from $4 \times 10^9/L$ to $91 \times 10^9/L$. Because her platelet count began to fall, she was given the third dose of romiplostim 1 day before induction of labor at 34 weeks'. A healthy normal female baby was born with a normal platelet count (no additional details were provided) (2).

BREASTFEEDING SUMMARY

No reports describing the use of eltrombopag during human lactation have been located. The molecular weight (about 443 for the free acid) and the long elimination half-life suggest that the drug will be excreted into breast milk, but the high protein binding should limit the amount excreted. The risk to a nursing infant from exposure to the drug in milk is unknown.

The maximum oral absorption of eltrombopag in adults is approximately 52%,

but the absorption in infants is unknown. However, eltrombopag chelates polyvalent cations such as calcium and iron, and, in adults, this interaction can decrease plasma systemic exposure by as much as 70% (1). Thus, chelation by the calcium in milk might prevent clinically significant amounts from being absorbed. Nevertheless, the safest course is not to breastfeed if the mother is taking eltrombopag. If she chooses to do so, the infant should be monitored for the same adverse effects observed in adults: nausea and vomiting, myalgia, dyspepsia, ecchymosis, hepatotoxicity (increases in alanine aminotransferase [ALT], aspartate aminotransferase [AST], and bilirubin), conjunctival hemorrhage, and cataracts.

EMTRICITABINE

Antiviral

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

The animal data suggest low risk, but the limited human pregnancy experience prevents a complete assessment of the embryo–fetal risk. If indicated, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Emtricitabine is a synthetic nucleoside analog reverse transcriptase inhibitor. It is indicated, in combination with other antiretroviral agents, for the treatment of HIV-1 infections. Emtricitabine is in the same antiviral class as abacavir, didanosine, lamivudine, stavudine, tenofovir, zalcitabine, and zidovudine. Plasma protein binding of emtricitabine is <4% and the plasma elimination half-life is about 10 hours (1).

Reproduction studies have been conducted in mice, rats, and rabbits. In mice and rabbits, no evidence of fetal variations or congenital malformations was observed at systemic exposures (AUC) about 60 and 120 times, respectively, the human exposure at the recommended human daily dose of 200 mg based on AUC (HE). Fertility was normal in mice offspring exposed in utero through sexual maturity at about 60 times the HE. In addition, no effects on fertility were observed in male rats exposed to about 140 times the HE, or in male and female mice exposed to about 60 times the HE (1,2).

Emtricitabine crosses the placenta to the fetus in mice and rabbits. The average fetal plasma:maternal plasma ratio was about 0.40 in mice and 0.50 in rabbits (2). The placental passage is consistent with the relatively low molecular weight (about 247), low plasma protein binding, and long plasma elimination half-life of the antiviral. These factors suggest also that the agent will cross the human placenta.

The Antiretroviral Pregnancy Registry reported, for the period January 1989

through July 2009, prospective data (reported before the outcomes were known) involving 4702 live births that had been exposed during the 1st trimester to one or more antiretroviral agents (3). Congenital defects were noted in 134, a prevalence of 2.8% (95% confidence interval [CI] 2.4–3.4). In the 6100 live births with earliest exposure in the 2nd/3rd trimesters, there were 153 infants with defects (2.5%, 95% CI 2.1–2.9). The prevalence rates for the two periods did not differ significantly. There were 288 infants with birth defects among 10,803 live births with exposure anytime during pregnancy (2.7%, 95% CI 2.4–3.0). The prevalence rate did not differ significantly from the rate expected in a nonexposed population. There were 631 outcomes exposed to emtricitabine (384 exposed in the 1st trimester and 247 exposed in the 2nd/3rd trimesters) in combination with other antiretroviral agents. There were 16 birth defects (11 in the 1st trimester exposure and 5 in the 2nd/3rd trimesters). In reviewing the birth defects of prospective and retrospective (pregnancies reported after the outcomes were known) registered cases, the Registry concluded that, except for isolated cases of neural tube defects with efavirenz exposure in retrospective reports, there was no other pattern of anomalies (isolated or syndromic) (3). (See Lamivudine for required statement.)

Two reviews, one in 1996 and the other in 1997, concluded that all women receiving antiretroviral therapy should continue to receive therapy during pregnancy and that treatment of the mother with monotherapy should be considered inadequate therapy (4,5). The same conclusion was reached in a 2003 review with the added admonishment that therapy must be continuous to prevent emergence of resistant viral strains (6). In 2009, the updated U.S. Department of Health and Human Services guidelines for the use of antiretroviral agents in HIV-1 infected patients continued the recommendation that therapy, with the exception of efavirenz, should be continued during pregnancy (7). If indicated, emtricitabine should not be withheld in pregnancy because the expected benefit to the HIV-positive mother outweighs the unknown risk to the fetus. Updated guidelines for the use of antiretroviral drugs to reduce perinatal HIV-1 transmission also were released in 2010 (8). Women receiving antiretroviral therapy during pregnancy should continue the therapy but, regardless of the regimen, zidovudine administration is recommended during the intrapartum period to prevent vertical transmission of HIV to the newborn (8).

Three studies have reported the pharmacokinetics of emtricitabine in pregnant women with HIV (9–11).

A brief 2009 study reported multi-class HIV resistance in a 38-year-old

pregnant woman with twins (12). Starting at 25 weeks', she was successfully treated with a multidrug combination that included emtricitabine. The twins were born at 32 weeks'. Both had negative blood tests for HIV (12).

BREASTFEEDING SUMMARY

Consistent with the molecular weight (about 247), low plasma protein binding (<4%), and long plasma elimination half-life (about 10 hours), emtricitabine is excreted into human breast milk. Five women in Abidjan, Cote d'Ivoire, who were exclusively breastfeeding their infants were given emtricitabine/tenofovir at the start of labor and one tablet daily for 7 days postpartum (13). Maternal blood and milk samples were drawn on days 1, 2, 3, and 7. The median breast milk doses of emtricitabine and tenofovir were 2% and 0.03%, respectively, of the proposed oral infant doses (13).

In developed countries, reports on the use of emtricitabine during lactation are unlikely because the drug is indicated in the treatment of patients with HIV infection. HIV-1 is transmitted in milk, and in developed countries, breastfeeding is not recommended (4,5,7,14–16). In developing countries, breastfeeding is undertaken, despite the risk, because there are no affordable milk substitutes available.

ENALAPRIL

Antihypertensive

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

The fetal toxicity of enalapril in the 2nd and 3rd trimesters is similar to other angiotensin-converting enzyme (ACE) inhibitors. The use of this drug during the 2nd and 3rd trimesters may cause teratogenicity and severe fetal and neonatal toxicity. Fetal toxic effects may include anuria, oligohydramnios, fetal hypocalvaria, intrauterine growth restriction (IUGR), prematurity, and patent ductus arteriosus. Anuria-associated anhydramnios/oligohydramnios may produce fetal limb contractures, craniofacial deformation, and pulmonary hypoplasia. Severe anuria and hypotension, resistant to both pressor agents and volume expansion, may occur in the newborn following in utero exposure to valsartan. Newborn renal function and blood pressure should be closely monitored.

FETAL RISK SUMMARY

Enalapril, an ACE inhibitor, is used for the treatment of hypertension. Following oral administration, the prodrug enalapril is bioactivated by hydrolysis to the active agent, enalaprilat. Use of the drug in pregnant rats produced fetal growth restriction and, in two fetuses, incomplete skull ossification (1).

Enalaprilat crosses the human placenta. In an in vitro experiment using a human placental lobe, enalaprilat crossed to the fetal side with a mean transfer of 2.99% (2). The maximum concentration on the fetal side was about 20–48 ng/mL.

A number of references on the use of enalapril during pregnancy have appeared (3–22). A 1991 review summarized the cases of enalapril-exposed pregnancies published prior to January 1, 1990 (23). Use of enalapril limited to the 1st trimester does not appear to present a significant risk to the fetus, but

fetal exposure after this time has been associated with teratogenicity and severe toxicity in the fetus and newborn, including death. Of interest, an apparent autosomal recessive syndrome of renal tubular dysplasia with fetal/neonatal anuric renal failure, IUGR, and skull ossification defects, but without exposure to ACE inhibitors, has been described in five infants from two separate kindreds (24).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 40 newborns had been exposed to enalapril during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Four (10.0%) major birth defects were observed (two expected), including (observed/expected) 2/0.4 cardiovascular defects and 1/0.1 polydactyly. No anomalies were observed in four other categories of defects (oral clefts, spina bifida, limb reduction defects, and hypospadias) for which specific data were available.

A European survey on the use of ACE inhibitors in pregnancy briefly reviewed the results obtained in nine mother–child pairs (3). Two spontaneous abortions occurred: one at 7 weeks in a 44-year-old woman and one at 11 weeks in a 41-year-old diabetic patient. Enalapril, 20 mg/day, had been used from conception until abortion in the first case and from conception until 6 weeks' gestation in the second. In both cases, factors other than the drug therapy were probably responsible for the pregnancy losses. In a third case, enalapril (30 mg/day) was started at 24 weeks; the patient, with severe glomerulopathy, delivered a stillborn infant 2 weeks later. It is not known whether enalapril therapy was associated with the adverse outcome. The remaining six women were being treated at the time of conception with 10–20 mg/day for essential hypertension or lupus-induced hypertension. Therapy was discontinued by 7 weeks' gestation in four pregnancies, and at 28 weeks in one, and enalapril was continued throughout gestation (40 weeks) in one. Two infants were small for gestational age; one had been exposed only during the first 4 weeks, and one was exposed throughout (40 weeks). No anomalies were mentioned, nor were any other problems in the exposed liveborn infants. The growth restriction was probably due to the severe maternal disease (3).

A 1988 case report described a woman with pregnancy-induced hypertension who was treated with methyldopa and verapamil for 6 weeks with poor control of her blood pressure (4). At 32 weeks' gestation, methyldopa was discontinued and enalapril (20 mg/day) was combined with verapamil (360 mg/day), resulting in good control. An elective cesarean section was performed after 17 days of combination therapy. Oligohydramnios was noted,

as was meconium staining. The 2100-g female infant was anuric during the first 2 days, although tests indicated normal kidneys without obstruction. A renal biopsy showed hyperplasia of the juxtaglomerular apparatus. She began producing urine on the 3rd day (2 mL in a period of 24 hours), 12 hours after the onset of peritoneal dialysis. She remained oliguric when dialysis was stopped at age 10 days, producing only 30 mL of urine in a period of 24 hours. By the 19th postnatal day, her urine output had reached 125 mL/24 hours. The plasma enalaprilat concentration was 28 ng/mL before dialysis and then fell to undetectable (<0.16 ng/mL) levels after dialysis. ACE levels (normal 95 nmol/mL-minute) were <1 (days 2 and 3), 2.1 (day 5), 15.6 (day 8), 127 (day 31), and >130 nmol/mL (day 90). Angiotensin II concentrations (normal 182 fmol/mL) were still suppressed (39.8) on day 31; plasma renin activity, active renin, and total renin were all markedly elevated until day 90. By this time, renal function had returned to normal. Clinical follow-up at 1 year of age was normal (4).

A renal transplant patient was treated with enalapril, azathioprine, atenolol, and prednisolone (doses not given) throughout pregnancy (5). Ultrasound at 32 weeks' gestation indicated oligohydramnios and asymmetrical growth restriction. A 1280-g (10th percentile) male infant with a head circumference of 25.7 cm (3rd percentile) was delivered by cesarean section. Severe hypotension (mean 25 mmHg), present at birth, was resistant to volume expansion and pressor agents. The newborn was anuric for 72 hours, then oliguric, passing only 2.5 mL during the next 36 hours. Ultrasonography revealed a normal-sized kidney and a normal urinary tract. Peritoneal dialysis was commenced on day 8, but the infant died 2 days later. Defects secondary to oligohydramnios were squashed facies, contractures of the extremities, and pulmonary hypoplasia. Ossification of the occipital skull was absent. A chromosomal abnormality was excluded based on a normal male karyotype (46,XY). The renal failure and skull hypoplasia were probably caused by enalapril (5).

A 24-year-old woman with malignant hypertension and familial hypophosphatemic rickets was treated from before conception with enalapril (10 mg/day), furosemide (40 mg/day), calciferol, and slow phosphate (6). Blood pressure was normal at 15 weeks' gestation as was fetal growth. However, oligohydramnios developed 2 weeks later; by 20 weeks' gestation, virtually no fluid was present. Fetal growth restriction was also evident at this time. Enalapril and furosemide therapy were slowly replaced by labetalol over the next week, and a steady improvement in amniotic fluid volume was noted by

24 weeks. Volume was normal at 27 weeks' gestation, but shortly thereafter, abruptio placentae occurred, requiring an emergency cesarean section. A 720-g (below 3rd percentile) male infant was delivered who died on day 6. A postmortem examination indicated a normal urogenital tract (6).

An 18-year-old woman with severe chronic hypertension had four pregnancies over an approximately 4-year period, all while taking ACE inhibitors and other antihypertensives (7). During her first pregnancy, she had been maintained on captopril and she delivered a premature, growth-restricted, but otherwise healthy female infant who survived. In the postpartum period, captopril was discontinued and enalapril (10 mg/day) was started while continuing atenolol (100 mg/day) and nifedipine (40 mg/day). She next presented in the 13th week of her second pregnancy with unchanged antihypertensive therapy. Fetal death occurred at 18 weeks' gestation. The 340-g male fetus was macerated but otherwise normal. Her third and fourth pregnancies, again with basically unchanged antihypertensive therapy except for the addition of aspirin (75 mg/day) at the 10th week, resulted in the delivery of an 1170-g female and a 1540-g male, both at 29 weeks (7).

The case of a 27-year-old woman with scleroderma renal disease who was treated with both enalapril and captopril at different times in her pregnancy was published in 1989 (8). Treatment with enalapril (10 mg/day) and nifedipine (60 mg/day) had begun approximately 4 years before the woman presented at an estimated 29 weeks' gestation. Because of concerns for the potential fetal harm induced by the current treatment, therapy was changed to methyldopa. This agent failed to control the woman's hypertension and therapy with captopril (150 mg/day) was initiated at approximately 33 weeks' gestation, 4 weeks prior to delivery of a normal male infant weighing 1740 g. No evidence of renal impairment was observed in the infant (8).

A woman with active systemic lupus erythematosus became severely hypertensive at 22 weeks' gestation (9). Therapy included prednisone, phenytoin (for one episode of tonic-clonic seizure activity), and the antihypertensive agents enalapril, hydralazine (used only briefly), clonidine, nitroprusside, nifedipine, and propranolol. A 600-g male infant with hyaline membrane disease was delivered by cesarean section at 26 weeks' gestation. Severe, persistent hypotension (mean blood pressure during first 24 hours 18–23 mmHg) was observed that was resistant to volume expansion and dopamine. Both kidneys were normal by ultrasonography but no urine was visualized in the bladder. The infant died on the 7th day. Gross and microscopic examination of the kidneys at autopsy revealed no abnormalities.

Nephrogenesis was appropriate for gestational age (9).

A 1710-g male infant, delivered by cesarean section for fetal distress at 35 weeks' gestation, had been exposed to enalapril (20 mg/day) and diazepam (5 mg/day) from the 32nd week of pregnancy for the treatment of maternal hypertension (10). Prior to this, treatment had consisted of a 2-week course of methyldopa and amiloride plus hydrochlorothiazide. Except for a few drops, the growth-restricted infant produced no urine, and peritoneal dialysis was started at 86 hours of age. Renal ultrasonography indicated normal kidneys without evidence of obstruction. Renal function slowly improved following dialysis, but some impairment was still present at 18 months of age (10).

Investigators at the FDA reviewed five cases of enalapril-induced neonatal renal failure, one of which had been published previously in a 1989 report (11). Enalapril doses ranged from 10 to 45 mg/day. Two of the mothers were treated throughout gestation, one was treated from 27 to 34 weeks' gestation, and one was treated during the last 3 weeks only. All of the infants required dialysis for anuria. Renal function eventually recovered in two infants, it was still abnormal 1 month after birth in one, and tubular acidosis occurred in the fourth infant 60 days after delivery. Hypotension was reported in three of the four newborns. The authors cautioned that if enalapril was used during pregnancy, then preparations should be made for neonatal hypotension and renal failure (11).

In a 1991 abstract, the FDA investigators updated their previous report on ACE inhibitors and perinatal renal failure by listing a total of 29 cases: 18 were caused by enalapril, 9 by captopril, and 2 by lisinopril (12). Of the 29 cases, 12 (41%) were fatal (another fatal case was listed but it was apparently not caused by renal failure), 9 recovered, and 8 had persistent renal impairment. Only 2 deaths occurred among dialyzed patients. Two cases of oligohydramnios resolved when therapy was stopped before delivery, but one of the infants was stillborn (12).

A 1990 case report suggested that structural kidney defects may be a consequence of enalapril therapy (13). A 22-year-old mother, with systemic lupus erythematosus and severe chronic hypertension, was treated throughout gestation with enalapril (20 mg/day), propranolol (40 mg/day), and hydrochlorothiazide (50 mg/day). Blood pressure was well controlled on this regimen, and no evidence of active lupus occurred during pregnancy. Normal amniotic fluid volume was documented at 16 weeks' gestation followed by severe oligohydramnios at 27 weeks. Although normal fetal growth was observed, the male infant was delivered at 34 weeks' gestation by emergency

cesarean section because thick meconium was found on amniocentesis. No meconium was found below the vocal cords. The profound neonatal hypotension induced by enalapril required aggressive treatment with fluids and pressor agents. The newborn had the characteristic features of the oligohydramnios sequence. Both kidneys were morphologically normal by renal ultrasonogram, but no urine output was observed, and no urine was found in the bladder. The infant died at about 25 hours of age. Pulmonary hypoplasia, a condition secondary to oligohydramnios, was found at autopsy. Except for their large size, approximately 1.5 times the expected weight, the kidneys were grossly normal with normal vessels and ureters and a contracted bladder. Microscopic examination revealed a number of kidney abnormalities: irregular corticomedullary junctions; glomerular maldevelopment with a decreased number of lobulations in many of the glomeruli, and some congested glomeruli; a reduced number of tubules in the upper portion of the medulla with increased mesenchymal tissue; and tubular distension in the cortex and medulla. The investigators could not determine whether the renal defects were due to reduced renal blood flow secondary to enalapril, a direct teratogenic effect of the drug, or an effect of the specific drug combination. However, no renal anomalies have been reported after use of the other two drugs (see Hydrochlorothiazide and Propranolol), and similar renal defects have not been reported as a complication of maternal lupus (13).

Three cases of in utero exposure to ACE inhibitors, one of which was enalapril, were reported in a 1992 abstract (14). The infant, delivered at 32 weeks' gestation because of severe oligohydramnios and fetal distress, had growth restriction, hypocalvaria, short limbs, and renal tubular dysplasia. Profound neonatal hypotension and anuria were observed at birth and improved only with dialysis, but the infant died at 9 days of age due to the renal failure (14).

A woman took enalapril (10 mg/day) and furosemide (80 mg/day) throughout gestation for hypertension and delivered a 2.76-kg male infant at 37 weeks' gestation (19). An ultrasound at 20 weeks' had noted oligohydramnios, multicystic kidneys, a small thorax, and no visible bladder. The newborn died a few minutes after birth. Autopsy revealed low set ears, small epicanthic folds, bilateral talipes, a markedly bell-shaped thorax, grossly cystic kidneys, and no apparent normal renal tissue. The karyotype was normal (19).

A 1997 case report described the pregnancy outcome of a woman who was treated with enalapril (20 mg/day) for gestational hypertension from about 28 weeks' gestation to delivery at 36 weeks' (20). Severe oligohydramnios had

developed shortly before delivery. The growth-restricted, 2000-g male infant had hypocalvaria, anuria, and profound hypotension. Peritoneal dialysis was started at age 3 days. Before dialysis, the serum ACE level was 7.4 $\mu\text{mol/mL}$ (normal 20–30 $\mu\text{mol/mL}$). After dialysis, the level was 20.5 $\mu\text{mol/mL}$, whereas enalaprilat concentrations in the infant's serum and dialysate were 6.92 and 3.3 mcg/mL, respectively. Blood pressure normalized after 4 days of dialysis but chronic renal failure persisted. At 8 months of age, expansion of the calvarial bones with gradual closing of the fontanelles was evident and development, other than growth, was normal. However, the renal failure had worsened and the infant was on the waiting list for a renal transplant (20).

Ten pregnancies treated with enalapril were reported in a 1997 study of 19 pregnancies exposed to ACE inhibitors (21). Enalapril therapy was stopped in the 1st trimester in eight pregnancies and at 14 and 15 weeks', respectively, in the others. No congenital anomalies or renal dysfunction were noted in the 10 neonates (21).

The outcomes of 21 pregnancies exposed to ACE inhibitors between 1991 and 1996 were reported using data from the Danish Birth Registry (22). Exposure to the agents occurred at a median of 8 weeks' gestation (range 5–15 weeks'). No fetal or neonatal complications attributable to the drug therapy were discovered (22).

A 1992 reference described the effects of ACE inhibitors on pregnancy outcome (25). Among 106,813 women enrolled in the Tennessee Medicaid program who delivered either a liveborn or stillborn infant, 19 had taken either enalapril, captopril, or lisinopril during gestation. One newborn, exposed in utero to enalapril, was delivered at 29 weeks' gestation for severe oligohydramnios, IUGR, and fetal distress. Gradual resolution of the infant's renal failure occurred following dialysis (25).

Fourteen cases of fetal hypocalvaria or acalvaria were reviewed in a 1991 reference, one of which was due to enalapril (26). It was speculated that the underlying pathogenetic mechanism in these cases was fetal hypotension.

In an article examining the teratogenesis of ACE inhibitors, evidence was cited linking fetal calvarial hypoplasia with the use of these agents after the 1st trimester (27). The mechanism was thought to be related to drug-induced oligohydramnios that allowed the uterine musculature to exert direct pressure on the fetal skull. This mechanical insult, combined with drug-induced fetal hypotension, could inhibit peripheral perfusion and ossification of the calvaria (27).

A study published in 1992 examined microscopically the kidneys of nine

fetuses from chronically hypertensive mothers, one of whom was taking enalapril (28). It was concluded that the renal defects associated with ACE inhibitors were due to decreased renal perfusion and were similar to the defects seen in other conditions related to reduced fetal renal blood flow (28).

Because the fetal toxicity observed in humans in the second half of pregnancy does not have a similar counterpart in experimental animals, a 2001 review compared the pharmacokinetic and pharmacodynamic aspects of enalapril in humans and animals (29). The human fetus is more vulnerable to enalapril-induced toxicity because the specific targets of ACE inhibitors, the kidney and the renin-angiotensin system, are developed before the end of the 1st trimester. This is earlier than the development in animal species, where these specific targets develop near term. In animals, the best concordance in fetal pharmacodynamics to the human is seen with the rhesus monkey, and the least concordance is in rats, which may be partly attributable to pharmacokinetics. Although the placental passage of enalapril in rats has not been studied, the passage of ACE inhibitors with structures similar to enalapril is very low (29).

A retrospective study using pharmacy-based data from the Tennessee Medicaid program identified 209 infants, born between 1985 and 2000, that had 1st trimester exposure to ACE inhibitors (30). Infants of mothers with evidence of diabetes, either before or during pregnancy, were excluded, as were those exposed to angiotensin-receptor antagonists (ARBs), ACE inhibitors or other antihypertensives beyond the 1st trimester, and exposure to known teratogens. Two comparison groups, other antihypertensives (N = 202) and no antihypertensives (N = 29,096), were formed. The number of major birth defects in each of the three groups was 18 (8.6%), 4 (2%), and 834 (2.9%), respectively. Compared with the no-antihypertensives group, exposure to ACE inhibitors was associated with a significantly increased risk of major defects (relative risk [RR] 2.71, 95% confidence interval [CI] 1.72–4.27). When the analysis was conducted by the type of defect, the highest rates were with cardiovascular defects, 9, 2, and 294 respectively, RR 3.72, 95% CI 1.89–7.30, and with central nervous system defects, 3, 0, and 80, respectively, RR 4.39, 95% CI 1.37–14.02. The major defects observed in the subject group were: atrial septal defect (N = 6) (includes three with pulmonic stenosis and/or three with patent ductus arteriosus [PDA]), renal dysplasia (N = 2), PDA alone (N = 2), and one each of ventricular septal defect, spina bifida, microcephaly with eye anomaly, coloboma, hypospadias, intestinal and choanal atresia, Hirschsprung disease, and diaphragmatic hernia (30). In an accompanying

editorial, it was noted that neither previous reports of 1st trimester exposure to ACE inhibitors nor the animal studies had observed an increased risk of birth defects (31). It also was noted that no mechanism for ACE inhibitor-induced teratogenicity was known. A subsequent communication raising concerns about the validity of the study in terms of adequate exclusion of diabetes, charting and coding errors in busy medical practices, and the effects of maternal obesity (32) was addressed by the investigators (33).

Enalapril and other ACE inhibitors are human teratogens when used in the 2nd and 3rd trimesters, producing fetal hypocalvaria and renal defects. The cause of the defects and other toxicity is probably related to fetal hypotension and decreased renal blood flow. The compromise of the fetal renal system may result in severe, and at times fatal, anuria, both in the fetus and in the newborn. Anuria-associated oligohydramnios may produce pulmonary hypoplasia, limb contractures, persistent PDA, craniofacial deformation, and neonatal death (34,35). IUGR, prematurity, and severe neonatal hypotension may also be observed. Two reviews of fetal and newborn renal function indicated that both renal perfusion and glomerular plasma flow are low during gestation and that high levels of angiotensin II may be physiologically necessary to maintain glomerular filtration at low perfusion pressures (36,37). Enalapril prevents the conversion of angiotensin I to angiotensin II and, thus, may lead to in utero renal failure. Since the primary means of removal of the drug is renal, the impairment of this system in the newborn prevents elimination of the drug and its active metabolite, enalaprilat, resulting in prolonged hypotension. Newborn renal function and blood pressure should be closely monitored. If oligohydramnios occurs, stopping enalapril may resolve the problem but may not improve infant outcome because of irreversible fetal damage (34). In those cases in which enalapril must be used to treat the mother's disease, the lowest possible dose should be used combined with close monitoring of amniotic fluid levels and fetal well-being. Guidelines for counseling exposed pregnant patients have been published and should be of benefit to health professionals faced with this task (27,34).

The observation in Tennessee Medicaid data of an increased risk of major congenital defects after 1st trimester exposure to ACE inhibitors raises concerns about teratogenicity that have not been seen in other studies. Medicaid data are a valuable tool for identifying early signals of teratogenicity, but are subject to a number of shortcomings, and their findings must be considered hypotheses until confirmed by independent studies.

A 2012 review of the use of ACE inhibitors and ARBs in the 1st trimester

concluded that there may be an elevated teratogenic risk, but the risk appeared to be related to other factors (38). The factors, that typically coexist with hypertension in pregnancy, included diabetes, advanced maternal age, and obesity.

BREASTFEEDING SUMMARY

A study published in 1989 was unable to demonstrate the excretion of enalapril and enalaprilat in breast milk (39). Direct concentrations of enalapril, however, were not measured in this study. Three women, 3–45 days postpartum, were treated with enalapril for hypertension. One woman with chronic glomerulonephritis and slightly impaired renal function was treated with 5 mg twice daily for 40 days before the study. The other two women, both with essential hypertension and normal renal function, were treated with 10 mg (duration not specified). ACE activity in the serum of the women was markedly depressed 4 hours after treatment with activity dropping from 18.7–24.0 to 0.4–0.7 U/mL (reference value in controls 28.0 U/mL). ACE activity in milk samples was not affected: 11.7–18.6 U/mL before the dose vs. 12.4–15.4 U/mL 4 hours after the dose (reference value in controls 9.1–22.6 U/mL), indicating that little if any of the drug was excreted into milk. Concentrations of enalaprilat in maternal serum ranged from 23.9 to 48.0 ng/mL in the two women with normal renal function and 179 ng/mL in the woman with renal impairment. Milk levels were all <0.2 ng/mL, the level of sensitivity for the assay (39).

In contrast to the above study, concentrations of both enalapril and enalaprilat were measured in a study published in 1991 (40). A woman, 12 months postpartum, had been treated with enalapril (10 mg/day) for essential hypertension for 11 months. Twenty-four hours after her last dose, she was given 10 mg, and milk samples were drawn at 0, 4, 8.75, and 24 hours. Serum samples were also drawn at various times over the next 24 hours. The total amount of the enalapril and enalaprilat measured in the milk over the 24-hour sample period were 81.9 and 36.1 ng, respectively. These values corresponded to 1.44 and 0.63 ng/mL, respectively. The peak concentration of enalapril, 2.05 ng/mL, occurred in the 4-hour sample, whereas that of enalaprilat, 0.75 ng/mL, occurred in the 8.75-hour sample. When milk levels were compared with serum concentrations at these sampling times, the milk:serum ratios were 0.14 and 0.02, respectively (40).

In a third study, milk and serum concentrations of enalapril and enalaprilat were measured in five women at 0, 4, 6, and 24 hours after a single 20-mg

dose (41). The mean maximum milk concentration of enalapril was 1.74 ng/mL, whereas that of enalaprilat was 1.72 ng/mL. No enalapril was measured in the milk of one patient. The milk:serum ratio for the parent compound and the metabolite varied from 0 to 0.043 and from 0.021 to 0.031, respectively (41).

Based on the above data, the amount of enalapril and enalaprilat that could potentially be ingested by a breastfeeding infant appears to be negligible and is probably clinically insignificant. The American Academy of Pediatrics classifies enalapril as compatible with breastfeeding (42).

ENCAINIDE

[Withdrawn from the market. See 8th edition.]

ENFLURANE

General Anesthetic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Enflurane is teratogenic in mice but not in rats. No reports of its use early in human gestation have been located. The absence of human experience during organogenesis prevents an assessment of the risk for structural anomalies. In addition, general anesthesia usually involves the use of multiple pharmacological agents. Although no teratogenicity has been observed with other halogenated general anesthetic agents, only halothane has 1st trimester human exposure data (see Halothane). The potential reproductive toxicity (spontaneous abortion and infertility) of occupational exposure to halogenated general anesthetic agents has not been adequately studied.

FETAL RISK SUMMARY

Enflurane, a nonflammable general inhalation anesthetic agent administered via vaporizer, is indicated for the induction and/or maintenance of anesthesia during surgery. It also provides analgesia for vaginal delivery and, in low concentrations, is used to supplement other general anesthetic agents during delivery by cesarean section. Enflurane is in the same class of volatile liquid halogenated agents as desflurane, halothane, isoflurane, methoxyflurane, and sevoflurane. It is closely related chemically to desflurane and isoflurane (1). The blood–gas partition coefficient is 1.9 (1). This is higher (i.e., increased solubility in blood) than the value for either isoflurane (1.46) or desflurane (0.42) (see Desflurane or Isoflurane).

Studies in animals have not revealed evidence of carcinogenic or mutagenic effects. Reproduction studies, conducted in rats and rabbits at doses up to four times the human dose, revealed no evidence of impaired fertility or fetal harm

(1).

In a 1981 study with mice, chronic exposure to subanesthetic and anesthetic concentrations of enflurane was evaluated. High exposures, about 100 times greater than the level of human occupational exposure in unscavenged operating rooms, were associated with minor developmental variations (lumbar ribs and increased pelvic cavitation) and defects (cleft palate, minor skeletal and visceral anomalies). The effects were greater than those observed with methoxyflurane, but less than those with halothane (2).

In a second study by the authors of the above report, the effects of four general anesthetic agents were compared in pregnant rats (3). The doses and agents used were nitrous oxide (75%; 0.55 MAC), enflurane (1.65%; 0.75 MAC), halothane (0.8%; 0.75 MAC), and isoflurane (1.05%; 0.75 MAC). (Note: The minimum alveolar anesthetic concentration [MAC] is the concentration that causes immobility in 50% of patients exposed to a noxious stimulus such as a surgical incision; it represents the ED₅₀ (4).) Each agent was administered for 6 hours on each of three consecutive days in one of three gestational periods: pregnancy days 8–10, 11–13, or 14–16. Compared with controls, significantly decreased maternal weight gain was observed in three of the groups (nitrous oxide, isoflurane, and enflurane) after exposure on days 14–16. Exposure on those days resulted in significantly decreased fetal weight in all four groups, and when exposure occurred on days 8–10 in three groups (all except nitrous oxide). Nitrous oxide exposure during days 14–16 resulted in significant increases in total fetal wastage and resorptions (threefold increases). However, no major or minor teratogenic effects were observed in any of the groups (3).

The teratogenic potential of isoflurane, enflurane, and sevoflurane was studied by evaluating the effect of each agent on the proliferation and differentiation of cells exiting from the G1 phase of the cell cycle (5). The theory behind the study was that normal development during embryogenesis, organogenesis, and histogenesis depended upon the proliferation and differentiative processes of cell migration (5). For example, valproate, a known human teratogen, is a potent G1-phase inhibitor of the *in vitro* proliferation rate at concentrations less than two times the therapeutic plasma concentration. At anesthetic concentrations less than two times the MAC, the antiproliferative potency of the three agents was isoflurane = enflurane >> sevoflurane. However, in the growth-arrested cell population, there was no specific accumulation of any cell-cycle phase and no specific effect on the G1 phase. The investigators concluded that the three agents lacked the specific *in vitro*

characteristics of valproate (5).

In a 1990 study, mice were exposed for 8 hours to sevoflurane and enflurane combined with three different concentrations of oxygen (6). Both anesthetic agents caused cleft palate, but the incidence was lower than that observed with halothane. Increasing the concentrations of oxygen lowered the incidence of the defect (6).

Reviews have concluded that, in general, inhalational anesthetics are freely transferred to fetal tissues (7,8) and, in most cases, the maternal and fetal concentrations are equivalent (8). The low molecular weight (about 185) and the presence of enflurane in the maternal brain support this assertion.

Two reports described the use of enflurane in 100 women for anesthesia for cesarean section (9,10). No increase in newborn adverse effects was observed.

A small 1983 study compared the neonatal outcomes in four groups (10 patients each) of women receiving general anesthesia for cesarean section: 50% nitrous oxide and 50% oxygen either alone, or combined with 0.5% halothane, 1.0% enflurane, or 0.75% isoflurane (11). One newborn had an Apgar score less than 7 at 1 minute (enflurane group), but all newborns in all groups had scores of 7 or greater at 5 minutes. There were no significant differences between the groups in neonatal neurobehavior assessment 2–4 hours after delivery or in maternal or umbilical blood gas analysis at delivery (11).

In a 1977 in vitro study, enflurane was shown to have a statistically significant depressive effect on myometrial strips from nonpregnant and gravid uteri (12). Three anesthetic agents, isoflurane, enflurane, and halothane, were studied at three concentrations (0.5, 1.0, and 1.5 MAC). The amount of depression was dose-related for each agent and was similar with all agents (12).

In a study to determine if pregnancy decreases the MAC, enflurane and halothane were administered to 16 women (8 with each agent) scheduled for pregnancy termination at 8–13 weeks' gestation (13). A comparison group of 16 nonpregnant women undergoing laparoscopic sterilization received either enflurane or halothane (8 in each group). In pregnant women, the median MAC of 1.15 volume% (range 0.95–1.25) was less than that in nonpregnant women, 1.65% volume% (range 1.45–1.75) ($p = 0.0007$). The percentage decrease (95% confidence interval) for pregnant women was 30% (24%–36%). Similar results were found with halothane (13).

Chronic occupational exposure to anesthetic gases in operating rooms during pregnancy has raised concerns that such exposure could cause birth defects

and spontaneous abortions (14). The concentration of enflurane in an operating-room environment was stated to 5–46 parts per million (ppm) near the anesthesiologist and 1–8 ppm near the surgeon. A 1988 review cited a number of studies investigating the possible association between occupational exposure to anesthetic gases and adverse pregnancy outcomes (7). The reviewer concluded that serious methodological weaknesses in these studies precluded arriving at a firm conclusion, but a slightly increased risk of miscarriage was a possibility. However, there was no evidence of an association between occupational exposure and congenital anomalies (7).

In a 1982 study, the infants of mothers who had received analgesia before vaginal delivery consisting of either enflurane, nitrous oxide (both mixed with oxygen), or no inhalation agent were evaluated for neurobehavior during the first 24 hours (15). The infants were tested with the Neurologic and Adaptive Capacity Score at 15 minutes, 2 hours, and 24 hours, and with the Early Neonatal Neurobehavioral Scale at 2 and 24 hours. For all groups, scores were the lowest at 2 hours, but no significant differences were measured between the groups (15).

A 2004 study, however, found a significant association between maternal occupational exposure to waste anesthetic gases during pregnancy and developmental deficits in their children, including gross and fine motor ability, inattention/hyperactivity, and IQ performance (see Nitrous Oxide).

Enflurane has been used immediately prior to delivery for analgesia and anesthesia. This use does not appear to affect the newborn any differently than other general anesthetic agents. The uterine effects of enflurane (relaxation and increased blood loss) also appear to be similar to other agents in this class, but the low concentrations used clinically minimize these actions (16). All anesthetic agents can cause depression in the newborn that may last for 24 hours or more but, again, this is lessened by the low doses.

BREASTFEEDING SUMMARY

Although enflurane has been administered during labor and delivery, the effects of this exposure on the infant that begins nursing immediately after birth have not been described. Enflurane is probably excreted into colostrum and milk as suggested by its presence in the maternal blood and its low molecular weight (about 185), but the toxic potential of this exposure for the infant is unknown. However, the risk to a nursing infant from exposure to enflurane via milk is probably very low (17,18). Another halogenated inhalation anesthetic, halothane, is classified as compatible with breastfeeding by the American

Academy of Pediatrics (see Halothane).

ENFUVRTIDE

Antiviral

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Although the animal data suggest low risk, the limited human pregnancy experience prevents a more complete assessment of embryo–fetal risk. However, enfuvirtide has not been detected in cord blood at delivery or on the fetal side in the ex vivo human placenta perfusion model. If indicated, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Enfuvirtide, a linear 36-amino acid synthetic peptide administered by SC injection, is an inhibitor of the fusion of HIV-1 with CD4+ cells. It is in the same antiviral subclass of entry inhibitors as maraviroc. Enfuvirtide is indicated, in combination with other antiretroviral agents, for the treatment of HIV-1 infection in treatment-experienced patients with evidence of HIV-1 replication despite ongoing antiretroviral therapy. Plasma protein binding of enfuvirtide is about 92%, primarily to albumin and, to a lesser extent, to α_1 -acid glycoprotein. The agent is thought to undergo catabolism to the constituent amino acids with subsequent recycling of the amino acids in the body pool. The mean elimination half-life is 3.8 hours (1).

Reproduction studies have been conducted in rats and rabbits. In these species, SC doses up to 27 and 3.2 times, respectively, the human dose based on BSA (HD) revealed no evidence of fetal harm. In male and female rats, SC doses up to 1.6 times the HD had no effect on fertility (1).

Consistent with the high molecular weight (4492) and protein binding, three studies have found that the drug does not cross the human placenta. No transfer to the fetal side was noted in an ex vivo study, even with very high concentrations on the maternal side (2). The mean concentration in the maternal compartment of three term placentas from healthy women was

12,400 ng/mL, 2.5 times the maximum concentration recommended for treated patients, but the drug was not detected (<50 ng/mL) in the fetal venous samples (2). In a clinical study, maternal enfuvirtide (doses not specified) concentrations in two patients immediately before delivery at term were 3647 and 4135 ng/mL, but the drug was undetectable in cord blood (<50 ng/mL) in both cases (3). In a third report, the drug was not detected in the cord blood samples of twins born at 34 weeks from a woman treated with SC enfuvirtide 90 mg twice daily from 25 to 34 weeks (4).

Three reports have described the use of enfuvirtide with other antivirals for multidrug-resistant HIV during the second half of pregnancy. Healthy infants were delivered without evidence of HIV infection at birth or during long-term follow-up (5–7).

The Antiretroviral Pregnancy Registry reported, for the period January 1989 through July 2009, prospective data (reported before the outcomes were known) involving 4702 live births that had been exposed during the 1st trimester to one or more antiretroviral agents (8). Congenital defects were noted in 134, a prevalence of 2.8% (95% confidence interval [CI] 2.4–3.4). In the 6100 live births with earliest exposure in the 2nd/3rd trimesters, there were 153 infants with defects (2.5%, 95% CI 2.1–2.9). The prevalence rates for the two periods did not differ significantly. There were 288 infants with birth defects among 10,803 live births with exposure anytime during pregnancy (2.7%, 95% CI 2.4–3.0). The prevalence rate did not differ significantly from the rate expected in a nonexposed population. There were 31 outcomes exposed to enfuvirtide (19 in the 1st trimester and 12 in the 2nd/3rd trimesters) in combination with other antiretroviral agents. There were no birth defects. In reviewing the birth defects of prospective and retrospective (pregnancies reported after the outcomes were known) registered cases, the Registry concluded that, except for isolated cases of neural tube defects with efavirenz exposure in retrospective reports, there was no other pattern of anomalies (isolated or syndromic) (8). (See Lamivudine for required statement.)

Two reviews, one in 1996 and the other in 1997, concluded that all women currently receiving antiretroviral therapy should continue to receive therapy during pregnancy and that treatment of the mother with monotherapy should be considered inadequate therapy (9,10). The same conclusion was reached in a 2003 review with the added admonishment that therapy must be continuous to prevent emergence of resistant viral strains (11). In 2009, the updated U.S. Department of Health and Human Services guidelines for the use of antiretroviral agents in HIV-1 infected patients continued the recommendation

that therapy, with the exception of efavirenz, should be continued during pregnancy (12). If indicated, enfuvirtide should not be withheld in pregnancy because the expected benefit to the HIV-positive mother outweighs the unknown risk to the fetus. Updated guidelines for the use of antiretroviral drugs to reduce perinatal HIV-1 transmission also were released in 2010 (13). Women receiving antiretroviral therapy during pregnancy should continue the therapy but, regardless of the regimen, zidovudine administration is recommended during the intrapartum period to prevent vertical transmission of HIV to the newborn (13).

BREASTFEEDING SUMMARY

No reports describing the use of enfuvirtide during human lactation have been located. The high molecular weight (4492) and protein binding (92%) should inhibit, but may not prevent, excretion into human breast milk. The effect on a nursing infant is unknown. However, enfuvirtide is a 36-amino acid peptide and any amounts that enter milk should be digested by the nursing infant.

Reports on the use of enfuvirtide during lactation are unlikely because the drug is indicated in the treatment of patients with HIV infection. HIV-1 is transmitted in milk, and in developed countries, breastfeeding is not recommended (9,10,12,14–16). In developing countries, breastfeeding is undertaken, despite the risk, because there are no affordable milk substitutes available.

ENOXACIN

[Withdrawn from the market. See 9th edition.]

ENOXAPARIN

Anticoagulant

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

The use of enoxaparin during pregnancy appears to present no more fetal and/or newborn risk, and perhaps less, than that from standard, unfractionated heparin or from no therapy.

FETAL RISK SUMMARY

Enoxaparin is a low-molecular-weight-heparin (LMWH) product prepared from porcine intestinal mucosa heparin. The anticoagulant is not teratogenic or embryotoxic in rats and rabbits (1).

Enoxaparin has an average molecular weight of about 4500 (1). Because this is a relatively large molecule, it does not cross the placenta (2,3) and, thus, presents a low risk to the fetus.

Several reports have described the use of enoxaparin during pregnancy without maternal or fetal complications (4–15).

A woman with an extensive lower limb venous thrombosis was treated with unfractionated heparin for 2 weeks starting at 11 weeks' gestation and then changed to enoxaparin (4). She was continued on enoxaparin until delivery of a healthy infant at 34 weeks' gestation.

A 1992 reference described the use enoxaparin in six pregnant women for the treatment and prophylaxis of thromboembolism (5). In two women treated from the 8th or 9th gestational week, one ended with a healthy term infant and the other was progressing normally at 18 weeks (outcome was not available at time of the report). Three other women were treated during the 2nd and/or 3rd trimesters and had normal term deliveries. In the remaining case, a woman with Sjögren's syndrome and a history of deep venous thrombosis (DVT) and pulmonary embolism, developed a DVT at 18 weeks' gestation. She was treated for 10 days with IV heparin and then started on enoxaparin 40 mg twice daily. The DVT recurred at 25 weeks' gestation and she was again treated with

a course of IV heparin followed by SC heparin. Due to severe fetal distress after 5 days of SC heparin, an emergency cesarean section was performed. The infant died a few minutes after birth, but permission for an autopsy was refused. An examination of the placenta showed multiple hemorrhages (5).

The use of enoxaparin for the achievement of successful thromboprophylaxis in 16 women during 18 pregnancies was described in a 1994 communication (6). The mean gestational age at the start of therapy was 10 weeks. Eight women had a history of thromboembolism, six had thrombophilia, and two had systemic lupus erythematosus. A 20 mg SC dose once daily was used in the first 11 women, but because of low anti-factor Xa levels, the dose was increased to 40 mg SC once daily in the last 7 pregnancies. From the 18 pregnancies, there were 2 missed abortions and 2 mid-trimester abortions, all in pregnancies of women with anticardiolipin syndrome (6).

The thromboprophylaxis of 41 pregnancies (34 women), most with 40 mg enoxaparin SC daily, was described in a 1996 report (7). Some of these cases had been reported earlier in a 1995 abstract (8). Only one thromboembolic event occurred, a hepatic infarction in a woman treated with 20 mg/day SC. No maternal hemorrhages were observed even though the therapy was continued throughout labor, delivery, and the immediate postpartum period. Nineteen of the women underwent 24 surgical procedures while receiving enoxaparin, including cervical cerclage (N = 2), amniocentesis (N = 5), 2nd trimester terminations (N = 4), and cesarean section (N = 13). Epidural anesthesia during labor was used in nine women. No abnormal bleeding was observed in any of these cases and there were no reports of intraventricular hemorrhage in the neonates (7).

Enoxaparin, usually 40 mg SC daily starting in the 1st trimester, was used for prophylaxis in 61 women (69 pregnancies) at high risk for thromboembolism in a prospective study published in 1997 (9). Some of these patients (N = 18) had been reported earlier (6). Mean steady-state plasma heparin levels, as determined by anti-factor Xa assay, following a 40 mg dose were three times as high as those with 20 mg, 0.09 vs. 0.03 U/mL, respectively, but were not affected by gestational age. No increased bleeding risk during pregnancy was observed and no episodes of thromboembolism in pregnancy occurred, although one patient, treated with 20 mg, had a postpartum pulmonary embolus. Further, no cases of epidural hematomas were observed in the 43 patients receiving regional analgesia or anesthesia. Six pregnancy losses were recorded, four described earlier (6) and two new cases of fetal deaths at 18 and 26 weeks, both in women with lupus anticoagulant and previous fetal loss.

Other than seven preterm deliveries, none of which were attributable to drug therapy, the remaining fetal and newborn outcomes were normal. Decreased bone density after delivery (lumbar spine or hip; 1 SD below the mean for nonpregnant age-matched women) was measured in 9 of 26 women after 28 pregnancies. In seven of these cases, unfractionated heparin had been used previously. Based on other published studies, the investigators could not determine whether the low bone density was present before treatment with enoxaparin, or if it was caused by pregnancy and breastfeeding, but a previous study with another LMWH (see Dalteparin) found no effect on bone density (9).

A 1997 case report described the use of enoxaparin (dose not specified) throughout most of the gestation, including labor, in a woman with congenital hypofibrinogenemia and protein S deficiency (10). A male infant with hypofibrinogenemia was delivered by cesarean section at 38 weeks' gestation.

A number of other studies (11–15) and reviews (3,16–22) have described the safe use of enoxaparin and other LMWH agents during pregnancy. Use of LMWH within 2 hours prior to cesarean section, however, was associated with an increase in wound hematoma (23). Also, lower maximum enoxaparin concentrations and anti-factor Xa activity levels occur during pregnancy compared with the nonpregnant state, thus requiring dose adjustments (24).

An opinion of the American College of Obstetricians and Gynecologists (ACOG) states that LMWH is at least as effective in pregnant patients with venous thrombosis, pulmonary embolism, or thrombophilic disorders as unfractionated heparin (25). Moreover, LMWHs have the advantages of ease of administration and less frequent laboratory monitoring. LMWHs may also reduce maternal complications, compared with standard heparin, such as bleeding, osteoporosis, and thrombocytopenia (3). However, there is inadequate information to recommend the use of LMWH in a pregnant woman with a mechanical heart valve (25).

BREASTFEEDING SUMMARY

No reports describing the use of enoxaparin during lactation have been located. However, due to the relatively high molecular weight of this drug, and its inactivation in the gastrointestinal tract if it was ingested orally, its passage into milk and subsequent risk to a nursing infant should be considered negligible.

ENTACAPONE

Anti-Parkinson Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

One report describing the use entacapone in human pregnancy has been located. The drug is teratogenic in rats at plasma exposures close to those observed in humans, but no teratogenicity was seen in rabbits. Entacapone is always used with levodopa/carbidopa and, although the data are very limited, these latter agents do not appear to present a major risk to the human fetus. (See Carbidopa and Levodopa.) Moreover, conditions requiring the use of levodopa/carbidopa during the childbearing years are relatively uncommon and, thus, the use of entacapone should also be uncommon. Although the near absence of human pregnancy experience prevents an assessment of the risk to the embryo–fetus, inadvertent exposure to entacapone during early gestation does not appear to represent a significant risk.

FETAL RISK SUMMARY

Entacapone is indicated as an adjunct to levodopa/carbidopa in patients experiencing end-of-dose “wearing off” effect. The agent is a selective and reversible inhibitor of catechol-O-methyltransferase (COMT), an enzyme involved in the metabolism of levodopa. Inhibition of COMT by entacapone allows for more sustained plasma levels of levodopa resulting in greater beneficial effects on the signs and symptoms of Parkinson’s disease. Entacapone is nearly completely metabolized and elimination is biphasic with elimination half-lives of 0.4–0.7 hours (β -phase; serum) and 2.4 hours (γ -phase; tissue) (1).

Entacapone did not impair fertility or general reproductive performance in rats at doses producing systemic exposures up to 28 times the human

exposure based on AUC from a maximum recommended daily dose of 1600 mg (HE-MRDD), but did delay mating at the highest dose. In addition, entacapone was mutagenic and clastogenic in one in vitro mouse assay but not in other assays (1).

Reproduction tests have been conducted in rats and rabbits. In pregnant rats treated during organogenesis, systemic exposure 34 times the HE-MRDD, without producing overt maternal toxicity, caused increased incidences of variations in fetal development. There was no evidence of impaired development in the offspring when this dose was given during late gestation and throughout lactation. When doses producing systemic exposures seven times the HE-MRDD or greater were given before mating and during early gestation, an increased incidence of fetal eye anomalies (microphthalmia, anophthalmia) was observed. In pregnant rabbits, systemic exposure 0.4 times the HE-MRDD or greater during organogenesis resulted in increased incidences of abortions, late/total resorptions, and decreased fetal weights. However, these doses were maternal toxic in rabbits. No teratogenic effects were observed in rabbits (1).

Although entacapone is always combined with levodopa/carbidopa, and levodopa is known to cause fetal toxicity and visceral and skeletal malformations in rabbits (see Levodopa), the potential reproductive toxicity and teratogenicity of combined entacapone–levodopa/carbidopa has not been studied in animals (1).

It is not known if entacapone crosses the human placenta to the fetus. The molecular weight (about 305) is low enough that embryo and fetal exposure probably occur, but the short elimination half-life will limit the degree of exposure.

A woman with a 12-year history of Parkinson's disease was treated throughout gestation with levodopa, carbidopa, entacapone, and bromocriptine (2). She gave birth at term to a 3175-g female infant, without deformities, with Apgar scores of 9, 10, and 10. Generalized seizures occurred in the infant 1 hour after birth followed by repeated episodes of shivering throughout the first day that responded to diazepam. Slowly improving hypotonia also was observed during the first week. Pneumonia was diagnosed but an extensive workup for the cause of seizures was negative. The child was developing normally at 1 year of age and has not had any other seizures (2).

BREASTFEEDING SUMMARY

No reports describing the use of entacapone during human lactation have been

located. The molecular weight (about 305) is low enough that excretion into milk should be expected, but the relatively short elimination half-life should limit the amount in milk. Entacapone is always given with levodopa/carbidopa. Even though levodopa inhibits prolactin release, normal lactation has been reported while women were being treated with the drug, and levodopa is excreted into breast milk. In addition, the effect of entacapone on levodopa metabolism will increase the amount of plasma levodopa available for transfer into milk. The use of carbidopa during lactation has also been described. (See Carbidopa.) Therefore, a nursing infant will probably be exposed to all three drugs via the milk. The effects of this multiple exposure on a nursing infant are unknown but warrant investigation.

ENTECAVIR

Antiviral

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >> Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated (HIV) No Human Data—Probably Compatible (Hepatitis B)

PREGNANCY SUMMARY

The human pregnancy experience with entecavir is limited. No structural anomalies have been reported. The animal data suggest low risk. If indicated, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Entecavir is a guanosine nucleoside analog with selective activity against hepatitis B virus (HBV). It is indicated for the treatment of chronic hepatitis B infection in adults with evidence of active viral replication and other evidence of persistent elevations in serum aminotransferases (ALT or AST) or histologically active disease. This indication is based on responses after 1-year of treatment in nucleoside-treatment-naïve and lamivudine-resistant adult patients with HBeAg-positive or HBeAg-negative chronic HBV infection with compensated liver disease and on more limited data in adult patients with HIV/HBV co-infection who have received prior lamivudine therapy. Binding to human serum proteins is low (about 13%) and only minor metabolites have been identified. The terminal elimination half-life is about 128–149 hours (1).

Reproduction studies have been conducted in rats and rabbits. Oral doses in these species resulting in systemic exposures up to about 28 and 212 times the human exposure achieved with the maximum recommended human dose of 1 mg/kg (MRHD), respectively, caused no embryo or maternal toxicity. In rats, doses 3100 times the MRHD caused maternal toxicity, embryo–fetal toxicity (resorptions), lower fetal body weights, tail and vertebral malformations, reduced ossification (vertebrae, sternebrae, and phalanges), and extra lumbar vertebrae and ribs. In rabbits, exposures 883 times the MRHD caused embryo–fetal toxicity (resorptions), reduced ossification (hyoid), and an

increased incidence of 13th rib. In a rat peri-postnatal study, systemic exposures greater than 94 times the MRHD revealed no evidence of adverse effects in offspring (1).

Long-term carcinogenicity studies in mice and rats were positive. In mice, exposures from 3 to 42 times the MRHD resulted in various tumors involving the lungs (may have been a species effect), hepatocellular carcinomas, hemangiomas of ovaries and uterus, and hemangiosarcomas of the spleen. In female rats, hepatocellular adenomas, and combined carcinomas and adenomas were observed at 24 times the MRHD, whereas skin fibromas were induced at 4 times the MRHD. In male and female rats, brain gliomas were induced at 35 and 24 times the MRHD, respectively. Entecavir was not mutagenic in various assays, but clastogenicity was observed in human lymphocyte culture (1).

No evidence of impaired fertility was observed in male and female rats given doses resulting in exposures greater than 90 times the MRHD. However, in other studies, exposures greater than 35 times the MRHD resulted in seminiferous tubular degeneration in rodents and dogs, but not in monkeys (1).

It is not known if entecavir crosses the human placenta. The molecular weight (about 277), minimal metabolism, and long elimination half-life suggest that the drug will cross to the embryo and fetus.

The Antiretroviral Pregnancy Registry reported, for the period January 1989 through July 2009, prospective data (reported before the outcomes were known) involving 4702 live births that had been exposed during the 1st trimester to one or more antiretroviral agents (2). Congenital defects were noted in 134, a prevalence of 2.8% (95% confidence interval [CI] 2.4–3.4). In the 6100 live births with earliest exposure in the 2nd/3rd trimesters, there were 153 infants with defects (2.5%, 95% CI 2.1–2.9). The prevalence rates for the two periods did not differ significantly. There were 288 infants with birth defects among 10,803 live births with exposure anytime during pregnancy (2.7%, 95% CI 2.4–3.0). The prevalence rate did not differ significantly from the rate expected in a nonexposed population. There were 10 outcomes exposed to entecavir (9 in the 1st trimester and 1 in the 2nd/3rd trimesters) in combination with other antiretroviral agents. There were no birth defects. In reviewing the birth defects of prospective and retrospective (pregnancies reported after the outcomes were known) registered cases, the Registry concluded that, except for isolated cases of neural tube defects with efavirenz exposure in retrospective reports, there was no other pattern of anomalies (isolated or syndromic) (2). (See Lamivudine for required statement.)

BREASTFEEDING SUMMARY

No reports describing the use of entecavir during human lactation have been located. The molecular weight (about 277), minimal metabolism, and long elimination half-life (128–149 hours) suggest that the drug will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown. Infants of HBsAg-positive or HBeAg-positive mothers should receive hepatitis B immune globulin at birth, followed by the start of the hepatitis B vaccine series soon after birth (3). After the infant receives the first dose of immune globulin, breastfeeding is then permitted (4). However, breastfeeding is contraindicated in women infected with HIV.

ENZALUTAMIDE

Antineoplastic (Antiandrogen)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of enzalutamide in human pregnancy have been located. However, such reports are unlikely because of the indication. Animal reproductive studies have not been conducted. If the drug was used in pregnancy, the mechanism of action suggests that it could cause fetal harm. A 2013 study concluded that the androgen receptor was a key regulator for myometrial cell proliferation and disruption of myometrial growth could affect the outcome of pregnancy and labor (1).

FETAL RISK SUMMARY

Enzalutamide is an oral antineoplastic that is given daily (160 mg/day). It is an androgen receptor inhibitor that acts on different steps in the androgen receptor signaling pathway. Enzalutamide is indicated for the treatment of patients with metastatic castration-resistant prostate cancer who have previously received docetaxel. The drug undergoes hepatic metabolism to an active and inactive metabolites. Enzalutamide is 97%–98% bound to plasma proteins, primarily to albumin, whereas the active metabolite is 95% bound to plasma protein. The mean terminal half-life after a single dose in patients is 5.8 days (range 2.8–10.2 days). After a single 160 mg dose in healthy volunteers, the mean terminal half-life for the active metabolite was about 7.8–10.6 days (2).

Reproduction studies in animals have not been conducted (2).

Long-term animal studies to evaluate the potential for carcinogenicity have not been conducted. The drug was not mutagenic in multiple assays. In a long-term study in male rats, atrophy of the prostate and seminal vesicles was observed at dose that was equal to the human exposure based on AUC (HE). In dogs, hypospermatogenesis and atrophy of the prostate and epididymides was observed at a dose that was 0.3 times the HE (2).

It is not known if enzalutamide or its active metabolite cross the human placenta. The molecular weight (about 464) and the long elimination half-life suggest that the drug will cross to the embryo–fetus, although the high plasma protein binding (97%–98%) might limit the amount crossing.

BREASTFEEDING SUMMARY

No reports describing the use of enzalutamide during human lactation have been located. However, such reports are unlikely because of the indication. Nevertheless, if the drug was used during breastfeeding, the molecular weight (about 464) of the parent drug and its long mean elimination half-life (5.8 days; range 2.8–10.2 days) in patients suggest that the drug will be excreted into breast milk, although the high plasma protein binding (97%–98%) might limit the amount excreted.

EPHEDRINE

Sympathomimetic/Bronchodilator

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Ephedrine is a sympathomimetic used widely for bronchial asthma, allergic disorders, hypotension, and the alleviation of symptoms caused by upper respiratory infections. It is a common component of proprietary mixtures containing antihistamines, bronchodilators, and other ingredients. Thus, it is difficult to separate the effects of ephedrine on the fetus from other drugs, disease states, and viruses. Ephedrine-like drugs are teratogenic in some animal species, but human teratogenicity has not been suspected (1,2).

FETAL RISK SUMMARY

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 373 of whom had 1st trimester exposure to ephedrine (3, pp. 345–356). For use anytime during pregnancy, 873 exposures were recorded (3, p. 439). No evidence for a relationship to large categories of major or minor malformations or to individual defects was found. However, an association in the 1st trimester was found between the sympathomimetic class of drugs as a whole and minor malformations (not life-threatening or major cosmetic defects), inguinal hernia, and clubfoot (3, pp. 345–356).

Ephedrine is routinely used to treat or prevent maternal hypotension following spinal anesthesia (4–7). Significant increases in fetal heart rate and beat-to-beat variability may occur, but these effects may have been the result of normal reflexes following hypotension-associated bradycardia. A recent study, however, has demonstrated the placental passage of ephedrine with fetal levels at delivery approximately 70% of the maternal concentration (8). The presence of ephedrine in the fetal circulation is probably a major cause of the fetal heart rate changes.

BREASTFEEDING SUMMARY

A single case report has been located describing adverse effects in a 3-month-old nursing infant of a mother consuming a long-acting preparation containing 120 mg of d-isoephedrine and 6 mg of dexbrompheniramine (9). The mother had begun taking the preparation on a twice daily schedule 1 or 2 days prior to onset of the infant's symptoms. The infant exhibited irritability, excessive crying, and disturbed sleeping patterns that resolved spontaneously within 12 hours when breastfeeding was stopped.

EPINASTINE

Antihistamine (Ophthalmic)

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of epinastine in human pregnancy have been located. The animal reproduction data, even though the comparison to the human dose was based on body weight, suggest low risk. Although the absence of human pregnancy experience prevents a more complete assessment, the very low systemic bioavailability, and the human experience with other agents in the antihistamine class, suggests that there is little if any embryo or fetal risk from epinastine.

FETAL RISK SUMMARY

Epinastine, a topically active H₁-receptor antagonist and inhibitor of histamine from mast cells, is indicated for the prevention of itching associated with allergic conjunctivitis. It is administered as a 0.05% ophthalmic solution. Systemic bioavailability is low with average maximum plasma concentrations of 0.04 ng/mL measured after one drop in each eye twice daily for 7 days. There was no accumulation in the plasma. Less than 10% of epinastine undergoes metabolism. Binding to plasma proteins (64%) is moderate, but the terminal plasma elimination half-life is prolonged (about 12 hours) (1).

Reproduction studies have been conducted in rats and rabbits. In pregnant rats, maternal toxicity with no embryo or fetal effects was observed with an oral dose that was about 150,000 times the maximum recommended ocular human dose based on body weight (MROHD). However, pup body weight gain was reduced at a dose that was about 90,000 times the MROHD. In pregnant rabbits, resorptions and abortion occurred at an oral dose that was about 55,000 times the MROHD (1).

Carcinogenicity studies in mice and rats were negative at doses up to 30,000

times the MROHD. Epinastine also was negative in multiple studies for mutagenic and clastogenic effects. There was no effect on fertility in male rats, but decreased fertility was noted in female rats at an oral dose of about 90,000 times the MROHD (1).

It is not known if epinastine crosses the human placenta. The molecular weight (about 250 for the free base), low metabolism, moderate plasma protein binding, and prolonged elimination half-life suggest that the antihistamine will cross the placenta. However, the low systemic bioavailability probably prevents clinically significant amounts of the drug from reaching the embryo and fetus.

BREASTFEEDING SUMMARY

No reports describing the use epinastine during human lactation have been located. The molecular weight (about 250 for the free base), low metabolism, moderate plasma protein binding (64%), and prolonged elimination half-life (about 12 hours) suggest that the antihistamine will be excreted into human breast milk. However, the low systemic bioavailability probably prevents clinically significant amounts of the drug from appearing in milk. Moreover, in general, antihistamines obtaining therapeutic systemic concentrations are classified as compatible with breastfeeding. Epinastine should be classified similarly.

EPINEPHRINE

Sympathomimetic/Bronchodilator

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

In situations such as maternal hypotension where a pressor agent is required, use of ephedrine is a better choice than epinephrine.

FETAL RISK SUMMARY

Epinephrine is a sympathomimetic that is widely used for conditions such as shock, glaucoma, allergic reactions, bronchial asthma, and nasal congestion. Because it occurs naturally in all humans, it is difficult to separate the effects of its administration from effects on the fetus induced by endogenous epinephrine, other drugs, disease states, and viruses.

The drug readily crosses the placenta (1). Epinephrine is teratogenic in some animal species, but human teratogenicity has not been suspected (2,3). The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 189 of whom had 1st trimester exposure to epinephrine (4, pp. 345–356). For use anytime during pregnancy, 508 exposures were recorded (4, p. 439). A statistically significant association was found between 1st trimester use of epinephrine and major and minor malformations. An association was also found with inguinal hernia after both 1st trimester and anytime use (4, pp. 477, 492). Although not specified, these data may reflect the potentially severe maternal status for which epinephrine administration is indicated.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 35 newborns had been exposed to epinephrine (route not specified) during the 1st trimester (F. Rosa, personal communication, FDA, 1993). No major birth defects were observed (1.5 expected).

Theoretically, epinephrine's α -adrenergic properties might lead to a decreased in uterine blood flow. A large intravenous dose of epinephrine, 1.5

mL of a 1:1000 solution during a 1-hour period to reverse severe hypotension secondary to an allergic reaction, may have contributed to intrauterine anoxic insult to a 28-week-old fetus (5). Decreased fetal movements occurred after treatment and the infant, delivered at 34 weeks' gestation, had evidence of intracranial hemorrhage at birth and died 4 days later.

BREASTFEEDING SUMMARY

No reports describing the use of epinephrine during human lactation have been located.

EPIRUBICIN

Antineoplastic

PREGNANCY RECOMMENDATION: Contraindicated—1st Trimester

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Epirubicin is a cell-cycle phase nonspecific anthracycline in the same antineoplastic class as daunorubicin, doxorubicin, idarubicin, and valrubicin. It is used as adjuvant therapy in patients with breast cancer. The mechanism of action includes the inhibition of nucleic acid (DNA and RNA), protein synthesis, and DNA helicase activity. There are no reports describing the use of this agent during organogenesis.

FETAL RISK SUMMARY

In reproduction studies, epirubicin was embryolethal (increased resorptions and postimplantation loss) in pregnant rats administered an IV dose about 0.04 times the maximum recommended single human dose based on BSA (MRHD) during days 5–15 of gestation (1). Intrauterine growth restriction (IUGR), but not teratogenicity, was also observed with this dose. Doses as low as 0.005 times the MRHD resulted in embryolethality, and IUGR was evident at a dose 0.0015 times the MRHD. At a dose approximately 2.5 times the MRHD given on days 9 and 10 of gestation, fetal deaths, reduced placental weight, and multiple congenital malformations (external: anal atresia, misshapen tail, abnormal genital tubercle; visceral: gastrointestinal, urinary, and cardiovascular systems; skeletal: deformed long bones and girdles, rib abnormalities, irregular spinal ossification) were observed (1). In contrast, a dose 0.02 times the MRHD during days 6–18 of gestation in rabbits was not embryotoxic or teratogenic (1). Administration of maternally toxic doses in rabbits caused abortions and delayed ossification, but no teratogenicity. In fertility studies with male and female rats, mice, rabbits, and dogs, various low doses of epirubicin were associated with atrophy of the testes and epididymis, reduced spermatogenesis, or uterine atrophy (1).

It is not known if epirubicin crosses the placenta. The molecular weight

(about 580) is low enough that transfer to the human embryo and fetus should be expected.

The manufacturer's product information describes two human pregnancies in which epirubicin was administered (1). In the first case, a 34-year-old woman at 28 weeks' gestation, who was diagnosed with breast cancer, was treated with epirubicin and cyclophosphamide every 3 weeks for three cycles. The last dose was given at 34 weeks' gestation and she delivered a healthy baby 1 week later. No follow-up of the infant after birth was mentioned. The second case involved a 34-year-old woman with breast cancer metastatic to the liver who was randomized to the FEC-50 regimen (epirubicin, 5-fluorouracil, and cyclophosphamide). She was removed from the study because of pregnancy, but the gestational age and number of doses received were not specified. The pregnancy ended with a spontaneous abortion (1).

A 30-year-old woman at about 25 weeks' gestation was treated with four courses of epirubicin (100 mg) and vincristine (2 mg) for non-Hodgkin's lymphoma (2). Prednisolone was also given during each treatment and then tapered. Her disease responded well to the therapy. Labor was induced at 34 weeks' gestation and she gave birth to a normal 2.32-kg, 44.5-cm long female infant with Apgar scores of 8 at 1 and 5 minutes. The mother has remained in complete remission and her child appeared to be doing well at 4 years of age.

A 1996 report described the case of a 39-year-old woman with extensive metastatic breast cancer who had a unilateral mastectomy and axillary dissection at 29 weeks' gestation (3). After surgery, she was started on combination chemotherapy with epirubicin (50 mg/m²), 5-fluorouracil (600 mg/m²), and cyclophosphamide (600 mg/m²). At 35 weeks' gestation, a few days after receiving her second course of therapy, she developed eclamptic tonic-clonic seizures. She subsequently delivered a healthy but growth-restricted (1650-g; <10th percentile) infant. Although hypertension and proteinuria were not detected before the seizures, both were documented in the postpartum period. No follow-up of the infant after delivery was reported.

A 1999 report from France described the outcomes of pregnancies in 20 women with breast cancer who were treated with antineoplastic agents (4). The first cycle of chemotherapy occurred at a mean gestational age of 26 weeks' with delivery occurring at a mean 34.7 weeks. A total of 38 cycles were administered during pregnancy with a median of two cycles per woman. None of the women received radiation therapy during pregnancy. The pregnancy outcomes included two spontaneous abortions (SAB) (both exposed in the 1st trimester), one intrauterine death (exposed in the 2nd trimester), and

17 live births, one of whom died at 8 days of age without apparent cause. The 16 surviving children were developing normally at a mean follow-up of 42.3 months (4). Epirubicin (E), in combination with various other agents (cyclophosphamide [C], fluorouracil [F], methotrexate [M], or vincristine [V]) was administered to 10 of the women at a mean dose of 70 mg/m² (range 50–100 mg/m²). The outcomes were two SAB (ECF, EMV; 1st trimester), one stillbirth (one cycle of EC at 23 weeks'), one neonatal death (one cycle of ECF 32 days before birth), and six surviving liveborn infants (one EC, five ECF; all in the 3rd trimester). One of the infants, exposed to two cycles of ECF with the last at 25 days before birth, had transient leukopenia (4).

Occupational exposure of the mother to antineoplastic agents during pregnancy may present a risk to the fetus. A position statement from the National Study Commission on Cytotoxic Exposure and a research article involving some antineoplastic agents are presented in the monograph for cyclophosphamide (see Cyclophosphamide).

BREASTFEEDING SUMMARY

No reports describing the use of epirubicin during human lactation have been located. The molecular weight (about 580) is low enough that excretion into breast milk should be expected. In addition, another anthracycline (see Doxorubicin) is excreted into human milk. Because of the potential for serious adverse effects, such as immune suppression, carcinogenesis, neutropenia, and unknown effects on growth, women receiving epirubicin should not breastfeed.

EPOETIN ALFA

Hematopoietic

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

The use of recombinant human erythropoietin (epoetin alfa) does not seem to present a major risk to the fetus. The glycoprotein does not cross the human placenta to the fetus. The severe maternal hypertension or worsening of renal disease requiring delivery of the fetus that occurred in four pregnancies may be an adverse effect of the drug therapy, a consequence of the preexisting renal disease or current pregnancy, or a combination of these factors. The contribution of epoetin alfa to the case of abruptio placentae in a woman with severe hypertension and chronic renal insufficiency is unknown. No cases of thrombosis were reported in pregnant women treated with epoetin alfa, but this is a potentially serious complication. Because anemia and the need for frequent blood transfusions also present significant risks to the mother and fetus, it appears that the benefits derived from the use of epoetin alfa outweigh the known risks.

FETAL RISK SUMMARY

Recombinant human erythropoietin (epoetin alfa), a 165-amino acid glycoprotein produced by a recombinant DNA method with the same biologic effects as endogenous erythropoietin, is used to stimulate red blood cell production.

Fetal toxicity (decreased growth, delays in appearance of abdominal hair, delayed eyelid opening, delayed ossification, and decreases in the number of caudal vertebrae) was observed in the offspring of pregnant rats dosed with 500 U/kg (five times the human dose) (1). In addition, a trend toward increased fetal wastage occurred in pregnant rats dosed with 100 and 500 U/kg. No fetal adverse effects were seen in rabbits at doses up to 500 U/kg from day 6 to 18 of gestation (1).

Epoetin alfa crosses the placenta in significant amounts to the fetus in pregnant mice (2) but not from the mother to the fetus (3) or from the fetus to the mother in sheep (4). Another study also found no transfer of recombinant epoetin alfa to the fetus in sheep and monkeys, in spite of high maternal concentrations (5). The question of human placental transfer of endogenous erythropoietin and epoetin alfa was examined in a 1993 review (6). Five reasons arguing against transfer were presented: poor correlation between maternal and fetal levels, high correlation between fetal plasma and amniotic fluid levels, high molecular weight, animal studies, and one human in vitro study (6). Since then, several studies have investigated whether or not epoetin alfa is transferred across the human placenta (7–15).

A 1992 study measured an elevated cord erythropoietin level (62 mIU/mL; normal <19) in an infant whose mother was receiving 150 U/kg/week (9000 U/week) of the drug (7). However, because the mother had insulin-dependent diabetes, a disease known to display elevated cord levels of erythropoietin (8–10), the investigators could not determine whether the cord concentrations were due to exogenous or endogenous erythropoietin (7). The lack of correlation between maternal and fetal erythropoietin concentrations, at least between 19 and 28 weeks' gestation, suggests that endogenous maternal erythropoietin does not cross the placenta to the fetus (10). At 7–12 weeks' gestation, however, mean maternal and extraembryonic coelomic fluid concentrations of endogenous erythropoietin were nearly identical, 15.4 mU/mL (range 6.8–32.1 mU/mL) compared with 15.45 mU/mL (range 5.6–29.4 mU/mL), respectively (11). Passage of maternal erythropoietin to the coelomic fluid via the decidualized endometrium was offered as a possible explanation for the identical levels. This latter study also found low amniotic fluid levels of erythropoietin, mean 5.0 mU/mL (range <5.0–5.8 mU/mL), at 7–12 weeks' gestation, but their samples may have been contaminated with coelomic fluid (11). An earlier study was unable to find endogenous erythropoietin in amniotic fluid before the 11th week of gestation (12). More recent investigations have demonstrated the lack of placental passage of recombinant epoetin alfa across the human placenta (13–15).

In the fetus, erythropoietin is primarily produced by the fetal liver during most of pregnancy (16). Erythropoietin binding sites have been found in the 1st trimester of pregnancy in the human fetal liver and lung (17) and in cultures of umbilical vein endothelial cells derived at cesarean section (18). A 1994 report compared the levels of endogenous erythropoietin measured in the umbilical serum in normal women at term and in premature labor, and in those with

preeclampsia or diabetes (19). Women with preeclampsia had the highest concentrations (95.8 mU/mL), followed by those with diabetes (38.0 mU/mL), women in premature labor (25.2 mU/mL), and normal women (21.1 mU/mL), demonstrating that fetal hypoxia was not the only factor that determines levels of this glycoprotein (19).

The first published report on the use of epoetin alfa in human pregnancy appeared in a 1990 abstract (20). A 28-year-old Japanese woman with chronic glomerulonephritis became pregnant 8 years after the start of dialysis and approximately 22 months after the initiation of weekly doses of epoetin alfa. She had been amenorrheic prior to epoetin alfa therapy; her menses returned 17 months after start of treatment. The duration of her dialysis treatments (in hours per week) was gradually increased throughout gestation. She received 4500–9000 U/week of epoetin alfa from the 20th gestational week (doses prior to this time were not specified) until delivery at 36 weeks' gestation. Her blood pressure was normal throughout pregnancy, as was intrauterine fetal growth. The 2396-g, healthy, male infant was normal at birth with Apgar scores of 9 and 9 at 1 and 5 minutes, respectively. He was discharged with his mother 12 days after birth.

A report published in 1991 described a 32-year-old hypertensive woman with end-stage renal disease of unknown origin, who had been on hemodialysis for 4 years (21). She was started on epoetin alfa early in the 1st trimester and continued until delivery (36 weeks by dates, 34 weeks by ultrasound). No transfusions were required during pregnancy. An emergency cesarean section was performed because of fetal distress secondary to severe maternal hypertension. The 1140-g male infant had Apgar scores of 7 and 8 at 1 and 5 minutes, respectively. No congenital malformations were noted in the infant, who was discharged home at 35 days of age.

A second 1991 publication involved a 37-year-old woman who was treated throughout pregnancy with escalating doses of epoetin alfa (22). The patient had received a renal transplant 9 years before pregnancy because of reflux nephropathy, but the onset of chronic rejection caused progressive renal failure. Due to persistent anemia, she was started on a regimen of epoetin alfa, 4000 U/week, and supplemental iron shortly before conception. The dose was increased at 18 weeks' gestation to 8000 U/week, and then to 12,000 U/week at 27 weeks. Hemodialysis was started during the 25th week of pregnancy because of severe renal failure, polyhydramnios, and fetal intrauterine growth restriction. Her blood pressure was controlled with atenolol and nifedipine. Severe intrauterine growth restriction and fetal distress were diagnosed at 31

weeks and, after betamethasone therapy for fetal lung maturation, a cesarean section was performed to deliver a 780-g female infant. Birth weight was below the 3rd percentile for gestational age. Although the growth restriction was attributed to the mother's renal disease, the use of atenolol was probably a factor (see Atenolol). Except for transient coagulopathy and thrombocytopenia found at birth, both thought to be due to the mother's condition or premature delivery, the infant progressed normally and was discharged home at 66 days of age with a weight of 2140 g.

A 1992 report described the use of epoetin alfa, combined with supplemental oral iron, in three human pregnancies that resulted in the birth of four (one set of twins) infants (7). The birth weights of the newborns were all at approximately the 50th percentile for gestational age (7). Two of the women developed polyhydramnios after starting treatment with epoetin alfa, and all developed preeclampsia or worsening renal impairment, but the authors could not determine whether these were effects of the drug treatment or the underlying disease (7). Hematocrit values were maintained in the targeted 30%–33% range, and no coagulation problems or significant changes in platelet counts were observed. The three pregnancies are described below.

A 30-year-old woman, with onset of renal disease secondary to immunoglobulin A nephropathy and chronic hypertension before pregnancy, was treated with epoetin alfa 50–65 U/kg/week starting in the 20th gestational week (7). Polyhydramnios was noted at 32 weeks' gestation. Because of worsening renal failure, labor induction was initiated at 35 weeks resulting in the delivery of a 2570-g male infant with Apgar scores of 8 and 8 at 1 and 5 minutes, respectively. The newborn had mild hyperbilirubinemia and required oxygen, but no other problems were noted. He was doing well at 3 months.

The second patient, a 33-year-old woman with hypertension, diabetes, and renal impairment, was treated with 150 U/kg/week of epoetin alfa beginning at 26 weeks' gestation (7). Polyhydramnios developed, and labor was induced at 32 weeks because of worsening renal function and superimposed preeclampsia. After maternal betamethasone therapy to accelerate fetal lung maturity, a 2020-g male infant was delivered, with Apgar scores of 4 and 7 at 1 and 5 minutes, respectively. The infant had mild hypoglycemia and hyperbilirubinemia and, initially, required oxygen therapy. He was discharged home at 2 weeks of age.

The third patient was a 26-year-old with renal disease secondary to crescentic segmental necrotizing glomerulonephritis following streptococcal pharyngitis (7). She was treated with azathioprine and prednisone throughout a

twin gestation to control her renal disease. Beginning at 14 weeks' gestation, she was treated with epoetin alfa, 85–160 U/kg/week, continuously until 33 weeks' gestation, except for a 4-week period at 23–27 weeks. Therapy was halted during that time because of a low ferritin level, and therapy was discontinued when it recurred at 33 weeks. Labor was induced at 35 weeks for worsening renal function. A cesarean section was required because of failure to descend, resulting in the delivery of a 2220-g female (Apgar scores of 4 and 8, respectively) and a 2410-g male (Apgar scores of 2 and 5, respectively). The infants were developing normally at 7 months of age (7).

The pregnancies of six women who became pregnant while on dialysis for end-stage renal disease and who were treated with epoetin alfa have been described (23,24). No effects on the mothers' blood pressure control were observed in these cases, and in one of the reports, the investigators found no evidence that the drug crossed the placenta to the fetuses (24).

A number of additional studies have been published describing the use of epoetin alfa during human pregnancy (25–32). In most of the studies or reports, the drug was used to treat the maternal anemia associated with severe renal disease (25–29), but in three reports, epoetin alfa was used in women with either heterozygous β thalassemia (30), hypoproliferative anemia and a low serum erythropoietin level (31), or acute promyelocytic leukemia (32). Except for a single complication in which abruptio placentae with resulting fetal death occurred at 23 weeks' gestation and drug therapy could not be excluded as a contributing factor (28), no other fetal and/or newborn adverse effects attributable to epoetin alfa were observed.

BREASTFEEDING SUMMARY

Epoetin is a 165-amino acid glycoprotein produced by recombinant DNA technology that has the same biologic activity as endogenous erythropoietin. No reports describing its use during lactation have been located. Passage into milk is not expected, but in the event that some transfer did occur, digestion in the nursing infant's gastrointestinal system would occur. Moreover, preterm infants have been treated directly with the drug (33). Thus, the risk to a nursing infant from ingestion of the agent via the milk appears to be nonexistent.

EPOPROSTENOL

Vasodilator

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably
Compatible

PREGNANCY SUMMARY

Epoprostenol is not teratogenic in animals, but the human data are too limited to assess with only three human cases involving exposure early in gestation. The placental transfer of the prostaglandin has not been characterized, but it is unlikely if clinically significant amounts of exogenous epoprostenol reach the fetus. Because the prostaglandin occurs naturally in the fetus, it is also unlikely that maternal administration would produce a direct adverse effect on the embryo or fetus. The adverse fetal outcomes that have been noted (bradycardia, fetal heart rate [FHR] decelerations, and death) were most likely due to severe maternal disease or other factors. Although the maternal benefits obtained from use of epoprostenol for severe preeclampsia have not been well documented, its use for pulmonary hypertension is beneficial and appears to far outweigh any potential risks to the fetus.

FETAL RISK SUMMARY

The naturally occurring prostaglandin, epoprostenol (prostacyclin, PGI₂, PGX), is a metabolite of arachidonic acid. Available in the United States since 1995, it is a potent direct vasodilator of pulmonary and systemic arterial vascular beds and an inhibitor of platelet aggregation. Epoprostenol is indicated for the long-term IV treatment of primary pulmonary hypertension (1).

Reproduction studies have revealed no evidence of impaired fertility or fetal harm in pregnant rats and rabbits at 2.5 and 4.8 times the recommended human dose based on BSA, respectively (1).

In animals, epoprostenol causes dose-related changes on the heart rate: bradycardia at low doses and reflex tachycardia secondary to vasodilation and

hypotension at higher doses. Other pharmacologic effects in animals include bronchodilation, inhibition of gastric acid secretion, and decreased gastric emptying (1).

No reports describing the placental transfer of epoprostenol have been located. The molecular weight (about 374) of the drug is low enough for placental transfer, but the clinical significance of this is unknown because the agent is rapidly hydrolyzed and undergoes enzymatic degradation in the plasma. In addition, other factors (e.g., ionization, placental metabolism) may limit transfer to the fetus. Continuous infusions of the prostaglandin, which reach steady-state plasma levels within 15 minutes in animals and are proportional to infusion rates, could potentially provide a reservoir to allow placental transfer. But the in vivo plasma half-life of tritium-labeled epoprostenol in animals is very short (2.7 minutes) (1). In humans, the in vitro half-life in blood is slightly longer, approximately 6 minutes, and the in vivo half-life, although it has not yet been determined, is expected to be no longer than this time (1). Thus, even if placental transfer does occur the amounts reaching the fetus may be clinically insignificant. The effects of adding to the endogenous concentrations of the prostaglandin in the fetus are unknown.

In an in vitro study, prostacyclin was shown to be a potent inhibitor of human fetal and maternal platelet aggregation and more potent than S-nitroso-N-acetylpenicillamine (a releaser of nitric oxide) (2). Moreover, fetal platelets were more sensitive to both agents than were maternal platelets.

The effects of various drugs on the production of maternal and fetal endogenous prostacyclin have been studied in in vivo and in vitro systems. For ritodrine, one study found an increase in the synthesis of the prostaglandin (3), whereas a second reported no effect (4). Ethanol was shown to decrease prostacyclin synthesis in a dose-related manner (5). No effect on prostacyclin production was shown with aspirin (6–8) or magnesium sulfate (9).

The enzymes involved in the synthesis of prostacyclin (PGI_2) and thromboxane A_2 (TXA_2) were studied in maternal and fetal platelets and venous endothelium in a 1991 publication (10). Three groups of pregnant women were studied: normal controls; mild preeclampsia; and severe preeclampsia. Based on their findings, the authors concluded that the production of both PGI_2 and TXA_2 was equal in mild preeclampsia, but in severe preeclampsia, the rise in TXA_2 exceeded that of PGI_2 .

A number of reports have described the use of epoprostenol for the treatment of severe preeclampsia (11–17) or pulmonary hypertension (18–20). In a 1980 case report, a 29-year-old woman at 27 weeks' gestation with

hypertension uncontrolled with oral methyldopa (3 g/day) and hydralazine (150 mg/day) was started on a continuous infusion of epoprostenol at 8 ng/kg/minute (11). Diastolic pressure fell from 140 to 80 mmHg and remained at or below 95 mmHg during the next 3 days. Adverse effects in the mother included flushing, tachycardia (95–100 beats/minute [bpm]), and transient, nonspecific chest and abdominal pain. On day 4 of therapy, prolonged (1–2 minutes) fetal bradycardia occurred (60 bpm) and delivery by cesarean section was initiated. During the induction phase of anesthesia, the epoprostenol infusion was stopped for 4 minutes. During this interval, the blood pressure rose to 200/100 mmHg but returned to 130/80 mmHg when the infusion was restarted. More than normal bleeding occurred during the procedure and the infusion was discontinued. The 730-g newborn was alive and making good progress at 3 weeks of age.

A continuous IV infusion of epoprostenol was started at 25 weeks' gestation in a 27-old-woman with preeclampsia only partially responsive to methyldopa, aspirin (300 mg every other day), and hydralazine (12). The woman had a history of two previous pregnancies complicated by pregnancy-induced hypertension, severe intrauterine growth restriction, and fetal death at 27 weeks' gestation. Epoprostenol was chosen because of a rise in her diastolic pressure to 90 mmHg, a slowing of fetal growth, and a falling maternal plasma concentration of 6-oxo-PGF_{1α} (6-keto-prostaglandin F_{1α}), the hydrolyzed product of epoprostenol (12). Mild nausea, facial flushing, and headache limited the dose tolerated by the patient to 4 ng/kg/minute. The maternal diastolic blood pressure stabilized at or below 85 mmHg and her pulse rate increased from 69 bpm to 84 bpm, but the FHR remained unchanged. In spite of almost continuous FHR monitoring, the fetus died on the 4th day of the infusion, after which a macerated 430-g female fetus was delivered. The authors speculated that intervention with epoprostenol came too late to save the pregnancy (12).

A study published in 1985 examined the effect of IV infusions of epoprostenol in five women (gestational ages 24–30 weeks) with severe preeclampsia that was unresponsive to various combinations of other antihypertensive therapy (methyldopa, hydralazine, labetalol, and atenolol) (13). The maximum continuous IV infusion doses tolerated by the patients ranged from 1 to 6 ng/kg/minute with durations varying from 5 hours to 11 days. Facial flushing, nausea and vomiting, and headache were dose-limiting adverse effects. Four infants were delivered by cesarean section when the infusions (duration 5 hours to 7 days) were stopped, but one newborn (mother treated for 4 days) died 5 hours after delivery (birth weight 480 g). Another fetus (600 g) was stillborn at

26 weeks' gestation on the 11th day of epoprostenol (2.5 ng/kg/minute). Ultrasound and FHR monitoring did not detect any significant changes in the fetus prior to death. The authors thought that the two deaths were not related to the drug. The blood pressures of the mothers were reduced, but dose-limiting adverse effects prevented satisfactory control in one patient. Epoprostenol had no effect on uterine activity in any of the cases (13).

No significant changes in placental (intervillous) and umbilical vein blood flow were measured in a study of 13 women (gestational ages 28–38 weeks) with either superimposed preeclampsia (N = 6) or preeclampsia (N = 7) (14). The infusion dose was increased in four increments (1, 2, 4, and 8 ng/kg/minute), each given for 20 minutes. All women experienced facial flushing and two complained of headache. Significant decreases in maternal blood pressure and consistent increases in maternal plasma or urinary 6-keto-prostaglandin $F_{1\alpha}$ levels were measured. In contrast, no changes in maternal or fetal pulse rates or uterine activity were observed. The fetuses were delivered 1–13 days after the study. Except for one 850-g newborn delivered at 30 weeks' gestation who died at age 2 days from respiratory distress syndrome, the other newborns (birth weights 980–2840 g) were well at birth and survived (14).

Two vasodilators, epoprostenol (N = 22) or dihydralazine (N = 25), were compared in a prospective randomized study of women with proteinuria and acute diastolic blood pressures >110 mmHg immediately before delivery (15). The mean gestational age in both groups was 36 weeks (range 32–40 weeks). The epoprostenol infusion was started at 0.5 ng/kg/minute and was increased to a maximum of 10 ng/kg/minute within 120 minutes, if needed to control the blood pressure. The initial dihydralazine dose was 0.5 mg/kg/minute and increased to a maximum of 1.5 mg/kg/minute, if needed. Both drugs were continued for 24 hours after delivery and during delivery for those requiring cesarean section. Increases in maternal pulse rate occurred in both groups, but the rise in the epoprostenol patients (6 bpm) was significantly less than the rise with dihydralazine (22 bpm) ($p = 0.0024$). Blood pressures were reduced in both groups, but the difference between them was not significant. Cesarean sections were performed in 13 (60%) (11 for FHR decelerations) of the epoprostenol group and in 20 (80%) (14 for FHR decelerations) of those receiving dihydralazine (ns). One neonatal death occurred in each group, but neither was related to the drug therapy (15).

A brief 1992 communication reported the treatment of a 35-year-old woman with thrombotic microangiopathy superimposed on preeclampsia at about 26 weeks' gestation (16). Epoprostenol was started at 2 ng/kg/minute and

increased to 20 ng/kg/minute over 24 hours with reduction of her blood pressure and a rise in the platelet count. After stabilization, therapy was stopped but restarted later when her condition worsened. Improvement was again achieved, but she was delivered at 28 weeks' because of oligohydramnios and growth restriction. The baby girl died a week later from respiratory arrest. In addition, the authors described, without details, the successful treatment of a 27-year-old patient with HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome (16). Epoprostenol has also been used to treat a severe case of HELLP syndrome in the immediate postpartum period (17).

A 1999 publication described the use of epoprostenol for the treatment of pulmonary hypertension in three women in the 3rd trimester (18). One patient, at 28 weeks' gestation, died from severe disease within hours of the diagnosis. The other two women delivered newborns of 3333 g and 2905 g, respectively, but the condition and status of the newborns was not mentioned.

In another case of primary pulmonary hypertension, a 34-year-old woman became pregnant with twins after 1.5 years of continuous IV infusion of epoprostenol (40 ng/kg/hour) (19). She was also taking warfarin, digoxin, furosemide, spironolactone, and ferrous sulfate. She first presented at 15 weeks' gestation at which time the warfarin was discontinued. A ultrasound examination 2 weeks later revealed the death of twin A and hydrocephalus and bilateral clubfeet in twin B. She refused pregnancy termination. She was treated twice for central catheter-related septicemia with vancomycin and gentamicin. The dose of epoprostenol was increased as pregnancy progressed, eventually reaching a dose of 60 ng/kg/hour. Betamethasone was given for lung maturity. Nitric oxide via nasal cannula was started just prior to cesarean section for breech presentation. A live, 2155-g male infant was delivered with Apgar scores of 7 and 8 at 1 and 5 minutes, respectively. The infant had severe hydrocephalus and facial anomalies consistent with fetal warfarin syndrome (19). He was alive but still hospitalized at the time of the report. The nitric oxide was discontinued after 40 days and the mother was discharged home 43 days after delivery on epoprostenol 77 ng/kg/hour.

A 2004 case report described the use of IV and inhaled epoprostenol for the treatment of severe primary pulmonary hypertension (20). The woman was started on the IV drug at 26 weeks' gestation. Because of concern that systemic administration could inhibit platelet aggregation and place the patient at risk during epidural catheter placement for labor, she was changed to inhaled epoprostenol at 35 weeks' gestation. A healthy, 2250-g male infant was

delivered vaginally with Apgar scores of 7 and 9 at 1 and 5 minutes, respectively. The infant was doing well at 6 months of age (20).

Three pregnant women with pulmonary arterial hypertension were treated with epoprostenol during pregnancy in a 2005 report (21). In two patients, epoprostenol and warfarin were begun before pregnancy with warfarin changed to low-molecular-weight heparin early in gestation. The third patient was started on epoprostenol at 16 weeks' gestation. The women were delivered by cesarean section at 32, 32, and 28 weeks', respectively, with birth weights of 1700, 1500, and 795 g, respectively. The latter infant, delivered from a mother with Eisenmenger syndrome, was delivered early because of growth restriction, but all three infants were alive and well (21).

BREASTFEEDING SUMMARY

No reports describing the use of epoprostenol during lactation have been located. There is potential for its use during breastfeeding, such as in postpartum women with pulmonary hypertension on long-term infusions of the drug. However, this situation must be exceedingly rare. Because of its rapid degradation at physiologic pH and probably in the gut, the clinical significance of any transfer into milk to a nursing infant is probably nil. Moreover, the prostaglandin has been given directly by inhalation to a premature neonate with beneficial effects (22).

EPROSARTAN

Antihypertensive

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of eprosartan during human pregnancy have been located. The antihypertensive mechanisms of action of eprosartan and angiotensin-converting enzyme (ACE) inhibitors are very close. That is, the former selectively blocks the binding of angiotensin II to AT₁ receptors, whereas the latter blocks the formation of angiotensin II itself. Therefore, use of this drug during the 2nd and 3rd trimesters may cause teratogenicity and severe fetal and neonatal toxicity that is identical to that seen with ACE inhibitors (see Captopril or Enalapril). Fetal toxic effects may include anuria, oligohydramnios, fetal hypocalvaria, intrauterine growth restriction, prematurity, and patent ductus arteriosus. Anuria-associated oligohydramnios may produce fetal limb contractures, craniofacial deformation, and pulmonary hypoplasia. Severe anuria and hypotension, that is resistant to both pressor agents and volume expansion, may occur in the newborn following in utero exposure to eprosartan. Newborn renal function and blood pressure should be closely monitored.

FETAL RISK SUMMARY

Eprosartan is a selective angiotensin II receptor blocker (ARB) that is used, either alone or in combination with other antihypertensive agents, for the treatment of hypertension. Eprosartan blocks the vasoconstrictor and aldosterone-secreting effects of angiotensin II by preventing angiotensin II from binding to AT₁ receptors.

Reproduction studies have been conducted in rats and rabbits (1). No teratogenic effects were observed in either species, but dose-related toxicity occurred in pregnant rabbits. In pregnant rats, no adverse effects on the fetus

or on the postnatal development and maturation of offspring were observed at oral doses up to approximately 0.6 times the human exposure based on AUC at the maximum recommended human dose or 800 mg/day (MRHD). Similarly, a dose approximately 0.8 times the MRHD did not result in fetal or maternal toxicity in pregnant rabbits. Increasing the dose to approximately 2.7 times the MRHD in pregnant rabbits, however, caused both maternal (reduced body weight, decreased food consumption, and death) and embryo–fetal (resorptions, abortions, and litter loss) toxicity (1).

It is not known if eprosartan crosses the human placenta. The molecular weight (about 521) is low enough that passage to the fetus should be expected.

A 2012 review of the use of ACE inhibitors and ARBs in the 1st trimester concluded that there may be an elevated teratogenic risk, but the risk appeared to be related to other factors (2). The factors, that typically coexist with hypertension in pregnancy, included diabetes, advanced maternal age, and obesity.

BREASTFEEDING SUMMARY

No reports describing the use of eprosartan during human lactation have been located. The molecular weight (about 521) is low enough that excretion into breast milk should also be expected. The effects of this exposure on a nursing infant are unknown. The American Academy of Pediatrics, however, classifies ACE inhibitors, a closely related group of antihypertensive agents, as compatible with breastfeeding (see Captopril and Enalapril).

EPTIFIBATIDE

Hematologic Agent (Antiplatelet)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Hold Breastfeeding

PREGNANCY SUMMARY

One report describing the use of eptifibatide in human pregnancy has been located. The animal data are reassuring but more human pregnancy experience is required to assess the risk this agent presents to the embryo–fetus. The primary risk, however, appears to be from maternal hemorrhage during drug administration. If this is adequately controlled, the benefits of the drug to the mother appear to far outweigh the unknown risks to the fetus.

FETAL RISK SUMMARY

The cyclic heptapeptide, eptifibatide, is indicated for the treatment of acute coronary syndrome in patients who will be managed medically or in those undergoing percutaneous coronary intervention. Eptifibatide acts as a reversible inhibitor of platelet aggregation by blocking the GP IIb/IIIa receptor on the platelet surface. It is in the same subclass of antiplatelet agents as abciximab and tirofiban. The drug undergoes some metabolism. Plasma protein binding is about 25% and the plasma elimination half-life is about 2.5 hours (1).

Reproduction studies with eptifibatide have been conducted in rats and rabbits. In pregnant rats and rabbits, continuous daily IV infusions at total daily doses up to about four times the maximum recommended human daily dose based on BSA (MRHDD) revealed no evidence of fetal harm. Although long-term studies in animals for carcinogenicity have not been conducted, no evidence of mutagenicity was found in several tests. Similarly, no evidence of impaired fertility or reproductive performance was observed in rats given daily doses up to about four times the MRHDD (1).

It is not known if eptifibatide crosses the human placenta to the fetus. The molecular weight (about 832), low plasma protein binding, and the elimination

half-life suggest that the drug will cross to the embryo–fetus. Moreover, the drug is given as a continuous IV infusion for periods up to 72 hours, thus allowing for prolonged contact at the maternal–fetal interface.

A 44-year-old woman at 8 weeks' gestation presented with an acute myocardial infarction (2). She was treated with intracoronary stent placement and clopidogrel (600 mg), heparin, and a 24-hour IV infusion of eptifibatide. The next day, she was started on clopidogrel, aspirin, and propranolol and discharged home on these agents. At 36 weeks, she underwent a planned cesarean section for a healthy infant (no further details on the newborn were provided) (2).

BREASTFEEDING SUMMARY

No reports describing the use of eptifibatide during lactation have been located. Because of the indications for eptifibatide, it is doubtful if such reports will be forthcoming. The molecular weight (about 832), low plasma protein binding, and the elimination half-life suggest that the drug will be excreted into breast milk. Moreover, the drug is given as a continuous IV infusion for periods up to 72 hours. The effect of this exposure for a nursing infant is unknown, but most likely the risk is very low or nil because the drug should be digested in the infant's gastrointestinal tract. Until data are available, however, the safest course is to hold breastfeeding while the drug is being infused.

ERGOCALCIFEROL

Vitamin

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Ergocalciferol (vitamin D₂) is converted in the liver to 25-hydroxyergocalciferol, which in turn is converted in the kidneys to 1,25-dihydroxyergocalciferol, one of the active forms of vitamin D. See Vitamin D.

BREASTFEEDING SUMMARY

See Vitamin D.

ERGOTAMINE

Sympatholytic (Antimigraine)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Small, infrequent doses of ergotamine used for migraine headaches do not appear to be fetotoxic or teratogenic, but idiosyncratic responses may occur that endanger the fetus. Larger doses or frequent use, however, may cause fetal toxicity or teratogenicity that is probably due to maternal and/or fetal vascular disruption. Based on one report, the combination of ergotamine, caffeine, and propranolol may represent an added risk. Because the risk has not been adequately defined, and also due to the oxytocic properties of the agent, ergotamine should be avoided during pregnancy.

FETAL RISK SUMMARY

Ergotamine is a naturally occurring ergot alkaloid that is used in the prevention or treatment of vascular headaches, such as migraine. The oxytocic properties of ergotamine have been known since the early 1900s, but because it produces a prolonged and marked increase in uterine tone that may lead to fetal hypoxia, it is not used for this purpose (1). A semisynthetic derivative, dihydroergotamine, has also been abandoned as an oxytocic for the same reason (2). (See Dihydroergotamine.) Small amounts of ergotamine have been reported to cross the placenta to the fetus (3).

Ergotamine is not an animal teratogen (4). In pregnant mice, rats, and rabbits, however, doses sufficient to affect maternal weight gain were fetotoxic, producing increased prenatal mortality and growth restriction. The mechanism proposed for these effects was an impairment of blood supply to the uterus and placenta (4). Another study demonstrating fetal death in pregnant rats arrived at the same conclusion (5). Ergotamine (0.25%) fed to pregnant sheep produced severe ergotism, fetal death, and abortions (6).

Most authorities consider ergotamine in pregnancy to be either

contraindicated or to be used sparingly and with caution, due to the oxytocic properties of the drug (7–10). Fortunately, the frequency of migraine attacks decreases during pregnancy, thus lessening the need for any medication (8–10).

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 25 of whom were exposed to ergotamine during the 1st trimester (11). Two malformed children were observed from this group, but the numbers are too small to draw any conclusion.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 59 newborns had been exposed to ergotamine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of nine (15.3%) major birth defects were observed (two expected). Specific data were available for six defect categories, including (observed/expected) 1/0.6 cardiovascular defects, 0/0 oral clefts, 0/0 spina bifida, 1/0 polydactyly, 0/0 limb reduction defects, and 1/0 hypospadias. The total number of defects is suggestive of an association, but other factors, such as the mother's disease, concurrent drug use, and chance may be involved.

A retrospective study published in 1978 evaluated the reproductive outcome of women attending a migraine clinic (12). The study group was composed of 777 women enrolling in the clinic for the first time. A control group composed of 182 wives of new male patients at the clinic was formed for comparison. Of the women with migraine, 450 (58%) had been pregnant vs. 136 (75%) of the women without migraine. The difference in the percentage of pregnancies may have been because all of the control women were married while the marriage status of the study women was not known (12). The incidence of at least one spontaneous abortion or stillbirth, 27% vs. 29%, including 1st trimester loss, and the occurrence of toxemia, 18% vs. 18%, were similar for the groups. The total number of pregnancies was 1142 in the study patients and 342 in the controls, with a mean number of pregnancies per patient of 2.54 vs. 2.51, respectively. The migraine group had 924 (81%) live births compared with 277 (81%) for the control women. Congenital defects observed among the live births totaled 31 (3.4%) for the study group vs. 11 (4.0%) for the controls (ns). Major abnormalities, found in 20 (2.2%) of the infants from the women with migraine compared with 7 (2.5%) of the infants from controls, were of similar distribution to those found in the geographic area of the clinic (12). Moreover, the incidence of defects was similar to the expected frequency for that location (12). Although the investigators were unable to document reliable and accurate

drug histories during the pregnancies because of the retrospective nature of the study, 70.8% of the women with migraine indicated they had used ergotamine in the past. They concluded, therefore, that ergotamine exposure during pregnancy, especially early in gestation, was highly likely, and that this drug and others used for the prevention or treatment of the disease were probably not teratogenic (12).

In contrast to the above study, six case reports have described adverse fetal outcomes attributable to ergotamine (13–18). An infant, who died at 4 weeks of age, was delivered at 24 weeks' gestation with a large rugated, perineal mass, no external genitalia or anal orifice, and a small, polycystic left kidney (13). Two separate sacs made up the mass, one of which resembled a urinary bladder with two ureteral and a vaginal orifice, and the other containing bowel, left ovary, uterus, and right kidney (13). The mother had used an ergotamine inhaler once or twice weekly during the first 8 weeks of pregnancy for migraine headaches. The inhaler delivered 0.36 mg of ergotamine per inhalation and she received two or three inhalations during each headache for a total dose of 0.72–1.08 mg once or twice weekly. The mother also smoked about 10 cigarettes daily.

A female infant with multiple congenital malformations was delivered from a woman who had used a proprietary preparation containing ergotamine, caffeine, belladonna, and pentobarbital during the 2nd month of pregnancy for migraine (14). Two other similar cases in pregnant women who did not receive an ergotamine preparation were included in the report. The birth defects included hydrocephalus, sacral or coccygeal agenesis, digital and muscle hypoplasia, joint contractures, short stature, short perineum, and pilonidal sinus. Because of the similarity of the cases, the authors thought it might be a new syndrome, which they termed cerebroarthrodigital syndrome, in which the primary pathogenetic event is a neural tube-neural crest dysplasia (14). Although they could not determine the cause, they considered an environmental agent, such as ergotamine, or a genetic cause as possibilities (14).

A 1983 report described a 27-year-old woman with migraine headaches who consumed up to 8 tablets/day of a preparation containing 1 mg of ergotamine tartrate and 100 mg of caffeine throughout a total of six pregnancies (15). The 1st pregnancy resulted in the birth of a 2200-g female infant, whose subsequent growth varied between the 3rd and 10th percentiles. She had no medical problems other than enuresis and hay fever. The woman's 2nd, 4th, 5th, and 6th pregnancies all ended in spontaneous abortions. A male infant was delivered in the 3rd pregnancy at 35 weeks' gestation. Birth weight, 1892 g,

and length, 43 cm, were at the 20th percentile for gestational age. The infant died at 25 days of age secondary to hyaline membrane disease and after two surgical attempts to correct jejunal atresia. At autopsy, a short small intestine with portions of incomplete or absent muscular coat around the bowel lumen was found. The authors could not exclude a hereditary cause for the anomaly, but they believed the most likely cause was a disruptive vascular mechanism resulting from an interruption of the superior mesenteric arterial supply to the affected organ (15).

In a suicide attempt, a 17-year-old pregnant woman, at 35 weeks' gestation, took a single dose of 10 ergotamine tablets (20 mg) (16). Five hours after ingestion, the fetal heart rate was 165 beats/minute with fetal movement. Uterine contractions were mild but frequent, with little relaxation between contractions. Fetal death occurred approximately 8.5 hours later, about 13.5 hours after ingestion. The most likely mechanism for the fetal death was impairment of placental perfusion by the uterine contractions resulting in fetal hypoxia (16). However, the authors considered two other possible mechanisms: arterial spasm causing decreased uterine arterial perfusion, and altered peripheral resistance and venous return resulting in fetal myocardial ischemia (16).

A 1988 case report described the result of a pregnancy complicated by severe migraine headaches (17). The mother consumed a variety of drugs, including 1–4 rectal suppositories/week during the first 14 weeks of gestation, with each dose containing ergotamine (2 mg), belladonna (0.25 mg), caffeine (100 mg), and phenobarbital (60 mg). Other medications, frequency of ingestion, and gestational weeks of exposure were propranolol (40 mg; 2/day; 0–20 weeks), acetaminophen/codeine (325 mg/8 mg; 6–20/day; 0–16 weeks), and dimenhydrinate (75 mg; 0–3/week; 0–12 weeks). The term, female infant was a breech presentation weighing 2860 g, with a length of 46 cm. The infant was microcephalic and paraplegic with underdeveloped and hypotonic lower limbs. The anal, knee, and ankle reflexes were absent. Sensation was absent to the level of the knees and variably absent on the thighs. This pattern was suggestive of a spinal cord defect in the upper lumbar region (17). Other abnormalities apparent were dislocated hips and marked bilateral talipes equinovarus. Computed tomography of the brain revealed a small organ with lissencephaly, a primitive Sylvian fissure, and ventriculomegaly (17). The above findings were compatible with arrest of cerebral development that occurred after 10–13 weeks (17). The authors concluded that the most likely etiology was a disruptive vascular mechanism, and that the combination of ergotamine,

caffeine, and propranolol may have potentiated the vasoconstriction (17).

In response to the case report above, a 1989 letter cited prospective and retrospective data from the Hungarian Case–Control Surveillance of Congenital Anomalies, 1980–1986 system (19). Among controls (normal infants, but including those with Down’s syndrome), 0.11% (18 of 16,477) had used ergotamine during pregnancy, whereas 0.14% (13 of 9460) of pregnancies with a birth defect had been exposed to the drug (ns). Four of the index cases, however, involved neural tube defects compared with none of the controls ($p < 0.01$), a finding that prompted the author to state that further study was required.

A female infant, the smaller of dizygotic twins, was born at 32 weeks’ gestation (18). Paraplegia and arthrogyrosis multiplex was present at birth and thought to be due to prenatal cord trauma. The mother had a severe reaction (intractable nausea, vertigo and dizziness requiring bed rest for 3 days) following the use of one rectal suppository containing ergotamine, caffeine, belladonna, and butalbital at 4.5 months’ gestation. Because of this reaction, the authors speculated that ergotamine may have caused vascular spasm of a fetal medullary artery that resulted in spinal cord ischemia and neuronal loss (18).

The accidental use at 38 weeks’ gestation of a rectal suppository containing ergotamine (2 mg) and caffeine (100 mg) in a woman with nonproteinuric hypertension produced sudden fetal distress that led to an emergency cesarean section (20). A growth-restricted, 2660-g female infant was delivered with Apgar scores of 4 and 8 at 1 and 5 minutes, respectively. The obstetrician, who was unaware of the drug administration, noted the strikingly small amount (100 mL) of blood loss during the procedure. The infant was doing well at 10 years of age.

A 1995 reference reviewed the teratogenicity of ergotamine (21). Because many of the reports of adverse outcomes following the use of the drug during pregnancy are consistent with vascular injury, and because ergotamine toxicity is known to cause vasospasm, the author recommended that the drug should be avoided during all parts of pregnancy (21). The use of the agent in small, appropriate doses, however, was thought to have a low teratogenic potential because ergotamine appeared to be teratogenic only at higher doses, or possibly in those cases involving idiosyncratic susceptibility (21). Recommendations for counseling of exposed women included not only determining the dosage and timing of exposure but also asking questions relating to the presence or absence of signs and symptoms of ergotism, past

usage, and possible continuing abuse (21).

BREASTFEEDING SUMMARY

Ergotamine is excreted into breast milk, but data quantifying this excretion have not been located. A 1934 study reported that 90% of nursing infants of mothers using an ergot preparation for migraine therapy had symptoms of ergotism (22). Because of the vomiting, diarrhea, and convulsions observed in this study, the American Academy of Pediatrics classifies ergotamine as a drug that has been associated with significant effects on some nursing infants and should be given to nursing mothers with caution (23). Moreover, ergotamine is a member of the same chemical family as bromocriptine, an agent that is used to suppress lactation. Although no specific information has been located relating to the effects of ergotamine on lactation, ergot alkaloids may hinder lactation by inhibiting maternal pituitary prolactin secretion (24).

ERIBULIN

Antineoplastic

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of eribulin in human pregnancy have occurred. Although developmental toxicity occurred in rats at maternal toxic doses, the doses were much less than the recommended human dose. Because of the risk for severe toxicity in an embryo and/or a fetus, eribulin should not be used in pregnancy.

FETAL RISK SUMMARY

Eribulin is a nontaxane microtubule dynamics inhibitor that is given IV on days 1 and 8 of a 21-day cycle. It is indicated for the treatment of patients with metastatic breast cancer who have previously received at least two chemotherapeutic regimens for the treatment of metastatic disease. There are no major metabolites of eribulin. Plasma protein binding is in the range of 49%–65%. The mean elimination half-life is about 40 hours (1).

Reproduction studies have been conducted in rats. In this species, IV doses were given during organogenesis (gestation days 8, 10, and 12) that were about 0.04–0.64 times the recommended human dose based on BSA (RHD). At the highest dose, abortions and severe external or soft-tissue malformations were observed. The malformations included the absence of a lower jaw, tongue, stomach, and spleen. At 0.43 times the RHD, increased embryo–fetal death/resorption, reduced fetal weights, and minor skeletal anomalies consistent with developmental delay were noted. However, at doses ≥ 0.43 times the RHD, maternal toxicity that included enlarged spleen, reduced maternal weight gain, and decreased food consumption occurred (1).

Studies of carcinogenicity have not been conducted. Eribulin was not mutagenic in bacterial assays but was mutagenic in other assays and was clastogenic in one assay. Although fertility studies have not been conducted, dog and rat toxicology studies have observed testicular toxicity in both species

suggesting that the drug may compromise male fertility (1).

It is not known if eribulin crosses the human placenta. The molecular weight (about 730 for the free base), lack of metabolism, moderate protein binding, and long half-life suggest that the drug will cross to the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use of eribulin during human lactation have been located. The molecular weight (about 730 for the free base), lack of metabolism, moderate protein binding, and long half-life suggest that the drug will be excreted into breast milk. Moreover, as a basic drug, higher concentrations of eribulin in milk compared with the plasma may occur. The effect of this exposure on a nursing infant is unknown but there is potential for severe toxicity. Consequently, breastfeeding during therapy with this agent should be considered contraindicated.

ERLOTINIB

Antineoplastic (Tyrosine Kinase Inhibitor)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Two reports describing the use of erlotinib in human pregnancy has been located. The animal data suggest risk, but the near absence of human pregnancy experience prevents a complete assessment of the embryo–fetal risk. If a woman receives erlotinib during pregnancy, she should be informed of the unknown risk to her embryo–fetus.

FETAL RISK SUMMARY

Erlotinib is an oral antineoplastic agent that is indicated, in combination with gemcitabine, for the first-line treatment of patients with locally advanced, unresectable or metastatic pancreatic cancer. The drug is a human epidermal growth factor type 1/epidermal growth factor receptor tyrosine kinase inhibitor in the same subclass as several other agents (see Appendix). Erlotinib is extensively metabolized by the liver to apparently inactive metabolites. The elimination half-life is about 32 hours. About 93% of erlotinib is bound to the plasma proteins albumin and alpha-1 acid glycoprotein (1,2).

Reproduction studies have been conducted in rats and rabbits. In pregnant rats and rabbits during organogenesis, there was no increased incidence of embryo–fetal lethality, abortion, or teratogenic effects with doses that achieved plasma concentrations that were about equal to those in humans from a 150 mg daily dose based on AUC (HDD). However, when pregnant rabbits were given a dose that produced exposures that were about three times the HDD, maternal toxicity with associated embryo–fetal lethality and abortion occurred. In addition, female rats given daily doses that were about 0.3 or 0.7 times the human dose based on BSA prior to mating, and through the first week of pregnancy had an increase in early resorptions resulting in a decrease

in the number of live fetuses (1).

Carcinogenic studies have not been conducted with erlotinib. Multiple tests for genotoxicity were negative, as were the effects on male and female rat fertility (1).

It is not known if erlotinib crosses the human placenta. The molecular weight (about 394 for the free base) and long elimination half-life suggest that the drug will cross. However, the extensive metabolism and moderately high plasma protein binding may limit the amount of active drug reaching the embryo–fetus.

A woman with metastatic nonsmall cell lung cancer was treated with six cycles of cisplatin, gemcitabine, and bisphosphonates that resulted in stable disease (3). No additional therapy was given for 12 months until progressive disease was found and erlotinib 100 mg/day was started. Pregnancy was diagnosed 2 months later. Conception was thought to have occurred at about the same time that erlotinib had been started. The drug was discontinued for the remainder of the pregnancy. At 42 weeks' gestation, a cesarean section delivered a normal, 3490-g female infant. No congenital malformations or other abnormalities were noted in the healthy infant (3).

A 2011 case report described a 38-year-old woman at 26 weeks' gestation who was diagnosed with lung cancer (4). The woman had never smoked. She was initially treated with erlotinib 100 mg/day and then changed about 2 weeks later to gefitinib 250 mg/day. Gefitinib was continued through the remainder of her pregnancy. At 36 weeks', she gave birth to a healthy 2.08-kg infant with an Apgar score of 9 at 1 minute. The baby weighed 2.98 kg 6 weeks later (4).

BREASTFEEDING SUMMARY

No reports describing the use of erlotinib during human lactation have been located. The molecular weight (about 394 for the free base) and long elimination half-life suggest that the drug will be excreted into breast milk. However, the extensive metabolism and moderately high plasma protein binding may limit the amount of active drug reaching the milk. The effects on a nursing infant are unknown, but there is a potential for severe toxicity. Moreover, the systemic bioavailability of erlotinib is markedly increased in adults when the dose is taken with food, and this might also occur in nursing infants. Therefore, until the amount of erlotinib in breast milk has been determined, the safest course is not to breastfeed.

ERTAPENEM

Antibiotic

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of ertapenem in human pregnancy have been located. No teratogenicity was observed in two animal species, although mild fetal toxicity was observed in one at a dose very close to that used in humans. Moreover, there is no evidence that any beta-lactam antibiotic (e.g., penicillins and cephalosporins) causes developmental toxicity in humans at therapeutic doses. Therefore, if the maternal condition requires the use of ertapenem, the antibiotic probably is safe at any time during gestation.

FETAL RISK SUMMARY

Ertapenem is a broad-spectrum carbapenem antibiotic that is administered by either IM injection or IV infusion. It is structurally related to the beta-lactam antibiotics and belongs to the same class as imipenem (available as imipenem-cilastatin) and meropenem.

Reproduction studies have been conducted in mice and rats. No evidence of structural teratogenicity was observed at IV doses up to three times the recommended human dose of 1 g based on BSA (mice) and 1.2 times the human exposure at the recommended dose of 1 g based on AUC (rats) (1). However, the maximum dose in mice resulted in decreased fetal weight and decreases in the average number of ossified sacrocaudal vertebrae. The antibiotic had no effect on mating performance, fecundity, fertility, or embryonic survival in either species (1).

Ertapenem crosses the placenta in rats, but this has not been studied in humans. The molecular weight (about 498) is low enough that passage to the fetus should be expected.

BREASTFEEDING SUMMARY

Ertapenem is excreted into breast milk (1). Five women 5–14 days postpartum were treated with 1 g IV daily for 3–10 days. Milk concentrations of the antibiotic were measured at random times for 5 consecutive days after the last dose. Samples obtained within 24 hours of the last dose ranged from <0.13 (lower limit of quantitation) to 0.38 mcg/mL. By day 5, ertapenem could not be detected in the milk of four women and was <0.13 mcg/mL in one woman (1).

The effects on a nursing infant from exposure to ertapenem via milk are unknown but are of doubtful clinical significance. Most antibiotics are excreted into breast milk in low concentrations, and adverse effects are rare. Potential problems for the nursing infant are modification of bowel flora, direct effects on the infant (e.g., allergic response), and interference with the interpretation of culture results if a fever workup is required.

ERYTHROMYCIN

Antibiotic

PREGNANCY RECOMMENDATION: Compatible (Excludes Estolate Salt)

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Most reports, including one animal study, have found no evidence of developmental toxicity with erythromycin. Although one report found an association with cardiovascular defects (see reference 17), the investigators could not determine if it was a true drug effect. There also is no evidence that maternal erythromycin treatment late in pregnancy causes infantile hypertrophic pyloric stenosis (IHPS). Because most studies do not indicate a risk, erythromycin can be used in pregnancy if indicated.

FETAL RISK SUMMARY

Erythromycin is a macrolide anti-infective that is in the same class as azithromycin, clarithromycin, dirithromycin, and troleandomycin.

The drug was not teratogenic in female rats fed erythromycin (up to 0.25% of the diet) before and during mating, and throughout gestation and weaning (1).

Erythromycin crosses the placenta but in concentrations too low to treat most pathogens (2–4). Fetal tissue levels increase after multiple doses (4). However, a case has been described in which erythromycin was used successfully to treat maternal syphilis but failed to treat the fetus adequately (5). During pregnancy, erythromycin serum concentrations vary greatly as compared with those in normal men and nonpregnant women, which might account for the low levels observed in the fetus (6).

The estolate salt of erythromycin has been observed to induce hepatotoxicity in pregnant patients (7). Approximately 10% of 161 women treated with the estolate form in the 2nd trimester had abnormally elevated levels of serum glutamic-oxaloacetic transaminase, which returned to normal after therapy was discontinued.

The use of erythromycin in the 1st trimester was reported in a mother who

delivered an infant with left absence-of-tibia syndrome (8). The mother was also exposed to other drugs, which makes a relationship to the antibiotic unlikely.

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 79 of whom had 1st trimester exposure to erythromycin (9, pp. 297–313). For use anytime during pregnancy, 230 exposures were recorded (9, p. 435). No evidence was found to suggest a relationship to large categories of major and minor malformations or to individual defects. Erythromycin, like many other antibiotics, lowers urine estriol concentrations (see also Ampicillin for mechanism and significance) (10). The antibiotic has been used during the 3rd trimester to reduce maternal and infant colonization with group B β -hemolytic streptococcus (11,12). Erythromycin has also been used during pregnancy for the treatment of genital mycoplasma (13,14). A reduction in the rates of pregnancy loss and low-birth-weight infants was seen in patients with mycoplasma infection after treatment with erythromycin.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 6972 newborns had been exposed to erythromycin during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 320 (4.6%) major birth defects were observed (297 expected). Specific data were available for six defect categories, including (observed/expected) 77/70 cardiovascular defects, 14/11 oral clefts, 1/3 spina bifida, 22/20 polydactyly, 14/12 limb reduction defects, and 11/17 hypospadias. These data do not support an association between the drug and congenital malformations.

Data from the Hungarian Case–Control Surveillance of Congenital Abnormalities, 1980–1996, regarding exposure to erythromycin during organogenesis were published in 1999 (15). Cases (N = 22,865) were fetuses or infants with congenital abnormalities, 113 (0.5%) of whom had been exposed to erythromycin. Among controls (N = 38,151), newborns without any congenital anomalies, 172 (0.5%) had been exposed to erythromycin. There were 20 cases and 43 controls exposed during the 2nd–3rd months (i.e., organogenesis), odds ratio (OR) 0.8, 95% confidence interval (CI) 0.5–1.4. For exposures during months 4–9, there were 78 cases and 112 controls, OR 1.2, 95% CI 0.9–1.6, and for the entire pregnancy, OR 1.1, 95% CI 0.9–1.5. The study found no detectable teratogenic risk from erythromycin (15).

A 2001 randomized study (ORACLE 1) was conducted in patients with preterm, prelabor rupture of fetal membranes to determine neonatal health benefits of three antibiotic regimens (16). The regimens, compared with a

placebo group (N = 1225), were erythromycin (250 mg) (N = 1197), amoxicillin (250 mg)–clavulanic acid (125 mg) (N = 1212), or both (N = 1192) four times daily for 10 days or until delivery. The primary outcome measures were specific outcomes or a composite of neonatal death, chronic lung disease, or major cerebral abnormality. For these neonatal outcomes, the two groups with ACA had no benefit over placebo, whereas erythromycin use resulted in significantly better outcomes (both composite and specific). When any-ACA exposure was compared with no-ACA for outcomes with suspected or proven NEC, the results were 92 (3.8%) and 58 (2.4%) ($p = 0.004$). The authors thought that a possible mechanism for this outcome was that the ACA combination selected for *Clostridium difficile* and that abnormal colonization of the neonatal intestinal tract was one possible mechanism for NEC (16).

A 2003 case–control study, using data from three Swedish health registers, was conducted to identify drug use in early pregnancy that was associated with cardiac defects (17). Cases (cardiovascular defects without known chromosome anomalies) (N = 5015) were compared with controls consisting of all infants born in Sweden (1995–2001) (N = 577,730). Associations were identified for several drugs, some of which were probably due to confounding from the underlying disease or complaint or multiple testing, but some were thought to be true drug effects. For erythromycin, there were 27 cases in 1588 exposures (OR 1.91, 95% CI 1.30–2.80). The study could not determine if the association was due to confounding, multiple testing, or a true drug effect (17).

Three reports have examined the association between maternal treatment with erythromycin during pregnancy and IHPS in their infants (18–20). The first report evaluated the presence of IHPS in the infants (not treated with erythromycin) of mothers who were prescribed a macrolide antibiotic within three pregnancy time periods (18). The antibiotics were primarily erythromycin, but included azithromycin and clarithromycin and the infants were not treated with erythromycin. For the three time periods, the relative risk for subsequent infant IHPS and 95% CI were: anytime in pregnancy, 1.15, 0.5–2.4; within 10 weeks of delivery, including delivery date 1.76, 0.7–4.2; and within 10 weeks of delivery, excluding delivery date 1.84, 0.8–4.4 (18).

The second report used data collected between 1976 and 1998 as part of an ongoing case–control surveillance program (19). Cases, 1044 infants with IHPS, were compared with two control groups, normal and malformed. Erythromycin exposure in case subjects were identified in three pregnancy time periods: 1–24 weeks, 25–40 weeks, and 33–40 weeks. The number of cases, OR, 95% CI for each time period with normal controls were: 26, 1.0, 0.6–1.6;

10, 0.6, 0.3–1.1; and 6, 0.7, 0.3–1.8, respectively. For malformed controls, the OR and 95% CI for each period was: 1.1, 0.8–1.7; 0.6, 0.3–1.1; and 0.6, 0.3–1.3, respectively. The results indicated no evidence of an increased risk of pyloric stenosis with erythromycin (19).

The third study, published in 2002, used the Tennessee Medicaid/Tenn Care 1985–1997 database (20). Among the 260,799 mother–infant pairs, 13,146 mothers filled prescriptions for erythromycin and 621 filled prescriptions for nonerythromycin macrolides (azithromycin, clarithromycin, clindamycin, dirithromycin) or lincomycin from 32 weeks' gestation through delivery. The number of infant IHPS cases, OR, and 95% CI, in the erythromycin group was 38, 1.17, 0.84–1.64 after 32 weeks' gestation. There were 22,418 mother–infant pairs with erythromycin exposure anytime in pregnancy with 53 cases, 1.15, 0.84–1.56. For nonerythromycin macrolides, the data for the two pregnancy periods were 3 cases, 2.45, 0.78–7.68 and, for anytime in pregnancy, 1287 exposures, 6 cases, 2.77, 1.22–6.30. Although the latter data reached statistical significance, the authors concluded that a causal inference was limited by the small number of infants and for other reasons (20).

In a 2003 Danish study, 188 women received a macrolide (see Breastfeeding Summary) within 30 days of birth and none of their infants had IHPS (21).

Several reports have described the use of erythromycin for the successful treatment of Chlamydia infection in the second half of pregnancy (22–27). Although such use is effective, fewer maternal gastrointestinal adverse effects have been observed with amoxicillin (see Amoxicillin) (25–27).

BREASTFEEDING SUMMARY

Erythromycin is excreted into breast milk (28). Following oral doses of 400 mg every 8 hours, milk levels ranged from 0.4 to 1.6 mcg/mL. Oral doses of 2 g/day produced milk concentrations of 1.6–3.2 mcg/mL. The milk:plasma ratio in both groups was 0.5 (28).

In a 1993 cohort study, diarrhea was reported in 32 (19.3%) nursing infants of 166 breastfeeding mothers who were taking antibiotics (29). For the 17 women taking erythromycin, diarrhea was observed in 2 (12%) infants. The diarrhea was considered minor because it did not require medical attention (29).

A 2003 study investigated the association between maternal use of macrolides and infantile hypertrophic pyloric stenosis (21). The Danish population–based cohort study comprised 1166 women who had a prescribed macrolide (azithromycin, clarithromycin, erythromycin, spiramycin, or

roxithromycin) from birth to 90 days postnatally compared with up to 41,778 controls. The ORs for stenosis was 2.3–3.0, depending on the postnatal period of exposure (42, 56, 70, or 90 days), but none were significant. When stratified by gender, the ORs for males were 1.8–3.1 and again were not statistically significant. For females, the OR at 70 and 90 days postbirth were 10.3 and 7.5, respectively, but only the former was significant (95% CI 1.2–92.3) (21).

Investigators from Israel examined the possible association between macrolide (azithromycin, clarithromycin, erythromycin, or roxithromycin) exposure in milk and infantile hypertrophic pyloric stenosis in a 2009 study (30). They compared 55 infants exposed to a macrolide antibiotic to 36 infants exposed to amoxicillin. In the macrolide group, 7 (12.7%) had an adverse reaction (rash, diarrhea, loss of appetite, somnolence), whereas 3 infants (8.3%) in the amoxicillin group had an adverse reaction (rashes, somnolence). The rates of adverse reactions were comparable. No cases of infantile hypertrophic pyloric stenosis were observed (30).

The American Academy of Pediatrics classified erythromycin as compatible with breastfeeding in 2001 (31).

ESCITALOPRAM

Antidepressant

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 3rd Trimester

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Human pregnancy experience with escitalopram is very limited. The animal data suggest that the risk to an embryo–fetus is low. Two large case–control studies did find increased risks for some birth defects, but the absolute risk appears to be small. However, selective serotonin reuptake inhibitor (SSRI) antidepressants have been associated with several developmental toxicities, including spontaneous abortions, low birth weight, prematurity, neonatal serotonin syndrome, neonatal behavioral syndrome (withdrawal), possibly sustained abnormal neurobehavior beyond the neonatal period, respiratory distress, and persistent pulmonary hypertension of the newborn (PPHN).

FETAL RISK SUMMARY

Escitalopram is the S-enantiomer of racemic citalopram. It is an SSRI that is indicated for the treatment of depression. The metabolites of escitalopram apparently do not contribute to the antidepressant activity. Plasma protein binding is moderate (56%), but the plasma elimination half-life is long (27–32 hours) (1).

All the antidepressant agents in this class (citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline) share a similar mechanism of action, although only citalopram and escitalopram have similar chemical structures. These differences could be construed as evidence against any conclusion that they share similar effects on the embryo, fetus, or newborn. In the mouse embryo, however, craniofacial morphogenesis appears to be regulated, at least in part, by serotonin. Interference with serotonin regulation by chemically different inhibitors produces similar craniofacial defects (2).

Regardless of the structural differences, therefore, some of the potential adverse effects on the pregnancy also may be similar.

Reproduction studies have been conducted in rats. In rats, doses up to ≥ 56 times the maximum recommended human dose of 20 mg/day based on BSA (MRHD) resulted in decreased fetal body weight and delayed ossification. Mild maternal toxicity (clinical signs and decreased body weight gain and food consumption) was evident at the developmental no-effect dose (28 times the MRHD). No teratogenicity was evident at any dose up to 75 times the MRHD. In rats treated throughout pregnancy and through weaning with doses up to 24 times the MRHD, slightly increased offspring mortality and growth restriction were observed at the highest dose. Mild maternal toxicity (same as noted above) was evident at the highest dose. The no-effect dose was 6 times the MRHD (1). (See also Citalopram for fertility studies in rats and teratology studies in rats and rabbits.)

It is not known if escitalopram crosses the human placenta. The molecular weight (about 324 for the free base), moderate plasma protein binding, and prolonged elimination half-life suggest that escitalopram will cross to the embryo and/or fetus.

A significant increase in the risk of low birth weight (<10th percentile) and respiratory distress after prenatal exposure to SSRIs was reported in 2006 (3). The population-based study, representing all live births (N = 119,547) during a 39-month period in British Columbia, Canada, compared pregnancy outcomes of depressed mothers treated with SSRIs with outcomes in depressed mothers not treated with medication and in nonexposed controls. The severity of depression in the depressed groups was accounted for by propensity score matching (3).

A brief 2005 report described significant associations between the use of SSRIs in the 1st trimester and congenital defects (4). The data were collected by the CDC-sponsored National Birth Defects Prevention Study in an ongoing case-control study of birth defect risk factors. Case infants (N = 5357) with major birth defects were compared with 3366 normal controls. A positive association was found with omphalocele (N = 161; odds ratio [OR] 3.0, 95% confidence interval [CI] 1.4–6.1). Paroxetine, which accounted for 36% of all SSRI exposures, had the strongest association with the defect (OR 6.3, 95% CI 2.0–19.6). The study also found a significant association between the use of any SSRI and craniosynostosis (N = 372; OR 1.8, 95% CI 1.0–3.2) (4). An expanded report from this group was published in 2007 (see reference 11).

A 2006 report using the database (1995–2003) of the Swedish Medical Birth

Registry examined the relationship between maternal use of antidepressants and major malformations and cardiac defects (5). There was no significant increase in the risk of major malformations with any antidepressant. The strongest effect among cardiac anomalies was with ventricular or atrial septum defects (VSDs-ASDs). Significant increases were found with paroxetine (OR 2.22, 95% CI 1.39–3.55) and clomipramine (OR 1.87, 95% CI 1.16–2.99) (5). In 2007, the analysis of the Registry database was expanded to include the years 1995–2004 (6). There were 6481 women (6555 infants) who had reported the use of SSRIs in early pregnancy. The number using a single SSRI (i.e., no other SSRI or non-SSRI antidepressant) during the 1st trimester was 2579 citalopram, 1807 sertraline, 908 paroxetine, 860 fluoxetine, 66 escitalopram, and 36 fluvoxamine. Only paroxetine was significantly associated with cardiovascular effects (20 cases; OR 1.63, 95% CI 1.05–2.53). Paroxetine also had the strongest association with VSDs-ASDs, but did not reach significance (13 cases; relative risk [RR] 1.81, 95% CI 0.96–3.09). When the analysis was repeated after excluding women with body mass index >26, born outside of Sweden, or with reported subfertility (N = 405), only paroxetine was significantly associated with any cardiac defect (13 cases, RR 2.62, 95% CI 1.40–4.50) and with VSDs-ASDs (8 cases, RR 3.07, 95% CI 1.32–6.04). The RR remained significant after also excluding women who took neuroleptics, sedatives, hypnotics, folic acid, nonsteroidal anti-inflammatory agents, or anticonvulsants (N = 340). Analysis of the combined SSRI group, excluding paroxetine, revealed no associations with cardiac defects or VSDs-ASDs. The study also found no association with omphalocele or craniostenosis (6).

A 2006 case report described a pregnancy of a 36-year-old woman who had stopped her treatment of obsessive-compulsive disorder immediately before conception (7). Escitalopram 20 mg/day was restarted at 24 weeks' gestation because of a major depressive episode. She was concerned about the risk for poor neonatal adaptation syndrome, so the escitalopram was gradually tapered during the last month of pregnancy. She delivered a healthy 3.6-kg male infant at term with Apgar scores of 9 and 10 at 1 and 5 minutes, respectively. Escitalopram 20 mg/day was restarted 15 days after delivery while she was breastfeeding. No adverse effects had been reported in the infant who was currently 3 months of age (7).

A 2007 study evaluated the association between 1st trimester exposure to paroxetine and cardiac defects by quantifying the dose–response relationship (8). A population-based pregnancy registry was used by linking three administrative databases so that it included all pregnancies in Quebec between

1997 and 2003. There were 101 infants with major congenital defects, 24 involving the heart, among the 1403 women using only one type of antidepressant during the 1st trimester. The use of paroxetine or other SSRIs did not significantly increase the risk of major defects or cardiac defects compared with non-SSRI antidepressants. However, a paroxetine dose >25 mg/day during the 1st trimester was significantly associated with an increased risk of major defects (OR 2.23, 95% CI 1.19–4.17) and of cardiac defects (OR 3.07, 95% CI 1.00–9.42) (8).

A 2007 review conducted a literature search to determine the risk of major congenital malformations after 1st trimester exposure to SSRIs and selective serotonin and norepinephrine reuptake inhibitors (SNRIs) (9). Fifteen controlled studies were analyzed. The data were adequate to suggest that citalopram, fluoxetine, sertraline, and venlafaxine were not associated with an increased risk of congenital defects. In contrast, the analysis did suggest an increased risk with paroxetine. The data were inadequate to determine the risk for the other SSRIs and SNRIs (9).

A case–control study, published in 2006, was conducted to test the hypothesis that exposure to SSRIs in late pregnancy was associated with PPHN (10). A total of 1213 women were enrolled in the study, 377 cases whose infants had PPHN and 836 matched controls and their infants. Mothers were interviewed by nurses that were blinded to the hypothesis. Fourteen case infants had been exposed to an SSRI after the 20th week of gestation compared with six control infants (adjusted odds ratio 6.1, 95% CI 2.2–16.8). The numbers were too small to analyze the effects of dosage, SSRI used, or reduction of the length of exposure before delivery. No increased risk of PPHN was found with the use of SSRIs before the 20th week or with the use of non-SSRI antidepressants at any time in pregnancy. If the relationship was causal, the absolute risk was estimated to be about 1% (10).

Two large case–control studies assessing associations between SSRIs and major birth defects were published in 2007 (11,12). The findings related to SSRIs as a group, as well as to four specific agents: citalopram, fluoxetine, paroxetine, and sertraline. An accompanying editorial discussed the findings and limitations of these and other related studies (13). Details of the studies and the editorial are described in the paroxetine review (see Paroxetine).

A prospective cohort study evaluated a large group of pregnancies exposed to antidepressants in the 1st trimester to determine if there was an association with major malformations (14). The patient population came from the Motherisk database and involved 928 cases that met their criteria. The 928 matched (for

age, smoking, and alcohol use) controls were pregnancies not exposed to antidepressants or known teratogens. In addition to the 21 escitalopram cases, the other cases were 113 bupropion, 184 citalopram, 61 fluoxetine, 52 fluvoxamine, 68 mirtazapine, 39 nefazodone, 148 paroxetine, 61 sertraline, 17 trazodone, and 154 venlafaxine. In the antidepressant group, there were 24 (2.5%) major defects compared with 25 (2.6%) in controls (OR 0.9, 95% CI 0.5–1.61). There were no major defects in the pregnancies exposed to bupropion, escitalopram, or trazodone (14).

Necrotizing enterocolitis was reported in an infant exposed throughout pregnancy and during breastfeeding to escitalopram 20 mg/day (15). A cesarean section had delivered a 3.033-kg female infant at 38 weeks' gestation. She was treated for 2 days for respiratory distress syndrome thought to be related to retained fetal lung fluid. On day 5 after birth, the initial symptoms of necrotizing enterocolitis were lethargy, decreased oral intake, and grossly bloody stools. She was discharged home after 15 days. The authors concluded that exposure to escitalopram was the cause of the necrotizing enterocolitis based on a detailed discussion of the pharmacologic effects of the drug. Because the mother was still taking escitalopram, further breastfeeding was stopped (15).

BREASTFEEDING SUMMARY

Consistent with the molecular weight (about 324 for the free base), moderate plasma protein binding (56%), and prolonged elimination half-life (27–32 hours), escitalopram is excreted into breast milk. In a 2006 study, multiple blood and milk samples were obtained from eight women taking a mean 10 mg/day of the drug for postpartum depression (16). The mean age of the infants was 3.6 months. The mean milk:plasma ratios for escitalopram and its metabolite were 2.2, and the absolute infant doses were 7.6 and 3.0 mcg/kg/day, respectively. The total (parent drug plus metabolite) was 5.3%. All of the infants had normal development and no adverse effects were observed (16).

A 2006 case report described a 32-year-old woman who began taking escitalopram after birth of a healthy 3.560-kg infant (17). Milk and blood samples were collected at 1 and 7 weeks after start of therapy. The mother was taking a 5-mg dose at week 1 and 10-mg dose at week 7. The milk:serum ratios at the two collection periods were 2.49 and 2.03, respectively, whereas the infant's daily doses were 3.74 and 11.4 mcg/kg/day, respectively. The weight-adjusted relative infant doses were 5.1% and 7.7%, respectively. No adverse effects were reported by the mother and the infant was in good health

(17).

Although no adverse effects in the nursing infants were reported in the above studies, adverse effects have been reported in infants exposed to citalopram (see Citalopram).

Until additional data are available, nursing infants whose mothers are taking escitalopram should be closely monitored for evidence of toxicity. The American Academy of Pediatrics classifies other SSRI antidepressants as drugs for which the effect on nursing infants is unknown but may be of concern (e.g., see Fluoxetine).

A 2010 study using human and animal models found that drugs that disturb serotonin balance such as SSRIs and SNRIs can impair lactation (18). The authors concluded that mothers taking these drugs may need additional support to achieve breastfeeding goals.

A 2012 prospective cohort study appears to have confirmed the above conclusion (19). The breastfeeding rates of 466 women were compared between three groups: (i) those who were taking an SSRI at the time of delivery (N = 167); (ii) those who stopped the SSRI before delivery (N = 117); and (iii) those not exposed (N = 182). The data were collected over a 10-year period by the California Teratogen Information Service Clinical Research Program. The first two groups were significantly less likely to initiate breastfeeding (OR 0.43, 95% CI 0.20–0.94 and OR 0.34, 95% CI 0.16–0.72, respectively) compared with unexposed women (19).

ESMOLOL

Sympatholytic

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably
Compatible

PREGNANCY SUMMARY

Cardioselective β_1 -adrenergic blocking agents are not thought to cause structural anomalies. However, maternal exposure to esmolol has resulted in persistent β -blockade of the fetus and/or newborn.

FETAL RISK SUMMARY

Esmolol is a short-acting cardioselective β_1 -adrenergic blocking agent that is structurally related to atenolol and metoprolol. The drug is used for the rapid, temporary treatment of supraventricular tachyarrhythmias (e.g., atrial flutter or fibrillation, sinus tachycardia) and for hypertension occurring during surgery. Because hypotension may occur with its use—up to 50% of patients in some trials—the potential for decreased uterine blood flow and resulting fetal hypoxia should be considered.

Reproduction studies in rats with IV doses up to 10 times the maximum human maintenance dose (MHMD) for 30 minutes daily revealed no evidence of embryo or fetal harm (1). Maternal toxicity and lethality were evident at 33 times the MHMD. Studies in pregnant rabbits with nonmaternal toxic doses also failed to demonstrate embryo or fetal harm (1).

In pregnant sheep, the mean fetal:maternal serum ratio at the end of an infusion of esmolol was 0.08 (2). The drug was not detectable in the fetus 10 minutes after the end of the infusion. However, the hemodynamic effects in the fetal sheep, in terms of decreases in mean arterial pressure and heart rate, were similar to those in the mothers.

A 31-year-old woman at 22 weeks' gestation complicated by a subarachnoid hemorrhage was treated with esmolol prior to induction of anesthesia (3). The estimated weight of her fetus, by ultrasound, was 350 g. She was administered

bolus doses of esmolol of up to 2 mg/kg with a continuous infusion of 200 mcg/kg/minute. Fetal heart rate (FHR) decreased from 139–144 to 131–137 beats/minute (bpm) during esmolol treatment. No loss in FHR variability was observed. Administration of the drug was continued during surgery. A healthy, 2880-g boy was delivered at 37 weeks' gestation who was alive and well at 9 months of age.

A 29-year-old woman at 38 weeks' gestation presented with supraventricular tachycardia thought to be due to thyrotoxicosis (4). The FHR was 150–160 bpm. A bolus dose of esmolol, 0.5 mg/kg, followed by a continuous infusion of 50 mcg/kg/minute was given to the mother. Approximately 20 minutes later, the FHR increased to 170–175 bpm, then 4 minutes later fell to 70–80 bpm. The severe bradycardia persisted despite stopping the esmolol and an emergency cesarean section was performed to deliver a 2660-g male infant. The infant's initial pulse was 60 bpm, but increased to 140 bpm within 60 seconds in response to oxygen therapy. The umbilical vein blood pH was 7.09. The mother's arrhythmia was successfully converted after delivery with verapamil. Both mother and infant recovered uneventfully. The authors speculated that the cause of the fetal bradycardia was an esmolol-induced decrease in placental blood flow or interference with fetal compensation for a marginal placental perfusion (4).

A laboring mother at 39 weeks' gestation had a recurrence of tachyarrhythmia (225–235 bpm) that resulted in symptomatic hypotension and fetal bradycardia (5). She was treated with esmolol by IV bolus and continuous infusion (total dose 1060 mg) until delivery of 3390-g female infant with Apgar scores of 7 and 9. Symptoms of β -blockade in the infant included hypotonicity, weak cry, and dusky appearance and apnea with feeding, but except for mild jaundice, other evaluations (calcium, magnesium, and glucose serum levels) were normal. The feeding difficulties had resolved by 48 hours of age and the other symptoms by 60 hours of age.

β -Blockade in the fetus and newborn was described in a case in which the mother was treated with esmolol, 25 mcg/kg/minute, for hypertrophic obstructive cardiomyopathy during labor (6). Within 10 minutes of starting esmolol and receiving IV fentanyl, the fetal heart declined from 160 to 100 bpm with loss of beat-to-beat variability. The newborn had Apgar scores of 8 and 9 at 1 and 5 minutes, respectively, but was hypotensive (mean arterial pressure 34–39 mmHg), mildly hypotonic, hypoglycemic, and fed poorly. All of the symptoms had resolved by 36 hours of age.

A 1994 report described a woman who suffered a myocardial infarction at 26

weeks' gestation who was treated with an infusion of esmolol and other agents (7). She eventually delivered a healthy female infant at 39 weeks.

A 2013 review on the treatment of hypertensive crisis in pregnancy and the postpartum period listed esmolol as one of the preferred agents for this condition (8). Maternal adverse effects included 1st-degree heart block, bradycardia, congestive heart failure, and bronchospasm. Fetal adverse effects included bradycardia and persistent β -blockade (8).

BREASTFEEDING SUMMARY

No reports describing the use of esmolol during lactation have been located. Because of the indications for this drug and the fact that it must be given by injection, the opportunities for use of esmolol while nursing are probably nil.

ESOMEPRAZOLE

Gastrointestinal Agent (Antisecretory)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

There is very limited human pregnancy data for esomeprazole. A study showing an association between in utero exposure to gastric acid suppressing drugs and childhood allergy and asthma requires confirmation. The animal data and human pregnancy experience with other drugs in this class suggest low risk, but the risk of esomeprazole cannot be fully assessed without additional human data. Until such data are available, if a proton pump inhibitor (PPI) is required, the safest course is to use omeprazole or other drugs in this class that have human data, such as lansoprazole or pantoprazole. (See also Omeprazole, Lansoprazole, and Pantoprazole.) Inadvertent exposure in pregnancy, however, does not appear to represent a clinically significant risk to the embryo or fetus.

FETAL RISK SUMMARY

Esomeprazole, a PPI, is the S-isomer of omeprazole, which is a mixture of the S- and R-isomers. It is in the same drug class as dexlansoprazole, lansoprazole, omeprazole, pantoprazole, and rabeprazole. Esomeprazole is indicated for the short-term (4–8 weeks) treatment and maintenance in the healing and symptomatic resolution of gastrointestinal reflux disease. It is also indicated for the reduction in the occurrence of gastric ulcers in patients receiving continuous nonsteroidal anti-inflammatory therapy and, in combination with amoxicillin and clarithromycin, for the treatment of patients with *Helicobacter pylori* infection and duodenal ulcers. Esomeprazole is extensively metabolized in the liver by cytochrome P450 isoenzymes, primarily CYP2C19, but also by CYP3A4. Approximately 3% of whites and 15%–20% of Asians lack CYP2C19 (i.e., “poor metabolizers”). Plasma concentrations in poor

metabolizers are about twice those of subjects with unaltered metabolism. In the plasma, esomeprazole is 97% protein bound with an elimination half-life of about 1–1.5 hours (1).

Reproduction studies have been conducted with esomeprazole in rats and rabbits. In these species, oral doses up to about 57 and 35 times, respectively, the human dose of 20 mg/day based on BSA (HD) revealed no evidence of impaired fertility or fetal harm (1).

Studies with omeprazole, a mixture of the S- and R-isomers, found no evidence of teratogenicity in rats and rabbits at doses up to 56 times the HD in both species. However, in rats given doses ranging about 5.6–56 times the HD, dose-related embryo–fetal toxicity and postnatal developmental toxicity were observed (toxicities not specified). In addition, in rabbits given doses ranging about 5.5–56 times the HD, dose-related increases in embryoletality, fetal resorptions, and pregnancy disruptions were noted (1). The no-adverse-effect levels in these studies were not specified.

The carcinogenic potential of esomeprazole was assessed using omeprazole studies. A significant dose-related occurrence of gastric enterochromaffin-like (ECL) cell carcinoid tumors and ECL cell hyperplasia were observed in male and female rats (1). In a mutagenic study with esomeprazole, the in vitro human lymphocyte chromosome aberration test was positive, but three other mutagenesis assays were negative (1).

Consistent with its molecular weight (about 345 for the anhydrous free base), esomeprazole probably crosses the human placenta. Although this has not been specifically studied with esomeprazole, omeprazole has been shown to cross to the fetus at term. (See Omeprazole.)

A meta-analysis of PPIs in pregnancy was reported in 2009 (2). Based on 1530 exposed compared with 133,410 not-exposed pregnancies, the odds ratio (OR) for major malformations was 1.12 and 95% confidence interval (CI) 0.86–1.45. There also was no increased risk for spontaneous abortions (OR 1.29, 95% CI 0.84–1.97) or preterm birth (OR 1.13, 95% CI 0.96–1.33) (2).

A population-based observational cohort study formed by linking data from three Swedish national health care registers over a 10-year period (1995–2004) was reported in 2009 (3). The main outcome measures were a diagnosis of allergic disease or a prescription for asthma or allergy medications. The drug types included in the study were gastric acid suppressors, including H₂-receptor antagonists, prostaglandins, PPIs, combinations for eradication of *H. pylori*, and drugs for peptic ulcer and gastro-esophageal reflux disease, such as sucralfate. Of 585,716 children, 29,490 (5.0%) met the diagnosis and 5645

(1%) had been exposed to gastric acid suppression therapy in pregnancy. Of these children, 405 (0.07%) were treated for allergic disease. For developing allergy, the OR was 1.43, 98% CI 1.29–1.59, irrespective of the drug, time of exposure during pregnancy, and maternal history of allergy. For developing childhood asthma, but not other allergic diseases, the OR was 1.51, 95% CI 1.35–1.69, irrespective of the type of acid-suppressive drug and the time of exposure in pregnancy. The authors proposed three possible mechanisms for their findings: (i) exposure to increased amounts of allergens could cause sensitization to digestion labile antigens in the fetus; (ii) maternal Th2 cytokine pattern could promote an allergy-prone phenotype in the fetus; and (iii) maternal allergen-specific IgE could cross the placenta and sensitize fetal immune cells to food and airborne allergens. Several limitations of the study that might have affected their findings were identified, including a general increase in childhood asthma but not necessarily an increase in allergic asthma (3). The study requires confirmation.

In a 2010 study from Denmark, covering the period 1996–2008, there were 840,968 live births among whom 5082 were exposed to PPIs between 4 weeks before conception and the end of the 1st trimester (4). In the exposed group, there were 174 (3.4%) major malformations compared with 21,811 (2.6%) not exposed to PPIs (adjusted prevalence odds ratio [aPOR] 1.23, 95 CI 1.05–1.44). When the analysis was limited to exposure in the 1st trimester, there were 118 (3.2%) major malformations among 3651 exposed infants (aPOR 1.10, 95% CI 0.91–1.34). For exposure to esomeprazole in the 1st trimester, there were 23 (3.4%) major birth defects among 668 live births (aPOR 1.19, 95% CI 0.77–1.84) (see Lansoprazole, Omeprazole, Pantoprazole, and Rabeprazole for their data). The data showed that exposure to PPIs in the 1st trimester was not associated with a significantly increased risk of major birth defects (4). An accompanying editorial discussed the strengths and weaknesses of the study (5).

A 2012 case report described the use of esomeprazole (40 mg/day) throughout pregnancy in a woman with an intestinal transplant (6). Other medications used were prednisone (5 mg/day), diphenoxylate-atropine (2 tablets/day), tacrolimus (12 mg/day), ferrous sulfate (650 mg/day), ascorbic acid (1 g/day), prenatal vitamins (1/day), and magnesium supplementation. At 39 3/7 weeks, labor was induced and she had a spontaneous vaginal delivery of a healthy female infant (6).

In a 2012 publication, the National Birth Defects Prevention study, a multi-site population-based case–control study, examined whether nausea/vomiting of

pregnancy (NVP) or its treatment were associated with the most common noncardiac defects (nonsyndromic cleft lip with or without cleft palate [CL/P], cleft palate alone [CP], neural tube defects [NTDs], and hypospadias) (7). PPI exposure included esomeprazole, lansoprazole, and omeprazole. There were 4524 cases and 5859 controls. NVP was not associated with cleft palate or NTDs, but modest risk reductions were observed for CL/P and hypospadias. Increased risks were found for PPIs (N = 7) and hypospadias (adjusted OR [aOR] 4.36, 95% CI 1.21–15.81), steroids (N = 10) and hypospadias (aOR 2.87, 95% CI 1.03–7.97), and ondansetron (N = 11) and CP (aOR 2.37, 95% CI 1.18–4.76) (7).

A third 2012 reference, using the Danish nationwide registries, evaluated the risk of hypospadias after exposure to PPIs during the 1st trimester and throughout gestation (8). The study period, 1997–2009, included all liveborn boys that totaled 430,569 of whom 2926 were exposed to maternal PPI use. Hypospadias was diagnosed in 20 (0.7%) exposed boys, whereas 2683 (0.6%) of the nonexposed had hypospadias (adjusted prevalence ratio [aPR] 1.1, 95% CI 0.7–1.7). For the 5227 boys exposed throughout pregnancy, 32 (0.6%) had hypospadias (PR 1.0, 95% CI 0.7–1.4). When the analysis was restricted to mothers with two or more PPI prescriptions, the aPR of overall hypospadias was 1.7 (95% CI 0.9–3.3) and 1.6 (95% CI 0.7–3.9) for omeprazole. The authors concluded that PPIs were not associated with hypospadias (8).

Five reviews on the treatment of gastroesophageal reflux disease (GERD) have concluded that PPIs can be used in pregnancy with relative safety (9–13). Because there is either very limited or no human pregnancy data for the three newest agents in this class (dexlansoprazole, esomeprazole, and rabeprazole), other drugs in the class are preferred.

BREASTFEEDING SUMMARY

No reports describing the use of esomeprazole, the S-isomer of omeprazole, during human lactation have been located. The molecular weight (about 345 for the anhydrous free base) is low enough that excretion into breast milk should be expected. The effect of esomeprazole on a nursing infant is unknown. The potential for toxic effects such as those seen in adults (e.g., headache, diarrhea, and abdominal pain) and the suppression of gastric acid secretion are a concern, as is the potential for the gastric tumors that have been observed in animals after long-term use.

Small amounts of omeprazole, a mixture of the S- and R-isomers, are excreted into milk, but the quantity excreted needs further clarification. (See

Omeprazole.) If a lactating woman's condition requires esomeprazole, consideration of the drug's properties might allow her to nurse without significantly exposing her infant. Esomeprazole is dosed once daily because the inhibition of gastric acid secretion is prolonged. In contrast, the plasma elimination half-life is short (about 1–1.5 hours). Thus, waiting 5–7.5 hours after a dose should eliminate up to 97% of the drug from the plasma. Moreover, the mean peak plasma concentration is reported to occur 1.6 hours after the dose (1), and waiting 5–7.5 hours would avoid the period when the greatest amount of drug is available to enter milk. Emptying both breasts near the end of the waiting period and discarding the milk completes the strategy to limit the infant's exposure. This strategy was used in one case involving omeprazole but warrants further study.

ESTAZOLAM

Hypnotic

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 1st and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of estazolam in human pregnancy have been located. The effects of this drug on the fetus should be similar to other benzodiazepines (see Diazepam). Maternal use near delivery may potentially cause neonatal motor depression and withdrawal.

FETAL RISK SUMMARY

Estazolam is a benzodiazepine hypnotic agent in the same general class as flurazepam, quazepam, temazepam, and triazolam. It is indicated for the short-term management of insomnia. The metabolites have low potencies and concentrations and are not significant contributors to the hypnotic activity of estazolam. Plasma protein binding of estazolam is high (93%) and the range of estimated elimination half-life varies from 10 to 24 hours (1).

Animal reproduction studies have apparently not been conducted with estazolam. The manufacturer considers the drug contraindicated in pregnancy (1).

It is not known if estazolam crosses the human placenta. The molecular weight (about 295) and moderately long elimination half-life suggest that the drug will be transferred to the embryo–fetus. Of note, the benzodiazepine, diazepam, freely crosses the placenta and accumulates in the fetal circulation (see Diazepam).

BREASTFEEDING SUMMARY

No reports describing the use of estazolam during human lactation have been located. The molecular weight (about 295) and moderately long elimination half-life (10–24 hours) suggest that the drug will be excreted into breast milk. Other

agents in this class are excreted into milk in low concentrations (e.g., see Quazepam and Temazepam). No toxicity was observed in the nursing infants exposed to these two agents. However, the effects, if any, on an infant's CNS function are unknown. In recognition of this, the American Academy of Pediatrics classified quazepam and temazepam, especially when taken by nursing mothers for long periods, as agents whose effects on an infant are unknown, but may be of concern. Estazolam should be classified similarly.

ESTRADIOL

Estrogenic Hormone

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Estrogens are contraindicated because there are usually no benefits from their use in pregnancy.

FETAL RISK SUMMARY

Estradiol and its salts (cypionate, valerate) are used for treatment of menopausal symptoms, female hypogonadism, and primary ovarian failure. The more potent synthetic derivative, ethinyl estradiol, has similar indications and is also used in oral contraceptives (see also Oral Contraceptives).

The Collaborative Perinatal Project monitored 614 mother–child pairs with 1st trimester exposure to estrogenic agents (including 48 with exposure to estradiol) (1, pp. 389, 391). An increase in the expected frequency of cardiovascular defects, eye and ear anomalies, and Down's syndrome was found for estrogens as a group but not for estradiol (1, pp. 389, 391, 395). Reevaluation of these data in terms of timing of exposure, vaginal bleeding in early pregnancy, and previous maternal obstetric history, however, failed to support an association between estrogens and cardiac malformations (2). An earlier study also failed to find any relationship with nongenital malformations (3).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 29 newborns had been exposed to ethinyl estradiol during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Four (13.8%) major birth defects were observed (one expected), including (observed/expected) 1/0.3 cardiovascular defects and 1/0 hypospadias. No anomalies were observed in four other categories of defects (oral clefts, spina bifida, polydactyly, and limb reduction defects) for which specific data were available. The number of exposures is too small for any conclusion.

Developmental changes in the psychosexual performance of boys have been attributed to in utero exposure to estradiol and progesterone (4). The mothers received an estrogen/progestogen regimen for their diabetes. Hormone-exposed males demonstrated a trend to have less heterosexual experience and fewer masculine interests than controls. Estradiol has been administered to women in labor in an attempt to potentiate the cervical ripening effects of prostaglandins (5). No detectable effect was observed.

BREASTFEEDING SUMMARY

Estradiol has been used to suppress postpartum breast engorgement in patients who did not desire to breastfeed. Following the administration of vaginal suppositories containing 50 or 100 mg of estradiol to six lactating women who wished to stop breastfeeding, less than 10% of the dose appeared in breast milk (6). The American Academy of Pediatrics classifies estradiol as compatible with breastfeeding (7).

ESTROGENS, CONJUGATED

Estrogenic Hormone

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Estrogens are contraindicated because there are usually no benefits from their use in pregnancy.

FETAL RISK SUMMARY

Conjugated estrogens are a mixture of estrogenic substances (primarily estrone). The Collaborative Perinatal Project monitored 13 mother–child pairs who were exposed to conjugated estrogens during the 1st trimester (1, pp. 389, 391). An increased risk for malformations was found, although identification of the malformations was not provided. Estrogenic agents as a group were monitored in 614 mother–child pairs. An increase in the expected frequency of cardiovascular defects, eye and ear anomalies, and Down’s syndrome was reported (1, p. 395). Reevaluation of these data in terms of timing of exposure, vaginal bleeding in early pregnancy, and previous maternal obstetric history, however, failed to support an association between estrogens and cardiac malformations (2).

An earlier study also failed to find any relationship with nongenital malformations (3). No adverse effects were observed in one infant exposed during the 1st trimester to conjugated estrogens (4). However, in an infant exposed during the 4th–7th weeks of gestation to conjugated estrogens, multiple anomalies were found: cleft palate, micrognathia, wormian bones, heart defect, dislocated hips, absent tibiae, bowed fibulae, polydactyly, and abnormal dermal patterns (5). Multiple other agents were also taken during this pregnancy, but only conjugated estrogens and prochlorperazine (see also Prochlorperazine) appeared to have been taken during the critical period for the malformations.

Conjugated estrogens have been used to induce ovulation in anovulatory

women (6). They have also been used as partially successful contraceptives when given within 72 hours of unprotected, mid-cycle coitus (7). No fetal adverse effects were mentioned in either of these reports.

BREASTFEEDING SUMMARY

No reports of adverse effects from conjugated estrogens in the nursing infant have been located. It is possible that decreased milk volume and decreased nitrogen and protein content could occur (see Mestranol, Ethinyl Estradiol).

ESTRONE

Estrogenic Hormone

See Estrogens, Conjugated.

ESZOPICLONE

Hypnotic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of eszopiclone in human pregnancy have been located. The animal data suggest low risk, but the absence of human pregnancy experience prevents further assessment. However, there is human pregnancy experience with racemic zopiclone. A small 1999 observational study compared the pregnancy outcomes of 40 women exposed in the 1st trimester to zopiclone with those of 40 nonexposed controls (1,2). The outcomes in the two groups were spontaneous abortions 7 vs. 3, respectively; elective abortions 1 vs. 0, respectively; and minor defects 1 vs. 1 (congenital dislocation of the hip in each group), respectively. No difference between the groups in the incidence of major defects was observed: 0/31 (0%) exposed vs. 1/37 (2.7%) controls. Taken in sum, the available data suggest that eszopiclone exposure in pregnancy probably is low risk, but until data are available, the safest course would be to use a hypnotic agent with published human pregnancy experience.

FETAL RISK SUMMARY

Eszopiclone is an oral nonbenzodiazepine sedative/hypnotic. It is the active component [(S)-isomer] of racemic zopiclone [(R,S)-zopiclone], a sedative/hypnotic that has been available outside the United States since the 1980s. Eszopiclone is indicated for the treatment of insomnia. It is extensively metabolized to inactive metabolites. Plasma protein binding is low, in the range of 52%–59%, and the terminal elimination half-life is about 6 hours (3).

Reproduction studies with eszopiclone have been conducted in rats and rabbits. In rats, oral doses during organogenesis up to 800 times the maximum recommended human dose based on BSA (MRHD-BSA), a maternal toxic

dose, revealed no evidence of structural defects in the fetuses. Slight reductions in fetal weight and evidence of developmental delay were observed with doses about 400 times the MRHD-BSA that also were maternal toxic. These fetal effects were not observed with a nontoxic maternal dose (about 200 times the MRHD-BSA). When eszopiclone was administered throughout pregnancy and lactation at doses ranging from about 200 to 600 times the MRHD-BSA, increased postimplantation loss, decreased postnatal pup weights and survival, and increased pup startle response were seen at all doses. No structural defects were observed in rabbits given oral doses during organogenesis up to 100 times the MRHD-BSA (3).

In female and male rats, the no-effect eszopiclone dose for fertility was 16 times the MRHD-BSA. The no-effect doses for increased preimplantation loss, abnormal estrus cycles, and decreases in sperm number and motility and increases in abnormal sperm were 80, 80, and 16 times, respectively, the MRHD-BSA (3).

Eszopiclone was not carcinogenic in female and male rats given gavage doses resulting in plasma concentrations about 80 and 20 times, respectively, the maximum recommended dose based on AUC (MRHD-AUC) (1). When racemic zopiclone was given in the diet to female and male rats, eszopiclone plasma concentrations were about 150 and 70 times, respectively, the MRHD-AUC. In this study, an increase in mammary gland adenocarcinoma (females) and thyroid gland follicular cell adenomas and carcinomas (males) were observed. Carcinogenicity (pulmonary carcinomas and carcinomas plus adenomas) also was noted in female mice given racemic zopiclone in a diet that resulted in eszopiclone plasma concentrations about eight times the MRHD-AUC. However, an increase in pulmonary tumors was not observed in female mice given gavage doses of eszopiclone resulting in plasma concentrations about 90 times the MRHD-AUC. In tests for mutagenicity or clastogenicity, eszopiclone and one of its metabolites produced mixed results. Results of various assays ranged from positive through equivocal to negative (3).

It is not known if eszopiclone crosses the human placenta. The low molecular weight (about 389), low plasma protein binding, and moderately long elimination half-life suggest that the drug will cross to the embryo and/or fetus. However, the extensive metabolism should limit the degree of embryo–fetal exposure.

BREASTFEEDING SUMMARY

No reports describing the use of eszopiclone [(S)-zopiclone] during human lactation have been located. However, racemic zopiclone is excreted into

breast milk. A 1982/1983 study found a milk:plasma AUC ratio of about 0.60 and 0.80 (both values reported) after a single 7.5-mg oral dose of zopiclone in three nursing mothers (4,5). For eszopiclone, the molecular weight (about 389), low plasma protein binding (52%–59%), and moderately long elimination half-life (about 6 hours) suggest that it also will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown, but sedation is a potential effect. In addition, there is concern for central nervous system toxicity with long-term use.

ETANERCEPT

Immunologic Agent (Immunomodulator)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Etanercept was not toxic or teratogenic in animal reproduction tests at doses much higher than those used clinically. Although the human pregnancy experience is limited, there is no firm evidence of embryo–fetal harm. However, the human data are too limited for a full assessment of the risk. If etanercept is used in pregnancy for the treatment of rheumatoid arthritis, health care professionals are encouraged to call the toll free number (877-311-8972) for information about patient enrollment in the OTIS Rheumatoid Arthritis Study.

FETAL RISK SUMMARY

Etanercept is a dimeric fusion protein, produced by recombinant DNA technology, consisting of the extracellular ligand-binding portion of the human kilodalton (p75) tumor necrosis factor receptor (TNFR) linked to the Fc portion of human immunoglobulin G1 (IgG1). The protein binds specifically to TNF, a cytokine involved in inflammatory and immune responses, to block its interaction with cell-surface TNFRs (1,2). Etanercept is in the same subclass of immunomodulators that inhibit TNF as adalimumab, certolizumab, golimumab, and infliximab. It is indicated for reducing the signs and symptoms and delaying structural damage in moderate to severe rheumatoid arthritis, including juvenile arthritis. The drug is administered by SC injection.

Reproduction studies in rats and rabbits at doses 60–100 times the human dose revealed no fetal harm (1,2). Animal fertility and carcinogenic studies have not been conducted with etanercept, but it was not mutagenic in in vitro and in vivo tests.

A 32-year-old woman with a 1-year history of rheumatoid arthritis and

infertility was treated with SC etanercept (25 mg twice weekly), oral methotrexate (2.5 mg/week), and rofecoxib (25 mg/day) (3). Three months after stopping methotrexate and rofecoxib, and 4 weeks after the last dose of etanercept (total dose 3300 mg over 64 months), she underwent ovulation induction and intrauterine insemination. A successful pregnancy occurred and she delivered a healthy, 2659-g female infant at term. The baby was doing well at 3 months of age (3).

A 37-year-old woman with infertility secondary to antiphospholipid antibodies and elevated natural killer (NK) cells was treated with etanercept (25 mg SC twice weekly), low-dose aspirin (81 mg/day), and low-molecular-weight heparin (enoxaparin 30 mg SC daily) (4). The woman also had a history of chronic leukopenia that was attributed to Epstein-Barr virus. She became pregnant 1 month after the start of therapy. All three agents were discontinued at gestational week 32. At about 38 weeks', she delivered a healthy male (about 2486-g) infant that was doing well at 21 months of age. Although it could not be proven, the authors speculated that etanercept might have played a role in the pregnancy by inhibiting TNF produced by the NK cells in the lining of the woman's uterus (4).

Etanercept was used in a woman who had experienced implantation failure in five previous in vitro fertilization treatments (5). Etanercept 25 mg SC every 4 days was started 4 weeks before ovulation induction and then discontinued upon commencement of gonadotropins. The woman delivered male twins at 34.5 weeks (no additional information provided) (5).

A survey of 600 members of the American College of Rheumatology, partially conducted to determine the outcomes of pregnancies exposed to disease-modifying antirheumatic drugs (DMARD) (etanercept, infliximab, leflunomide, and methotrexate), was published in 2003 (6). From the 175 responders, the outcomes of 15 pregnancies exposed to etanercept were 6 full-term healthy infants, 1 spontaneous abortion (SAB) (also taking methotrexate), 1 elective abortion (EAB), 3 unknown outcomes, and 4 women still pregnant (6).

An early review recommended that pregnancy should be excluded before etanercept was administered to women of childbearing age and that effective contraception should be used during treatment (7). Another review speculated that etanercept could disrupt pregnancy because of its anticytokine activity (8). However, this theoretical concern has not been shown clinically (9).

The preliminary results of an ongoing prospective collaborative study of rheumatoid arthritis medicines in pregnancy conducted by the Organization of Teratology Information Specialists (OTIS) have been reported (10,11). The

study covered the period 1999–2004. There were 33 women exposed in the 1st trimester to either etanercept (N = 29) or infliximab (N = 4). The outcomes of these pregnancies were compared with 77 prospectively ascertained disease-matched controls (did not use anti-TNF α agents) and 50 prospectively ascertained healthy controls. Three controls were lost to follow-up. There was no difference between the groups in the number of SABs and EABs. One malformation (1/33; 3.0%) was reported in the subject group (a chromosomal anomaly, trisomy 18; spontaneously aborted by a woman exposed to etanercept). Major malformations in the other groups were 4.0% (3/75) in disease-matched controls and 4.1% (2/49) in healthy controls. However, women exposed to etanercept or infliximab and disease-matched controls were significantly more likely to give birth to infants <37 weeks' gestation and to have lower-birth-weight full-term infants than healthy controls. These results suggested that the disease itself was the causal factor (10,11).

A 2006 communication from England described the pregnancy outcomes of 23 women directly exposed to TNF α agents at the time of conception (17 etanercept, 3 adalimumab, and 3 infliximab) (12). Additional therapy included methotrexate in nine women and leflunomide in two. There also were nine patients (4 etanercept, 5 infliximab) that discontinued therapy before conception. The outcomes for the 32 pregnancies were 7 SABs, 3 EABs, and 22 live births. No major anomalies were observed in the live births, including one infant exposed to adalimumab and methotrexate early in gestation (12).

A 2007 case report and literature review described the use of etanercept in two pregnancies (13).

In the first pregnancy, the woman was started on etanercept 25 mg twice weekly before conception. Her pregnancy was diagnosed at about 2 months' gestation. Although ultrasound revealed no abnormalities and normal growth, she elected to terminate the pregnancy. The second case involved a 21-year-old woman who was treated before conception with etanercept 25 mg twice weekly and prednisone 5 mg/ day. She became pregnant about 9 months later with her last dose of etanercept given at about 4 weeks' gestation. At term, she gave birth to a healthy 3.520-kg male infant. During the neonatal period, the infant was treated for a urinary tract infection and jaundice. Adrenal congenital hyperplasia with 21-hydroxylase deficiency, known in the father, was detected at 5 days of age and treated with prednisone. At 2 years of age, the child was developing normally (13).

A report using data from the FDA database described 61 congenital anomalies in 41 children born to mothers taking a TNF antagonist (22

etanercept and 19 infliximab) (14). The authors concluded that 24 of the children had one or more of the congenital anomalies that are part of VACTERL association (vertebral anomalies, anal atresia, cardiac defects, tracheoesophageal, renal, and limb abnormalities) and the rate was higher than historical controls (14). An accompanying editorial, however, concluded that the evidence for teratogenicity or with the VACTERL association was lacking (15). Many of the anomalies reported occur commonly, such as ventricular septal defects. In addition, such databases have selection bias (only cases with adverse outcomes are reported and emphasis is placed on exposures to new drugs) (15).

A 2009 study from France reported the outcomes of 15 women who took anti-TNF drugs during pregnancy (10 etanercept, 3 infliximab, and 2 adalimumab) (16). The drugs were given in the 1st, 2nd, and 3rd trimesters in 12, 3, and 2 cases, respectively. The outcomes were 2 SABs, 1 EAB, and 12 healthy babies without malformation or neonatal illness. They also reviewed the literature regarding the use of anti-TNF agents in pregnancy and found more than 300 cases. They concluded that, although only 29 were treated throughout gestation, the malformation rate was similar to the general population (16).

A woman with severe rheumatoid arthritis that was well controlled with etanercept was diagnosed with a pregnancy at 6 weeks' gestation (17). Etanercept was discontinued but restarted at 20 weeks' because of worsening arthritis. She was continued throughout the remainder of pregnancy. She gave birth at 39 weeks to 2.740-kg female infant with Apgar scores of 10 and 10. No malformations were observed in the newborn (17).

A 40-year-old woman was treated with SC etanercept 25 mg twice weekly and prednisolone 9 mg/day before and throughout pregnancy (18). Maternal blood concentrations of etanercept were measured in each trimester and at delivery. The concentrations decreased during pregnancy from 3849 ng/mL in the 1st trimester to 2239 ng/mL at delivery. She gave birth at 36 weeks' to a 1.906-kg female infant with Apgar scores of 8 and 9. The cord serum concentration at delivery was 81 ng/mL, about 4% of the mother's concentration. No abnormalities were observed in the infant (18).

BREASTFEEDING SUMMARY

In the case described above (18), the mother exclusively breastfed her infant while continuing the same dose of etanercept. Maternal blood concentrations at postpartum weeks 1, 3, and 12 were relatively constant (2306–3512 ng/mL), whereas the infant's serum concentrations, 81 ng/mL at birth, decreased from

21 ng/mL at 1 week to not detectable (detection level not stated) at 12 weeks. A breast milk concentration, measured at 12 weeks, was 3.5 ng/mL (18).

A woman 30 days after delivery was started on SC etanercept 25 mg twice weekly for an acute flare of arthritis (19). She did not breastfeed her infant. After the fifth dose, a blood sample (data not shown) was drawn and daily milk samples were obtained on postpartum days 44–49. The peak concentration in milk was 75 ng/mL, 1 day after the dose, and the concentration in the other samples declined from 50 to 25 mcg/mL. The estimated dose a nursing infant would have received was 50–90 mcg/day (19).

There is a marked difference in the milk concentrations in the two studies. The timing of the samples in relationship to the dose was only provided in the first case, and then only in approximate terms. Nevertheless, the milk concentrations are very low and there appeared to be no systemic absorption by the one infant that was breastfed. If confirmed, this would be evidence that the protein is digested in the infants' gastrointestinal tract. Although additional data are required, the limited information suggests that breastfeeding is compatible with maternal use of etanercept.

ETHACRYNIC ACID

Diuretic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Although limited 1st trimester human experience has not shown an increased incidence of malformations, ethacrynic acid is not recommended for use in pregnant women (1). Diuretics do not prevent or alter the course of toxemia, but they may decrease placental perfusion (see also Chlorothiazide) (2–4). In general, diuretics are not recommended for the treatment of gestational hypertension because of the maternal hypovolemia characteristic of this disease.

FETAL RISK SUMMARY

Ethacrynic acid is a potent diuretic. It has been used for toxemia, pulmonary edema, and diabetes insipidus during pregnancy (5–14).

Reproduction studies in mice and rabbits at doses up to 50 times the human dose showed no evidence of external malformations (15). Doses of 10 or 2.5 times the human dose in rats and dogs, respectively, did not impair fertility or growth and development of pups. Intrauterine growth restriction was observed in the offspring of rats at a dose 50 times the human dose, but there was no effect on survival or postnatal development (15).

Ototoxicity has been observed in a mother and her newborn following the use of ethacrynic acid and kanamycin during the 3rd trimester (see also Kanamycin) (16).

BREASTFEEDING SUMMARY

No reports describing the use of ethacrynic acid during lactation have been located (see also Chlorothiazide). The manufacturer recommends that ethacrynic acid not be used in nursing mothers (15).

ETHAMBUTOL

Antituberculosis Agent

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

The literature supports the safety of ethambutol in combination with isoniazid and rifampin during pregnancy (1–5). One investigator studied 38 patients (42 pregnancies) receiving antitubercular therapy (1). The minor abnormalities noted were within the expected frequency of occurrence. Another researcher observed six aborted fetuses at 5–12 weeks of age (2). Embryonic optic systems were specifically examined and were found to be normal. Most reviewers consider ethambutol, along with isoniazid and rifampin, to be the safest antituberculosis therapy (6,7). However, long-term follow-up examinations for ocular damage have not been reported, causing concern among some clinicians (8).

FETAL RISK SUMMARY

No reports linking the use of ethambutol with congenital defects have been located. The drug crosses the placenta to the fetus (9,10). In a woman who delivered at 38 weeks' gestation, ethambutol concentrations in the cord and maternal blood 30 hours after an 800-mg (15 mg/kg) dose were 4.1 and 5.5 ng/mL, respectively, with a cord:maternal serum ratio of 0.75 (9). The amniotic fluid ethambutol level was 9.5 ng/mL. These levels were within the range (1–5 ng/mL) required to inhibit the growth of *Mycobacterium tuberculosis* (9).

BREASTFEEDING SUMMARY

Ethambutol is excreted into human milk. Milk concentrations in two women (unpublished data) were 1.4 mcg/mL (after an oral dose of 15 mg/kg) and 4.60 mcg/mL (dosage not given) (11). Corresponding maternal serum levels were 1.5 and 4.62 mcg/mL, respectively, indicating milk:serum ratios of approximately 1:1. The American Academy of Pediatrics classifies ethambutol

as compatible with breastfeeding (12).

ETHANOL

Sedative

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Hold Breastfeeding

PREGNANCY SUMMARY

Ethanol is a teratogen and its use during pregnancy, especially during the first 2 months after conception, is associated with significant risk to the fetus and newborn. Heavy maternal use is related to a spectrum of defects collectively termed the fetal alcohol syndrome. Even moderate use may be related to spontaneous abortions and to developmental and behavioral dysfunction in the infant. A safe dose of alcohol in pregnancy has not been established and a woman should abstain from any intake during pregnancy.

FETAL RISK SUMMARY

The teratogenic effects of ethanol (alcohol) have been recognized since antiquity, but this knowledge gradually fell into disfavor and was actually dismissed as superstition in the 1940s (1). Approximately three decades later, the characteristic pattern of anomalies that came to be known as the fetal alcohol syndrome (FAS) were rediscovered, first in France and then in the United States (2–5). By 1981, over 800 clinical and research papers on the FAS had been published (6).

Mild FAS (low birth weight) has been induced by the daily consumption of as little as two drinks (1 ounce of absolute alcohol or about 30 mL) in early pregnancy, but the complete syndrome is usually seen when maternal consumption is four to five drinks (60–75 mL of absolute alcohol) per day or more. The Council on Scientific Affairs of the American Medical Association and the American Council on Science and Health have each published reports on the consequences of maternal alcohol ingestion during pregnancy (7,8). The incidence of the FAS, depending upon the population studied, is estimated to be between 1/300 and 1/2000 live births with 30%–40% of the offspring of alcoholic mothers expected to show the complete syndrome (7). The true incidence may be even higher because the diagnosis of FAS can be delayed for

many years (9) (e.g., see reference 25 below). In addition, the incidence of alcohol abuse seems to be rising. A 1989 report found that alcohol abuse during 1987 in 1032 pregnant women was 1.4% compared with 0.7% of 5602 pregnant women during 1977–1980 (10). The difference in frequency was significant ($p < 0.05$).

Heavy alcohol intake by the father prior to conception has been suspected of producing the FAS (11,12), although this association has been challenged (13). The report by the AMA Council states that growth restriction and some adverse aspects of fetal development may be due to paternal influence but conclusive evidence for the complete FAS is lacking (7).

Evidence supporting an association between “regular drinking” by the father in the month before conception and the infant’s birth weight was published in two reports, both by the same authors (14,15). “Regular drinking” was defined as “an average of at least 30 mL of ethanol daily or of 75 mL or more on a single occasion at least once a month” (14). “Occasional drinking” was defined as anything less than this. The mean birth weight, 3465 g, of 174 infants of “regular drinking” fathers was 181 g less than the mean birth weight, 3646 g, of 203 infants of “occasional drinking” fathers, a significant difference ($p < 0.001$). Using regression analysis, a 137-g decrease in birth weight was predicted (15). Statistical significance was also present when the data were categorized by sex (males 3561 vs. 3733 g, females 3364 vs. 3538 g), percentage of infants less than 3000 g (15% vs. 9%), and percentage of infants at or greater than 4000 g (12% vs. 23%). Infant characteristics unrelated to the father’s drinking were length, head circumference, gestational age, and Apgar scores (15). Consideration of the mother’s drinking, smoking, and marijuana use did not change the statistical significance of the data. Nor could the differences be attributed to any of 20 reproductive and socioeconomic variables that were examined, including paternal smoking and marijuana use. No increases in structural defects were detected in the infants of the “regular drinking” fathers, but the sample size may have been too small to detect such an increase (14). In contrast to these data, other researchers have been unable to find an association between paternal drinking and infant birth weight (16). Thus, additional research is required, especially because the biologic mechanisms for the proposed association have not been determined (15).

The mechanism of ethanol’s teratogenic effect is unknown but may be related to acetaldehyde, a metabolic byproduct of ethanol (7). One researcher reported higher blood levels of acetaldehyde in mothers of children with FAS than in alcoholics who delivered normal children (17). However, the analysis

techniques used in that study have been questioned, and the high concentrations may have been due to artifactual formation of acetaldehyde (18). At the cellular level, alcohol or one of its metabolites may disrupt protein synthesis, resulting in cellular growth restriction with serious consequences for fetal brain development (19). Other proposed mechanisms that may contribute, as reviewed by Shepard (20), include poor protein intake, vitamin B deficiency, lead contamination of alcohol, and genetic predisposition. Of interest, metronidazole, a commonly used anti-infective agent, has been shown to markedly potentiate the fetotoxicity and teratogenicity of alcohol in mice (21). Human studies of this possible interaction have not been reported.

Complete FAS consists of abnormalities in three areas with a fourth area often involved: (a) craniofacial dysmorphism, (b) prenatal and antenatal growth deficiencies, (c) central nervous system dysfunction, and (d) various other abnormalities (7,8). Problems occurring in the latter area include cardiac and renogenital defects and hemangiomas in about one half of the cases (3–5, 22). Cardiac malformations were described in 43 patients (57%) in a series of 76 children with the FAS evaluated for 0–6 years (age: birth to 18 years) (23). Functional murmurs (12 cases, 16%) and ventricular septal defects (VSD) (20 patients, 26%) accounted for the majority of anomalies. Other cardiac lesions present, in descending order of frequency, were: double outlet right ventricle and pulmonary atresia, dextrocardia (with VSD), patent ductus arteriosus with secondary pulmonary hypertension, and cor pulmonale. Liver abnormalities have also been reported (24, 25). Behavioral problems, including minimal brain dysfunction, are long-term effects of the FAS (1).

Ten-year follow-up of the original 11 children who were first diagnosed as having the FAS was reported in 1985 (25). Of the 11 children, 2 were dead, 1 was lost to follow-up, 4 had borderline intelligence with continued growth deficiency and were dysmorphic, and 4 had severe intelligence deficiency as well as growth deficiency and dysmorphic appearance. Moreover, the degree of growth deficiency and intellectual impairment was directly related to the degree of craniofacial abnormalities (25). In the eight children examined, height, weight, and head circumference were deficient, especially the latter two parameters. The authors concluded that the slow head growth after birth may explain why, in some cases, the FAS is not diagnosed until 9–12 months of age (25). Cardiac malformations originally observed in the infants, atrial septal defect (one), patent ductus arteriosus (one), and ventricular septal defect (six), had either resolved spontaneously or were no longer clinically significant. Three new features of the FAS were observed: dental malalignments, malocclusions,

and eustachian tube dysfunction (associated with maxillary hypoplasia and leading to chronic serous otitis media) (25).

Fetal Alcohol Syndrome (2–9,11–13, 22–38)

Craniofacial

Eyes: short palpebral fissures, ptosis, strabismus, epicanthal folds, myopia, microphthalmia, blepharophimosis

Ears: poorly formed concha, posterior rotation, eustachian tube dysfunction

Nose: short, upturned hypoplastic philtrum

Mouth: prominent lateral palatine ridges, thinned upper vermilion, retrognathia in infancy, micrognathia or relative prognathia in adolescence, cleft lip or palate, small teeth with faulty enamel, Class III malocclusion, poor dental alignment

Maxilla: hypoplastic

Central nervous system

Dysfunction demonstrated by mild to moderate retardation, microcephaly, poor coordination, hypotonia, irritability in infancy, and hyperactivity in childhood

Growth

Prenatal (affecting body length more than weight) and postnatal deficiency (length, weight, and head circumference)

Cardiac

Murmurs, atrial septal defect, ventricular septal defect, great vessel anomalies, tetralogy of Fallot

Renogenital

Labial hypoplasia, hypospadias, renal defects

Cutaneous

Hemangiomas, hirsutism in infancy

Skeletal

Abnormal palmar creases, pectus excavatum, restriction of joint movement, nail hypoplasia, radioulnar synostosis, pectus carinatum, bifid xiphoid, Klippel–Feil anomaly, scoliosis

Muscular

Hernias of diaphragm, umbilicus or groin, diastasis recti

A study published in 1987 found that craniofacial abnormalities were closely related to alcohol consumption in a dose–response manner (39). Although a distinct threshold was not defined, the data indicated that the consumption of more than six drinks (90 mL of ethanol) per day was clearly related to

structural defects, with the critical period for alcohol-induced teratogenicity around the time of conception (39). A 1989 study that examined 595 live singleton births found a significant correlation between alcohol use in the first 2 months of pregnancy and intrauterine growth restriction and structural abnormalities (40). Analysis of alcohol use during the other periods of pregnancy did not show a significant association with these outcomes.

A prospective study, conducted between 1974 and 1977 at the Kaiser Permanente health maintenance organization in Northern California, was conducted to determine whether light to moderate drinking during pregnancy was associated with congenital abnormalities (41). A total of 32,870 women met all of the criteria for enrollment in the study. Of the total study population, 15,460 (47%) used alcohol during pregnancy, 17,114 (52%) denied use, and 296 (1%) provided incomplete information on their drinking. Of those drinking, 14,502 (94%) averaged less than one drink/day, 793 (5%) drank one to two drinks/day, 127 (0.8%) consumed three to five drinks/day, and 38 (0.2%) drank six or more drinks/day. The total (major and minor) malformation rates were similar between nondrinkers and light (less than one drink/day) or moderate (one to two drinks/day) drinkers; 78.1/1000, 77.3/1000, and 83.2/1000, respectively. A significant trend ($p = 0.034$) was found with increasing alcohol use and congenital malformations of the sex organs (e.g., absence or hypertrophy of the labia, clitoris, and vagina; defects of the ovaries, fallopian tubes, and uterus; hypoplastic or absent penis or scrotum; intersex and unspecified genital anomalies) (41). Rates per 1000 for defects of the sex organs in nondrinkers and the four drinking groups were 2.8, 2.6, 6.3, 7.9, and 26.3, respectively. Genitourinary malformations (i.e., cryptorchidism, hypospadias, and epispadias) also followed an increasing trend with rates per 1000 women of 27.2, 27.5, 31.5, 47.2, and 78.9 (p value for trend = 0.04), respectively. At the levels of alcohol consumption observed in the study, no increase in the other malformations commonly associated with the FAS was found with increasing alcohol use.

A strong association between moderate drinking (>30 mL of absolute alcohol twice per week) and 2nd trimester (15–27 weeks) spontaneous abortions has been found (27,28). Alcohol consumption at this level may increase the risk of miscarriage by 2–4-fold, apparently by acting as an acute fetal toxin. Consumption of smaller amounts of alcohol, such as one drink (approximately 15 mL of absolute alcohol) per week, was not associated with an increased risk of miscarriage in a 1989 report (42).

Ethanol was once used to treat premature uterine contractions. In a

retrospective analysis of women treated for premature labor between 1968 and 1973, 239 singleton pregnancies were identified (43). In 136, the women had received oral and/or IV ethanol, in addition to bed rest and oral β -mimetics. The remaining 103 women had been treated only with bed rest and oral β -mimetics. The alcohol group received an average of 38 g of ethanol/day for 2–34 days. In addition, 73 of these women continued to use oral alcohol at home as needed to arrest uterine contractions. Treatment with ethanol was begun at 12 weeks' gestation or less in 82 (60.3%) of the treated women. The mean birth weights of the alcohol-exposed and nonexposed infants were similar, 3385 vs. 3283 g, respectively. No significant differences were found between the groups in the number of infants who were small for gestational age (weight or length <10th percentile), birth length, fetal and neonatal deaths, and infants with anomalies. No relationship was found between ethanol dose and birth weight, length, or neonatal outcome. None of the exposed infants had features of the typical fetal alcohol syndrome. Psychomotor development (age to sit, walk, speak sentences of a few words, and read) and growth velocity were similar between the two groups. One of the infants whose mother had been treated with IV alcohol was growth restricted from birth to 14 years of age. Eight (6.1%) of 131 alcohol-exposed infants were considered to have problems in school (hyperactivity, carelessness) compared with 2 (2.0%) of 99 controls, but the difference was not significant. Other complications observed were aphasia and impaired hearing in two infants of the treated group and a third infant with blindness in the right eye (this infant was delivered at 27 weeks' gestation and the condition was thought to be due to oxygen therapy). The authors concluded that the alcohol treatment for threatened 1st or 2nd trimester abortions did not cause fetal damage (43). However, an earlier study concluded that adverse effects occurred after even short-term exposure (44). This conclusion was reached in an evaluation of 25 children, 4–7 years of age whose mothers had been treated with alcohol infusions to prevent preterm labor (44). In comparison with matched controls, seven children born during or within 15 hours of termination of the infusion had significant pathology in developmental and personality evaluations.

Two reports have described neural tube defects in six infants exposed to heavy amounts of alcohol during early gestation (45,46). Lumbosacral meningocele was observed in five of the newborns and anencephaly in one. One of the infants also had a dislocated hip and clubfeet (45).

A possible association between maternal drinking and clubfoot was proposed in a short 1985 report (47). Three of 43 infants, delivered from maternal

alcoholics, had fetal talipes equinovarus (clubfoot), an incidence significantly greater than expected ($p < 0.00001$).

Gastroschisis has been observed in dizygotic twins delivered from a mother who consumed 150–180 mL of absolute ethanol/day during the first 10 weeks of gestation (48). Although an association could not be proven, the authors speculated that the defects resulted from the heavy alcohol ingestion.

A 1982 report described four offspring of alcoholic mothers with clinical and laboratory features of combined FAS and DiGeorge syndrome (49). Several characteristics of the two syndromes are similar, including craniofacial, cardiac, central nervous system, renal, and immune defects (49). Features not shared are hypoparathyroidism (part of DiGeorge syndrome) and skeletal anomalies (part of FAS). A possible causative relationship was suggested between maternal alcoholism and the DiGeorge syndrome.

An unusual chromosomal anomaly was discovered in a 2-year-old girl whose mother drank heavily during early gestation (50). The infant's karyotype revealed an isochromosome for the long arm of number 9: 46,XX,-9,+i(9q). The infant had several characteristics of the FAS, including growth restriction. The relationship between the chromosomal defect and alcohol is unknown.

Prospective analysis of 31,604 pregnancies found that the percentage of newborns below the 10th percentile of weight for gestational age increased sharply as maternal alcohol intake increased (51). In comparison with nondrinkers, mean birth weight was reduced 14 g in those drinking less than one drink per day and 165 g in those drinking three to five drinks per day. The risk for growth restriction was markedly increased by the ingestion of one to two drinks each day. Other investigators discovered that women drinking more than 100 g of absolute alcohol/week at the time of conception had an increased risk of delivering a growth-restricted infant (52). The risk was twice that of women ingesting less than 50 g/week. Of special significance, the risk for growth restriction was not reduced if drinking was reduced later in pregnancy. However, a 1983 report found that if heavy drinkers reduced their consumption in mid-pregnancy, growth impairment was also reduced, although an increased incidence of congenital defects was still evident (53). Significantly smaller head circumferences have been measured in offspring of mothers who drank more than an average of 20 mL of alcohol/day compared with nondrinkers (54). In this same study, the incidence of major congenital anomalies in drinkers and nondrinkers was 1.2% vs. none (54). These authors concluded that there was no safe level of alcohol consumption in pregnancy.

Alcohol ingestion has been shown to abolish fetal breathing (55). Eleven

women, at 37–40 weeks' gestation, were given 0.25 g/kg of ethanol. Within 30 minutes, fetal breathing movements were almost abolished and remained so for 3 hours. No effect on gross fetal body movements or fetal heart rate was observed. However, a 1986 report described four women admitted to a hospital because of marked alcohol intoxication (56). In each case, fetal heart rate tracings revealed no or poor variability and no reactivity to fetal movements or external stimuli. Because of suspected fetal distress, an emergency cesarean section was performed in one patient, but no signs of hypoxia were present in the healthy infant. In the remaining three women, normalization of the fetal heart rate patterns occurred within 11–14 hours when the mothers became sober.

A study of the relationship between maternal alcohol ingestion and the risk of respiratory distress syndrome (RDS) in their infants was published in 1987 (57). Of the 531 infants in the study, 134 were delivered at a gestational age of 28–36 weeks. The 134 mothers of these preterm infants were classified by the amount of alcohol they consumed per occasion into abstainers (N = 58) (none), occasional (N = 21) (less than 15 mL), social (N = 15) (15–30 mL), binge (N = 12) (greater than 75 mL), and alcoholic (N = 28). The incidence of RDS in the infants from the five groups was 44.8%, 38.1%, 26.7%, 16.7%, and 21.4%, respectively. The difference between abstainers and those frankly alcoholic was significant ($p < 0.05$). Moreover, assuming equal intervals of alcohol intake among the five groups, the decrease in incidence of RDS with increasing alcohol intake was significant ($p < 0.02$). Adjustment of the data for smoking, gestational age, birth weight, Apgar score, and sex of the infant did not change the findings. The authors concluded that chronic alcohol ingestion may have enhanced fetal lung maturation (57).

Neonatal alcohol withdrawal has been demonstrated in offspring of mothers ingesting a mean of 21 ounces (630 mL) of alcohol/week during pregnancy (58). In comparison to infants exposed to an equivalent amount of ethanol only during early gestation or to infants whose mothers never drank, the heavily exposed infants had significantly more withdrawal symptoms. No differences were found between the infants exposed only during early gestation and those never exposed. Electroencephalogram (EEG) testing of infants at 4–6 weeks of age indicated that the irritability and tremors may be due to a specific effect of ethanol on the fetal brain and not to withdrawal or prematurity (59). Persistent EEG hypersynchrony was observed in those infants delivered from mothers who drank more than 60 mL of alcohol/day during pregnancy. The EEG findings were found in the absence of dysmorphology and as a result, the authors

suggested that this symptom should be added to the definition of the FAS (59).

Combined fetal alcohol and hydantoin syndromes have been described in several reports (60–63). The infants exhibited numerous similar features from exposure to alcohol and phenytoin. The possibility that the agents are also carcinogenic in utero has been suggested by the finding of ganglioneuroblastoma in a 35-month-old boy and Hodgkin's disease in a 45-month-old girl, both with the combined syndromes (see also Phenytoin) (61–63). Adrenal carcinoma in a 13-year-old girl with FAS has also been reported (64). These findings may be fortuitous, but long-term follow-up of children with the FAS is needed.

An unusual cause of FAS was described in 1981 (65). A woman consumed, throughout pregnancy, 480–840 mL/day of an over-the-counter cough preparation. Since the cough syrup contained 9.5% alcohol, the woman was ingesting 45.6–79.8 mL of ethanol/day. The infant had the typical facial features of the FAS, plus an umbilical hernia and hypoplastic labia. Irritability, tremors, and hypertonicity were also evident.

A safe level of maternal alcohol consumption has not been established (7,8,66). Based on practical considerations, the American Council on Science and Health recommends that pregnant women limit their alcohol consumption to no more than two drinks daily (1 ounce or 30 mL of absolute alcohol) (8). However, the safest course for women who are pregnant, or who are planning to become pregnant, is abstinence (7,66).

BREASTFEEDING SUMMARY

Although alcohol passes freely into breast milk, reaching concentrations approximating maternal serum levels, the effect on the infant has been considered insignificant except in rare cases or at very high concentrations (67). Recent research on the effects of chronic exposure of the nursing infant to alcohol in breast milk, however, should cause a reassessment of this position.

Chronic exposure to alcohol in breast milk was found to have an adverse effect on psychomotor development of breastfeeding infants in a 1989 report (68). In this study, "breastfed" was defined as a breastfeeding child who received no more than 473 mL (16 ounces) of its nourishment in the form of supplemental feedings/day. Statistical methods were used to control for alcohol exposure during gestation. Of the 400 infants studied, 153 were breastfed by mothers who were classified as "heavier" drinkers (i.e., an average daily consumption of 1 ounce of ethanol or about two drinks, or binge drinkers who consumed 2.5 ounces or more of ethanol on a single occasion). The population

sampled was primarily white, well-educated, middle-class women who belonged to a health maintenance organization. The investigators measured the mental and psychomotor development of the infants at 1 year of age using the Bayley Scales of Infant Development. Mental development was unrelated to maternal drinking during breastfeeding. In contrast, psychomotor development was adversely affected in a dose–response relation ($p = 0.006$ for linear trend). The mean Psychomotor Development Index (PDI) of infants of mothers who had at least one drink daily was 98, compared with 103 for infants of mothers consuming less alcohol ($p < 0.01$). The decrease in PDI was even greater if only those women not supplementing breastfeeding were considered. Regression analysis predicted that the PDI of totally breastfed infants of mothers who consumed an average of two drinks daily would decrease by 7.5 points. These associations persisted even after more than 100 potentially confounding variables, including maternal tobacco, marijuana, and heavy caffeine exposures, were controlled for during pregnancy and the first 3 months after delivery. The authors cautioned that their findings were only suggestive and should not be extrapolated to other patient populations because of the relative homogeneity of their sample (68). Although the conclusions of this study have been criticized and defended (69,70), judgment on the risks to the nursing infant from alcohol in milk must be withheld until additional research has been completed.

The toxic metabolite of ethanol, acetaldehyde, apparently does not pass into milk even though considerable levels can be measured in the mother's blood (71). One report calculated the amount of alcohol received in a single feeding from a mother with a blood concentration of 100 mg/dL (equivalent to a heavy, habitual drinker) as 164 mg, an insignificant amount (72). Maternal blood alcohol levels have to reach 300 mg/dL before mild sedation might be seen in the baby. However, a 1937 report described a case of alcohol poisoning in an 8-day-old breastfed infant whose mother drank an entire bottle (750 mL) of port wine (73). Symptoms in the child included deep sleep, no response to painful stimuli, abnormal reflexes, and weakly reactive pupils. Alcohol was detected in the infant's blood. The child made an apparently uneventful recovery. Potentiation of severe hypoprothrombic bleeding, a pseudo-Cushing's syndrome, and an effect on the milk-ejecting reflex have been reported in nursing infants of alcoholic mothers (74–76).

Because of the risk of toxicity in a nursing infant, the safest course would be to hold nursing for 1–2 hours for each ounce of alcohol consumed, thereby allowing the alcohol level in milk to decrease. The American Academy of

Pediatrics classifies ethanol as compatible with breastfeeding, although it is recognized that adverse effects may occur (77). The Institute of Medicine recommends a maximum daily consumption of 0.5 g/kg ethanol (78).

ETHCHLORVYNOL

Hypnotic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports linking the use of ethchlorvynol with congenital defects have been located.

FETAL RISK SUMMARY

In pregnant rats, a dose of 40 mg/kg/day was associated with an increase in the number of stillbirths and a lower survival rate among the offspring (1).

The Collaborative Perinatal Project reported 68 patients with 1st trimester exposure to miscellaneous tranquilizers and nonbarbiturate sedatives, 12 of which had been exposed to ethchlorvynol (2). For the group as a whole, six infants with malformations were delivered, but details on individual exposures were not given.

Animal data indicate that rapid equilibrium occurs between maternal and fetal blood with maximum fetal blood levels measured within 2 hours of maternal ingestion (3). The authors concluded that following maternal ingestion of a toxic or lethal dose, delivery should be accomplished before equilibrium occurs. Neonatal withdrawal symptoms, consisting of mild hypotonia, poor suck, absent rooting, poor grasp, and delayed-onset jitteriness, have been reported (B.H. Rumack, P.A. Walravens, personal communication, Department of Pediatrics, University of Colorado Medical Center, 1981). The mother had been taking 500 mg daily during the 3rd trimester.

BREASTFEEDING SUMMARY

No reports describing the use of ethchlorvynol during human lactation have been located. Because the drug rapidly crosses the placenta to the fetus, excretion into milk should be expected. Sedation of the nursing infant is a

possible consequence.

ETHINAMATE

[Withdrawn from the market. See 8th edition.]

ETHINYL ESTRADIOL

Estrogenic Hormone

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Estrogens are contraindicated because there are usually no benefits from their use in pregnancy.

FETAL RISK SUMMARY

Ethinyl estradiol is used frequently in combination with progestins for oral contraception (see Oral Contraceptives). The Collaborative Perinatal Project monitored 89 mother–child pairs who were exposed to ethinyl estradiol during the 1st trimester (1, pp. 389, 391). An increased risk for malformations was found, although identification of the malformations was not provided. Estrogenic agents as a group were monitored in 614 mother–child pairs. An increase in the expected frequency of cardiovascular defects, eye and ear anomalies, and Down's syndrome was reported (1, p. 395).

Reevaluation of these data in terms of timing of exposure, vaginal bleeding in early pregnancy, and previous maternal obstetric history, however, failed to support an association between estrogens and cardiac malformations (2). An earlier study also failed to find any relationship with nongenital malformations (3). In a smaller study, 12 mothers were exposed to ethinyl estradiol during the 1st trimester (4). No fetal abnormalities were observed. Ethinyl estradiol has also been used as a contraceptive when given within 72 hours of unprotected midcycle coitus (5). Use of estrogenic hormones during pregnancy is contraindicated.

BREASTFEEDING SUMMARY

Estrogens are frequently used for suppression of postpartum lactation (6, 7). Very small amounts are excreted in milk (7). When used in oral contraceptives, ethinyl estradiol has been associated with decreased milk production and

decreased composition of nitrogen and protein content in human milk (8). Although the magnitude of these changes is low, the differences in milk production and composition may be of nutritional importance to nursing infants of malnourished mothers. If breastfeeding is desired, the lowest dose of oral contraceptives should be chosen. Monitoring of infant weight gain and the possible need for nutritional supplementation should be considered (see Oral Contraceptives).

ETHIODIZED OIL

Diagnostic

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Ethiodized oil contains a high concentration of organically bound iodine. Use of this agent close to term has been associated with neonatal hypothyroidism (see Diatrizoate).

BREASTFEEDING SUMMARY

See Potassium Iodide.

ETHIONAMIDE

Anti-infective (Antituberculosis)

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Although the animal reproductive suggest risk, the human data suggest that the risk probably is low. If indicated, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

The oral anti-infective agent, ethionamide, is indicated for the treatment of tuberculosis when *Mycobacterium tuberculosis* is resistant to isoniazid or rifampin, or when the patient is intolerant to other drugs. Although it apparently has not been studied, the relatively low molecular weight (about 166) suggests that it is transferred to the fetus.

Ethionamide was teratogenic in rats and rabbits at doses higher than those used in humans (1). Nishimura and Tanimura (2), Shepard (3), and Schardein (4) reviewed nine animal studies involving pregnant mice, rats, and rabbits. All of the studies, except one, showed various developmental anomalies.

Five human studies describing the outcome of pregnancies exposed to ethionamide have been briefly reviewed in three sources (2–4). Only one of the studies found an increased incidence of birth defects, reporting 7 cases, 2 of which were Down's syndrome, from 23 exposed infants (2–4). The other reports found no association with congenital malformations (4).

A 2003 study reported the outcomes of seven pregnancies treated for multidrug-resistant tuberculosis (5). The seven women received multiple anti-infective agents. Two patients (one throughout and one postpartum) were treated with ethionamide. In 2005, the same group reported the long-term follow-up of six of the offspring; a seventh child, not exposed to ethionamide was lost to follow-up (6). The average age of the children was 3.7 years and each underwent a comprehensive clinical evaluation. None had hearing loss and

all had normal vision and neurologic analysis. Of the two exposed to ethionamide (current age and time of exposure) one had mild speech delay (4.6 years; throughout and postpartum) and one was hyperactive (5.1 years; postpartum only). Both infants were breastfed (6). Neither of the two conditions appears to be related to ethionamide.

BREASTFEEDING SUMMARY

One report mentioned that two mothers were taking ethionamide and other antitubercular medications while breastfeeding their infants (6). However, no reports have been located that measured the drug in milk. The relatively low molecular weight (about 166) suggests that ethionamide will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown.

ETHOSUXIMIDE

Anticonvulsant

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Ethosuximide is a succinimide anticonvulsant indicated for the treatment of petit mal epilepsy (1). Ethosuximide has a much lower teratogenic potential than the oxazolidinedione class of anticonvulsants (see also Trimethadione and Paramethadione) (2, 3). However, combination therapy with other anticonvulsants markedly increases the risk of structural anomalies. The succinimide anticonvulsants have been considered the anticonvulsants of choice for the treatment of petit mal epilepsy during the 1st trimester.

FETAL RISK SUMMARY

Ethosuximide has been associated with structural anomalies, but the data are not adequate to prove a definite causal relationship (1). In many of the cases described below, the mother was receiving combination therapy with anticonvulsants known to be human teratogens.

Consistent with its low molecular weight (about 141), the drug crosses the human placenta with many newborns having concentrations within the therapeutic range (1, 4, 5). In eight pregnancies, the mean maternal and fetal ethosuximide concentrations at birth were 40.15 and 35.82 mcg/mL, respectively, with the time of the last dose ranging from 4.5 to 16 hours before birth. The mean fetal:maternal ratio was 0.97 and the neonatal half-life in three infants was 32–38 hours (4). In another case, the plasma drug concentrations in the mother and cord blood were 240 and 250 $\mu\text{mol/L}$, respectively, a ratio of 1.0 (5).

In 163 pregnancies exposed to ethosuximide in combination with other anticonvulsants, abnormalities were observed in 10 pregnancies: patent ductus arteriosus (8 cases); cleft lip and/or palate (7 cases); mongoloid facies, short neck, altered palmar crease, and an accessory nipple (1 case); and

hydrocephalus (1 case) (2,6–15). Spontaneous hemorrhage in the neonate following in utero exposure to ethosuximide also has been reported (see also Phenytoin and Phenobarbital) (12).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 18 newborns had been exposed to ethosuximide during the 1st trimester (F. Rosa, personal communication, FDA, 1993). No major birth defects were observed (one expected).

A 1984 publication described the outcomes of 13 newborns from 10 epileptic mothers compared with pair-matched controls (4). Eleven of the mothers received combination therapy with one or more anticonvulsants (carbamazepine, clonazepam, phenobarbital, phenytoin, primidone, or valproic acid). Two infants had major structural anomalies (hare lip and bilateral clefting) with combination therapy (ethosuximide with phenobarbital or primidone). The mean number of minor anomalies was higher compared with controls (6.2 vs. 2.1), but the number and types did not differ from previous reports of anticonvulsant therapy. Sedation and poor sucking were observed in seven infants, six of whom had been exposed in utero to phenobarbital or primidone. Withdrawal symptoms, characterized by hyperexcitability and other symptoms, lasting for several weeks were observed in five infants, two of whom were exposed to phenobarbital or primidone (4).

The Lamotrigine Pregnancy Registry, an ongoing project conducted by the manufacturer, was first published in January 1997 (16). The final report was published in July 2010. The Registry is now closed. Among nine prospectively enrolled pregnancies exposed to ethosuximide and lamotrigine, with or without other anticonvulsants, eight were exposed in the 1st trimester resulting in seven live births without defects and one spontaneous abortion. There was one exposure in the 2nd/3rd trimesters resulting in a live birth without defects (16).

A 1992 report analyzed pooled data from five prospective European studies involving 1379 children exposed in utero to anticonvulsants (17). There were 13 pregnancies exposed to ethosuximide monotherapy with 1 major defect, and 44 exposed to combination therapy (5 with phenobarbital and 39 with valproic acid) with 5 major defects. These outcomes were not significantly different in comparison with other anticonvulsants (17).

BREASTFEEDING SUMMARY

Ethosuximide freely enters the breast milk in concentrations similar to the maternal serum. Five reports measured milk:plasma ratios of 0.86–1.0

(4,5,18–20). In one case, the infant's plasma concentration of ethosuximide was 120 $\mu\text{mol/L}$, compared with the mother's level of 370 $\mu\text{mol/L}$, a ratio of 0.32, but the milk:plasma ratio was 1.0 (5). One fully breastfed infant was sedated at birth with poor sucking and had no weight gain during 4 weeks of breastfeeding (4). Hyperexcitability lasting several weeks has been observed in infants exposed in utero to ethosuximide (4). This condition does not appear to be related to maternal use of the drug during breastfeeding because it also was noted in nonbreastfed infants. No other adverse effects in infants exposed to ethosuximide from milk have been reported. The American Academy of Pediatrics classifies ethosuximide as compatible with breastfeeding (21).

ETHOTOIN

Anticonvulsant

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably
Compatible

PREGNANCY SUMMARY

Although the human pregnancy experience is very limited, the embryo–fetal risk is thought to be lower than the more potent phenytoin.

FETAL RISK SUMMARY

Ethotoin is a low-potency hydantoin anticonvulsant (1). The fetal hydantoin syndrome has been associated with the use of the more potent phenytoin (see Phenytoin). Only six reports describing the use of ethotoin during the 1st trimester have been located (2–4). Cleft lip/palate and patent ductus arteriosus were observed in two of the offspring (3,4).

BREASTFEEDING SUMMARY

No reports describing the use of ethotoin during human lactation have been located. However, a more potent hydantoin anticonvulsant (see Phenytoin) is considered compatible with breastfeeding and ethotoin should be classified the same.

ETHYL BISCOUMACETATE

Anticoagulant

See Coumarin Derivatives.

ETHYNODIOL

Progestogenic Hormone

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Ethinodiol should not be used in pregnancy because there are no benefits for the mother, embryo, or fetus. The agent is used primarily in oral contraceptives (see Oral Contraceptives).

BREASTFEEDING SUMMARY

See Oral Contraceptives.

ETIDRONATE

Bisphosphonate

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Although the dose comparisons were based on body weight, etidronate did not cause developmental toxicity in animals at doses that were close to those used in humans. Two reports have described the use of bisphosphonates before or during six human pregnancies. Because the oral bioavailability is low and the plasma clearance is rapid, clinically significant amounts of etidronate may not cross the human placenta. Nonetheless, the drug is slowly released from bone over weeks to years. The amount of drug retained in bone and eventually released back into the systemic circulation is directly related to the dose and duration of treatment. Thus, administration before pregnancy may result in low-level, continuous exposure throughout gestation. The use of etidronate in women who may become pregnant or during pregnancy is not recommended. However, based on the animal and limited human data, inadvertent exposure during early pregnancy does not appear to represent a major risk to the embryo–fetus.

FETAL RISK SUMMARY

Etidronate (EHDP), a hydrophilic bisphosphonate, is a synthetic analog of pyrophosphate that binds to the hydroxyapatite found in bone to inhibit bone resorption. Etidronate is indicated for the treatment of symptomatic Paget's disease of bone and in the prevention and treatment of heterotopic ossification after total hip replacement or because of spinal cord injury. Other agents in this pharmacologic class are alendronate, ibandronate, pamidronate, risedronate, tiludronate, and zoledronic acid. Only about 3% of an oral dose is absorbed into the systemic circulation. Etidronate is not metabolized. The plasma half-life

ranges from 1 to 6 hours. About half of the absorbed drug is distributed to bone from which it is slowly released over a prolonged period. Although the elimination half-life from bone is not known with certainty, the clearance from bone in animals is up to 165 days (1).

Reproduction studies have been conducted with etidronate in rats and rabbits. In pregnant rats and rabbits, doses 5–20 times the human clinical dose based on body weight (HCD) did not cause teratogenic or other adverse effects in the offspring. At doses 15–60 times the HCD, etidronate exposure in pregnant rats was associated with skeletal anomalies in the offspring. These defects were thought to be secondary to the action of etidronate on bone. Decreased live births were observed with maternally toxic doses 25–300 times the HCD (1). Shepard reviewed four animal studies in which etidronate was given orally, subcutaneously, or intraperitoneally to mice, rats, and rabbits during gestation (2). Skeletal abnormalities were produced with high doses, but no other developmental toxic effects were observed.

No evidence of carcinogenic effects was observed in long-term studies in rats (1). Studies for mutagenic and clastogenic effects apparently have not been conducted.

It is not known if etidronate crosses the human placenta. The relatively low molecular weight (250), the absence of metabolism, and the prolonged clearance from bone all suggest that exposure of the embryo–fetus will occur. The relatively short plasma half-life, low lipid solubility, and oral bioavailability should limit this exposure.

A 1992 case report described the in utero treatment of a fetus with etidronate early in the 3rd trimester (3). Based on ultrasonography and the mother's obstetric history, a presumptive diagnosis of a rare disorder, idiopathic arterial calcification of infancy (IACI), was made in the fetus at 29 weeks' gestation. The fetus was treated with two courses of etidronate by percutaneous umbilical vein puncture. Fetal distress occurred 1 week later and the 1700-g female infant was delivered by emergency cesarean section with Apgar scores of 2 and 6 at 1 and 5 minutes, respectively. IACI was confirmed in the neonate 1 week after birth. The infant was treated with etidronate over the next several months. Radiographs of her skeleton showed severe growth plate malformations resembling rickets that were thought to be secondary to etidronate. The infant died at 7.5 months of age despite aggressive therapy for prematurity and her disease (3).

A 2008 review described 51 cases of exposure to bisphosphonates before or during pregnancy: alendronate (N = 32), pamidronate (N = 11), etidronate (N =

5), risedronate (N = 2), and zoledronic acid (N = 1) (4). The authors concluded that although these drugs may affect bone modeling and development in the fetus, no such toxicity has yet been reported.

BREASTFEEDING SUMMARY

No reports describing the use of etidronate during lactation have been located. The molecular weight (250) and the lack of metabolism suggest that the drug will be excreted into breast milk, but the low plasma concentrations and relatively short plasma half-life (1–6 hours) suggest that minimal amounts will be excreted into milk. Moreover, the oral bioavailability of etidronate, at least in adults, is only 3%. Although the effect of exposure on a nursing infant is unknown, it appears to be negligible.

ETODOLAC

Nonsteroidal Anti-inflammatory

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 1st and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of etodolac in human pregnancy have been located. The animal data suggest low risk for congenital malformations. A brief 2003 editorial on the potential for nonsteroidal anti-inflammatory drug (NSAID)–induced developmental toxicity concluded that NSAIDs, and specifically those with greater COX-2 affinity, had a lower risk of this toxicity in humans than aspirin (1).

Constriction of the ductus arteriosus in utero is a pharmacologic consequence arising from the use of prostaglandin synthesis inhibitors during late pregnancy, as is inhibition of labor, prolongation of pregnancy, and suppression of fetal renal function (see also Indomethacin) (2). Persistent pulmonary hypertension of the newborn may occur if these agents are used in the 3rd trimester close to delivery (2,3). Women attempting to conceive should not use any prostaglandin synthesis inhibitor, including etodolac, because of the findings in a variety of animal models that indicate these agents block blastocyst implantation (4,5). Moreover, as noted above, NSAIDs have been associated with spontaneous abortions (SABs) and congenital malformations. The risk for these defects, however, appears to be low.

FETAL RISK SUMMARY

The NSAID etodolac is used in the treatment of arthritis, and acute and chronic pain. Etodolac is in a NSAID subclass (pyranocarboxylic acid) that contains no other members.

In reproduction studies with rats, the drug produced isolated occurrences of alterations in limb development (polydactyly, oligodactyly, syndactyly, and

unossified phalanges) at doses close to human clinical doses (2–14 mg/kg/day). These same doses produced oligodactyly and synostosis of metatarsals in rabbits. However, a clear drug or dose–response relationship was not established. Similar to other agents in this class, etodolac increased the incidence of dystocia, prolonged gestation, and decreased pup survival in rats (6).

It is not known if etodolac crosses the human placenta. The molecular weight (about 287) is low enough that passage to the fetus should be expected.

A combined 2001 population-based observational cohort study and a case–control study estimated the risk of adverse pregnancy outcome from the use of NSAIDs (7). The use of NSAIDs during pregnancy was not associated with congenital malformations, preterm delivery, or low birth weight, but a positive association was discovered with SABs. A similar study, also published in 2001, failed to find a relationship, in general, between NSAIDs and congenital malformations, but did find a significant association with cardiac defects and orofacial clefts (8). In addition, a 2003 study found a significant association between exposure to NSAIDs in early pregnancy and SABs (9). (See Ibuprofen for details on these three studies.)

BREASTFEEDING SUMMARY

No reports describing the use of etodolac during lactation have been located. Because of the relatively low molecular weight (about 287), the excretion of etodolac into breast milk should be expected. Moreover, because of its long termination adult plasma half-life (7.3 hours), other agents may be preferred during lactation. One reviewer listed several low-risk alternatives (diclofenac, fenoprofen, flurbiprofen, ibuprofen, ketoprofen, ketorolac, and tolmetin) if a NSAID is required while nursing (10).

ETOMIDATE

Hypnotic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

The human pregnancy experience with etomidate is limited to women undergoing cesarean section. A 1988 review found no reports of congenital malformations in children of women anesthetized with this agent (1). The animal data suggest risk (embryo–fetal death), but the dose was based on body weight and may not be relevant. However, no structural anomalies have been observed in animals. When used immediately before birth, etomidate causes a transient decrease in newborn cortisol concentrations. The clinical significance of this effect is unknown. Although the data are limited, use of etomidate for induction of general anesthesia at or near term does not appear to represent a risk of fetal or newborn harm.

FETAL RISK SUMMARY

Etomidate is a rapid, short-acting hypnotic drug without analgesic activity that is given as an IV injection. Etomidate is indicated for the induction of general anesthesia. The agent is metabolized in the liver to inactive metabolites. Blood concentrations of etomidate decrease rapidly up to 30 minutes after injection and thereafter more slowly with an elimination half-life about 75 minutes (2, 3).

Reproduction studies have been conducted in rats and rabbits. In rats, doses that were ≥ 1 times the human dose (based on body weight) were embryocidal. In rats and rabbits, doses that were 1–16 and 5–15 times the human dose, respectively, resulted in decreased pup survival. The highest doses caused maternal toxicity including death. No teratogenicity has been observed in animals (2, 3).

Studies for carcinogenicity and mutagenicity have not been conducted. No impairment of fertility was noted in male and female rats (2, 3).

It is not known if etomidate crosses the human placenta early in pregnancy but it does at term. A 1988 abstract described seven women undergoing elective cesarean section (4). General anesthesia was induced with a 0.3 mg/kg IV dose of etomidate. The elimination half-life was 132 minutes. At delivery, the fetal:maternal ratio was 0.51. Etomidate was detected in the urine of the newborns up to 16 hours after birth (4). One study reported an umbilical:maternal vein ratio of 0.5 after use of the drug for cesarean section in 20 women (5). Apgar scores were ≥ 7 and 9/10 at 1 and 5 minutes, respectively. Another study measured an umbilical:maternal ratio of 0.48 in 20 women at cesarean section (6). A 1992 study of 20 women undergoing cesarean section also found that the drug crossed to the fetus (7). All of these results are consistent with the relatively low molecular weight (about 244) of etomidate.

In one of the studies described above, etomidate was associated with a transient reduction in neonatal cortisol concentrations in comparison with a methohexitone group (6). The difference between the two groups was most evident 2 hours after birth. There was no difference at 5 hours. The decrease was thought to be secondary to inhibition of cortisol synthesis in the adrenal cortex, a known effect of etomidate (6). In another study, 11 mothers undergoing elective cesarean sections were given 0.3 mg/kg etomidate for induction of general anesthesia (8). Serum cortisol in the newborns was compared with 11 newborns of mothers who had been given thiopentone for induction. At 1 hour of age, the cortisol concentrations were significantly lower ($p < 0.001$) in the etomidate group (8).

One of the first reports describing the use of etomidate for induction of general anesthesia before cesarean section was published in 1984 (9). Seventy-two women received the agent and no clinical effects were observed in the newborns. Other reports also have described the use of etomidate for this purpose, apparently without harm to the newborns (10–14).

BREASTFEEDING SUMMARY

No reports describing the use of etomidate during human lactation have been located. Such studies are not expected because of the indication for the drug. However, the drug crosses the placenta when given for cesarean section (4–7). In one study involving 20 women who had received a single 0.3 mg/kg IV dose, etomidate was detected in the colostrum (7). Mean colostrum drug concentrations at 30 and 120 minutes after the dose were 79.3 ng/mL (range 0–420 ng/mL) and 16.2 ng/mL (range 0–60 ng/mL), respectively. Etomidate

was not detected in any sample 4 hours after the dose. The colostrum:plasma ratio at 30 minutes was 1.2; at 120 minutes, plasma concentrations were undetectable (7). Because of the very small amounts of colostrum that are available at these times, the risk to a nursing infant probably is nil.

ETOPOSIDE

Antineoplastic

PREGNANCY RECOMMENDATION: Human and Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Etoposide is a potent animal teratogen and potentially may be a teratogen in humans, but exposure during organogenesis has not been reported. Five cases of maternal exposure to this agent and other antineoplastics during the 2nd and 3rd trimesters resulted in growth restriction and/or severe myelosuppression in three fetuses–newborns, two of whom were delivered prematurely, and one had reversible alopecia. Successful pregnancies, commencing after etoposide treatment, have also been reported.

FETAL RISK SUMMARY

Etoposide (VP-16, VP-16-213) is a semisynthetic derivative of podophyllotoxin used as an antineoplastic agent. Low doses of the drug, 1/20th–1/2 of the recommended clinical dose based on BSA, are teratogenic and embryocidal in rats and mice (1). A dose-related increase in the occurrence of embryotoxicity and congenital malformations was observed in these animals. Defects included decreased weight, skeletal anomalies, retarded ossification, exencephaly, encephalocele, and anophthalmia. The drug is also mutagenic in mammalian cells and, although not tested in animals, should be considered a potential carcinogen in humans (1).

When etoposide was administered intraperitoneally to pregnant mice during organogenesis, various anomalies were observed, including exencephaly, encephalocele, hydrocephalus, gastroschisis (including abnormal stomach or liver), microphthalmia or anophthalmia, dextrocardia (including missing lung lobe), and axial skeleton defects (2). In whole-embryo rat culture, a concentration of 2 micro-M (no-observed-adverse-effect-level 1.0 micro-M; embryotoxic range 2–5 micro-M) produced growth restriction and brain anomalies (hypoplasia of prosencephalon and edema of rhombencephalon) and microphthalmia (3).

Reported use of etoposide during human pregnancy is limited to five cases (4–8). A 21-year-old woman with a dysgerminoma was treated surgically at 26 weeks' gestation, followed 6 days later with etoposide (100 mg/m²) and cisplatin (20 mg/m²), daily for 5 days at 3- to 4-week intervals (4). Four cycles of chemotherapy were given. Because of oligohydramnios and probable intrauterine growth restriction, labor was induced and she delivered a healthy, 2320-g female infant at 38 weeks. The hematologic profile of the newborn was normal, as was her development at 9 months of age.

A 36-year-old woman at 25 weeks' gestation was treated for acute myeloid leukemia with combination chemotherapy consisting of two courses of etoposide (400 mg/m²/day, days 8–10), cytarabine (1 g/m²/day, days 1–3), and daunorubicin (45 mg/m²/day, days 1–3) (5). No fetal growth was observed during serial ultrasound examinations from 30 to 32 weeks. An emergency cesarean section was performed because of fetal distress at 32 weeks' gestation, 11 days after the second course of chemotherapy. The pale, 1460-g (10th percentile) female infant required resuscitation at birth. Analysis of the cord blood revealed anemia and leukopenia, and profound neutropenia and thrombocytopenia were discovered at 30 hours of age. Following successful therapy, the child, at 1 year of age, was no longer receiving any treatment, had normal peripheral blood counts, and was apparently progressing normally.

A 32-year-old woman at 26 weeks' gestation presented with an unknown primary, poorly differentiated adenocarcinoma of the liver and with a mass in the posterior chamber of the right eye (6). She was treated with daily doses of etoposide (165 mg), bleomycin (30 mg), and cisplatin (55 mg), for 3 days. The patient became profoundly neutropenic, developed septicemia, and went into premature labor. A 1190-g female infant was born with Apgar scores of 3 and 8 at 1 and 5 minutes, respectively. Severe respiratory distress was successfully treated over the next 10 days. Although the antineoplastics were chosen because they are highly protein bound (etoposide, 97%; cisplatin, 90% of plasma platinum; bleomycin, no data) and less likely to cross the placenta, marked leukopenia with neutropenia developed in the infant on day 3 (10 days after in utero exposure to the chemotherapy). Scalp hair loss and a rapid loss of lanugo were observed at 10 days of age. By 12 weeks of age, substantial hair regrowth had occurred, and at 1 year follow-up, the child was developing normally, except for moderate bilateral sensorineural hearing loss. The investigators could not determine if the deafness was due to the in utero exposure to cisplatin or to the maternal and/or neonatal aminoglycoside therapy. The alopecia and bone marrow depression in the infant were

attributed to etoposide.

Treatment of nonlymphoblastic acute leukemia, diagnosed at 18 weeks' gestation, was described in a brief 1993 report (7). Therapy consisted of two courses of etoposide (100 mg/m²/day) and daunorubicin (60 mg/m²/day) on days 1–3, and cytarabine (100 mg/m²/day) on days 1–7. Follow-up therapy consisted of mitoxantrone, cytarabine, and amsacrine. The patient eventually delivered a term, 2930-g, healthy male infant who was developing normally.

Non-Hodgkin's lymphoma, diagnosed in a 36-year-old woman at 22 weeks' gestation, was treated with a 12-week chemotherapy course consisting of etoposide (125 mg/m²), vincristine (1.4 mg/m²), and bleomycin (9 mg/m²) in weeks 2, 4, 6, 8, 10, and 12, and cyclophosphamide (375 mg/m²) and doxorubicin (50 mg/m²) in weeks 1, 3, 5, 7, 9, and 11 (8). Prednisolone was given during the entire 12-week period. A healthy, 3200-g male infant, delivered 3 weeks after the completion of therapy, was alive and well at 21 months of age. At this time also, the mother had just delivered another healthy male infant.

Seven reports, including the one above, have described women who became pregnant following treatment with etoposide (8–14) and one report described the return of normal menstrual function after etoposide therapy (15). One woman delivered a normal term infant following treatment for choriocarcinoma with nine courses of etoposide (100 mg/m²/day), cisplatin, dactinomycin, and intrathecal methotrexate 2 years prior to conception (9). Pregnancies occurred, about 6–7 years after treatment, in 3 women from a group of 128 who had been previously treated with high-dose chemotherapy for refractory or relapsed Hodgkin's disease (10). The current chemotherapy regimen consisted of etoposide (600–900 mg/m²), cyclophosphamide, and carmustine, followed by either autologous bone marrow or peripheral progenitor cell transplantation. One of the women conceived after receiving a donated ovum and delivered a healthy child. A second one became pregnant with twins after receiving ovulatory stimulating agents, but aborted both at 5 1/2 months' gestation. The third woman spontaneously conceived and delivered a healthy child.

Two women had normal pregnancies and babies after treatment with high-dose chemotherapy for relapsed Hodgkin's disease and non-Hodgkin's lymphoma, respectively (11). The first patient was treated with etoposide (800 mg/m²), carmustine, and melphalan, followed by autologous stem cell transplantation (ASCT). She conceived 19 months after completion of treatment. The second woman received etoposide (1000 mg/m²), cyclophosphamide, and carmustine, followed by ASCT. She became pregnant

33 months later.

Of 33 women (>18 years old) treated with multiple courses of chemotherapy for ovarian germ cell tumors and fertility conserving surgery, 14 (42%) had successful pregnancies (12). No congenital abnormalities in their offspring were observed. The chemotherapy consisted of etoposide (100 mg/m² × 3 days/course), bleomycin, cisplatin, cyclophosphamide, dactinomycin, methotrexate, vincristine, and folinic acid.

A 1993 report described return of ovulation in 25 women under 40 years of age from a group of 34 patients treated with etoposide for gestational trophoblastic disease (13). Nine apparently healthy infants were delivered from the group. In another study, 12 women with methotrexate-resistant gestational trophoblastic disease were treated with etoposide (100 mg/m²/day × 5 days every 10 days) (14). Two of the women had successful pregnancies, 3 and 4 years, respectively, after treatment.

Etoposide (200 mg/m²/day × 5 days) was successfully used to treat a cervical pregnancy in one woman (15). Her baseline menstrual function returned 60 days after completion of therapy, but it was not stated if she attempted to conceive. A man, who had received etoposide for acute nonlymphoblastic leukemia in a cumulative dose of 3193 mg/m², fathered two children, one of whom had a unspecified birthmark (16). There is no evidence that the treatment, that also included irradiation to the brain and lumbar spine, vincristine, thioguanine, doxorubicin, cyclophosphamide, and cytarabine, resulted in the birth defect.

Occupational exposure of the mother to antineoplastic agents during pregnancy may present a risk to the fetus. A position statement from the National Study Commission on Cytotoxic Exposure and a research article involving some antineoplastic agents are presented in the monograph for cyclophosphamide (see Cyclophosphamide).

BREASTFEEDING SUMMARY

Etoposide is excreted into breast milk (17). After delivery of a healthy, 2960-g female at 34 weeks' gestation, a 28-year-old woman with acute promyelocytic leukemia in remission (see Mitoxantrone for details of treatment during gestation) was treated with a second consolidation course of cytarabine and mitoxantrone followed by a third consolidation course consisting of etoposide (80 mg/m², days 1–5), mitoxantrone (6 mg/m², days 1–3), and cytarabine (170 mg/m², days 1–5). She maintained milk secretion by pumping her breasts

during the chemotherapy courses. The peak milk concentrations of etoposide measured on days 3, 4, and 5 of therapy were approximately (exact concentrations or times of sample collections were not specified) 0.6, 0.6, and 0.8 mcg/mL, respectively. Milk concentrations of etoposide were undetectable within 24 hours of drug administration on each day. The rapid disappearance of etoposide from the milk is compatible with the lack of plasma accumulation and an elimination half-life of 4–11 hours in adults (1). Against medical advice, the mother began breastfeeding 21 days after drug administration (see Mitoxantrone).

Because of the potential for severe toxicity in a nursing infant, such as bone marrow depression, alopecia, and carcinogenicity, breastfeeding should be stopped for at least 55 hours after the last dose of etoposide to account for the elimination half-life range noted above. However, if other antineoplastic agents have also been administered, breastfeeding should be withheld until all of the agents have been eliminated from the mother's system.

ETRAVIRINE

Antiviral

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit
>>Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

There is limited human pregnancy experience with etravirine. No structural defects have been reported. The animal data suggest low risk. If indicated, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Etravirine is a specific, non-nucleoside reverse transcriptase inhibitor (NNRTI). It is in the same antiviral class as delavirdine, efavirenz, and nevirapine. Etravirine is indicated, in combination with other antiretroviral agents, for the treatment of HIV-1 infection in antiretroviral treatment–experienced adult patients who have evidence of viral replication and HIV-1 strains resistant to an NNRTI and other antiretroviral agents. The drug is metabolized by the liver to metabolites that are at least 90% less active than etravirine. Plasma protein binding of etravirine is 99.6% to albumin and about the same to alpha 1-acid glycoprotein. The elimination half-life is prolonged (41 ± 20 hours) (1).

Animal reproduction studies have been conducted in rats and rabbits. In pregnant rats and rabbits, no evidence of fetal harm was observed at exposures equivalent to the exposure from the recommended human dose of 400 mg/day (1).

Etravirine crosses the human placenta at 34 weeks (2). The etravirine umbilical cord blood concentrations in twins from a mother taking 200 mg twice daily were 577 and 1020 ng/mL. The presence of the drug in fetal blood is consistent with the molecular weight (about 435), prolonged elimination half-life, and lipid solubility.

The Antiretroviral Pregnancy Registry reported, for the period January 1989 through July 2009, prospective data (reported before the outcomes were known) involving 4702 live births that had been exposed during the 1st trimester

to one or more antiretroviral agents (3). Congenital defects were noted in 134, a prevalence of 2.8% (95% confidence interval [CI] 2.4–3.4). In the 6100 live births with earliest exposure in the 2nd/3rd trimesters, there were 153 infants with defects (2.5%, 95% CI 2.1–2.9). The prevalence rates for the two periods did not differ significantly. There were 288 infants with birth defects among 10,803 live births with exposure anytime during pregnancy (2.7%, 95% CI 2.4–3.0). The prevalence rate did not differ significantly from the rate expected in a nonexposed population. There were 18 outcomes exposed to etravirine (9 in the 1st trimester and 9 in the 2nd/3rd trimesters) in combination with other antiretroviral agents. There were no birth defects. In reviewing the birth defects of prospective and retrospective (pregnancies reported after the outcomes were known) registered cases, the Registry concluded that, except for isolated cases of neural tube defects with efavirenz exposure, there was no other pattern of anomalies (isolated or syndromic). (See Lamivudine for required statement.)

Two reviews, one in 1996 and the other in 1997, concluded that all women currently receiving antiretroviral therapy should continue to receive the therapy during pregnancy and that treatment of the mother with monotherapy should be considered inadequate (4,5). The same conclusion was reached in a 2003 review with the added admonishment that therapy must be continuous to prevent emergence of resistant viral strains (6). In 2009, the updated U.S. Department of Health and Human Services guidelines for the use of antiretroviral agents in patients infected with HIV-1 continued the recommendation that therapy, with the exception of efavirenz, should be continued during pregnancy (7). If indicated, etravirine should not be withheld in pregnancy because the expected benefit to the HIV-positive mother outweighs the unknown risk to the fetus. Updated guidelines for the use of antiretroviral drugs to reduce perinatal HIV-1 transmission also were released in 2010 (8). Women receiving antiretroviral therapy during pregnancy should continue the therapy but, regardless of the regimen, zidovudine administration is recommended during the intrapartum period to prevent vertical transmission of HIV to the newborn (8). Health care professionals are encouraged to register patients exposed to etravirine during pregnancy in the Antiviral Pregnancy Registry by calling 1-800-258-4263.

BREASTFEEDING SUMMARY

No reports describing the use of etravirine during lactation have been located. The molecular weight (about 435), long elimination half-life (41 ± 20 hours), and

lipid solubility suggest that the drug will be excreted into breast milk. However, the high (up to 99.6%) protein binding might limit the amount of exposure. The effect of exposure on a nursing infant is unknown.

Reports on the use of etravirine during human lactation are unlikely, however, because the antiviral agent is used in the treatment of HIV-1 infection. HIV-1 is transmitted in milk, and in developed countries, breastfeeding is not recommended (4,5,7,9–11). In developing countries, breastfeeding is undertaken, despite the risk because no affordable milk substitutes are available. Until 1999, no studies had been published that examined the effect of any antiretroviral therapy on HIV-1 transmission in milk. In that year, a study involving zidovudine was published that measured a 38% reduction in vertical transmission of HIV-1 infection despite breastfeeding when compared with controls (see Zidovudine).

ETRETINATE

Vitamin

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Etretinate, an orally active synthetic retinoid and vitamin A derivative, is used for the treatment of severe recalcitrant psoriasis. It is contraindicated in pregnant women and in those likely to become pregnant. Following oral administration, etretinate is stored in subcutaneous fat and is slowly released over a prolonged interval (1,2). In some patients after chronic therapy, detectable serum drug levels may occur up to 2.9 years after treatment has been stopped (2,3). Due to this variable excretion pattern, the exact length of time to avoid pregnancy after discontinuing treatment is unknown (2,3).

FETAL RISK SUMMARY

As with other retinoids (see also Isotretinoin and Vitamin A), etretinate is a potent animal teratogen (4). Data accumulated since release of this drug now indicate that it must be considered a human teratogen as well (1–3,5,6).

As of June 1986, a total of 51 pregnancies had occurred during treatment with etretinate (1,7,8). Of these pregnancies, 23 were still ongoing at the time of the reports and were unable to be evaluated (1). In the remaining 28 cases, 17 resulted in normal infants and 3 were normal fetuses after induced abortion. Skeletal anomalies were evident in eight cases: three liveborns, one stillbirth at 5 months, and four induced abortions. In addition, marked cerebral abnormalities, including meningomyeloceles, were observed in the stillborn and in three of the aborted fetuses.

A 1988 correspondence listed 22 documented etretinate exposures during pregnancy in West Germany as of September 1988 (9). The outcomes of these pregnancies were six induced abortions (no anomalies observed), four spontaneous abortions (no anomalies observed), six normal infants, and six

infants with malformations (9).

Fifty-three pregnancies are known to have occurred following discontinuance of etretinate therapy (1,10). Malformations were observed in a fetus and an infant among the 38 pregnancies with known outcomes. In one case, a 22-year-old woman, treated intermittently over 5 years, became pregnant 4 months after etretinate therapy had been stopped (1,11,12). Serum concentrations of etretinate and the metabolite, etretin, were 7 and 8 ng/mL, respectively, during the 8th week of gestation (6 months after the last dose). Following induced abortion at 10 weeks' gestation, the fetus was found to have unilateral skeletal defects of the lower limb consisting of a rudimentary left leg with one toe, missing tibia and fibula, and a hypoplastic femur (11,12). Evaluation of the face, skull, and brain was not possible. The defect was attributed to etretinate.

The second case also involved a 22-year-old woman who conceived 51 weeks after her last dose of etretinate (10). Other than the use of metoclopramide at 8 weeks' gestation for nausea and vomiting, no other drug history was mentioned. A growth-restricted (2850 g, 46 cm long, 3rd percentile) female infant was delivered by cesarean section at 38 weeks' gestation. Multiple congenital anomalies were noted involving the central nervous system, head, face, and heart, which included tetralogy of Fallot, microcephaly, hair whorls, small mandible, asymmetrical nares, protruding ears with malformed antihelices, absent lobules, and enlarged, keyhole-shaped entrances to the external ear canals, strabismus, left peripheral facial nerve palsy, and poor head control. Etretinate was detected in the mother's serum 3.5 months after delivery, but the concentration was below the test's lower limit of accuracy (2 ng/mL). No etretinate was detected in the infant's serum. Etretinate was considered responsible for the defects based partially on the presence of the drug in the mother's serum, and the fact that the pattern of malformation was identical to that observed with isotretinoin, another synthetic retinoid. The author also concluded that women treated with etretinate should avoid conception indefinitely (10).

Some of the defects noted in the above infant are also components of the CHARGE (coloboma, heart defects, choanal atresia, retardation, genital [males only], and ear anomalies) association (13), but in a response, the author of the case immediately above noted that such a relationship does not exclude etretinate as the etiology of the defects (14). Others have questioned whether an indefinite recommendation to avoid pregnancy is practical or necessary (15,16). In West Germany, 2 years of conception avoidance are recommended

followed by determination of serum levels of etretinate and its metabolites (16). In six women treated with etretinate from 4 to 78 months, plasma concentrations of the drug were detected after 12 months in three patients (4, 8, and 8 ng/mL) and after 18 months in one patient (10 ng/mL) (16). Two women had no measurable etretinate 12 and 14 months after stopping therapy. The metabolites, acitretin and cis-acitretin, were detectable in two women (at 8 and 18 months) and five women (at 8–18 months).

The range of malformations, as listed by the manufacturer, includes meningomyelocele, meningoencephalocele, multiple synostoses, facial dysmorphism, syndactylies, absence of terminal phalanges, malformations of hip, ankle and forearm, low-set ears, high palate, decreased cranial volume, and alterations of the skull and cervical vertebrae (2).

Pronounced jaundice with elevations of the transaminase enzymes, glutamic-oxaloacetic transaminase and glutamic-pyruvic transaminase, was observed in an otherwise normal male newborn following in utero exposure to etretinate (17). The cause of the liver pathology was unknown. No other abnormalities were observed, and the infant was normal at 5 months of age.

One source has suggested that male patients treated with etretinate should avoid fathering children during treatment; if this does occur, ultrasound of the fetus is indicated (18). Although there is no evidence that etretinate adversely affects sperm, and even if it did, that this could result in birth defects, the authors defended their comment as practicing “defensive” medicine (19, 20).

BREASTFEEDING SUMMARY

It is not known if etretinate is excreted into human milk (2). The closely related retinoid, vitamin A, is excreted (see Vitamin A) and the presence of etretinate in breast milk should be expected. The manufacturer considers use of the drug during lactation to be contraindicated due to the potential for adverse effects (2).

EVANS BLUE

Dye (Diagnostic)

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports linking the use of Evans blue with congenital defects have been located.

FETAL RISK SUMMARY

Evans blue is teratogenic in some animal species (1). The dye has been injected intra-amniotically for diagnosis of ruptured membranes without apparent effect on the fetus except for temporary staining of the skin (2,3). The use of Evans blue during pregnancy for plasma volume determinations has been routine (4–8). No toxicity in the fetus or newborn have been attributed to this use.

BREASTFEEDING SUMMARY

No reports describing the use of Evans blue during lactation have been located.

EVENING PRIMROSE OIL

Herb

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible (Labor Induction)

No Human Data—No Relevant Animal Data (Before Term)

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Although there are limited published data, the use of evening primrose oil (EPO) for labor induction is apparently common among nurse-midwives. No adverse effects have been reported in the fetus or newborn. The embryo–fetal risk for other purposes or during other portions of pregnancy is unknown. One source recommended avoiding its use in pregnancy (1).

FETAL RISK SUMMARY

The seeds of evening primrose, a large plant native to North America, contain 14% of oil. It is grown commercially. The oil from the commercial variety of evening primrose contains the fatty acids cis-linoleic acid and gamma-linolenic acid in concentrations of 72% and 9%, respectively. Essential fatty acids are involved in cellular structural elements and as precursors of prostaglandins. Reported uses of EPO in nonpregnant patients include rheumatoid arthritis and diabetic neuropathy. The typical dose used in clinical trials with nonpregnant patients is 6–8 g/day in adults and 2–4 g/day in children (2).

Based on a national survey of nurse-midwifery education programs, EPO was the most frequently mentioned herbal preparation for the induction of labor (3). Twenty-three (64%) of 36 respondents stated that they discussed the use of EPO with their students. The doses prescribed varied widely and included both oral and vaginal doses (3).

A 1999 study examined the effect of EPO on the length of pregnancy (4). Oral doses of EPO from the 37th gestational week until birth did not shorten pregnancy or decrease the overall length of labor, but was associated with an increase in prolonged rupture of membranes, oxytocin augmentation, arrest of

descent, and vacuum extraction.

A 2003 review examined the pregnancy outcomes when herbal therapies were used (5). It concluded that EPO was safe for labor induction.

A 2006 randomized, double-blind, placebo controlled trial compared the effects of EPO and placebo on the Bishop score and cervical length in 71 women at term (6). One capsule of EPO (strength not specified) given three times daily for 1 week significantly improved the Bishop score and reduced cervical length compared with placebo. Significantly fewer subjects required cesarean sections compared with placebo. No adverse effects of EPO were observed in fetuses monitored by the biophysical profile and nonstress tests or in the birth weights of newborns (6).

BREASTFEEDING SUMMARY

Fatty acids, such as cis-linoleic and gamma-linolenic, are natural constituents of breast milk (2). In a placebo-controlled trial, 18 subjects were given a total daily dose of 2800-mg linoleic acid and 320 mg of gamma-linoleic acid, whereas 18 controls received placebos (7). The study was conducted for 8 months starting between the 2nd and 6th month of lactation. Not surprisingly, subjects had significantly higher milk concentrations of the fatty acids at the end of the study, whereas controls had decreased levels. No adverse effects were reported in the mothers or infants (7).

EVEROLIMUS

Antineoplastic (mTOR Inhibitor)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Only two reports describing the use of everolimus in human pregnancy have been located and, in both cases, normal infant outcomes occurred. Severe embryo toxicities, in the absence of maternal toxicity, were observed in one animal species at exposures much lower than those occurring in humans taking the recommended dose. The limited human pregnancy experience prevents a full assessment of the embryo–fetal risk. The manufacturer advises women of childbearing potential to use an effective method of contraception during treatment and for up to 8 weeks after ending treatment (1). If a woman becomes pregnant while receiving everolimus, she should be advised of the potential for embryo–fetal harm.

FETAL RISK SUMMARY

Everolimus is a mTOR inhibitor (mammalian target of rapamycin) that is available as oral tablets. It is indicated for the treatment of various cancers and for prophylaxis of organ rejection in kidney and liver transplantation. The other agent in this subclass is temsirolimus. After oral absorption, everolimus is metabolized to relatively inactive metabolites. Plasma protein binding is about 74% and the mean elimination half-life is about 30 hours (1, 2). Everolimus is a derivative of sirolimus (see Sirolimus) (3). Reproduction studies have been conducted in rats and rabbits. Oral doses given to rats before mating and through organogenesis resulted in increased resorptions, preimplantation and postimplantation loss, decreased number of live fetuses, malformation (e.g., sternal cleft), and retarded skeletal development. The embryo–fetal toxicities occurred at about 4% of the exposure (AUC) in patients receiving the recommended human dose (RHD) of 10 mg/day and in the absence of maternal toxicity. In a prenatal and postnatal study with rats, no adverse effects on

delivery or lactation or maternal toxicity were noted at a dose that was about 10% of the RHD based on BSA. However, this dose was associated with a slight reduction in pup body weight and survival, but no drug-related effects on offspring development were observed. In rabbits, embryotoxicity as evident as an increase in resorptions occurred at a dose that was about 1.6 times the RHD based on BSA. However, maternal toxicity also was evident (1).

Two-year studies for carcinogenicity in mice and rats were negative, as were multiple assays for genotoxic and mutagenic effects. Everolimus caused infertility in male rats that was partially reversible when the drug exposure was stopped. In female rats, the increases in preimplantation loss suggested that the drug may reduce female fertility (1).

It is not known if everolimus crosses the human placenta. The molecular weight (about 958), moderate plasma protein binding, and long elimination half-life suggest that the drug will cross to the embryo–fetus.

In a 2011 case report, a woman with a kidney transplant conceived while receiving everolimus (4). The pregnancy was discovered at 12 weeks' gestation. Because of worsening renal function, proteinuria, and severe hypertension during week 30, a cesarean section was performed to deliver a 1.280-kg healthy female infant with an Apgar score of 10. No congenital anomalies were noted. The infant had normal growth without detectable disorders at 12 months of age (4).

A 2012 case report described the pregnancy outcome of a woman who had received a kidney transplant 4 years before conceiving (5). The woman received everolimus, cyclosporine, and corticosteroids throughout pregnancy. At term, she gave birth to a healthy, 3.020-kg infant with an initial Apgar score of 9. The child was in good health at 3 years of age (5).

BREASTFEEDING SUMMARY

No reports describing the use of everolimus during human lactation have been located. The molecular weight (about 958), moderate (about 74%) plasma protein binding, and long (about 30 hours) elimination half-life suggest that the drug will be excreted into breast milk. Based on animal data, the concentration in milk may exceed the maternal plasma concentration. The effect of this exposure on a nursing infant is unknown. However, marked toxicity has been observed in adults, such as gastrointestinal disorders (stomatitis, diarrhea, nausea, vomiting), infections, anorexia, respiratory (cough, dyspnea, epistaxis, pneumonitis), skin and subcutaneous disorders, headache, and other toxicities.

EXEMESTANE

Antineoplastic (Hormone)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of exemestane in human pregnancy have been located. The animal data suggest moderate risk. The antineoplastic is indicated for postmenopausal women with breast cancer who have been treated with tamoxifen for 2–3 years. The drug prevents the conversion of androgens to estrogen. Because estrogen is required to maintain pregnancy, exemestane is contraindicated in pregnancy.

FETAL RISK SUMMARY

Exemestane is an oral steroidal aromatase inactivator that binds irreversibly to the enzyme, thus preventing conversion of androgens to estrogen both in pre- and postmenopausal women. It is indicated for adjuvant treatment of postmenopausal women with estrogen-receptor positive early breast cancer who have received 2–3 years of tamoxifen and are changed to exemestane for completion of a total of 5 consecutive years of adjuvant hormonal therapy. The drug is extensively metabolized in inactive or minimally active compounds. Plasma protein binding to albumin and α_1 -acid glycoprotein is 90%. The mean terminal half-life is about 24 hours (1).

Reproduction studies have been conducted in rats and rabbits. When rats were given a daily dose that was about 1.5 times the recommended human daily dose based on BSA (RHDD) from 14 days before mating to day 15 or 20 of gestation, an increase in placental weight was observed. At doses about ≥ 8 times the RHDD, prolonged gestation, abnormal or difficult labor, increased resorption, reduced number of live fetuses, decreased fetal weight, and retarded ossification were observed. No malformations were observed with doses that were about 320 times the RHDD. Exemestane and its metabolites crossed the rat placenta at doses about equal to the RHDD resulting in approximately equal concentrations in maternal and fetal blood. In rabbits, daily

doses given during organogenesis that were about 70 times the RHDD caused a decrease in placental weight. At about 210 times the RHDD, abortions, an increase in resorptions, and a decrease in fetal body weight occurred but no increase in malformations occurred (1,2).

A 2-year carcinogenicity study in mice resulted in an increased incidence of hepatocellular adenomas and/or carcinomas in both males and females, and an increased incidence of renal tubular adenomas in males. The doses used in male and female mice produced plasma AUC levels that were 34 and 75 times the AUC in postmenopausal patients at the recommended clinical dose. No evidence of carcinogenicity was observed in a separate study with rats. The drug was not mutagenic in two assays and was not clastogenic in an in vivo assay. In fertility studies, untreated female rats showed reduced fertility when mated with male rats given doses of exemestane that were ≥ 200 times the RHDD (1,2).

It is not known if exemestane or its metabolites cross the human placenta. The molecular weight (about 296) and long elimination half-life suggest that exposure of the embryo and/or fetus to the parent drug and metabolites will occur.

BREASTFEEDING SUMMARY

No reports describing the use exemestane during human lactation have been located. The molecular weight (about 296) and long elimination half-life (about 24 hours) suggest that the drug will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown. However, because the drug prevents conversion of androgens to estrogen, breastfeeding is contraindicated if the woman is receiving exemestane.

EXENATIDE

Antidiabetic Agent

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of exenatide in human pregnancy have been located. The developmental toxicity (structural anomalies, neonatal death) that was observed in one animal species suggests moderate risk. However, the absence of any human pregnancy experience prevents a more-complete assessment of the embryo–fetal risk. Until such data are available, the best course is to avoid exenatide in pregnancy.

FETAL RISK SUMMARY

Exenatide (also known as exendin-4) enhances glucose-dependent insulin secretion from pancreatic beta cells, suppresses inappropriately elevated glucagon secretion, and slows gastric emptying (1). It is a 39-amino acid peptide amide that is administered SC. Exenatide is indicated as adjunctive therapy to improve glycemic control in patients with type 2 diabetes mellitus who are taking metformin, a sulfonylurea, or a combination of these agents but have not achieved adequate glycemic control. It is eliminated primarily by glomerular filtration with subsequent proteolytic degradation. The mean elimination half-life is 2.4 hours (1).

Reproduction studies with exenatide have been conducted in mice and rabbits. No evidence of fetal harm was observed in mice given SC doses producing systemic exposures up to 390 times the exposure from the maximum recommended human dose based on AUC (MRHD) before and during mating, and through day 7 of gestation. During organogenesis (days 6 through 15), reduced fetal and neonatal growth, cleft palates (some with holes), and irregular skeletal ossification of rib and skull bones were observed at SC doses producing systemic exposures three times the MRHD. An increase in neonatal

deaths was noted on postpartum days 2–4 with an SC dose producing a systemic exposure three times the MRHD from day 6 through lactation day 20 (weaning) (1).

In pregnant rabbits, irregular skeletal ossifications were observed with an SC dose producing a systemic exposure 12 times the MRHD during organogenesis (days 6 through 18) (1).

No evidence of carcinogenicity was observed in mice given SC doses resulting in systemic exposures up to 95 times the MRHD over a 2-year period. In a 2-year study in female rats, however, a dose-related increase in benign thyroid C-cell adenomas was observed with systemic exposures that were 5–130 times the MRHD. Exenatide was not mutagenic or clastogenic in various assays and did not impair fertility in mice in a 4-week study with an exposure 390 times the MRHD (1).

A 2003 *ex vivo* study using single human cotyledons from healthy term placentas investigated whether exenatide crossed the placenta (2). Consistent with the drug's high molecular weight (about 4187) and the short elimination half-life, the fetal:maternal ratio was ≤ 0.017 . Although these results might not be reproducible throughout gestation, it is likely that embryo and/or fetal exposure to exenatide is negligible.

BREASTFEEDING SUMMARY

No reports describing the use of exenatide during human lactation have been located. The high molecular weight (about 4187) and short elimination half-life (2.4 hours) suggest that clinically insignificant amounts will be excreted into breast milk. What little is excreted will probably be digested in the stomach of the nursing infant. Therefore, although the effect of the exposure on a nursing infant is unknown, the risk appears to be negligible. Nevertheless, blood glucose monitoring of the infant should be considered.

EZETIMIBE

Antilipemic Agent

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of ezetimibe in human pregnancy have been located. Although the animal data suggest low risk, the lack of human pregnancy experience prevents an assessment of the risk this agent presents to the embryo and fetus. Generally, discontinuing treatment of hypercholesterolemia during pregnancy is not thought to put the mother at risk. If treatment during pregnancy is mandated, ezetimibe appears to be a better choice than treatment with HMG-CoA reductase inhibitors (i.e., “statins” are contraindicated) or the fibric acid derivative fenofibrate.

FETAL RISK SUMMARY

Ezetimibe selectively inhibits the intestinal absorption of cholesterol and related phytosterols. It is indicated, either alone or in combination with HMG-CoA reductase inhibitors, as adjunctive therapy to diet for the reduction of cholesterol and triglycerides in patients with primary hypercholesterolemia. Ezetimibe is extensively metabolized in the small intestine and liver and both the parent compound and the metabolite are pharmacologically active. In addition, both are highly bound (>90%) to plasma proteins and have an elimination half-life of about 22 hours (1,2).

Reproduction studies have been conducted in rats and rabbits. In rats, there was no evidence of impaired fertility or embryo-lethal effects at doses up to about 10 times the human exposure at 10 mg/day based on AUC for total ezetimibe (HD). At the highest dose, increased incidences of skeletal abnormalities (extra pair of thoracic ribs, unossified cervical vertebral centra, and shortened ribs) were noted. In rabbits, doses up to about 150 times the HD did not cause embryo-lethal effects, but an increased incidence of extra

thoracic ribs was observed (1,2).

No evidence of carcinogenicity was observed in mice and rats administered high doses over a 2-year period. There was also no evidence of mutagenic, clastogenic, or genotoxic effects with various other assays (1,2).

It is not known if ezetimibe or its active metabolite crosses the human placenta. The parent compound does cross the rat and rabbit placentas (1,2). The molecular weight (about 409 for the parent compound) and prolonged elimination half-life suggest that passage to the human embryo and/or fetus will occur, but the high plasma protein binding should limit the transfer.

BREASTFEEDING SUMMARY

No reports describing the use of ezetimibe during human lactation have been located. The molecular weight (about 409 for the parent compound) and the prolonged elimination half-life (about 22 hours) for both ezetimibe and its active metabolite suggest that the drug and/or its metabolite will be excreted into breast milk. However, the high plasma protein binding (>90%) should limit the amount excreted. The effect on a nursing infant from this exposure is unknown. If ezetimibe is taken during lactation, the nursing infant should be closely observed for adverse effects that are commonly seen in adults (e.g., headache, diarrhea, pharyngitis, sinusitis, arthralgia).

EZOGABINE

Anticonvulsant

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of ezogabine in human pregnancy have been located. The animal data in two species suggest risk but the absence of human pregnancy experience prevents a better assessment. If a woman becomes pregnant while taking the drug or is prescribed the drug during pregnancy, she should be advised of the absence of human data and the potential risk to her embryo and/or fetus. Pregnant women taking ezogabine are encouraged to enroll in the North American Antiepileptic Drug Pregnancy Registry by calling the toll-free number 1-800-233-2334.

FETAL RISK SUMMARY

Ezogabine is a potassium channel opener that is available as oral tablets. It is indicated as adjunctive treatment of partial-onset seizures in patients aged 18 years and older. Ezogabine is metabolized to an N-acetyl metabolite (NAMR) that has antiepileptic activity but less than the parent drug, as well as inactive metabolites. Plasma protein binding of ezogabine and NAMR are about 80% and 45%, respectively, whereas the elimination half-lives are 7–11 hours for both molecules (1).

Reproductive studies have been conducted in rats and rabbits. In rats given ezogabine during organogenesis, fetal skeletal variations were observed. When the drug was given throughout pregnancy and lactation, increased prenatal and postnatal mortality, decreased body weight gain, and delayed reflex development in the offspring were observed. The no-effect dose for embryo–fetal toxicity in both of these periods produced maternal plasma exposures (AUC) of ezogabine and NAMR that were less than those in humans at the maximum recommended human dose (MRHD). In rabbits, exposure throughout

organogenesis resulted in decreased fetal body weights and increased incidences of fetal skeletal variations. The no-effect dose for embryo–fetal toxicity was associated with plasma levels of ezogabine and NAMR that were less than those in humans at the MRHD. In both rats and rabbits, the maximum doses evaluated were by maternal toxicity (acute neurotoxicity) (1).

In a 1-year study, a dose-related increase in the frequency of lung neoplasms was noted in male mice. No evidence of carcinogenicity was observed in a 2-year study in rats. In studies for mutagenicity with ezogabine, three assays were negative and one was positive. For assays with NAMR, one was negative and one was positive. In male and female rats, ezogabine had no effect on fertility, reproductive performance, or early embryonic development at doses producing a plasma ezogabine exposure (AUC) less than that in humans at the MRHD (1).

It is not known if ezogabine or its active metabolite NAMR crosses the placenta. The molecular weight of ezogabine (about 303), and the moderate plasma protein binding and long elimination half-lives of the parent drug and active metabolite suggest that both will cross to the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use of ezogabine during human lactation have been located. The molecular weight of ezogabine (about 303) and the moderate plasma protein binding (80% for ezogabine; 45% for the active metabolite [NAMR]) and long elimination half-lives (7–11 hours for both) suggest that ezogabine and NAMR will be excreted into breast milk. Although the systemic absorption in infants is unknown, the parent drug is well absorbed in adults. The drug is best avoided during breastfeeding because of the concern for clinically significant toxicity in a nursing infant.

F

FACTOR XIII CONCENTRATE (HUMAN)

Hematologic Agent (Antihemophilic)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Factor XIII concentrate (human) (FXIII) is a necessary therapy for patients with congenital deficiency of FXIII. In women without such therapy, severe bleeding will occur, as well as abortions if they become pregnant.

FETAL RISK SUMMARY

FXIII is a heat-treated, lyophilized coagulation factor XIII concentrate made from pooled human plasma. It is an endogenous plasma glycoprotein consisting of two A-subunits and two B-subunits that circulates in blood and is present in platelets, monocytes, and macrophages. FXIII is indicated for routine IV prophylactic treatment of congenital FXIII deficiency. The effectiveness of the product is based on maintaining a trough FXIII activity of about 5%–20%. The half-life of FXIII is about 6.6 days (1).

Reproduction studies in animal have not been conducted.

Congenital FXIII deficiency is associated with severe bleeding, impaired wound healing and, in pregnancy, a high risk of spontaneous abortions (2–4). Several sources have described the use of FXIII throughout pregnancy to prevent these complications (5–11). Because FXIII is an endogenous substance, no adverse effects were expected or reported in the offspring of exposed pregnancies.

BREASTFEEDING SUMMARY

No reports describing the use of FXIII during human lactation have been

located. However, congenital FXIII deficiency is a life-threatening disorder. FXIII is an endogenous glycoprotein and excretion into breast milk should not occur. However, even if small amounts were excreted during the colostrum phase, it should be digested in the infant's gut and have no effect on a nursing infant. Consequently, if a mother with this condition chooses to breastfeed her infant, FXIII should not be withheld.

FAMCICLOVIR

Antiviral

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

The limited human pregnancy experience and the animal reproductive data suggest that the risk for the embryo–fetus is low. The manufacturer (Novartis Pharmaceuticals) maintains a pregnancy registry to monitor the maternal–fetal outcomes of women exposed to famciclovir during pregnancy (1). Patients can be registered by calling (888) 669-6682.

FETAL RISK SUMMARY

Famciclovir is a prodrug administered orally for the treatment of infections involving herpes simplex virus types 1 and 2, or varicella zoster virus. After administration, the drug undergoes rapid biotransformation to penciclovir, the active antiviral compound. Specific indications are the treatment of recurrent episodes of genital herpes and the management of acute herpes zoster (shingles) (1).

Carcinogenic, but not embryotoxic or teratogenic, effects were observed in animal studies with famciclovir. A significant increase in the incidence of mammary adenocarcinoma was seen in female rats administered famciclovir 600 mg/kg/day, 1.5–9.0 times the levels achieved with the recommended human doses based on AUC comparisons for penciclovir. At this dose in female rats and at doses ≤ 2.4 times the human dose (AUC comparison) in male mice, marginal increases in the incidence of SC tissue fibrosarcomas and squamous cell carcinomas of the skin were observed. The tumors, however, were not observed in male rats and female mice. The reason for these gender differences is apparently unknown (1).

Both famciclovir and the active metabolite, penciclovir, were tested for teratogenicity in pregnant rats and rabbits. Based on the penciclovir levels

achieved with the recommended human doses (AUC comparison), oral doses of famciclovir 2.7–10.8 times (rats) and 1.4–5.4 times (rabbits) those concentrations had no effect on embryo and fetal development. IV famciclovir also had no effect on embryo and fetal development in either the rat or the rabbit at doses up to 1.5–6 and 1.1–4.5 times, respectively, the human dose, based on BSA (HD). A similar lack of toxicity was observed with IV penciclovir at doses in pregnant rats and rabbits 0.3–1.3 and 0.5–2.1 times, respectively, the HD (1).

It is not known whether famciclovir or its active metabolite, penciclovir, crosses the placenta to the fetus. Because of the molecular weight of famciclovir (about 321), passage to the fetus should be expected.

A 1998 noninterventional observational cohort study described the outcomes of pregnancies in women who had been prescribed one or more of 34 newly marketed drugs by general practitioners in England (2). Data were obtained by questionnaires sent to the prescribing physicians one month after the expected or possible date of delivery. Of 1067 exposed pregnancies, famciclovir was taken during the 1st trimester in 7 pregnancies. The outcomes of these pregnancies included one ectopic pregnancy; two missed abortions; and four normal, full-term infants.

A 2010 review on the safety of famciclovir in all types of patients stated that the drug should be avoided in pregnant and lactating women because of the lack of data (3).

BREASTFEEDING SUMMARY

No studies describing the use of famciclovir during breastfeeding have been located. The drug is probably excreted into human milk and there is a potential for toxicity. Until human data are available, women taking famciclovir should not breastfeed (3).

FAMOTIDINE

Gastrointestinal Agent (Antisecretory)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

The animal reproductive data suggest low risk, but the human pregnancy experience is limited. Nevertheless, there is no evidence that histamine H₂-receptor antagonists pose a clinically significant risk to the embryo or fetus. A study showing an association between in utero exposure to gastric acid suppressors and childhood allergy and asthma requires confirmation.

FETAL RISK SUMMARY

Famotidine, a reversible competitive inhibitor of histamine H₂-receptors (H₂ blockers), is more potent than either cimetidine or ranitidine. It is indicated for the treatment of gastric and duodenal ulcers, in the treatment of gastroesophageal reflux disease (GERD), and in the therapy of pathologic hypersecretory conditions, such as Zollinger-Ellison syndrome. The drug undergoes minimal first-pass metabolism. Plasma protein binding is low (15%–20%) and the elimination half-life is 2.5–3.5 hours (1).

Reproduction studies have been conducted in rats and rabbits. No significant evidence of impaired fertility or harm to the fetus at oral doses up to 2000 and 500 mg/kg/day (comparison to the human dose not stated), respectively, or IV doses up to 200 mg/kg/day in both species were observed. Sporadic abortions were observed in rabbits given maternal toxic (decreased food intake) oral doses that were 250 times the usual human dose (1). In published studies in rats and rabbits, using oral doses ≤2000 mg/kg/day and IV doses of 100–200 mg/kg/day, found no evidence of impaired fertility, fetotoxic effects, teratogenicity, or changes in postnatal behavior attributable to famotidine (2,3).

Famotidine is known to cross the term human placenta based on in vitro studies (4). This is consistent with the molecular weight (about 337), low plasma protein binding, and the elimination half-life.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 33 newborns had been exposed to famotidine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Two (6.1%) major birth defects were observed (one expected). No anomalies were observed in six defect categories (cardiovascular defects, oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available. The number of exposures is too small to draw any conclusions.

A 1996 prospective cohort study compared the pregnancy outcomes of 178 women who were exposed during pregnancy to H2 blockers with 178 controls matched for maternal age, smoking, and heavy alcohol consumption (5). All of the women had contacted a teratology information service concerning gestational exposure to H2 blockers (subjects) or nonteratogenic or nonfetotoxic agents (controls). Among subjects (mean daily dose in parentheses), 71% took ranitidine (258 mg), 16% cimetidine (487 mg), 8% famotidine (32 mg), and 5% nizatidine (283 mg). There were no significant differences between the outcomes of subjects and controls in terms of live births, spontaneous abortions (SABs) and elective abortions (EABs), gestational age at birth, delivery method, birth weight, infants small for gestational age, or major malformations. Among subjects, there were 3 birth defects (2.1%) among the 142 exposed to H2 blockers in the 1st trimester: one each of atrial septal defect, ventricular septal defect, and tetralogy of Fallot. There were 5 birth defects (3.0%) among the 165 exposed anytime during pregnancy. For controls, the rates of defects were 3.5% (1st trimester) and 3.1% (anytime). There were also no differences between the groups in neonatal health problems and developmental milestones, but two children (one subject and one control) were diagnosed as developmentally delayed. The investigators concluded that 1st trimester exposure to H2 blockers did not represent a major teratogenic risk (5).

Data from the Swedish Medical Birth Registry were presented in 1998 (6). A total of 553 infants (6 sets of twins) were delivered from 547 women who had used acid-suppressing drugs early in pregnancy. Famotidine was the only acid-suppressing drug exposure in 58 infants. Three other offspring were exposed in utero to famotidine combined either with cimetidine (one infant) or with ranitidine (two infants). The odds ratio (OR) for malformations after H2 blockers was 0.86, 95% confidence interval (CI) 0.33–2.23. Of the 19 infants with birth defects, 9 had been exposed to H2 blockers, 1 of whom had also been exposed to omeprazole. No birth defects were observed in those exposed

to famotidine (see Omeprazole for additional details of this study) (6).

A population-based observational cohort study formed by linking data from three Swedish national healthcare registers over a 10-year period (1995–2004) was reported in 2009 (7). The main outcome measures were a diagnosis of allergic disease or a prescription for asthma or allergy medications. The drug types included in the study were gastric acid suppressors, including H2 blockers, prostaglandins, proton pump inhibitors, combinations for eradication of *Helicobacter pylori*, and drugs for peptic ulcer and gastroesophageal reflux disease. Of 585,716 children, 29,490 (5.0%) met the diagnosis and 5645 (1%) had been exposed to gastric acid suppression therapy in pregnancy. Of these children, 405 (0.07%) were treated for allergic disease. For developing allergy, the OR was 1.43, 98% CI 1.29–1.59, irrespective of the drug, time of exposure during pregnancy, and maternal history of allergy. For developing childhood asthma, but not other allergic diseases, the OR was 1.51, 95% CI 1.35–1.69, irrespective of the type of acid-suppressive drug and the time of exposure in pregnancy. The authors proposed three possible mechanisms for their findings: (i) exposure to increased amounts of allergens could cause sensitization to digestion labile antigens in the fetus; (ii) maternal Th2 cytokine pattern could promote an allergy-prone phenotype in the fetus; and (iii) maternal allergen-specific IgE could cross the placenta and sensitize fetal immune cells to food and airborne allergens. Several limitations of the study that might have affected their findings were identified, including a general increase in childhood asthma but not necessarily an increase in allergic asthma (7). The study requires confirmation.

A 2005 study evaluated the outcomes of 553 pregnancies after exposure to H2 blockers, 501 (91%) in the 1st trimester (8). The data were collected by the European Network of Teratology Information Services (ENTIS). The agents and number of cases were famotidine 75, cimetidine 113, nizatidine 15, ranitidine 335, and roxatidine 15. No increase in the number of major malformations were noted (8).

A 2009 meta-analysis of published studies was conducted to assess the safety of H2 blockers that were used in 2398 pregnancies (9). Compared with 119,892 nonexposed pregnancies, the OR for congenital malformations was 1.14 (95% CI 0.89–1.45), whereas the ORs and 95% CIs for SABs, preterm birth, and small for gestational age were 0.62 (0.36–1.05), 1.17 (0.94–1.147), and 0.28 (0.06–1.22), respectively. The authors concluded that H2 blockers could be used safely in pregnancy (9).

Four reviews on the treatment of GERD have concluded that H2 blockers,

with the possible exception of nizatidine, could be used in pregnancy with relative safety (10–13).

A 2010 study from Israel identified 1148 infants exposed in the 1st trimester to H₂ blockers (13). No association with congenital malformations was found (OR 1.03, 95% CI 0.80–1.32). Moreover, no association was found with EABs, perinatal mortality, premature delivery, low birth weight, or low Apgar scores (14).

BREASTFEEDING SUMMARY

Famotidine is concentrated in breast milk, but to a lesser degree than either cimetidine or ranitidine (15). Following a single 40-mg dose administered to eight postpartum women who were not breastfeeding, the mean milk:plasma ratios at 2, 6, and 24 hours were 0.41, 1.78, and 1.33, respectively. The mean peak milk concentration, 72 ng/mL, occurred at 6 hours compared with 2 hours for plasma (mean 75 ng/mL). Exposure of the nursing infant to famotidine via milk has not been reported. Although a potential risk may exist for adverse effects, the American Academy of Pediatrics classifies a similar drug (cimetidine) as compatible with breastfeeding. A 1991 reference source suggested that because famotidine and two other H₂ blockers, nizatidine and roxatidine, are less concentrated in milk, they might be preferred in the nursing woman in place of cimetidine or ranitidine (16).

FEBUXOSTAT

Antigout (Uricosuric)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of febuxostat in human pregnancy have been located. The animal reproduction data suggest low risk, but the absence of human pregnancy experience prevents a complete assessment of the embryo–fetal risk. Because this agent will be taken for long periods, the best course would be to consider other uricosurics with pregnancy experience, such as probenecid.

FETAL RISK SUMMARY

Febuxostat is a xanthine oxidase inhibitor that acts by decreasing serum uric acid. It is in the same class of uricosurics as allopurinol, probenecid, and sulfipyrazone. Febuxostat is indicated for the chronic management of hyperuricemia in patients with gout. It is metabolized to four pharmacologically active metabolites, all of which occur in human plasma at a much lower concentration than the parent drug. Febuxostat, taken once daily, is highly bound to plasma protein (about 99%) and the mean terminal elimination half-life is about 5–8 hours (1).

Reproduction studies have been conducted in rats and rabbits. No teratogenicity was observed in these species with oral doses up to 40 and 51 times, respectively, the human plasma exposure at 80 mg/day for equal BSA (HPE) during organogenesis. In rats, doses up to 40 times the HPE during organogenesis and through the lactation period were associated with an increase in neonatal mortality and a reduction in neonatal body weight gain (1). However, a no-observed-effect-level was not established.

In 2-year studies for carcinogenic effects conducted in rats and mice, increased transitional cell papilloma and carcinoma of the urinary bladder were

observed. The urinary bladder neoplasms were secondary to calculus formation in the kidney and bladder. Febuxostat was mutagenic in one assay but was negative in other assays. No effect on fertility or reproductive performance was observed in male and female rats given doses up to 35 times the HPE (1).

It is not known if febuxostat or any of the active metabolites cross the human placenta. The molecular weight (about 316) and long elimination half-life suggest that the drug will cross to the embryo–fetus. The extensive plasma protein binding may limit the exposure.

BREASTFEEDING SUMMARY

No reports describing the use of febuxostat during human lactation have been located. The molecular weight (about 316) and long elimination half-life (about 5–8 hours) suggest that the drug will be excreted into breast milk. The extensive plasma protein binding (about 99%) may limit the exposure. The effect of this exposure on a nursing infant is unknown. If the mother does decide to nurse, the infant should be observed for the most common adverse effects reported in adults: liver function abnormalities, nausea, arthralgia, and rash. However, because the drug will be taken for long periods, the best course might be to avoid it during breastfeeding.

FELBAMATE

Anticonvulsant

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

There is limited information on the effects of felbamate in human pregnancy. The drug is structurally similar to meprobamate. Serious adult toxicity, including fatal cases of aplastic anemia and acute liver failure, was reported to the manufacturer in July and September 1994. One adverse pregnancy outcome, an infant with mental retardation whose mother was on monotherapy, has been reported to the FDA (F. Rosa, personal communication, FDA, 1994), but the relationship to the drug is unknown.

FETAL RISK SUMMARY

Citing information obtained from the manufacturer, one review stated that 10 women had become pregnant while enrolled in clinical trials of the drug and were subsequently dropped from the studies (1). Two of these women underwent elective termination of their pregnancies. A third patient was changed to phenytoin at 4 weeks' gestation and had a spontaneous abortion at 9.5 weeks. The remaining seven women eventually gave birth without any problems, but details on these pregnancies, whether felbamate or other anticonvulsants were continued throughout gestation, and the status of the newborns were not provided.

Felbamate was not teratogenic in rats and rabbits at doses up to 13.9 times and 4.2 times, respectively, the human daily dose based on body weight, or 3 times and <2 times, respectively, the human dose based on BSA (2). In rats, however, there was a decrease in pup weight and an increase in pup deaths during lactation. The cause of the deaths was not known. The no-effect dose in rats was 6.9 times the human dose based on body weight (1.5 times based on BSA) (2).

The drug crosses the placenta without accumulation in pregnant rats (2,3). Transplacental passage apparently has not been described in humans but should occur because of the low molecular weight (about 238).

The Lamotrigine Pregnancy Registry, an ongoing project conducted by the manufacturer, was first published in January 1997 (4). The final report was published in July 2010. The Registry is now closed. There were two prospectively enrolled pregnancies exposed in the 1st trimester to felbamate and lamotrigine, with and without other anticonvulsants, resulting in a live birth without defects and an induced abortion (4).

BREASTFEEDING SUMMARY

Felbamate is excreted into human breast milk (2). No reports have been located that describe the effects, if any, of exposure to this anticonvulsant via breast milk in human infants. Because of the potential for serious toxicity (e.g., aplastic anemia and acute liver failure) in a nursing infant, felbamate probably should not be used during breastfeeding.

FELODIPINE

Calcium Channel Blocker

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Although the animal data suggest risk, the very limited human pregnancy experience prevents a complete assessment of the embryo–fetal risk. However, there is no evidence that drugs in this class are teratogenic.

FETAL RISK SUMMARY

Felodipine is a calcium channel-blocking agent used in the treatment of hypertension. The drug is teratogenic in rabbits, producing digital anomalies consisting of a reduction in size and degree of ossification of the terminal phalanges (1). The frequency and severity of the defects appeared to be dose-related over a range of 0.4–4 times the maximum recommended human dose based on BSA (MRHD). The defects may have been related to decreased uterine blood flow (1). Similar effects were not observed in rats or monkeys. In the latter species, however, an abnormal position of the distal phalanges was observed in about 40% of the fetuses. At doses four times the MRHD, delayed parturition with difficult labor, an increased incidence of stillbirths, and a decreased incidence of postnatal survival were noted in rats (1).

A prospective, multicenter cohort study of 78 women (81 outcomes, 3 sets of twins) who had 1st trimester exposure to calcium channel blockers, including 1% to felodipine, was reported in 1996 (2). Compared with controls, no increase in the risk of major congenital malformations was found. A 1997 report described three pregnant women treated with felodipine for chronic essential hypertension (3). Therapy was started before or during the 1st trimester in each case. One woman, treated with felodipine and atenolol throughout gestation, delivered a growth-restricted, 2020-g (<5th percentile) female infant at 37 weeks' with Apgar scores of 8 and 9 at 1 and 5 minutes, respectively.

The intrauterine growth restriction was most likely due to atenolol and hypertension. The birth weights of the other two infants were in the 10th and 15th percentile. Although a contribution from felodipine cannot be excluded, the low weights were probably secondary to maternal hypertension.

BREASTFEEDING SUMMARY

No reports describing the use of felodipine during human lactation have been located. Because of its relatively low molecular weight (about 384), however, excretion into human milk should be expected. The effect of this exposure on a nursing infant is unknown.

FENFLURAMINE

[Withdrawn from the market. See 9th edition.]

FENOFIBRATE

Antilipemic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Only two reports describing the use of fenofibrate in human pregnancy has been located. Although the near absence of human pregnancy experience prevents an assessment of the risk, the combined animal data are reason for concern if this drug is used for prolonged periods in pregnancy. As with other antilipemic agents, there is apparently no benefit in otherwise healthy women from the use of fenofibrate during gestation. However, fenofibrate may be of benefit to treat or prevent hyperlipidemia-associated pancreatitis. If used during pregnancy, the woman should be informed of the limited human data.

FETAL RISK SUMMARY

Fenofibrate is a prodrug that is rapidly hydrolyzed by esterases after oral administration to the active metabolite, fenofibric acid. The active metabolite is further metabolized to inactive metabolites. Fenofibric acid is indicated as adjunctive therapy to diet for the treatment of primary hypercholesterolemia or mixed dyslipidemia, and for hypertriglyceridemia. Fenofibric acid is extensively bound to serum protein (about 99%) and has an elimination half-life of 20 hours (1,2).

Reproduction studies have been conducted in pregnant rats and rabbits (1,2). The drug was embryocidal and teratogenic in pregnant rats given 7–10 times the maximum recommended human dose based on BSA (MRHD). At 9 times the MRHD given before and throughout gestation to rats, reproductive toxicity included delayed parturition in 100% of the dams, a 60% increase in postimplantation loss with a decrease in litter size, reduced birth weight, an increase in spina bifida, and decreased pup survival (40% at birth, 4% during

neonatal period, and 0% to weaning). Similar findings were observed at seven times the MRHD given from day 15 of gestation through weaning. When pregnant rats were dosed at 10 times the MRHD during organogenesis, an increased incidence of congenital malformations was observed, including domed head/hunched shoulders/rounded body/abnormal chest, kyphosis, stunted fetuses, elongated sternal ribs, malformed sternebrae, extra foramen in palatine, misshapen vertebrae, and supernumerary ribs (1). Embryocidal effects were also observed in rabbits. Doses 9 and 18 times the MRHD caused abortions in 10% and 25% of the dams, respectively. At 18 times the MRHD, 7% of the fetuses died (1,2).

Fenofibrate had no mutagenic potential in four different tests, but the drug was carcinogenic in rats, significantly increasing the incidence of liver carcinoma, pancreatic carcinoma and adenomas, and benign testicular interstitial cell tumors in a dose-related manner (1,2). Some of these tumors (pancreatic acinar adenomas and testicular interstitial cell tumors) were also seen in a second strain of rats at lower doses (1,2).

It is not known if fenofibrate or fenofibric acid crosses the human placenta. Fenofibrate is rapidly metabolized and is not detected in the plasma (1,2). The molecular weight of the metabolite, fenofibric acid (about 319), and the prolonged elimination half-life suggest that the drug will cross, but the high serum protein binding should limit the amount available for transfer to the embryo or fetus.

A 2011 case report described the use of fenofibrate in the 3rd trimester (3). A 30-year-old G4P1SAB2 woman with adequately treated hypothyroidism presented at 32 weeks' gestation with hypertriglyceridemia-associated pancreatitis. Diet alone did not control her dyslipidemia and she was started on an unspecified dose of fenofibrate. Recurrence of pancreatitis was prevented and at 35 weeks' gestation she gave birth spontaneously to a healthy, 2452-g male infant with Apgar scores of 8 and 9, presumably at 1 and 5 minutes (3).

A 30-year-old woman with high triglyceride levels was started on fenofibrate 267 mg/day (4). One year later, an unplanned pregnancy was diagnosed at 8 weeks' gestation and the drug was stopped. At 36 weeks, a cesarean section delivered a healthy 3200-g (75th percentile) male infant with Apgar scores of 7, 9, and 10 at 1, 5, and 10 minutes, respectively. No congenital anomalies were found and the infant was healthy at 1 year of age (4).

BREASTFEEDING SUMMARY

No reports describing the use of fenofibrate in human lactation have been

located. The relative low molecular weight of the active metabolite (about 319) suggests that it is excreted into breast milk. Although the effect of this exposure on a nursing infant is unknown, women taking fenofibrate should probably not breastfeed because of potential toxicity in a nursing infant.

FENOLDOPAM

Antihypertensive

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The absence of human pregnancy experience prevents an assessment of the fetal risk from exposure to fenoldopam mesylate, but the animal data are reassuring. Because it is used for the emergency reduction of severe hypertension, the maternal benefit probably outweighs the unknown fetal risk. However, rapid reduction of maternal blood pressure may compromise the placental perfusion, resulting in fetal hypoxia and subsequent bradycardia. Fetal death is a potential consequence of this effect. Fetal heart rate monitoring, therefore, is recommended during IV infusions of fenoldopam.

FETAL RISK SUMMARY

An IV infusion of fenoldopam mesylate, a dopamine D₁-like receptor agonist, is indicated for the short-term (up to 48 hours), rapid-onset, management of severe hypertension. It is a vasodilator, affecting coronary, renal, mesenteric, and peripheral arteries in animals.

Reproduction studies have been conducted in rats and rabbits with oral doses up to 200 mg/kg/day and 25 mg/kg/day, respectively (1). Although maternal toxicity was evident at the highest doses, no evidence of impaired fertility or fetal harm was observed.

It is not known if fenoldopam mesylate crosses the human placenta. The molecular weight (about 402) is low enough that transfer to the fetus should be expected.

BREASTFEEDING SUMMARY

No reports describing the use of fenoldopam mesylate in human lactation have been located. The molecular weight (about 402) suggests that excretion into breast milk probably occurs. The effect of this exposure on a nursing infant is unknown. Because of the nature of the indication, opportunities for use of this drug during breastfeeding are probably very rare.

FENOPROFEN

Nonsteroidal Anti-inflammatory

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 1st and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Prostaglandin synthesis inhibitors can cause constriction of the ductus arteriosus in utero (see also Indomethacin) (1). Persistent pulmonary hypertension of the newborn may occur if these agents are used in the 3rd trimester close to delivery (1,2). These drugs also have been shown to inhibit labor and prolong pregnancy, both in humans (3) (see also Indomethacin), and in animals (4). Women attempting to conceive should not use any prostaglandin synthesis inhibitor, including fenoprofen, because of the findings in various animal models that indicate these agents block blastocyst implantation (5,6). Moreover, nonsteroid anti-inflammatory drugs (NSAIDs) have been associated with spontaneous abortions (SABs) and congenital malformations. The absolute risk for these defects, however, appears to be low.

FETAL RISK SUMMARY

Fenoprofen is an NSAID in the same subclass (propionic acids) as five other agents (flurbiprofen, ibuprofen, ketoprofen, naproxen, and oxaprozin). It is indicated for the relief of the signs and symptoms of rheumatoid arthritis and osteoarthritis (7).

Fenoprofen given to rats during pregnancy and continued until labor resulted in prolonged parturition (7).

It is not known if fenoprofen crosses the human placenta. The molecular weight (about 559) is low enough that passage to the fetus should be expected. However, in one study, the drug was used during labor (8). No data were given except that the drug could not be detected in cord blood or amniotic fluid.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 191 newborns had been exposed to fenoprofen during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of six (3.1%) major birth defects were observed (eight expected), including (observed/expected) 1/2 cardiovascular defects and 1/1 polydactyly. No anomalies were observed in four other categories of defects (oral clefts, spina bifida, limb reduction defects, and hypospadias) for which specific data were available. These data do not support an association between the drug and congenital defects.

A combined 2001 population-based observational cohort study and a case–control study estimated the risk of adverse pregnancy outcome from the use of NSAIDs (9). The use of NSAIDs during pregnancy was not associated with congenital malformations, preterm delivery, or low birth weight, but a positive association was discovered with SABs. A similar study, also published in 2001, failed to find a relationship, in general, between NSAIDs and congenital malformations, but did find a significant association with cardiac defects and orofacial clefts (10). In addition, a 2003 study found a significant association between exposure to NSAIDs in early pregnancy and SABs (11) (see Ibuprofen for details on these three studies).

A brief 2003 editorial on the potential for NSAID-induced developmental toxicity concluded that NSAIDs, and specifically those with greater cyclooxygenase-2 (COX-2) affinity, had a lower risk of this toxicity in humans than aspirin (12).

BREASTFEEDING SUMMARY

Fenoprofen passes into breast milk in very small quantities. The milk:plasma ratio in nursing mothers given 600 mg every 6 hours for 4 days was approximately 0.017 (8). Although the clinical significance of this amount is unknown, another NSAID in the same subclass is classified as compatible with breastfeeding by the American Academy of Pediatrics (see Ibuprofen).

FENOTEROL

[Withdrawn from the market. See 9th edition.]

FENTANYL

Narcotic Agonist Analgesic

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

The National Birth Defects Prevention Study discussed below found evidence that opioid use during organogenesis is associated with a low absolute risk of congenital birth defects.

Respiratory depression in the newborn is a potential complication if fentanyl is used close to delivery. As with all opioids, neonatal withdrawal may occur after chronic, long-term exposure during pregnancy.

FETAL RISK SUMMARY

Fentanyl is an opioid analgesic. When given by IV injection, the terminal elimination half-life is 219 minutes. Although not teratogenic in rats, fentanyl impaired fertility and was embryotoxic at IV doses 0.3 times the upper human dose given for a period of 12 days (1).

The placental transfer of fentanyl has been documented in the 1st and 2nd trimesters (2) and at term (3–7). A study published in 1998 measured fentanyl concentrations in fetal fluids (amniotic and/or chorionic cavities), fetal blood (after 12 weeks' gestation), and maternal serum 5–22 minutes after an IV bolus (1.5 mcg/kg) in 42 healthy women scheduled for pregnancy termination (between 6 and 16 weeks) under general anesthesia (2). Fentanyl was detected in amniotic fluid at less than 12 weeks', but not later, and in fetal blood. None of the samples of chorionic fluid, however, contained detectable fentanyl (2).

In a study comparing women in labor who received 50 or 100 mcg of fentanyl IV every hour as needed (N = 137) (mean dose 140 mcg, range 50–600 mcg) to those not requiring analgesia (epidural or narcotic) (N = 112), no statistical differences were found in newborn outcome in terms of the incidence of depressed respirations, Apgar scores, and the need for naloxone (3). In blinded measurements taken at 2–4 and 24 hours, no differences were

observed between the two groups of infants in respiratory rate, heart rate, blood pressure, adaptive capacity, neurologic evaluation, and overall assessment. The last dose of fentanyl was given at a mean of 112 minutes before delivery. Cord blood levels of the narcotic were always significantly lower than maternal serum levels (cord:maternal ratios were approximately 0.5 but exact data were not given) ($p < 0.03$). Doses used were considered equianalgesic to 5–10 mg of morphine or 37.5–75 mg of meperidine (3).

Respiratory depression has been observed in one infant whose mother received epidural fentanyl during labor (4). Fentanyl may produce loss of fetal heart rate (FHR) variability without causing fetal hypoxia (3,5). However, no effect on FHR variability or accelerations was observed when epidural fentanyl was given to women receiving adequate epidural lidocaine analgesia (6). The narcotic has been combined with bupivacaine for spinal anesthesia during labor (7,8). In four studies, the addition of fentanyl to bupivacaine had no effect on neonatal respiration (9,10–12) and, in two, did not adversely affect neurobehavioral scores (9,12). Placental transfer of fentanyl was documented in one study with cord:maternal venous plasma ratios of 1.12 for total drug and 1.20 for free drug (9). A study of a continuous epidural infusion of fentanyl and bupivacaine found no accumulation of either drug over a 1- to 15-hour interval in 21 laboring women and observed no adverse fetal effects (13). The mean cord:maternal venous fentanyl concentration was 0.94.

In 15 women undergoing elective cesarean section, fentanyl 1 mcg/kg given IV within 10 minutes of delivery produced an average cord blood:maternal blood ratio over 10 minutes of 0.31 (range 0.06–0.43) (14). No respiratory depression was observed, and all neurobehavioral scores were normal at 4 and 24 hours.

A 1998 case report described respiratory muscle rigidity in a newborn that was attributed to fentanyl (15). Because of severe maternal disease (pulmonary valve stenosis with congestive heart failure and pregnancy-induced hypertension) and Doppler measurements showing periodically absent diastolic flow in the umbilical cord, a cesarean section under general anesthesia was performed at 31 weeks' gestation to deliver a 1440-g male infant. Betamethasone had been given to the mother for fetal lung maturation before delivery. The mother was premedicated with morphine (7.5 mg) and scopolamine (0.3 mg), followed by fentanyl (300 mcg; note: reference states "mg" but assumed to be "mcg"), diazepam (7.5 mg), ketamine (300 mg), and vecuronium (7 mg). The newborn had no respiratory movements and had a heart rate of about 100 beats/minute (Apgar score 3 at 1 minute). Attempts to

ventilate the infant by mask and then by intubation with positive pressure produced no chest movements until 8 minutes after delivery. A chest X-ray showed normal lungs with no sign of hyaline membrane disease. After treatment of severe respiratory alkalosis at 1 hour of age, the infant made an uneventful recovery and was developing normally at 1 year of age. The author attributed the chest wall rigidity to fentanyl because this is a common adverse effect in adults administered the agent during anesthesia (15).

A 31-year-old woman was treated with transdermal fentanyl patches (125 mcg/hr) throughout gestation for severe cervical and lumbar spinal injuries sustained in a road traffic accident before conception (16). An elective cesarean section was performed at 38 weeks' gestation to deliver a healthy, 3.13-kg female infant with Apgar scores of 9 at 1 and 5 minutes, respectively. The infant's head circumference was 35.4 cm (50th percentile). Blood concentrations of fentanyl were as follows: mother (predelivery) 3.56 ng/mL, infant 1.23 ng/mL (at birth), 0.31 ng/mL (day 1), and <0.25 ng/mL (day 2). At 24 hours of age, the bottle-fed baby was noted to be jittery, fisting, and irritable with a high-pitched cry. The mean Finnegan scores (an assessment of acute opioid withdrawal in newborns based on nursing observations) on days 1 and 2 were 4.5 ("mild" is 0–7) with a single peak of 11 ("abstinence" is 8–11) at 72 hours of age. Finnegan scores were consistently less than 4 by day 4 and, at 96 hours of age the infant had no signs of opioid withdrawal. No drug therapy of the withdrawal was required at any time. The infant was developing normally at follow-up (16).

Results of a National Birth Defects Prevention Study (1997–2005) were published in 2011 (17). This population-based case–control study examined the association between maternal use of opioid analgesics and >30 types of major structural birth defects. In 17,449 case mothers, therapeutic opioid use was reported by 454 (2.6%) compared with 134 (2.0%) of 6701 control mothers. Indications for use of opioid analgesics were surgical procedures (41%), infections (34%), chronic diseases (20%), and injuries (18%). Dose, duration, or frequency was not evaluated. The exposure period evaluated was from 1 month before to 3 months after conception. Limiting the exposure period to the first 2 months after conception produced similar results. Infants with >1 defect were included in multiple birth defect categories. The following opioids were included (number of cases for each agent not specified): codeine, hydrocodone, hydromorphone, fentanyl, meperidine, methadone, morphine, oxycodone, pentazocine, propoxyphene, and tramadol. The birth defect, total number, number exposed, and the adjusted odds ratio (aOR) with 95%

confidence interval (CI) were as follows (see below table):

| Birth Defect | Total | Cases | aOR (95% CI) |
|--|-------|-------|---------------|
| Spina bifida | 718 | 26 | 2.0 (1.3–3.2) |
| <i>Any heart defect (20 types)</i> | 7724 | 211 | 1.4 (1.1–1.7) |
| Atrioventricular septal defect | 175 | 9 | 2.4 (1.2–4.8) |
| Teratology of Fallot | 672 | 21 | 1.7 (1.1–2.8) |
| Conotruncal defect | 1481 | 41 | 1.5 (1.0–2.1) |
| Conoventricular septal defect | 110 | 6 | 2.7 (1.1–6.3) |
| Left ventricular outflow tract obstruction defect | 1195 | 36 | 1.5 (1.0–2.2) |
| Hypoplastic left heart syndrome | 357 | 17 | 2.4 (1.4–4.1) |
| Right ventricular outflow tract obstruction defect | 1175 | 40 | 1.6 (1.1–2.3) |
| Pulmonary valve stenosis | 867 | 34 | 1.7 (1.2–2.6) |
| Atrial septal defect (ASD) | 511 | 17 | 2.0 (1.2–3.6) |
| Ventricular septal defect + ASD | 528 | 17 | 1.7 (1.0–2.9) |
| Hydrocephaly | 301 | 11 | 2.0 (1.0–3.7) |
| Glaucoma/anterior chamber defects | 103 | 5 | 2.6 (1.0–6.6) |
| Gastroschisis | 726 | 26 | 1.8 (1.1–2.9) |

The authors speculated that the activity of opioids and their receptors as growth regulators during development of the embryo might be a mechanism to explain the above findings. The exposure data were obtained by retrospective maternal self-report; the authors acknowledged that recall bias and misclassification might have affected their results. They concluded that the absolute risk was a modest absolute increase above the baseline risk for birth defects (17).

BREASTFEEDING SUMMARY

Fentanyl is excreted into milk. A study published in 1992 measured fentanyl colostrum concentrations in 13 healthy women who had received fentanyl (2

mcg/kg) during cesarean section or postpartum tubal ligation (18). Serum and colostrum samples were collected at six intervals up to 10 hours after drug administration. The peak serum and colostrum fentanyl levels occurred at 0.75 hours, with mean values of 0.19 and 0.40 ng/mL, respectively, falling to undetectable and 0.05 ng/mL, respectively, at 10 hours. Colostrum fentanyl concentrations were always greater than serum levels at every measurement. It was concluded that breastfeeding was safe because of the low colostrum concentrations and the low oral bioavailability of fentanyl (18).

The American Academy of Pediatrics classifies fentanyl as compatible with breastfeeding (19).

FESOTERODINE

Urinary Tract Agent (Antispasmodic)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of fesoterodine in human pregnancy have been located. Reproduction studies in animals observed developmental toxicity but only at levels causing maternal toxicity. There was no evidence of drug-induced malformations or developmental delay in surviving offspring. Although the absence of human pregnancy experience prevents a full assessment of the embryo–fetal risk, there is no evidence that other anticholinergics (e.g., see Atropine) cause developmental toxicity. Until human experience is available, the safest course is to avoid fesoterodine in pregnancy. However, if inadvertent exposure in pregnancy does occur, the embryo–fetal risk probably is low.

FETAL RISK SUMMARY

The prodrug fesoterodine is a competitive muscarinic receptor antagonist (anticholinergic) that inhibits urinary bladder smooth muscle. After oral administration, fesoterodine is converted to the active metabolite, 5-hydroxymethyl tolterodine (5-HT), the same metabolite responsible for the action of tolterodine (see also Tolterodine). 5-HT undergoes hepatic metabolism to inactive compounds. Because of the rapid and extensive metabolism, fesoterodine cannot be detected in the plasma. Fesoterodine is indicated for the treatment of overactive bladder with symptoms of urge urinary incontinence, urgency, and frequency. It is the same subclass as darifenacin, flavoxate, oxybutynin, solifenacin, tolterodine, and trospium. Plasma protein binding of 5-HT is about 50%, primarily to albumin and α_1 -acid glycoprotein, and the terminal half-life is about 6–9 hours (range about 4–20 hours) (1,2).

Reproduction studies have been conducted in mice and rabbits. In mice, oral

doses resulting in exposures 6–27 times the expected human exposure (AUC) from the maximum recommended human dose of 8 mg (MRHD) caused no dose-related teratogenicity. One case of cleft palate was observed at each dose tested, but the incidence was within the background historical range. However, increased resorptions and decreased live fetuses were observed. In a prenatal and postnatal development study in mice with an oral dose that was 40% of the dose used in the teratogenicity study, maternal toxicity (decreased body weight) and delayed ear opening of the pups was observed (1).

In rabbits, oral doses producing exposures that were 3–11 times the MRHD were associated with retardation of bone development in the fetuses. No dose-related teratogenicity was observed in rabbits given SC doses up to 9–11 times the exposure from the MRHD, but maternal toxicity and retarded bone development in fetuses (incidence within the background historical range) were observed. Maternal toxicity was observed at exposures three times the MRHD in the absence of any fetal effects (1).

Fesoterodine was not carcinogenic in a 2-year study with oral doses in mice and rats. The drug was not mutagenic nor genotoxic in multiple assays. In mice, fesoterodine had no effect on reproductive function, fertility, or early embryonic development at maternally nontoxic doses (1).

It is not known if 5-HT crosses the human placenta. The molecular weight (about 342), low plasma protein binding, and prolonged terminal half-life suggest that it will cross to the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use of fesoterodine during human lactation have been located.

The molecular weight of the active metabolite 5-HT (about 342), its low plasma protein binding (about 50%), and its long terminal half-life (about 6–9 hours with a range of about 4–20 hours) suggest that it will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown. Although neonates are particularly sensitive to anticholinergic agents, atropine is classified as compatible with breastfeeding by the American Academy of Pediatrics (see Atropine).

FEVERFEW

Herb

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of feverfew in human pregnancy have been located. The only animal reproduction study used a dose, based on weight, that was much higher than a typical human dose. This dose comparison cannot be assessed because doses should be compared based on BSA or AUC. Although embryoletality was suggested by the study, this outcome did not reach statistical significance. Moreover, no structural anomalies were observed in the study. The herb has been used in traditional and folk medicine for approximately 2500 years, so it is doubtful if consumption of the herb is associated with major birth defects. Feverfew does have emmenagogue activity and might cause abortion but, apparently, the doses used for this purpose have not been quantified. Its reported use for morning sickness, again without specifying a dose, suggests that a dose–effect relationship exists. Because the toxic dose is unknown, feverfew should not be used in pregnancy.

FETAL RISK SUMMARY

Feverfew is a plant that grows wild throughout the world, including North America. It is a short, bushy plant with a height up to 1 m (about 3.3 feet) and yellow flowers that bloom from July to October. The herb has been used in traditional and folk medicine for approximately 2500 years. The name feverfew comes from its antipyretic properties. It has been known as “medieval aspirin.” Feverfew has been used for a long list of medical conditions, including migraine. It also has been used to treat labor, menstrual disorders, potential miscarriage, morning sickness, and as an abortifacient. Because of the risk of abortion, it is considered contraindicated in pregnancy (1–3).

A large number of chemicals have been identified in feverfew. The major

biologically active constituents are thought to be the sesquiterpene lactones, 85% of which are parthenolide. Other chemicals found in the plant are flavonoids, volatile oils, and miscellaneous other substances (1).

Because of the absence of animal reproduction studies, a 2006 study was conducted to screen pregnant rats to determine if a full reproductive study was warranted (3). The daily feverfew dose used was 839 mg/kg, which was 58.7 times the recommended human dose of 1 g/day (assumed to be in a 70-kg adult). Rats were treated daily on either gestational days (GDs) 1–8 to establish if the herb affects implantation and early development, or GDs 8–15 to detect if feverfew affects major organ development. In the GD1–8 group, an increase in preimplantation loss was observed, but the increase was not statistically significant. However, the number of liveborn pups was significantly fewer in the GD1–8 group compared with the GD8–15 group. There was also some indication that fetuses had lower weights than controls in the GD8–15 group, but this may have been due to the increased number of runts (defined as two standard deviations less than the mean litter weight of the controls) in the feverfew-exposed group. None of the treated fetuses had gross internal or external structural anomalies. Based on the overall results, the investigators concluded that a full reproductive study was warranted (3).

It is not known if feverfew crosses the human placenta. The dried leaf powder is standardized to contain at least 0.2% of parthenolide that has a molecular weight of about 248 (4). The molecular weight alone suggests that it will cross to the embryo and/or fetus.

BREASTFEEDING SUMMARY

No reports describing the use of feverfew during lactation have been located. The dried leaf powder is standardized to contain at least 0.2% of parthenolide that has a molecular weight of about 248 (4). The molecular weight alone suggests that it will be excreted into breast milk. Because of the potential risk of toxicity for a nursing infant, women consuming feverfew should not breastfeed (1,2).

FEXOFENADINE

Antihistamine

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of fexofenadine during human pregnancy have been located. However, studies in rats found dose-related embryo and fetal toxicity, but the risk to a human fetus cannot be assessed at this time. Because of the extensive human data available, several reviews have recommended that oral first-generation antihistamines (e.g., chlorpheniramine or tripeleminamine) should be considered if antihistamine therapy during pregnancy (especially in the 1st trimester) is required (1–3). The second-generation agents, cetirizine or loratadine, were considered acceptable alternatives, except during the 1st trimester, if a first-generation antihistamine was not tolerated.

FETAL RISK SUMMARY

Fexofenadine is a second-generation (peripherally selective), histamine H₁-receptor antagonist that is used for the relief of symptoms associated with seasonal allergic rhinitis (4). It is a metabolite of another second-generation antihistamine, terfenadine (no longer available). As a group, second-generation antihistamines are less sedating than first-generation agents.

Fertility studies in rats and reproduction studies in rats and rabbits have been conducted with fexofenadine. In rats, doses producing systemic exposures that were ≥3 times the human exposure obtained with a 60-mg twice-daily dose (HTD) were associated with a dose-related decrease in the number of implantations and an increase in the number of postimplantation losses. No evidence of teratogenicity was noted in pregnant rats and rabbits at oral doses up to 4 and 47 times the HTD, respectively. However, dose-related decreases in pup weight gain and survival were observed in rats at three times the HTD

(4).

It is not known if fexofenadine crosses the human placenta to the fetus. The molecular weight (about 502 for the free base) is low enough that transfer to the fetus should be expected.

BREASTFEEDING SUMMARY

Consistent with the molecular weight (about 502 for the free base), fexofenadine is excreted into breast milk. Four lactating women were given terfenadine (60 mg every 12 hours for four doses), and then milk and plasma samples were collected after the last dose at various times for 30 hours (5). None of the parent compound was detected in the milk or plasma. The maximum concentrations of the active metabolite fexofenadine were 309 and 41 ng/mL, respectively—both occurring approximately 4 hours after the last dose. Based on the 12-hour excretion, the mean milk:plasma ratio was 0.21. The maximum estimated exposure of a nursing infant was 0.45% of the recommended maternal weight-corrected dose (5).

The above estimated exposure of a nursing infant may not be applicable when the mother is actually taking fexofenadine. Moreover, the effect of this exposure on a nursing infant is unknown because the four women did not nurse their infants during the study. However, the American Academy of Pediatrics classifies fexofenadine as compatible with breastfeeding (6).

FIDAXOMICIN

Antibiotic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of fidaxomicin in human pregnancy have been located. The animal reproduction data suggest low risk. Because only minimal amounts (in the ng/mL range) of fidaxomicin are detected in the systemic circulation, the drug is probably compatible in pregnancy.

FETAL RISK SUMMARY

Fidaxomicin is an oral macrolide antibacterial agent. It is indicated in adults (≥ 18 years of age) for the treatment of *Clostridium difficile*–associated diarrhea. The drug is in the same macrolide antibacterial class as azithromycin, clarithromycin, dirithromycin, erythromycin, and troleandomycin. Fidaxomicin acts in the gastrointestinal tract. Systemic absorption is minimal with plasma concentrations in the ng/mL range. It is metabolized to an active metabolite (OP-1118) in the gut and both the parent drug and metabolite are excreted in the feces with elimination half-lives of 9 and 10 hours, respectively (1).

Reproduction studies have been conducted in rats and rabbits. In these species, IV doses producing plasma exposures that were about 200 and 66 times, respectively, the human exposure based on AUC (HE) revealed no evidence of fetal harm (1).

Long-term carcinogenicity studies have not been conducted with fidaxomicin. Neither the parent drug nor OP-1118 was mutagenic in two assays, but fidaxomicin was clastogenic in one test. No effects on fertility in male and female rats were observed with systemic exposures that were about 100 times the HE (1).

It is not known if fidaxomicin crosses the human placenta. Minimal concentrations of other macrolide antibacterials cross the placenta (e.g.,

azithromycin and erythromycin) and fidaxomicin might also cross. However, fidaxomicin plasma concentrations are minimal and any exposure of the embryo–fetus should be clinically insignificant.

BREASTFEEDING SUMMARY

No reports describing the use of fidaxomicin during human lactation have been located. Because plasma concentrations of the antibacterial are minimal (ng/mL range), adverse effects in a nursing infant are not expected.

FILGRASTIM

Hematopoietic

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably
Compatible

PREGNANCY SUMMARY

Neither the animal nor the human pregnancy data suggest a major risk for the human embryo or fetus from maternal filgrastim therapy. Although the human pregnancy experience is limited, no congenital malformations or other toxicities attributable to filgrastim have been observed. The cases submitted to the manufacturer suggest selective reporting (i.e., preferentially reporting of abnormal outcomes). Amounts sufficient to produce a biological effect in the fetus apparently cross the human placenta, at least in the 2nd and 3rd trimesters. Additional study is warranted, but filgrastim treatment should not be withheld because of pregnancy.

FETAL RISK SUMMARY

The human granulocyte colony-stimulating factor (G-CSF) filgrastim is a 175-amino acid glycoprotein produced by recombinant DNA technology. Filgrastim is indicated to decrease the incidence of infection, as manifested by febrile neutropenia, in patients with nonmyeloid malignancies receiving myelosuppressive chemotherapy associated with a significant incidence of severe neutropenia with fever. The agent is administered either SC or IV. The elimination half-life is approximately 3.5 hours (1).

Reproduction studies with filgrastim have been conducted in rats and rabbits. No effects on fertility were observed in male and female rats at doses ≤ 500 mcg/kg. (Note: The human dose is 5–10 mcg/kg/day.) In pregnant rats treated during organogenesis, IV injections ≤ 575 mcg/kg/day were not associated with fetal death, teratogenicity, or behavioral effects. In offspring of pregnant rats treated with doses >20 mcg/kg/day, a delay of external differentiation

(detachment of auricles and descent of testes) and slight growth restriction were observed. These effects may have been due to lower maternal body weight during rearing and nursing. At 100 mcg/kg/day, newborn pups had decreased body weights and a slightly decreased 4-day survival rate. Treating pregnant rabbits during organogenesis with doses of 80 mcg/kg/day resulted in increased resorptions and embryoletality but not external defects. This dose, however, was maternally toxic (genitourinary bleeding and decreased body weight and food consumption) (1).

Filgrastim crosses the rat placenta late in gestation (2). In a rat study, filgrastim (50 mcg/kg) was given twice daily for 2, 4, and 6 days before delivery. Filgrastim crossed the placenta within 30 minutes, reaching peak fetal serum levels 4 hours after the dose. Peak serum levels in the fetuses were 1000-fold lower than levels measured in the dams, but the agent still induced bone marrow and spleen myelopoiesis in the fetus and neonate (2). In a continuation of this study, the investigators demonstrated that the 6-day course of filgrastim administered before delivery significantly increased the survival of pups that were infected at birth with Group B β -hemolytic Streptococcus (3).

Although it has a very high molecular weight (18,800), filgrastim also crosses the human placenta, at least in the 2nd and 3rd trimesters. A single IV dose of filgrastim (25 mcg/kg) was given to 11 women (1 set of twins) with an imminent delivery at ≤ 30 weeks' gestation (4). Ten infants were delivered within 30 hours of the dose (mean 10.8 hours) ("early delivery"), and two infants were delivered at 54 and 108 hours ("late delivery"). Three of 10 cord blood samples in the "early delivery" group had G-CSF levels higher than those of 10 untreated controls, but there was no difference in cord blood neutrophil concentrations. Cord blood from the two infants in the "late delivery" group had G-CSF levels similar to those of controls but much higher neutrophil levels that remained elevated for 1 week. The investigators concluded that filgrastim crossed the placenta in amounts sufficient to produce a biologic effect in the fetus, and that this effect was most noticeable in cases where delivery was delayed at least 30 hours after a dose (4).

A 1998 study by the same investigators as above evaluated the effects of filgrastim therapy in women in preterm labor (5). Of the 26 women enrolled in the study, 16 (eight G-CSF subjects and eight controls) delivered within 3 weeks of the dose and were eligible for evaluation. G-CSF cases received a single 25 mcg/kg dose administered as an IV infusion over 4 hours, whereas controls received an IV infusion without the drug. No adverse effects on pregnancy duration or maternal discomfort were noted. Neutrophil production

was assessed by bone marrow aspiration in neonates 24 hours after delivery. The mean time between G-CSF or placebo administration and delivery was 3.9 and 6.3 days, respectively. Compared with controls, the neonates of case mothers had a significantly greater marrow proliferative pool and a significant improvement in Scores for Neonatal Acute Physiologic State (5).

A 27-year-old patient at 26 weeks' gestation was diagnosed with acute myeloid leukemia (6). Because she was otherwise well, she decided to hold chemotherapy to allow the fetus to mature. The woman became neutropenic and, at 27 weeks' gestation, developed fever secondary to a systemic infection. In addition to antibiotics, a 12-day course of filgrastim (dose not specified) was given to allow further time for fetal maturation. A cesarean section was performed at 32 weeks' gestation to deliver a healthy baby boy (weight and other details not provided). The infant was doing well at 5 months of age (6).

A brief 1996 report described the use of filgrastim in a pregnant woman with acute promyelocytic leukemia (7). In addition to other treatment, filgrastim (75 mcg/day SC) was given for 7 days early in the 2nd trimester. She eventually delivered a healthy female infant at term (7).

A number of other studies have reported the use of filgrastim in human pregnancy (8–12). In four studies, the outcomes of 15 pregnancies were (period of exposure shown in parentheses) as follows: one normal infant (3rd trimester) (8); two normal infants (throughout); one with bilateral hydronephrosis (throughout); two with cyclic neutropenia (throughout and 3rd trimester; mothers also had the disorder); one normal infant (1st trimester); three elective abortions (EABs) (1st trimester; one fetus with “abnormal embryogenesis”); and one infant with cardiac septal defects (3rd trimester) (9); one normal infant (2–3 weeks' gestation); one normal infant and one spontaneous abortion (SAB) (treatment before pregnancy in both) (10); and one normal infant (3rd trimester) (11).

Two reports from the Severe Chronic Neutropenia International Registry (SCNIR), one in 2002 (12) and the other in 2003 (13), discussed the outcomes of 23 pregnancies in women who were treated with filgrastim. Three women became pregnant during clinical trials and, although they were excluded from the study, continued to receive commercially available filgrastim (12). Two of the women with cyclic neutropenia had normal infants (one with cyclic neutropenia; one electively aborted her first pregnancy, then carried a second pregnancy to term). The third woman had idiopathic neutropenia and she had an EAB because of abnormal bleeding but subsequently died (12). The

Registry also collected data on 20 pregnancies in women who had been exposed to filgrastim and 105 pregnancies in women who were not exposed to the agent (historical controls) (13). The outcomes of the exposed group, treated for an average of two trimesters (range one to three), were 13 normal infants, 3 SABs, and 4 EABs (nonmedical). Among the 105 historical controls, there were 75 live births (includes two sets of twins and five infants with medical conditions—primarily respiratory), 24 SABs, and 8 EABs (12,13).

The SCNIR also reported the outcomes of nine pregnancies based on information submitted to the manufacturer (12). Of the nine cases, there were four normal infants, one SAB, and four infants with congenital renal and/or cardiac malformations (12).

BREASTFEEDING SUMMARY

No reports describing the use of filgrastim during human lactation have been located. Filgrastim is a glycoprotein and, although it may be excreted into breast milk, it would probably be digested in a nursing infant's stomach. The risk to a nursing infant is unknown but appears to be low to nonexistent. Therefore, treatment with filgrastim should not be held because of breastfeeding.

FINGOLIMOD

Immunologic Agent (Immunomodulator)

PREGNANCY RECOMMENDATION: No Human Data—Contraindicated

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of fingolimod in human pregnancy have been located. The receptor affected by fingolimod is involved in angiogenesis and vascular formation during embryogenesis. An increase in malformations has been noted in rats given doses similar to the recommended human dose based on BSA (RHD). Reduced pre- and postnatal survival and an increase in learning deficits have also been seen. In rabbits, an increase in embryo–fetal death and growth restriction has been noted, with the no-effect-dose-level approximately 20 times the RHD. On the basis of the termination half-life of the drug, the manufacturer suggests that fingolimod be discontinued at least 2 months before attempting conception.

FETAL RISK SUMMARY

Fingolimod is an orally administered drug that modulates sphingosine 1-phosphate receptors. Its active metabolite, fingolimod-phosphate, binds with high affinity to sphingosine 1-phosphate receptors and blocks capacity of lymphocytes to egress from the lymph nodes. It is indicated for the treatment of patients with relapsing forms of multiple sclerosis to delay the frequency of clinical exacerbations and to delay the accumulation of physical disability. Both fingolimod and its active metabolite are highly (99.7%) plasma protein bound. The terminal elimination half-life for both is 6–9 days. The receptor affected by fingolimod affects angiogenesis and is known to be involved in vascular formation during embryogenesis (1,2).

Reproduction studies have been conducted in rats and rabbits. In rats, at oral doses of 0.03–10 mg/kg/day, increased incidences of malformations and embryo–fetal deaths were observed at all but the lowest dose. The lowest end of the dosing range in these studies is less than the RHD. The most common

malformations reported in rats were persistent truncus arteriosus and ventricular septal defects. In addition, in rats administered fingolimod during pregnancy and lactation at 0.05–0.5 mg/kg/day, pup survival was decreased at all doses and learning deficits were seen at the highest dose. The lowest dose administered is similar to the RHD. In rabbits, increased incidences of embryo–fetal mortality and growth restriction were seen at doses of 1.5 and 5 mg/kg/day. The no-effect dose in rabbits was about 20 times the RHD (1).

The carcinogenic potential of fingolimod was evaluated in mice and rats. In mice at oral doses of 0.025–2.5 mg/kg/day for up to 2 years, the incidence of malignant lymphoma was increased at the mid and high doses. However, in rats at doses up to 50 times the RHD, no increase in tumors was seen. Both in vitro and in vivo assays for fingolimod were negative for mutagenicity.

No effects on male and female fertility in rats were noted at the highest dose tested, which is approximately 200 times the RHD (1).

It is not known if fingolimod or its active metabolite crosses the human placenta. The relatively low molecular weight (about 307) and the long terminal half-life suggest that the drug will cross, but the high plasma protein binding may limit the exposure of the embryo–fetus (1,3).

BREASTFEEDING SUMMARY

No reports describing the use of fingolimod during human lactation have been located. The molecular weight (about 307) and the long terminal half-life (6–9 days) suggest that the drug and its active metabolite will be excreted into breast milk, but the high plasma protein binding (99.7%) may limit the amount (1,3). The effect of this exposure on a nursing infant is unknown.

FLAVOXATE

Urinary Tract Agent (Antispasmodic)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The available human pregnancy data available for flavoxate are very limited and are completely lacking for 1st trimester exposure. Moreover, most of the treated women apparently received short-term therapy (i.e., no more than a few doses), and none involved the oral route with tablets, the only available form of the drug in the United States. The limitations also include a lack of information on the growth and development of the exposed infants. Although these uncertainties markedly limit the validity of any fetal safety assessment, the absence of reported toxicity in the fetus and newborn coupled with the lack of fetal toxicity in animals appears to indicate that the use of flavoxate during the second half of pregnancy presents a small, if any, risk to the fetus. The potential fetal effects of flavoxate exposure in the first half of pregnancy are unknown.

FETAL RISK SUMMARY

Flavoxate is a tertiary amine that is a direct inhibitor of smooth muscle spasm of the urinary tract. The drug also possesses some antimuscarinic (i.e., atropine-like) activity. It is used for the symptomatic relief of urinary tract discomfort resulting from inflammatory conditions. Flavoxate is in the same subclass as darifenacin, oxybutynin, solifenacin, tolterodine, and trospium.

Reproduction studies in mice, rats, and rabbits at doses up to 34 times the human therapeutic dose found no evidence of impaired fertility or fetal harm (1–3). At doses approximately 40 times the therapeutic dose, cleft palate (not thought to be drug-induced) and fetal resorption occurred in mice, and intrauterine growth restriction was observed in fetal mice and rabbits (3).

No reports on the placental transfer of flavoxate have been located. The

molecular weight (about 392 for the free base) is low enough that passage to the fetus should be expected.

One presentation at a 1975 conference in Yugoslavia described the use of flavoxate during human pregnancy (4). Although specific obstetric data were not provided, IV flavoxate, often as a single dose in combination with antibiotics, was routinely used in pregnant women for the treatment of pyelonephritis. In addition, the effect of flavoxate on uterine contractions, using total IV doses ranging from 100 to 600 mg, was studied in 30 women at term and in 5 women with premature labor at 7–8 months. Uterine contractions were not modified in any of these patients and no fetal or newborn adverse effects were observed.

A 1984 source cited a 1972 study in which IM flavoxate, 100 mg 3 times daily followed by 400 mg/day by suppository, was used as a tocolytic in 66 women with premature labor (3). The 1984 source cited a second study that involved a reduction in the duration of labor in 120 women with a 100-mg IV dose of flavoxate (3). In neither of the cited studies were adverse effects noted in the mothers or fetuses.

BREASTFEEDING SUMMARY

No reports describing the use of flavoxate during lactation have been located. The molecular weight of the drug (about 392 for the free base) is low enough that excretion into milk should be expected. The effect of this exposure on a nursing infant is unknown.

FLECAINIDE

Antiarrhythmic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

The limited human pregnancy experience includes only one case in which flecainide was used in the 1st trimester. Although the animal data suggest moderate risk, the human data are too limited to allow a complete assessment of risk to the embryo. However, the fetal risk from treatment of refractory fetal arrhythmias appears to be low.

FETAL RISK SUMMARY

Flecainide is an antiarrhythmic agent that is structurally related to encainide and procainamide. In one breed of rabbits, flecainide produced dose-related teratogenicity and embryotoxicity at approximately four times the usual human dose (1). Structural defects observed were club paws, sternbrae and vertebrae abnormalities, and pale hearts with contracted ventricular septum. Similar toxic effects and malformations were not observed in a second breed of rabbits, or in mice and rats, but dose-related delayed sternbral and vertebral ossification was observed in rat fetuses (1).

Two 1988 reports of human use of flecainide during pregnancy may have described a single incidence of exposure to the drug (2,3). IV flecainide was given to a pregnant woman at 30 weeks' gestation for persistent fetal supraventricular tachycardia resistant to digoxin (2,3). The fetal heart rate pattern quickly converted to a sinus rhythm and the mother was maintained on oral flecainide, 100 mg 3 times daily, until delivery was induced at 38 weeks' gestation. The 3450-g female infant had no cardiac problems during the 10 days of observation. Flecainide concentrations in the cord blood and maternal serum at delivery 5 hours after the last dose were 533 and 833 ng/mL, respectively, a ratio of 0.63 (2).

Flecainide 100 mg twice daily, combined with the β -blocker sotalol, was used throughout gestation in one woman for the treatment of ventricular tachycardia and polymorphous ventricular premature complexes associated with an aneurysm of the left ventricle (4). A cesarean section was performed at approximately 37 weeks' gestation. Flecainide concentrations in umbilical cord and plasma samples at delivery, 11 hours after the last dose, were 0.394 and 0.455 mcg/mL, respectively, a ratio of 0.86. No adverse effects, including bradycardia, were observed in the fetus or newborn, who was growing normally at 1 year of age.

A 22-year-old woman at approximately 31 weeks' gestation was treated with flecainide, 100 mg every 8 hours, for fetal arrhythmia associated with fetal hydrops unresponsive to therapeutic levels of digoxin (5). Therapeutic levels of flecainide were measured in the mother over the next 4 days, during which time the fetal heart rate (FHR) converted to a normal sinus rhythm of 120 beats/minute. Approximately 2 days later, a nonreactive nonstress test was documented and flecainide and digoxin were discontinued, but the FHR returned to pretreatment levels within 36 hours. Flecainide was restarted at 150 mg every 12 hours, and within 30 minutes of the first dose, the FHR converted to normal. This dose was continued for 4 days, during which time the FHR remained normal at 120 beats/minute, but with a nonreactive nonstress test. Gradual reduction of the dose to 50 mg every 12 hours maintained a normal FHR with return of a reactive nonstress test and normal beat-to-beat variability. Fetal ascites was completely resolved after 10 days of therapy. A normal 3480-g infant, Apgar scores of 9 and 10 at 1 and 5 minutes, respectively, was delivered vaginally at 41 weeks' gestation. Maternal and fetal serum trough levels at delivery were 0.2 and 0.1 mcg/mL, respectively (5). A postnatal echocardiogram performed on the newborn was normal.

A 1991 report described the experimental use of flecainide, 300–400 mg/day orally, in 14 women at a mean gestational age of 31 weeks (range 23–36 weeks) to treat fetal hydrops and ascites secondary to supraventricular tachycardias or atrial flutter (6). The duration of treatment ranged from 2 days to 5 weeks. Although specific data were not given, the cord:maternal plasma ratio at birth was approximately 0.80, and all fetuses had flecainide concentrations within the usual therapeutic range (400–800 mcg/L). Twelve of the fourteen newborns were alive and well at the time of the report, and one infant, not under treatment at the time, died of sudden infant death syndrome at 4.5 months of age. One intrauterine death occurred after 3 days of therapy and may have been caused by either a flecainide-induced arrhythmia or fetal blood

sampling (6).

A woman in the 3rd trimester was initially treated with flecainide 100 mg orally twice daily, then decreased to 50 mg twice daily, for fetal tachycardia that resolved within 4 days (7). The fetal ascites and polyhydramnios also resolved around this time. Approximately 6 weeks after treatment was begun, she gave birth to a 3320-g, male infant. The cord blood:maternal serum ratio of the drug was 0.97 (235.4/241.2 ng/mL), but the flecainide concentration in the amniotic fluid was 6426.5 ng/mL, about 27 times the level in the fetus.

Other publications have described the successful use of flecainide for the treatment of fetal tachycardia (8–14), and in one of these, flecainide and digoxin were considered the drugs of choice for this condition (8). However, flecainide is superior to digoxin for the treatment of tachycardia in hydropic fetuses (9,10).

The loss of FHR variability and accelerations was described in a case of supraventricular tachycardia treated with 300 mg/day of flecainide during the 3rd trimester (11). The heart rate of the 3690-g male infant returned to a reactive pattern 5 days after delivery. One day later, the infant's serum concentration of flecainide was below the detection level. A general review of drug therapy used for the treatment of fetal arrhythmias was published in 1994 (12). Flecainide has also been used to treat new-onset maternal ventricular tachycardia presenting during the 3rd trimester (15).

Conjugated hyperbilirubinemia thought to be caused by flecainide was described in a 1995 reference (16). Flecainide, 150 mg twice daily, was started at about 28 weeks' gestation for the treatment of fetal supraventricular tachycardia after a trial of digoxin and adenosine had failed to halt the arrhythmia. Other fetal complications, in addition to the arrhythmia, were polyhydramnios, ascites, pericardial effusion, cardiomegaly, and tricuspid and mitral valve regurgitation. Successful conversion to a sinus rhythm occurred within 24 hours. The mother discontinued the therapy 1 week later, and a second course of flecainide was started when the fetal tachycardia and ascites reoccurred. The 2843-g, male infant, delivered vaginally at 36 weeks, developed transient conjugated hyperbilirubinemia within a few days of birth. The authors attributed the hyperbilirubinemia to flecainide because no other cause of the toxicity could be found and the drug is known to produce a similar condition in adults. Follow-up of the infant at 2 months of age revealed that the liver toxicity had resolved and, at 28 months of age, the child was continuing to do well (16).

BREASTFEEDING SUMMARY

Flecainide is concentrated in breast milk (4,17), but no reports of infant exposure to the drug from nursing have been located. A woman was treated throughout gestation and in the postpartum period with flecainide, 100 mg twice daily, and sotalol (see Sotalol) (4). Simultaneous samples of milk and plasma were drawn 3 hours after the second daily dose on the 5th and 7th days postpartum. Flecainide concentrations on day 5 were 0.891 and 0.567 mcg/mL, respectively, and 1.093 and 0.500 mcg/mL, respectively, on day 7. Milk:plasma ratios were 1.57 and 2.18, respectively. The infant was not breastfed (4).

Eleven healthy women volunteers who intended not to breastfeed were given flecainide 100 mg orally every 12 hours for 5.5 days starting on postpartum day 1 (17). The breasts were emptied by a mechanical breast suction pump every 3–4 hours during the study. Peak milk levels of the drug occurred at 3–6 hours after a dose with a mean half-life of elimination of 14.7 hours. The highest daily average concentration of the drug ranged from 270 to 1529 ng/mL, with milk:plasma ratios on days 2, 3, 4, and 5 of 3.7, 3.2, 3.5, and 2.6, respectively. An estimated maximum steady-state concentration of flecainide in an infant consuming approximately 700 mL of milk per day (assumed to be the total milk production) was 62 ng/mL, an apparently nontoxic level. Based on this, the investigators concluded that the risk of adverse effects in a nursing infant whose mother was consuming flecainide was minimal (17). The American Academy of Pediatrics classifies flecainide as compatible with breastfeeding (18).

FLOSEQUINAN

[Withdrawn from the market. See 9th edition.]

FLOXURIDINE

Antineoplastic (Antimetabolite)

PREGNANCY RECOMMENDATION: Contraindicated—1st Trimester

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of floxuridine in human pregnancy have been located. The drug has caused some form of developmental toxicity (structural anomalies, functional deficits, and death) in several animal species. Although the magnitude of human risk is unknown, floxuridine is best avoided in pregnancy, especially in the 1st trimester, because it interferes with DNA, RNA, and protein synthesis.

FETAL RISK SUMMARY

Floxuridine, a fluorinated pyrimidine, is a prodrug antineoplastic antimetabolite that is given by intra-arterial infusion. It is rapidly metabolized to one of two active agents, 5-fluorouracil or floxuridine-monophosphate, and several inactive metabolites (see also Fluorouracil). It is classified as an antimetabolite in the subclass of pyrimidine analogs. In addition to fluorouracil, other antineoplastic agents in the subclass are capecitabine and gemcitabine. Floxuridine is indicated for the palliative management of gastrointestinal adenocarcinoma metastatic to the liver. Pharmacokinetic data are not available (1,2).

Reproduction studies have been conducted in the chick embryo, mice, and rats. The drug was teratogenic in the three species at doses that were 4.2–125 times the recommended human therapeutic dose. Malformations included cleft palates, skeletal defects and deformed appendages, paws, and tails (2). In addition, a 1998 study concluded that the postpubertal reproduction dysfunction observed in male mice that had been exposed to floxuridine as embryos resulted from excessive cell death in the developing brain (3).

Long-term carcinogenicity studies have not been conducted with floxuridine. Floxuridine and its active metabolite, fluorouracil, are known to be mutagenic. With the exception of the above study, reproductive performance and fertility studies have not been conducted with floxuridine. However, fluorouracil is

known to cause chromosomal aberrations and changes in chromosome organization of spermatogonia, as well as transient infertility in rats. In female rats, intraperitoneal doses of fluorouracil administered in the preovulatory phase of oogenesis significantly reduced the number of fertile matings, delayed the development of embryos, increased the incidence of preimplantation lethality, and induced chromosomal anomalies in the embryos (2).

It is not known if floxuridine or its active metabolites cross the human placenta. The molecular weight of the parent compound (about 246) suggests that the drug will cross to the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use of floxuridine during human lactation have been located. The antineoplastic agent is converted into two active metabolites, 5-fluorouracil and floxuridine-monophosphate (see also Fluorouracil). The molecular weight of the parent compound (about 246) suggests that the drug will be excreted into breast milk. If a nursing woman is treated with floxuridine, breastfeeding should be avoided because the drug interferes with DNA, RNA, and protein synthesis.

FLUCONAZOLE

Antifungal

PREGNANCY RECOMMENDATION: Human Data Suggest Risk (≥ 400 mg/day)

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Although the data are very limited, the use of fluconazole during the 1st trimester appears to be teratogenic with continuous daily doses of 400 mg/day or more. The malformations may resemble those observed in the Antley-Bixler syndrome. The published experience with the use of smaller doses, such as those prescribed for vaginal fungal infections, suggests that the risk for adverse outcomes is low, if it exists at all. In those instances in which continuous, high-dose fluconazole is the only therapeutic choice during the 1st trimester, the patient should be informed of the potential risk to her fetus.

FETAL RISK SUMMARY

Fluconazole is a triazole antifungal agent in the same class as itraconazole, posaconazole, terconazole, and voriconazole.

In studies with pregnant rabbits, abortions were noted at a dose 20–60 times the recommended human dose (RHD) but no fetal anomalies (1). In pregnant rats, doses < 20 –60 times the RHD produced increases in fetal anatomical variants (supernumerary ribs, renal pelvis dilation, and delays in ossification). At doses 20 to ≥ 60 times the RHD, embryo deaths were observed as well as structural abnormalities consisting of wavy ribs, cleft palate, and abnormal craniofacial ossification (1). These effects were thought to be consistent with inhibition of estrogen synthesis (1).

One hypothesis for the teratogenic effects of phenytoin involves the production of toxic intermediates, such as an epoxide (arene oxide) (2). Because fluconazole inhibits the cytochrome P450 pathway responsible for phenytoin metabolism, authors of a 1999 study reasoned that the drug combination could provide a test of the hypothesis. The theory was not

supported, however, when pretreatment with a nonembryotoxic fluconazole dose doubled (from 6.2% to 13.3%) the incidence of phenytoin-induced cleft palate in mice. Administering both drugs closely together significantly increased the incidence of resorptions ($p < 0.05$) but not malformations. This lack of effect on malformations may have been related to the increased embryoletality of the combination (2). The mechanism for the teratological interaction between the drugs was unknown.

It is not known if fluconazole crosses the human placenta. The molecular weight (about 306) is low enough that passage to the fetus should be expected.

A case published in 1992 described the pregnancy outcome in a 22-year-old black woman who was treated before and throughout gestation with fluconazole, 400 mg/day orally, for disseminated coccidioidomycosis (3). Premature rupture of the membranes occurred at 27 weeks' gestation; 1 week later, a cesarean section was performed because of chorioamnionitis. A 1145-g female infant with grossly dysmorphic features and with Apgar scores of 0 and 6 at 1 and 5 minutes, respectively, was delivered. The infant died shortly after birth. Anatomic abnormalities included cranioschisis of the frontal bones, craniostenosis of the sagittal suture, hypoplasia of the nasal bones, cleft palate, humeral-radial fusion, bowed tibia and femur, bilateral femoral fractures, contractures of both upper and lower extremities, an incompletely formed right thumb, medial deviation of both feet with a short left first toe, and short right first, fourth, and fifth toes (3). No evidence of coccidioidomycosis was found on microscopic examination.

A 1996 publication described three infants (one of whom is described above) with congenital malformations who had been exposed to fluconazole in utero during the 1st trimester or beyond (4). One woman with *Coccidioides immitis* meningitis took 800 mg/day of fluconazole through the first 7 weeks of pregnancy, then resumed the therapy during the 9th week of gestation and continued until delivery by cesarean section at 38 weeks' gestation. The male infant was small for gestational age (1878 g), was cyanotic, and had a poor tone. He suffered a femur fracture when his limbs were straightened for measurement shortly after birth. Multiple malformations were observed, involving the head and face: brachycephaly, maxillary hypoplasia, small ear helices, exotropia, craniofacial disproportion, large anterior fontanelle, trigonocephaly, supraorbital ridge hypoplasia, and micrognathia; the skeleton: femoral bowing, femoral fracture, thin clavicles, ribs, and long bones, and diffuse osteopenia; and the heart: tetralogy of Fallot, pulmonary artery

hypoplasia, patent foramen ovale, and patent ductus arteriosus.

The pregnancy outcome of a woman (her second pregnancy), first described by Lee et al. in 1992 (3), was also reviewed in the above 1996 reference. In her next pregnancy (her third), she delivered a healthy male infant (4). Although she had been told to take fluconazole 400 mg/day, nontherapeutic serum levels documented that the patient was not compliant with these instructions. After this, the woman conceived a fourth time, and therapeutic serum fluconazole concentrations were documented while she was taking 400 mg/day. Therapy was discontinued when her pregnancy was diagnosed at 4 months' gestation. The full-term female infant (weight not specified) had multiple malformations involving the head and face: cleft palate, low ears, tracheomalacia, rudimentary epiglottis, and proptosis; the skeleton: femoral bowing, clavicular fracture, thin wavy ribs, absent distal phalanx (toe), and arachnodactyly; and the heart: ventricular septal defect and pulmonary artery hypoplasia. The infant died at age 3 months from complications related to her tracheomalacia.

The anomalies noted in the 1992 case report were at first thought to be consistent with an autosomal recessive genetic disorder known as the Antley-Bixler syndrome (3). However, because of the second case in the same mother and the third infant, the defects were now thought to represent the teratogenic effect of fluconazole (4). Moreover, several of the defects observed were similar to those described in fetal rats exposed to fluconazole.

The FDA in January 1996 received a report of congenital defects in an infant exposed to 800 mg/day of fluconazole during the 1st trimester (F. Rosa, personal communication, FDA, 1996). Similar to the case described by Lee et al. (3), the infant had craniostenosis of the sagittal suture and a rare bilateral humeral–radial fusion anomaly. Other malformations were rocker-bottom feet and orbital hypoplasia. Additional individual adverse reports involving fluconazole that were received by the FDA included three cases of cleft palate, one case each of miscarriage with severe shortening of all limbs and of syndactyly, both after a single 150-mg dose in the 1st trimester, and single cases of hydrocephalus, omphalocele, and deafness.

A 1997 case report described a 27-year-old woman with chronic *C. immitis* meningitis who was treated with fluconazole (400 mg/day through the fourth or fifth week, then 800 mg/day) during the first 9 weeks of an unknown pregnancy (5). Fluconazole was stopped when the pregnancy was diagnosed and amphotericin B therapy was initiated. At 22 weeks' gestation, amphotericin B was discontinued and fluconazole was restarted at 1200 mg/day. Spontaneous rupture of the membranes occurred at 31 weeks and a 1300-g male infant was

delivered by cesarean section. Craniofacial anomalies noted in the newborn included a soft calvarium, widely separated sutures, prominent forehead, mild exorbitism, a large pear-shaped nose, and small ears with overfolded helices (5). Other malformations included immobile elbows, hypoplastic nails, subluxed hips, rocker-bottom feet, and bilateral radialhumeral synostosis. Because of the similarity to the other reported cases, the authors concluded that fluconazole produces an Antley-Bixler-like syndrome (5). (Note: The malformations observed in this infant are very similar to those described by Rosa above, and may have been the same case.)

In contrast to the above adverse outcomes, a retrospective review of 289 pregnancies was reported in which the mothers received either a single 150-mg dose (N = 275), multiple 50-mg doses (N = 3), or multiple 150-mg doses (N = 11) of fluconazole (6). All of the women were treated during (gestational age of exposure not specified) or shortly before pregnancy for vaginal candidiasis, even though the authors noted that fluconazole was contraindicated for the treatment of this condition in pregnancy. The outcomes of the 289 pregnancies included 178 infants (5 sets of twins), 39 (13.5%) spontaneous abortions, 38 elective abortions, 2 ectopic pregnancies, and 37 unknown outcomes. Four infants with anomalies were observed, but in each case the mother had taken fluconazole before conception (1 week to >26 weeks before the last monthly menstrual period).

A prospective study published in 1996 compared the pregnancy outcomes of 226 women exposed to fluconazole during the 1st trimester with 452 women exposed to nonteratogenic agents (7). The dosage taken by the exposed group consisted of a single, 150 mg dose (N = 105, 47%), multiple doses of 150 mg (N = 81, 36%), 50-mg single dose (N = 3, 1%), 50-mg multiple doses (N = 23, 10%), 100-mg single dose (N = 5, 2%), or 100-mg multiple doses (N = 9, 4%). Most women (90.7%) were treated for vaginal candidiasis. There were no differences between the two groups in the number of miscarriages, stillbirths, congenital malformations, prematurity, low birth weight, cesarean section, or prolonged hospital stay. Seven (4.0% of live births) of the exposed women delivered infants with anomalies compared with 17 (4.2% of live births) of controls. There was no pattern among the congenital anomalies in the exposed group except for two cases of trisomy 21.

A brief 1996 case report described a normal pregnancy outcome in a 24-year-old woman treated with 21 days of fluconazole (600 mg/day) (because of intolerance to amphotericin B) for *Torulopsis glabrata* fungemia beginning at 14 weeks' gestation (8). Although the patient's course was complicated by

shock and intracerebral hemorrhage, she eventually delivered at term a healthy 2.95-kg infant (sex not specified) who was doing well at 18 months of age.

In another 1996 case report, a 24-year-old woman at about 19 weeks' gestation had chorioretinitis, candidiasis, fever, pneumonia, and low body weight attributed to *Candida albicans* sepsis (9). Because of massive nausea and vomiting after a test dose of amphotericin B, she was treated with IV fluconazole (10 mg/kg/day or about 400 mg/day) for 16 days and then the same dosage orally for another 34 days. She responded well to the antifungal therapy and gave birth at 39 weeks to a healthy 2.834-kg female infant with Apgar scores of 8 and 9 at 1 and 5 minutes, respectively. The infant had normal growth and mental development at 2 years of age (9).

A regional drug information center reported the pregnancy outcomes of 16 women (17 outcomes, 1 set of twins) who had called to inquire about the effect of fluconazole on their pregnancies (10). The median fluconazole dose was 300 mg (range 150–1000 mg) starting at a mean 4 weeks' gestation (range 1–26 weeks). The twins were stillborn (no malformations), but the other 15 newborns were normal.

A 1998 noninterventional observational cohort study described the outcomes of pregnancies in women who had been prescribed one or more of 34 newly marketed drugs by general practitioners in England (11). Data were obtained by questionnaires sent to the prescribing physicians one month after the expected or possible date of delivery. In 831 (78%) of the pregnancies, a newly marketed drug was thought to have been taken during the 1st trimester with birth defects noted in 14 (2.5%) singleton births of the 557 newborns (10 sets of twins). In addition, two birth defects were observed in aborted fetuses. However, few of the aborted fetuses were examined. Fluconazole was taken during the 1st trimester in 48 pregnancies, but the dose and duration of therapy were not specified. The outcomes of these pregnancies included 4 spontaneous abortions, 5 elective abortions, 4 pregnancies lost to follow-up, and 37 normal newborns (3 premature; 2 sets of full-term twins) (11). Although no congenital malformations were observed, the study lacked the sensitivity to identify minor anomalies because of the absence of standardized examinations. Late-appearing major defects may also have been missed due to the timing of the questionnaires.

A short 1998 report described the pregnancy outcome of a 38-year-old woman who had been treated with a single 150-mg oral dose of fluconazole about the date of conception (12). Chorionic villus sampling was conducted at 12 weeks' gestation finding a normal karyotype (46,XY). The male infant,

delivered by cesarean section at 39 weeks', had an encephalocele. Echocardiography revealed dextrocardia and that both the pulmonary artery and the aorta emerged from the right ventricle (12). He died at 7 days of age. The cause of the anomalies was unknown, but it could not have been secondary to fluconazole because of the timing of the exposure.

A 42-year-old woman with achalasia at 31 weeks' gestation was diagnosed with *Candida* esophagitis (13). IV fluconazole, 150 mg/day, was given for 14 days with resolution of the vomiting and lessening of her nausea. She was treated before and after fluconazole with parenteral hyperalimentation. An apparently healthy 2.438-kg female infant, Apgar scores of 9 and 9 at 1 and 5 minutes, respectively, was delivered at 38 weeks' gestation.

In a 1999 report, fluconazole exposures and pregnancy outcomes were examined using the Danish Jutland Pharmaco-Epidemiological Prescription Database (14). A total of 165 women who had received a single, oral 150-mg dose of fluconazole for vaginal candidiasis just before or during pregnancy from 1991 to 1996 were identified. Of these, 121 had been exposed during the 1st trimester. The outcomes of exposed women were compared with the outcomes of 13,327 women who had not received any prescription medication during their pregnancies (controls). In the comparison of exposed newborns with controls, no elevated risk for preterm delivery (odds ratio [OR] 1.17, 95% confidence interval [CI] 0.63–2.17) or low birth weight (OR 1.19, 95% CI 0.37–3.79) was discovered. Similarly, the prevalence of congenital malformations was 3.3% (4 of 121) in exposed compared with 5.2% (697 of 13,327) in controls (OR 0.65, 95% CI 0.24–1.77) (14).

In a 2005 case, a woman with HIV infection was treated with multiple drugs, including fluconazole 400 mg/day, during pregnancy (15). The infant, delivered at 37 weeks', was noted to have seizures secondary to withdrawal from methadone and multiple malformations. Examination at 9 months of age revealed craniosynostosis, shallow orbital region, hypoplastic supraorbital ridges, hypertelorism, mild ptosis, radioulnar synostosis, and metacarpophalangeal–proximal interphalangeal symphalangism of D2–D5 bilaterally. Antley-Bixler and other syndromes were excluded. Compared with four previous cases, the findings in the present case of craniosynostosis, multiple symphalangism, and long-bone abnormalities were similar and suggested a clearly identifiable phenotype (15).

A 1998 review concluded that the risk of embryo–fetal harm was low when small doses were used, such as those for vaginal fungal infections (16).

In a 2013 case report, a woman at 21 3/7 weeks' gestation had a cervical

cerclage for early labor (17). A culture of the amniotic fluid taken before the cerclage placement was positive for *C. albicans*. Because she refused removal of the cerclage, she was treated with an 800-mg IV dose of fluconazole, followed by 400 mg/day orally. After a 14-day course of fluconazole, a repeat amniotic fluid culture remained positive for the fungus. The woman still refused removal of the cerclage. A 40-mg dose of fluconazole was then instilled into the amniotic fluid, followed by another 800 mg IV loading dose and 400 mg/day. A terconazole 80-mg vaginal suppository was given nightly. Intra-amniotic fluconazole was given weekly, with the next two doses being 100 mg and 80 mg. Four weeks later, at 27 2/7 weeks, an emergent cesarean section for placental abruption delivered a viable female infant with Apgar scores of 5 and 7. The infant was discharged home after a 67-day stay in the neonatal intensive care unit. A second case very similar to that above also was reported. This patient presented at 23 1/7 weeks and was treated similar to the first case until she underwent cesarean delivery for presumed placental abruption at 31 5/7 weeks. The 1.62-kg female infant had Apgar scores of 7 and 8 and, after a 39-day stay, was discharged home without sequelae (17).

A registry-based cohort of liveborn infants in Denmark that examined 1st trimester exposure to fluconazole was published in 2013 (18). No increased risk of birth defects with oral doses of 150 mg or 300 mg was found in the 7352 exposed pregnancies (prevalence 2.86%) compared with 968,236 unexposed pregnancies (prevalence 2.60%) (OR 1.06, 95% CI 0.92–1.21). However, a significantly increased risk for tetralogy of Fallot was found (7 cases vs. 287 cases; prevalence 0.10% vs. 0.03%; OR 3.13, 95% CI 1.49–6.71). As noted by the authors, the absolute risk for tetralogy of Fallot was small and requires confirmation from other studies (18).

BREASTFEEDING SUMMARY

Fluconazole is excreted into human milk (19,20). A 42-year-old lactating 54.5-kg woman was taking fluconazole 200 mg once daily (19). On her 18th day of therapy (8 days postpartum), milk samples were obtained at 0.5 hour before a dose and at 2, 4, and 10 hours after a dose. Serum samples were drawn 0.5 hour before the dose and 4 hours after the dose. On her last day of therapy (20 days postpartum), milk samples were again collected at 12, 24, 36, and 48 hours after the dose. Peak milk concentrations of fluconazole, up to 4.1 mcg/mL, were measured 2 hours after the mother's dose. The milk:plasma ratios at 0.5 hour before dose and 4 hours after dose were both 0.90. The elimination half-lives in the milk and serum were 26.9 hours and 18.6 hours,

respectively. No mention was made of the nursing infant (19).

A 29-year-old woman who was nursing her 12-week-old infant developed a vaginal fungal infection (20). Breastfeeding was halted at the patient's request and she was given 150 mg of fluconazole orally. Fluconazole concentrations were determined in milk (pooled from both breasts) and plasma samples obtained at 2, 5, 24, and 48 hours after the dose. Milk concentrations were 2.93, 2.66, 1.76, and 0.98 mcg/mL, respectively, while plasma concentrations were 6.42, 2.79, 2.52, and 1.19 mcg/mL, respectively. The milk:plasma ratios were 0.46, 0.85, 0.85, and 0.83, respectively, with half-lives of 30 and 35 hours, respectively, in the milk and plasma. The author estimated that after three plasma half-lives, 87.5% of the dose would have been eliminated from a woman with normal renal function, thereby greatly reducing the amount of drug a nursing infant would ingest (20).

Although the risk to a nursing infant from exposure to fluconazole in breast milk is unknown, the safe use of this antifungal agent in neonates has been reported (21–23). A brief 1989 report described a 48-day-old infant, born at 36 weeks' gestation, who was treated with IV fluconazole, 6 mg/kg/day, for disseminated *C.albicans* (21). The dosage was reduced to 3 mg/kg/day when a slight, transient increase in serum transaminase values was measured. The infant was discharged home at 80 days of age in good condition. In the second case, IV fluconazole 6 mg/kg/day was administered for 20 days to an approximately 6-week-old, premature infant (born at 28 weeks' gestation) with a disseminated *C.albicans* infection (22). Results of follow-up studies of the infant during the next 4 months were apparently normal. In a similar case, a 1-month-old premature infant was treated with IV fluconazole (5 mg/kg for 1 hour daily) for 21 days and orally for 8 days for meningitis caused by a *Candida* species (23). He was doing well at 9 months of age.

A mother, breastfeeding her third infant, experienced severe pain from cracked nipples associated with a fungal infection (24). She had successfully breastfed her two previous infants for 1–2 years. The fungal infection was successfully treated with fluconazole (200 mg loading dose, then 100 mg/day for 15 days, and then 200 mg/day for 15 days) (24).

The safety of fluconazole during breastfeeding cannot be completely extrapolated from these cases, but the dose administered to these infants far exceeds the amount they would have received via breast milk. Since no drug-induced toxicity was encountered in the infants, fluconazole is probably safe to use during breast feeding. The American Academy of Pediatrics classifies fluconazole as compatible with breastfeeding (25).

FLUCYTOSINE

Antifungal

PREGNANCY RECOMMENDATION: Contraindicated—1st Trimester

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

A major concern with flucytosine exposure in the 1st trimester is that it is partially metabolized to 5-fluorouracil, a known human teratogen (see below). Thus, if possible, avoiding the 1st trimester is the best course.

FETAL RISK SUMMARY

Flucytosine is indicated only in the treatment of serious infections caused by susceptible strains of *Candida* and/or *Cryptococcus*. The drug is partially metabolized and binding to serum proteins is low. The mean half-life is about 4 hours (1).

Reproduction studies have been conducted in rats, mice, and rabbits. Flucytosine was teratogenic in rats at doses 0.27–4.7 times the maximum recommended human dose (MRHD), producing vertebral fusions, cleft lip and palate, and micrognathia. In mice, a dose 2.7 times the MRHD was associated with a low, nonsignificant, incidence of cleft palate. Flucytosine was not teratogenic in rabbits at 0.68 times the MRHD (1).

Consistent with its molecular weight (about 129), low metabolism and serum protein binding, and moderate half-life, flucytosine crosses the human placenta. A woman at 21 weeks' gestation with cryptococcal meningitis was treated with flucytosine and amphotericin B for 1 week before elective termination (2). Both agents were found in the amniotic fluid and cord blood.

Following oral administration, about 4% of flucytosine is metabolized within the gut or by fungal organisms to 5-fluorouracil, an antineoplastic agent (1,3). Fluorouracil is suspected of producing congenital defects in humans (see Fluorouracil).

Several case reports of pregnant patients treated with flucytosine, usually in combination with amphotericin B, in the 2nd and 3rd trimesters have been

located (4–8). No defects were observed in the newborns.

BREASTFEEDING SUMMARY

No reports describing the use of flucytosine during lactation have been located. Because of the potential for serious adverse effects in a nursing infant, breastfeeding is not recommended when taking flucytosine.

FLUDARABINE PHOSPHATE

Antineoplastic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Only one report describing the use of fludarabine in human pregnancy has been located. In that report, exposure occurred in the 2nd trimester and no fludarabine-induced toxicity was thought to have occurred. However, the animal reproduction data suggest risk if the drug is used during organogenesis. Thus, if indicated, avoiding exposure during the 1st trimester would be the best course. The manufacturer states that women of childbearing potential and fertile males must take contraceptive measures during and at least for 6 months after the cessation of therapy (1,2).

FETAL RISK SUMMARY

Fludarabine phosphate, available in oral and IV formulations, is a synthetic purine antimetabolite that is rapidly dephosphorylated in the plasma to an active metabolite. It is a fluorinated nucleotide analog of vidarabine. Fludarabine is in the same antineoplastic subclass of purine analogs and related agents as cladribine, clofarabine, mercaptopurine, pentostatin, and thioguanine. It is indicated as a single agent for the treatment of adult patients with B-cell chronic lymphocytic leukemia whose disease has not responded to or has progressed during or after treatment with at least one standard alkylating-agent containing regimen. Plasma protein binding of the active metabolite is about 19%–29% and the terminal half-life is about 20 hours (1,2).

Reproduction studies have been conducted in rats and rabbits. In rats during organogenesis, repeated IV doses that were 1.5 and 4.5 times the recommended human oral dose based on BSA (RHOD) caused an increase in resorptions, skeletal and visceral malformations (cleft palate, exencephaly, and vertebrae deformities), and decreased body weights. The highest dose was

maternal toxic (slight body weight decreases). In rabbits, repeated IV doses that were ≥ 0.3 times the RHOD were associated with a significant increase in malformations, including cleft palate, hydrocephaly, adactyly, brachydactyly, fusion of the digits, diaphragmatic hernia, heart and great vessel defects, and vertebrae and rib anomalies. At 2.4 times the RHOD, increases in embryo (increased resorptions) and fetal (decreased live fetuses) lethality were observed (1,2).

Studies for carcinogenesis have not been conducted. Both the parent drug and the active metabolite were clastogenic but not mutagenic. Fertility studies in mice, rats, and dogs have shown dose-related adverse effects on the male reproductive system that included decreases in testicular weights and degeneration and necrosis of spermatogenic epithelium in the testes (1,2).

It is not known if fludarabine crosses the human placenta. The molecular weights of the parent drug and active metabolite, 365 and 269, respectively, the low plasma protein binding, and the elimination half-life suggest that both compounds will cross to the embryo–fetus.

In a 2009 case report, a woman with relapse of acute myeloid leukemia at 22 weeks' gestation was treated with fludarabine, cytarabine, mitoxantrone, idarubicin, and gemtuzumab ozogamicin (3). The fetus developed signs of idarubicin-induced cardiomyopathy, transient cerebral ventriculomegaly, anemia, and intrauterine growth restriction. The newborn, delivered at 33 weeks by cesarean section, showed no congenital malformations.

A 20-year-old woman with Fanconi anemia became pregnant 93 months after allogeneic stem cell transplantation from an unrelated donor (4). The preparative regimen for the transplantation consisted of fludarabine, cyclophosphamide, methotrexate, tacrolimus, and antithymocyte globulin. She gave birth at 38 weeks' gestation to a normal, 2828-g male infant after an uncomplicated pregnancy.

BREASTFEEDING SUMMARY

No reports describing the use of fludarabine during human lactation have been located. The molecular weights of the parent drug and active metabolite, 365 and 269, respectively, the low plasma protein binding (19%–29%), and the elimination half-life (20 hours) suggest that both compounds will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown. However, in patients treated with the drug, clinically significant toxicities were observed that involved the hematopoietic, nervous, pulmonary, gastrointestinal, cardiovascular, and genitourinary systems, as well as the skin. Taken in sum,

the potential risks suggest that if a woman is receiving fludarabine, she should not breastfeed her infant.

FLUMAZENIL

Antidote

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably
Compatible

PREGNANCY SUMMARY

No reports describing the use of flumazenil during the 1st trimester in humans have been located. Two cases, however, have reported use of the agent in the 3rd trimester. In addition, a second case report (1) was cited in a 2003 review (2). Although an assessment of the teratogenic risk in humans cannot be made, the animal data suggest the risk is low. Moreover, the indication for flumazenil is such that the maternal benefit should far outweigh the unknown embryo–fetal risk. Therefore, if indicated, flumazenil should not be withheld during pregnancy (3).

FETAL RISK SUMMARY

Flumazenil, a benzodiazepine receptor antagonist, rapidly inhibits the actions of benzodiazepines on the CNS. It is indicated for the complete or partial reversal of the sedative effects of benzodiazepines following therapeutic use or for the management of benzodiazepine overdose. Although it has weak partial agonist activity in some animals, flumazenil has little or no agonist action in humans. After IV administration, flumazenil has a mean terminal half-life of 54 minutes (range 41–79 minutes). Approximately 50% of the agent is protein bound in the plasma and the metabolites are inactive (4).

Reproduction studies have been conducted in rats and rabbits. No evidence of impaired fertility was observed in male and female rats at oral doses up to 120 times the human exposure based on AUC obtained with the maximum recommended IV dose of 5 mg (HEMRD). In rats and rabbits, no teratogenicity was observed when flumazenil was given during organogenesis at oral doses up to 120–600 times the HEMRD. However, embryocidal effects (increased pre- and postimplantation losses) were noted in rabbits at 200 times the

HEMRD. The no-effect dose was 60 times the HEMRD. In rats, oral doses 120 times the HEMRD during lactation resulted in decreased pup survival and increased pup liver weight at weaning. Other adverse effects noted were delayed incisor eruption and ear opening. The no-effect level was 24 times the HEMRD (4).

It is not known if flumazenil crosses the human placenta to the embryo/fetus. The molecular weight (about 303) and moderate plasma protein binding suggest that transfer may occur, but the very short elimination half-life will limit the embryo–fetal exposure.

A 1993 case report described the use of flumazenil in a 22-year-old woman at 36 weeks' gestation (5). The woman was somnolent but was able to respond appropriately to questions. She had taken 50–60 5-mg tablets of diazepam. After initial emergency treatment, serum levels approximately 7 hours after ingestion of diazepam and two metabolites (oxazepam and N-desmethyldiazepam) were 1.9, 0.8, and 0.9 $\mu\text{mol/L}$, respectively. The fetal heart rate was 130–160 beats/minute with decreased variability, absence of accelerations, and occasional decelerations. Flumazenil, 0.3 mg IV, was given to distinguish between fetal asphyxia and an influence of benzodiazepines. Shortly afterward, the patient awakened and the fetal heart rate was noted to have accelerations and increased variability. Approximately 24 hours later, the maternal and fetal symptoms recurred and a second 0.3 mg dose of IV flumazenil was given. Both the mother and the fetus responded as before and no further doses were required. Two weeks later, she delivered a healthy 3620-g (head circumference 33 cm) male infant with Apgar scores of 7, 10, and 10 at 1, 5, and 10 minutes, respectively. No adverse effects of the overdose were observed in the infant who was discharged home with his mother at 5 days of age (5).

BREASTFEEDING SUMMARY

No reports describing the use of flumazenil during human lactation have been located.

The molecular weight (about 303) and moderate plasma protein binding suggest that transfer into breast milk may occur, but the very short elimination half-life (mean 54 minutes) will mitigate this transfer. IV flumazenil has been given directly to neonates to reverse the sedative effects of diazepam administered to the mother immediately before delivery (6,7). If indicated, flumazenil should not be withheld during lactation. However, because of the potential for adverse effects in a nursing infant that may be similar to those

observed in treated adults (such as fatigue, nausea/vomiting, agitation, and cutaneous vasodilation), holding breastfeeding for a few hours after the last dose to allow drug elimination from the mother should be considered.

FLUNISOLIDE

Respiratory Agent (Corticosteroid)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The animal data suggest risk, but the limited human pregnancy experience prevents a complete assessment of the embryo–fetal risk. Moreover, human pregnancy data exist only for inhaled flunisolide. Inhaled corticosteroids play an important role in preventing acute exacerbations of asthma. In a position statement from a joint committee of the American College of Obstetricians and Gynecologists (ACOG) and the American College of Allergy, Asthma, and Immunology (ACAAI) published in 2000, either beclomethasone or budesonide were considered the inhaled steroids of choice for use during pregnancy (1).

FETAL RISK SUMMARY

The oral inhaled formulation of the corticosteroid flunisolide is indicated for the maintenance treatment of asthma as prophylactic therapy (2). The nasal spray product is indicated for the management of the nasal symptoms of seasonal or perennial rhinitis (3). Flunisolide has potent anti-inflammatory and antiallergic activity, but it is not a bronchodilator and is not indicated for the relief of bronchospasm. Total systemic bioavailability of inhaled flunisolide is 40%. The agent is rapidly metabolized by the liver to low potency or inactive metabolites; the plasma half-life of flunisolide is about 1.8 hours. Plasma accumulation has not been observed after 2 weeks of therapy with 2 mg/day (2). After use of the nasal spray, 50% of the dose reaches the systemic circulation as unmetabolized flunisolide with a plasma half-life of 1–3 hours (3).

Reproduction studies have been conducted with oral flunisolide in rats and rabbits. As with other corticosteroids, flunisolide was teratogenic and fetotoxic at daily oral doses of 1180 mcg/m² and 480 mcg/m², respectively (2,3). A reproduction study in pregnant mice observed dose-related teratogenicity (cleft

palate) and reduced fetal weight, but the SC doses also caused maternal toxicity (reduced body weight) (4). Another study used pregnant rats and observed dose-related growth restriction, multiple congenital defects, and increased mortality (5).

The maximum recommended daily human dose (MRDHD) for the inhaled and nasal formulations are 2000 mcg and 464 mcg, respectively (2,3). If the systemic bioavailability of the two formulations are 40% (800 mcg) and 50% (232 mcg), respectively, and if a typical patient has a BSA of about 1.8 m², then the systemic bioavailable doses are about 444 and 129 mcg/m², respectively. Thus, based on systemic bioavailability, the dose in rats causing developmental toxicity was about 3 and 9 times the MRDHD, respectively, and in rabbits, about 1 and 4 times the MRDHD, respectively.

It is not known if flunisolide crosses the human placenta. The molecular weights of the formulations (about 434 and 444) are low enough to cross the placenta, but the short elimination half-lives and extensive metabolism should limit the amount reaching the embryo or fetus.

A 2004 study examined the effect of inhaled corticosteroids on low birth weight, preterm births, and congenital malformations in pregnant asthmatic patients (6). The inhaled steroids and the number of patients were beclomethasone (N = 277), fluticasone (N = 132), triamcinolone (N = 81), budesonide (N = 43), and flunisolide (N = 25). Compared with the general population, the study found no increased incidence of small-for-gestational-age infants (less than 10th percentile for gestational age), low birth weight (<2500 g), preterm births, and congenital malformations (6).

In another 2004 study, 722 asthmatic women used inhaled corticosteroids during pregnancy (7). Although the number of subjects using flunisolide was not mentioned, there were no significant relationships between the inhaled steroid users and low birth weight, small for gestational age, major malformations, gestational hypertension, or preterm birth (7).

The two studies cited above suggest that the embryo–fetal risk is low. However, the one study (7) examining perinatal outcomes was too small to have identified an association with oral clefts, if it had existed. Systemic corticosteroids are known to be associated with a low risk for isolated, nonsyndromic oral clefts (cleft lip and/or palate) when used in the 1st trimester, as well as fetal growth restriction when used for long periods later in gestation. (See Hydrocortisone.).

A 2006 meta-analysis on the use of inhaled corticosteroids during pregnancy was published in 2006 (8). The analysis included five agents: beclomethasone,

budesonide, flunisolide, fluticasone, and triamcinolone. The results showed that these agents do not increase the risk of major congenital defects, preterm delivery, low birth weight, and pregnancy-induced hypertension. Thus, they could be used during pregnancy (8).

BREASTFEEDING SUMMARY

No reports describing the use of flunisolide during human lactation have been located. The molecular weights of the inhaled and nasal spray formulations (about 434 and 444) are low enough for excretion into breast milk, but the short elimination half-lives and extensive metabolism should limit the amount. Other corticosteroids are excreted into milk in low concentrations (see Prednisone), and the passage of flunisolide into milk should be expected. The effects of this exposure on a nursing infant are unknown, but the amounts excreted into milk should be low. Therefore, use of flunisolide during breastfeeding probably is compatible.

FLUNITRAZEPAM

[Withdrawn from the market. See 9th edition.]

FLUOCINOLONE

Corticosteroid (Topical/Ophthalmic Implant)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Systemic corticosteroids are known to cause dose-related developmental toxicity (i.e., growth restriction and structural anomalies) in animals and humans. The limited pregnancy experience with fluocinolone does not appear to represent a risk, probably because the systemic amounts were insufficient to cause embryo or fetal toxicity. Although the amount of topical fluocinolone reaching the systemic circulation is uncertain, suppression of the hypothalamic–pituitary–adrenal (HPA) axis has been observed when other topically fluorinated corticosteroids were used for long periods in nonpregnant patients (see Fluocinonide). Use of occlusive dressings will increase the amount absorbed. Because the amounts absorbed systemically from topical fluocinolone are unknown and probably highly variable, a less-potent agent should be considered for pregnant women requiring long-term topical corticosteroid therapy. Fluocinolone is not absorbed systemically in detectable amounts from the ocular implant, so the embryo–fetal risks from this therapy appear to be negligible.

FETAL RISK SUMMARY

Fluocinolone is a potent, synthetic, fluorinated corticosteroid that has anti-inflammatory, antipyretic, and vasoconstrictive properties. It is available in various topical formulations as a cream, ointment, solution, shampoo, and oil in concentrations ranging from 0.01% to 0.2%. It also is available as an ocular implant (0.59 mg) that is indicated for the treatment of chronic noninfectious uveitis affecting the posterior segment of the eye (3). Topical fluocinolone is indicated for the relief of the inflammatory and pruritic manifestations of corticosteroid-responsive dermatoses (1,2). Systemic absorption of detectable

amounts has not been observed after administration of the ocular implant (3). However, systemic absorption probably occurs with topical use. The degree of absorption is affected by inflammation, integrity of the epidermal barrier, and the use of occlusive dressings. Suppression of the HPA axis is a potential complication after topical use (1,2) and has occurred with other fluorinated corticosteroids (see Fluocinonide).

A number of animal reproduction studies have demonstrated that corticosteroids cause developmental toxicity (growth restriction, structural anomalies, and death) (see Hydrocortisone). Potent topical corticosteroids also can cause structural anomalies after dermal application (2,3).

It is not known if fluocinolone crosses the human placenta. The molecular weight (about 453 as the acetone) is low enough that exposure of the embryo and fetus should be expected from the amounts absorbed systemically. The placenta does contain an enzyme that degrades corticosteroids (e.g., see Betamethasone, Dexamethasone, Hydrocortisone, and Prednisolone), although active drug still crosses.

The use of fluocinolone for the treatment of pruritus vulvae in 17 pregnant women was described in a 1967 reference (4). Typically, the treatment was given five to seven times over a 24-hour period before voluntarily discontinuance after two or three days. No information was given about the pregnancy outcomes.

A large 1997 case–control study of the teratogenic potential of oral and topical corticosteroids involving 1,923,413 total births from 1980 to 1994 was conducted with the Hungarian Case–Control Surveillance of Congenital Abnormalities (5). Among the 20,830 malformed case infants, 73 (0.35%) used a topical corticosteroid during the 1st trimester compared with 118 (0.33%) of the 35,727 normal control infants ($p = 0.69$). The number of cases and controls that used topical fluocinolone cream was 16 and 47, respectively (5).

A 2003 review stated that a topical product containing fluocinolone, hydroquinone, and tretinoin (Tri-Luma[®]) was effective for the treatment of melasma, a localized facial hyperpigmentation also known as the “mask of pregnancy” (6). Tretinoin, when given systemically, is a known human teratogen (see Tretinoin [Systemic]) and, although the systemic bioavailability is poor, concerns have been raised with topical tretinoin (see Tretinoin [Topical]). Thus, the safest course is to avoid use of the combination in pregnancy, at least during the 1st trimester.

BREASTFEEDING SUMMARY

No reports describing the use of fluocinolone during human lactation have been located.

If fluocinolone reaches the systemic circulation, the molecular weight (about 453 as the acetonide) is low enough that excretion into breast milk should be expected. The amount of topically applied fluocinolone reaching the systemic circulation is uncertain, but suppression of the HPA axis has been observed with other topically applied fluorinated corticosteroids (see Fluocinonide) in nonpregnant patients. Because of this uncertainty, if a nursing woman requires long-term topical therapy, consideration should be given to a less-potent corticosteroid.

FLUOCINONIDE

Corticosteroid (Topical)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

The only report describing the use of fluocinonide in human pregnancy involved a woman in the 3rd trimester. The amount of topically applied fluocinonide reaching the systemic circulation is uncertain, but suppression of the hypothalamic–pituitary–adrenal (HPA) axis has been observed in nonpregnant patients. Use of occlusive dressings will increase the amount absorbed. Moreover, it is not known if the amounts absorbed can cause the congenital defects and growth restriction observed in humans with systemic corticosteroids. One manufacturer recommends treatment for no more than 2 weeks with a total dosage not exceeding 60 g/week (1). If a pregnant woman requires long-term topical corticosteroid therapy, the use of a less-potent agent should be considered.

FETAL RISK SUMMARY

Fluocinonide is a potent, synthetic, fluorinated corticosteroid that has anti-inflammatory, antipruritic, and vasoconstrictive properties. It is available in various topical formulations, such as creams, ointments, gels, and solutions in concentrations of 0.05% or 0.1%. Fluocinonide is indicated for the relief of the inflammation and pruritic manifestations of corticosteroid-responsive dermatoses (1). Systemic absorption does occur with topical use with the amount of absorption affected by inflammation, the integrity of the epidermal barrier, and the use of occlusive dressings. Suppression of the HPA axis is a potential complication. Application of a 0.1% cream twice daily in pediatric and adult patients has been associated with suppression of the HPA axis (1).

A number of animal reproduction studies have demonstrated that corticosteroids cause developmental toxicity (growth restriction, structural

anomalies, and death) (see Hydrocortisone). Potent topical corticosteroids also can cause structural anomalies after dermal application (1).

It is not known if fluocinonide crosses the human placenta. The molecular weight (about 495) is low enough that exposure of the embryo and fetus should be expected. The placenta does contain an enzyme that degrades corticosteroids (e.g., see Betamethasone, Dexamethason, Hydrocortisone, and Prednisolone), although some active drug still crosses. The amount of fluocinonide reaching the systemic circulation apparently has not been measured, but amounts sufficient to suppress the HPA axis has been shown clinically, as indicated above.

A 2006 case report described a 21-year-old woman in the 3rd trimester with a diagnosis of food-induced acute generalized exanthematous pustulosis (2). She was successively treated with fluocinonide cream 0.05% and tapering doses of systemic methylprednisolone (doses and durations not specified). She eventually gave birth at 40 weeks' gestation to a healthy male infant (2).

BREASTFEEDING SUMMARY

No reports describing the use of fluocinonide during human lactation have been located.

If fluocinonide reaches the systemic circulation, the molecular weight (about 495) is low enough that excretion into breast milk should be expected. The amount of topically applied fluocinonide reaching the systemic circulation is uncertain, but suppression of the HPA axis has been observed in nonpregnant patients. Because of this uncertainty, if a nursing woman requires long-term topical corticosteroid therapy, consideration should be given to a less-potent corticosteroid.

FLUORESCEIN SODIUM

Diagnostic Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity (IV) Limited Human Data—Probably Compatible (Topical)

PREGNANCY SUMMARY

One report has described the use of fluorescein sodium in human pregnancy. Use of the topical solution in the eye (as well as IV injection) produces measurable concentrations of the dye in the systemic circulation (see references 5 and 6) and passage to the fetus should be expected.

FETAL RISK SUMMARY

The diagnostic agent, fluorescein sodium (dye and coloring Yellow No. 8), is available as a topical solution, dye-impregnated paper strips, and as a solution for IV injection.

No adverse fetal effects were observed in the offspring of pregnant albino rats administered IV sodium fluorescein (10%) at a dose of 5 mL/kg (1). The agent crossed the placenta and distributed throughout the fetuses within 15 minutes. Using phenobarbital in mature rats exposed in utero to multiple maternal IV doses of 10% sodium fluorescein, the investigators determined that in utero exposure to the dye had no effect on their drug detoxification systems later in life (1). No adverse effects on fetal development were observed when pregnant rats and rabbits were treated by gavage with multiple high doses (up to 1500 mg/kg in rats and up to 250 mg/kg in rabbits) of sodium fluorescein during organogenesis (2). Similarly, no adverse fetal outcomes occurred when pregnant rabbits were administered multiple 1.4-mL IV doses of 10% sodium fluorescein during the first two-thirds of gestation (3).

A 2009 report described a 45-year-old woman with choroidal neovascularization and an unknown pregnancy, who received fluorescein angiography at 9 weeks and verteporfin at 12 weeks (4). Pregnancy was diagnosed at about 25 weeks. At about 37 weeks, she gave birth

spontaneously to a healthy, 2410-g female infant without congenital anomalies and with Apgar scores of 9 and 10. The normal infant was doing well at 16 months of age (4).

BREASTFEEDING SUMMARY

Fluorescein sodium is excreted into breast milk (5,6). A 29-year-old woman, who suffered acute central vision loss shortly after prematurely delivery of twins, was administered a 5-mL IV dose of 10% fluorescein sodium for diagnostic angiography (5). Her hospitalized infants were not fed her milk because of concern that the fluorescein in the milk could cause a phototoxic reaction if consumed (a severe bullous skin eruption was observed in a premature infant receiving phototherapy for hyperbilirubinemia shortly after administration of IV fluorescein angiography [7]). Milk concentrations of the dye were measured in seven samples collected between 6 and 76 hours after fluorescein administration. The highest and lowest concentrations, 372 ng/mL and 170 ng/mL, were measured at 6 and 76 hours, respectively. The elimination half-life of fluorescein in the woman's milk was approximately 62 hours (5).

In a second case, a 28-year-old woman at 3 months postpartum was administered a topical 2% solution in both eyes (6). Her infant was not allowed to breastfeed on the day of instillation. Absorption into the systemic circulation was documented with plasma fluorescein concentrations of 36 and 40 ng/mL at 45 and 75 minutes, respectively, after the dose. Milk concentrations at 30, 60, and 90 minutes were 20, 22, and 15 ng/mL, respectively. Because of these data, the authors recommended that mothers should not breastfeed for 8–12 hours after fluorescein topical administration (6).

The two mothers in the above cases either did not breastfeed or temporarily withheld nursing to allow the dye to clear from their milk because of concerns for a fluorescein-induced phototoxic reaction in their infants. Although the American Academy of Pediatrics classifies fluorescein as compatible with breastfeeding (8), the much higher milk concentrations obtained following IV fluorescein indicate that a risk may exist, especially in those infants undergoing phototherapy, and feeding should be temporarily withheld (9).

FLUOROURACIL

Antineoplastic

PREGNANCY RECOMMENDATION: Contraindicated—1st Trimester

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Fluorouracil is classified as an antimetabolite in the subclass of pyrimidine analogs. Other antineoplastic agents in the subclass are capecitabine, cytarabine, floxuridine, and gemcitabine. It is frequently used in combination with other antineoplastics. Structural anomalies are a potential complication if this agent is given systemically during the 1st trimester.

FETAL RISK SUMMARY

Fluorouracil was embryotoxic and teratogenic in mice, rats, and hamsters given parenteral doses equivalent to the human dose (1). Although not teratogenic in monkeys, divided doses above 40 mg/kg resulted in abortions. Animal reproduction studies with topical fluorouracil have not been conducted (1).

When applied topically in patients with actinic keratoses, the amount of fluorouracil absorbed systemically is approximately 6% (1). The amount absorbed from mucous membranes is unknown. One manufacturer reported an infant with cleft lip and palate from a woman who appropriately used topical fluorouracil and a second infant with a ventricular septal defect from a woman who used the drug topically on mucous membranes (1). In addition, spontaneous abortions (SAB) have been reported following use on mucous membrane areas (1). It is not known if there is a causative relationship between the topically applied drug and these outcomes.

Following systemic therapy in the 1st trimester (also with exposure to 5 rad of irradiation), multiple defects were observed in an aborted fetus: radial aplasia; absent thumbs and three fingers; hypoplasia of lungs, aorta, thymus, and bile duct; aplasia of esophagus, duodenum, and ureters; single umbilical artery; absent appendix; imperforate anus; and a cloaca (2).

A 33-year-old woman with metastatic breast cancer was treated with a modified radical mastectomy during her 3rd month of pregnancy, followed by

oophorectomy at 13 weeks' gestation (3). Chemotherapy, consisting of 5-fluorouracil, cyclophosphamide, and doxorubicin, was started at approximately 11 weeks' gestation and continued for six 3-week cyclic courses. Methotrexate was substituted for doxorubicin at this time and the new three-drug regimen was continued until delivery by cesarean section at 35 weeks of a 2260-g female infant. No abnormalities were noted at birth, and continued follow-up at 24 months of age revealed normal growth and development. Toxicity consisting of cyanosis and jerking extremities has been reported in a newborn exposed to fluorouracil in the 3rd trimester (4).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 14 newborns had been exposed to fluorouracil (includes nonsystemic administration) during the 1st trimester (F. Rosa, personal communication, FDA, 1993). One (7.1%) major birth defect was observed (one expected). No anomalies were observed in six defect categories (cardiovascular defects, oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available.

In a brief 1997 report, three pregnant women with breast cancer were successfully treated with two or three courses of vinorelbine (20–30 mg/m²) and fluorouracil (500–750 mg/m²) at 24, 28, and 29 weeks' gestation, respectively (5). Delivery occurred at 34, 41, and 37 weeks' gestation, respectively. One patient also required six courses of epidoxorubicin and cyclophosphamide. Her infant developed transient anemia at 21 days of age that resolved spontaneously. No adverse effects were observed in the other two newborns. All three infants were developing normally at about 2–3 years of age (5).

A 1999 report from France described the outcomes of pregnancies in 20 women with breast cancer who were treated with antineoplastic agents (6). The first cycle of chemotherapy occurred at a mean gestational age of 26 weeks, with delivery occurring at a mean 34.7 weeks. A total of 38 cycles were administered during pregnancy with a median of two cycles per woman. None of the women received radiation therapy during pregnancy. The pregnancy outcomes included two SAB (both exposed in the 1st trimester), one intrauterine death (exposed in the 2nd trimester), and 17 live births, one of whom died at 8 days of age without apparent cause. The 16 surviving children were developing normally at a mean follow-up of 42.3 months (6). Fluorouracil (F), in combination with various other agents (cyclophosphamide [C], doxorubicin [D], epirubicin [E], mitoxantrone [M], or vinorelbine [V]) was

administered to 16 of the women at a mean dose of 535 mg/m² (range 300–750 mg/m²). The outcomes were one SAB (FCE; 1st trimester), one neonatal death (one cycle of FCE 32 days before birth), and 14 surviving liveborn infants (five FEC, four FV, two FDC, two FCM, and one FD in the 2nd or 3rd trimester). One of the infants, exposed to two cycles of FCE with the last at 25 days before birth, had transient leukopenia and another was growth restricted (1460-g, born at 33 weeks' gestation after two cycles of FCM) (6).

Amenorrhea has been observed in women treated with fluorouracil for breast cancer, but this was probably caused by concurrent administration of melphalan (7,8) (see also Melphalan). The long-term effects of combination chemotherapy on menstrual and reproductive function have been described in two 1988 reports (9,10). In one report, only 2 of the 40 women treated for malignant ovarian germ cell tumors received fluorouracil (9). The results of this study are discussed in the monograph for cyclophosphamide (see Cyclophosphamide). The other report described the reproductive results of 265 women who had been treated from 1959 to 1980 for gestational trophoblastic disease (10). Single-agent chemotherapy was administered to 91 women, including 54 cases in which fluorouracil was the only agent used; sequential (single agent) and combination therapies were administered to 67 and 107 women, respectively. Of the total group, 241 were exposed to pregnancy and 205 (85%) of these women conceived, with a total of 355 pregnancies. The time interval between recovery and pregnancy was 1 year or less (8.5%), 1–2 years (32.1%), 2–4 years (32.4%), 4–6 years (15.5%), 6–8 years (7.3%), 8–10 years (1.4%), and more than 10 years (2.8%). A total of 303 (4 sets of twins) liveborn infants resulted from the 355 pregnancies, 3 of whom had congenital malformations: anencephaly, hydrocephalus, and congenital heart disease (one in each case). No gross developmental abnormalities were observed in the dead fetuses. Cytogenetic studies were conducted on the peripheral lymphocytes of 94 children, and no significant chromosomal abnormalities were noted. Moreover, follow-up of the children, more than 80% of the group older than 5 years of age (the oldest was 25 years old), revealed normal development. The reproductive histories and pregnancy outcomes of the treated women were comparable to those of the normal population (10).

Occupational exposure of the mother to antineoplastic agents during pregnancy may present a risk to the fetus. A position statement from the National Study Commission on Cytotoxic Exposure and a research article involving some antineoplastic agents are presented in the monograph for cyclophosphamide (see Cyclophosphamide).

BREASTFEEDING SUMMARY

No reports describing the use of fluorouracil during lactation have been located. The low molecular weight (about 130) probably indicates that the drug is excreted into milk. Because of the potential for severe toxicity in a nursing infant, women should not nurse while receiving fluorouracil.

FLUOXETINE

Antidepressant

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 3rd Trimester

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

The available animal and human experience indicates that fluoxetine is not a major teratogen. However, one animal study has shown that fluoxetine can produce changes, perhaps permanently, in the fetal brain. Moreover, the increased rate of three or minor anomalies found in one investigation may be evidence that the drug does adversely affect embryonic development. The other studies cited above lacked the sensitivity to identify minor anomalies because of the absence of standardized examinations. Two large case–control studies did find increased risks for some birth defects, but the absolute risk appears to be small. However, selective serotonin reuptake inhibitor (SSRI) antidepressants, including fluoxetine, have been associated with several developmental toxicities, including spontaneous abortions (SABs), low birth weight, prematurity, neonatal serotonin syndrome, neonatal behavioral syndrome (withdrawal), possibly sustained abnormal neurobehavior beyond the neonatal period, respiratory distress, and persistent pulmonary hypertension of the newborn (PPHN).

FETAL RISK SUMMARY

Fluoxetine, an SSRI, is used for the treatment of depression. The chemical structure of fluoxetine is unrelated to other antidepressant agents.

All of the antidepressant agents in the SSRI class (citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline) share a similar mechanism of action, although they have different chemical structures. These differences could be construed as evidence against any conclusion that they share similar effects on the embryo, fetus, or newborn. In the mouse embryo, however, craniofacial morphogenesis appears to be regulated, at least in part, by

serotonin. Interference with serotonin regulation by chemically different inhibitors produces similar craniofacial defects (1). Regardless of the structural differences, therefore, some of the potential adverse effects on pregnancy outcome may also be similar.

Reproduction studies in rats and rabbits revealed no evidence of teratogenicity when using up to 1.5 and 3.6 times the maximum recommended human daily dose based on BSA (MRHDD), respectively, throughout organogenesis (2,3). In rats, however, doses of 1.5 times the MRHDD during gestation or 0.9 times the MRHDD during gestation and lactation were associated with an increase in stillbirths, a decrease in pup weight, and a decrease in pup survival during the first 7 days postpartum (2). The no-effect dose for pup mortality was 0.6 times the MRHDD (2). There was no evidence of developmental neurotoxicity in the surviving pups exposed to 1.5 times the MRHDD during gestation (2).

Using uterine rings from midterm (gestation day 14) and term pregnant rats, fluoxetine, and two other antidepressants (imipramine and nortriptyline), were shown to attenuate the activity of serotonin-induced spontaneous uterine contractions (4). Although a direct myometrial role could not be demonstrated for these monoamine reuptake inhibitors, the investigators discussed several other possible pathways that fluoxetine could induce preterm delivery (4).

Administration of fluoxetine to pregnant rats produced a down-regulation of fetal cortical ³H-imipramine binding sites that was still evident 90 days after birth (5). The clinical significance of this finding to the development of the human fetal brain is unknown.

In a study to determine if fluoxetine increased the bleeding risk in neonates, pregnant rats were administered fluoxetine (5.62 mg/kg/day) from day 7 of gestation until the delivery (6). The dose was approximately five times the maximum recommended human dose. Compared with controls, fluoxetine-exposed pups had a significantly higher frequency of skin hematomas. The mechanism was thought to be related to the inhibition of serotonin uptake by platelets (6).

Both fluoxetine and the active metabolite, norfluoxetine, cross the placenta and distribute within the embryo or fetus in rats (7). Consistent with the relatively low molecular weight (about 310 for the free base), fluoxetine and the metabolite desmethylfluoxetine (norfluoxetine) cross the human term placenta. In an in vitro experiment using a single placental cotyledon, the mean steady-state placental transfer for the two compounds was 8.7% and 9.1%, respectively (8). A 2003 study of the placental transfer of antidepressants

found cord blood:maternal serum ratios for fluoxetine and its metabolite that ranged from 0.32 to 1.36 and 0.12 to 1.58, respectively (9). The dose-to-delivery interval was 9–37 hours, with the highest ratio for the parent drug and metabolite occurring at 26 hours. Moreover, two studies (cited below as references 19 and 20), have documented the human placental transfer of the antidepressant and its active metabolite at term.

During clinical trials with fluoxetine, a total of 17 pregnancies occurred during treatment, even though the women were required to use birth control, suggesting lack of compliance (3). No pregnancy complications or adverse fetal outcomes were observed.

A prospective evaluation of 128 women treated with a mean daily dose of 25.8 mg of fluoxetine during the 1st trimester was reported in 1993 (10). Two matched control groups were selected: one with exposure to tricyclic antidepressants (TCAs) and the other with exposure only to nonteratogens. No differences were found in the rates of major birth defects (2, 0, and 2, respectively) among the groups. An increased risk was observed, although not statistically significant, in the rate of SAB when the fluoxetine group was compared with those in the nonteratogen group, 14.8% vs. 7.8% (relative risk 1.9; 95% confidence interval [CI] 0.92–3.92). Because only 74 TCA 1st trimester exposures were available for matching, comparisons between the three groups were based on 74 women in each group. The rates of SAB from this analysis were 13.5% (fluoxetine), 12.2% (TCAs), and 6.8% (nonteratogens), again without reaching statistical significance (10).

A 1992 prospective multicenter study evaluated the effects of lithium exposure during the 1st trimester in 148 women (11). One of the pregnancies was terminated at 16 weeks' gestation because of a fetus with a rare congenital heart defect—Ebstein's anomaly. The fetus had been exposed to lithium, fluoxetine, trazodone, and L-thyroxine during the 1st trimester. The defect was probably caused by lithium exposure.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 142 newborns had been exposed to fluoxetine, 109 during the 1st trimester (F. Rosa, personal communication, FDA, 1994). Two (1.8%) major birth defects were observed (five expected), but details of the abnormalities were not available. No anomalies were observed in eight defect categories (cardiovascular defects, oral clefts, spina bifida, polydactyly, limb reduction defects, hypospadias, brain defects, and eye defects) for which specific data were available. These data do not support an association between the drug and congenital defects.

A 1993 letter to the editor from representatives of the manufacturer summarized the postmarketing database for the antidepressant (12). Of the 1103 prospectively reported exposed pregnancies, 761 of which had potentially reached term, data were available for 544 (71%) outcomes, including 91 elective terminations. Among the remaining 453 pregnancies, there were 72 (15.9%) SABs; 2 (0.4%) stillbirths; and 20 (4.4%) infants with major malformations, 7 of which were identified in the postperinatal period. Details of the aborted fetuses and stillbirths were not given. The malformations observed in the perinatal period were abdominal wall defect (in one twin), atrial septal defect, constricted band syndrome, hepatoblastoma, bilateral hydroceles, gastrointestinal anomaly, intestinal blockage, macrostomia, stubbed and missing digits, trisomy 18, trisomy 21, and ureteral disorder (2 cases). The postperinatal cases included an arrhythmia, pyloric stenosis (2 cases), tracheal malacia (3 cases), and volvulus. Additional 28 cases of major malformations reported retrospectively to the manufacturer were mentioned, but no details were given other than the fact that the malformations lacked similarity and were not indicative of a pattern of anomalies (12).

A review that appeared in 1996 (before reference 14) examined the published data relating to the safety of fluoxetine use during gestation and lactation in both experimental animals and humans (13). Using previously published criteria for identifying human teratogens, the authors concluded that the use of fluoxetine during pregnancy did not result in an increased frequency of birth defects or effects on neurobehavior (13).

A prospective study published in 1996 compared the pregnancy outcomes of 228 women who took fluoxetine with 254 nonexposed controls (14). The rates of spontaneous abortion in the two groups were 10% (exposed) and 8.5% (controls), but 13.6% (23 of 169) among those who were enrolled in the study during the 1st trimester and who had 1st trimester exposure. No significant difference in the rates of major defects among liveborn infants from subjects and controls was observed and no anomaly patterns were evident in either group. A total of 250 infants (97 study and 153 controls) were examined (by a physician who was unaware of the infant's drug exposure [15]) for minor anomalies and among those with three or more anomalies, 15 (15.5%) were exposed and 10 (6.5%) were not exposed ($p = 0.03$). In comparison with those infants who were exposed to fluoxetine during the 1st trimester or not exposed at all, late-exposed infants had a significant increase in perinatal complications, including prematurity (after excluding twins), rate of admission to special-care nurseries (after excluding preterm infants), poor neonatal adaptation, lower

mean birth weight and shorter length in full-term infants, and a higher proportion of full-term infants with birth weights at ≤ 10 th percentile. Moreover, two (2.7%) of the full-term infants who were exposed late had PPHN, a complication that is estimated to occur in the general population at a rate of 0.07%–0.10%. Although the authors concluded that the number of major structural anomalies and the rate of SABs were not significantly increased by fluoxetine exposure in this study, the increased rate of three or more minor anomalies, an unusual finding, is indicative that the drug does affect embryonic development and raises the concern of occult malformations, such as those involving brain development (14).

A 1993 case report described possible fluoxetine-induced toxicity in a term 3580-g male newborn (15). The infant's 17-year-old mother had taken the antidepressant (20 mg/day) throughout most of her pregnancy for severe depression and suicidal ideation. The infant was initially alert and active with mild hypoglycemia (33 mg/dL). At 4 hours of age, marked acrocyanosis was noted and the infant became jittery. Tachypnea developed with a respiratory rate of 70. His condition continued to worsen with symptoms peaking at 36 hours. The symptoms included continuous crying, irritability, moderate to marked tremors, increased muscle tone, a hyperactive Moro reflex, and emesis. An extensive diagnostic workup, including a drug screen, was negative. The cord blood fluoxetine and norfluoxetine levels were 26 ng/mL and 54 ng/mL, respectively, both within a nontoxic range for adults. The infant was asymptomatic at 96 hours of age at which time the serum levels of the parent drug and metabolite were <25 ng/mL and 55 ng/mL, respectively. The toxicity was attributed to fluoxetine (15).

A case report in 1997 described a 3020-g male newborn who was delivered at term from a 34-year-old woman with obsessive-compulsive disorder treated with fluoxetine 60 mg/day (16). Apgar scores were 7 and 8 at 1 and 5 minutes, respectively. The newborn was jittery and hypertonic with mild grunting, flaring, and retracting. Scattered petechiae on the face and trunk and a cephalohematoma were noted. A right, nondisplaced clavicular fracture was noted on chest X-ray. On the 2nd day of life, the serum fluoxetine and norfluoxetine concentrations were 129 ng/mL and 227 ng/mL, respectively, both in the normal adult range. The mother did not breastfeed the infant. Marked improvement in the jitteriness was observed by 2 weeks of age and by 5 months of age, the infant was considered normal. The symptoms, including the bruising and bleeding, were thought to have been caused by the antidepressant (16).

In a 1996 descriptive case series, the European Network of the Teratology Information Services (ENTIS) prospectively examined the outcomes of 689 pregnancies exposed to antidepressants (17). Multiple drug therapy occurred in about two-thirds of the mothers. Fluoxetine was used in 96 pregnancies. The outcomes of these pregnancies were 15 elective abortions, 13 SABs, 1 stillbirth, 60 normal newborns (includes 6 premature infants), 3 normal infants with neonatal disorder (asphyxia and bradycardia, periventricular bleeding; gastroesophageal regurgitation and bradycardia; and withdrawal symptoms), 2 infants with minor defects (angioma right eyebrow and pilonidal sinus), and 2 infants with congenital defects. The defects (all exposed in the 1st trimester or longer) were ventricular septal defect; and hypospadias (exposed to multiple other agents) (17).

Using data from the manufacturer's prospective pregnancy registry, postnatal complications that had been reported in 112 pregnancies (115 infants) exposed to fluoxetine during the 3rd trimester were tabulated in a 1995 reference (18). Maternal doses were 10–80 mg/day, but were not reported in 20 pregnancies. Postnatal complications, unrelated to congenital malformations, were noted in 15 singleton term infants, including 2 infants with jitteriness and 3 with irritability. Irritability was also observed in one premature infant (gestational age not given). Except in one infant, the complications were considered mild and transitory. No relationship to the maternal dose was observed, but plasma drug levels were not measured in any of the infants (18).

A study published in 1997 described the outcomes among 796 pregnancies with confirmed 1st trimester exposure to fluoxetine that had been reported prospectively to the manufacturer's worldwide fluoxetine pregnancy registry (19) (this is an update of the data presented in reference 12). Of the total number, 37 pregnancies were identified during clinical trials and 759 from spontaneous reports. SABs occurred in 110 (13.8%) cases and, for the remaining 686 pregnancies, malformations, deformations, and disruptions occurred in 34 (5.0%). No consistent pattern of defects was observed and only one minor malformation was reported. Moreover, no recurring patterns of malformations, increase in unusual defects, or adverse outcomes were observed in 89 infants from 426 retrospectively reported pregnancies. Based on these data, the authors concluded that it was unlikely that the drug was related to an increased risk of malformations (19).

The neurodevelopment of children ages 16–86 months, who had been exposed in utero for varying lengths of duration to fluoxetine (N = 55) or TCAs (N = 80), were described in 1997 (20). A control group (N = 84) of children not

exposed to any agent known to adversely affect the fetus was used for comparison. Assessments of neurodevelopment were based on tests for global IQ and language development and were conducted in a blinded manner. No statistically significant differences were found between the three groups in terms of gestational age at birth, birth weight, and weight, height or head circumference at testing. The mean global IQ scores in the fluoxetine, tricyclic, and control groups were 117, 118, and 115, respectively (ns). Moreover, there were no significant differences in the language scores, or assessment of temperament, mood, arousability, activity level, distractibility, or behavior problems. In addition, no significant differences between the three groups were found with analysis of the data by comparing those exposed only during the 1st trimester to those exposed throughout pregnancy (20).

A 1998 noninterventional observational cohort study described the outcomes of pregnancies in women who had been prescribed ≥ 1 of 34 newly marketed drugs by general practitioners in England (21). Data were obtained by questionnaires sent to the prescribing physicians 1 month after the expected or possible date of delivery. In 831 (78%) of the pregnancies, a newly marketed drug was thought to have been taken during the 1st trimester with birth defects noted in 14 (2.5%) singleton births of the 557 newborns (10 sets of twins). In addition, two birth defects were observed in aborted fetuses. However, few of the aborted fetuses were examined. Fluoxetine was taken during the 1st trimester in 52 pregnancies. The outcomes of these pregnancies included 2 ectopic pregnancies, 6 SABs, 6 elective abortions, 11 cases lost to follow-up, 25 normal newborns (1 premature), and 2 infants with major malformations. The birth defects were spina bifida with hydrocephalus (the mother also took dothiepin, sodium valproate, and carbamazepine) and congenital hypothyroidism. In addition, one newborn with a normal chromosome pattern had a minor congenital anomaly (single palmar creases) (21).

Two reviews published in 1998 (22,23) and a meta-analytical review published in 2000 (24) concluded that fluoxetine was not associated with human teratogenicity.

In a 1998 case report, a 32-year-old woman with bipolar disorder took fluoxetine, buspirone, and carbamazepine (see Breastfeeding Summary for doses and further details) throughout gestation (25). At 42 weeks' gestation she gave birth to a healthy 3940-g female infant. The mother continued her medications for 3 weeks while exclusively breastfeeding the infant. She reported seizure-like activity in her infant at 3 weeks, 4 months, and 5.5 months of age (25).

Five male infants exposed to citalopram (30 mg/day), paroxetine (10–40 mg/day), or fluoxetine (20 mg/day) during gestation exhibited withdrawal symptoms at or within a few days of birth and lasting up to 1 month (26). Symptoms included irritability, constant crying, shivering, increased tonus, eating and sleeping problems, and convulsions.

A 2002 prospective study compared two groups of mother–child pairs exposed to antidepressants throughout gestation (40 exposed to fluoxetine and 46 to tricyclics) with 36 nonexposed, not depressed controls (27). Offspring were studied between the ages of 15 and 71 months for effects of antidepressant exposure in terms of IQ, language, behavior, and temperament. Exposure to antidepressants did not adversely affect the measured parameters, but IQ was significantly and negatively associated with the duration of depression, and language was negatively associated with the number of depression episodes after delivery (27).

The effect of SSRIs on birth outcomes and postnatal neurodevelopment of children exposed prenatally was reported in 2003 (28). Thirty-one children (mean age 12.9 months) exposed during pregnancy to SSRIs (15 sertraline, 8 paroxetine, 7 fluoxetine, and 1 fluvoxamine) were compared with 13 children (mean age 17.7 months) of mothers with depression who elected not to take medications during pregnancy. All of the mothers had healthy lifestyles. The timing of the exposures was 71% in the 1st trimester, 74% in the 3rd trimester, and 45% throughout. The average duration of breastfeeding in the subjects and controls was 6.4 and 8.5 months. Twenty-eight (90%) subjects nursed their infants, 17 of who took SSRIs (10 sertraline, 4 paroxetine, and 3 fluoxetine) compared with 11 (85%) controls, 3 of who took sertraline. There were no significant differences between the groups in terms of gestational age at birth, premature births, birth weight, and length or, at follow-up, in sex distribution or gain in weight and length (expressed at percentage). Seven (23%) of the exposed infants were admitted to a neonatal intensive care unit (six respiratory distress, four meconium aspiration, and one cardiac murmur) compared with none of the controls (ns). Follow-up examinations were conducted by a pediatric neurologist, psychologist, and a dysmorphologist who were blinded as to the mother's medication status. The mean Apgar scores at 1 and 5 minutes were lower in the exposed group than in controls (7.0 vs. 8.2, and 8.4 vs. 9.0, respectively). There was one major defect in each group: small asymptomatic ventricular septal defect (exposed); bilateral lacrimal duct stenosis that required surgery (control). The test outcomes for mental development were similar in the groups, but significant differences in the subjects included a slight delay in

psychomotor development and lower behavior motor quality (tremulousness and fine motor movements) (28).

A 2004 prospective study examined the effect of four SSRIs (citalopram, fluoxetine, paroxetine, and sertraline) on newborn neurobehavior, including behavioral state, sleep organization, motor activity, heart rate variability, tremulousness, and startles (29). Seventeen SSRI-exposed, healthy, full-birth-weight newborns and 17 nonexposed, matched controls were studied. A wide range of disrupted neurobehavioral outcomes were shown in the subject infants. After adjustment for gestational age, the exposed infants were found to differ significantly from controls in terms of tremulousness, behavioral states, and sleep organization. The effects observed on motor activity, startles, and heart rate variability were not significant after adjustment (29).

A 2003 prospective study evaluated the pregnancy outcomes of 138 women treated with SSRI antidepressants during gestation (30). Women using each agent were 73 fluoxetine, 36 sertraline, 19 paroxetine, 7 citalopram, and 3 fluvoxamine. Most (62%) took an SSRI throughout pregnancy and 95% were taking an SSRI at delivery. Birth complications were observed in 28 infants, including preterm birth (9 cases), meconium aspiration, nuchal cord, floppy at birth, and low birth weight. Four infants (2.9%) had low birth weight, all exposed to fluoxetine (40–80 mg/day) throughout pregnancy, including two of the three infants of mothers taking 80 mg/day. One infant had Hirschsprung disease, a major defect, and another had cavum septi pellucidi (neither the size of the cavum nor the SSRI agents were specified) (30). The clinical significance of the cavum septi pellucidi is doubtful as it is nearly always present at birth but resolves in the first several months (31).

In 2004, an expert panel of the National Toxicology Program (NTP) Center for the Evaluation of Risks to Human Reproduction (CEHR) evaluated the developmental toxicity of fluoxetine (32). The panel concluded that fluoxetine, especially when used late in pregnancy, caused developmental toxicity that was characterized by an increased rate of poor neonatal adaptation, such as jitteriness, tachypnea, hypoglycemia, hypothermia, poor tone, respiratory distress, weak or absent cry, diminished pain reactivity, or desaturation with feeding (32). Other toxicities included low birth weight and decreased duration of gestation. The panel also concluded that fluoxetine can impair human fertility as demonstrated by reversible, impaired sexual function, specifically orgasm. The mechanism of these effects was unknown but could be related to the drug, disease, or to the pharmacological action of the drug (32).

A 2005 meta-analysis of seven prospective comparative cohort studies

involving 1774 patients was conducted to quantify the relationship between seven newer antidepressants and major malformations (33). The antidepressants were bupropion, fluoxetine, fluvoxamine, nefazodone, paroxetine, sertraline, and trazodone. There was no statistical increase in the risk of major birth defects above the baseline of 1%–3% in the general population for the individual or combined studies (33).

The database of the World Health Organization (WHO) was used in a 2005 report on neonatal SSRI withdrawal syndrome (34). Ninety-three suspected cases with either neonatal convulsions or withdrawal syndrome were identified in the WHO database. The agents were 64 paroxetine, 14 fluoxetine, 9 sertraline, and 7 citalopram. The analysis suggested that paroxetine might have an increased risk of convulsions or withdrawal compared with other SSRIs (34).

Evidence for the neonatal behavioral syndrome that is associated with in utero exposure to SSRIs and serotonin and norepinephrine reuptake inhibitors (SNRIs) (collectively called serotonin reuptake inhibitors [SRIs]) in late pregnancy was reviewed in a 2005 reference (35). The report followed a recent agreement by the FDA and manufacturers for a class labeling change about the neonatal syndrome. Analysis of case reports, case series, and cohort studies revealed that late exposure to SRIs carried an overall risk ratio of 3.0 (95% CI 2.0–4.4) for the syndrome compared with early exposure. The case reports (N = 18) and case series (N = 131) involved 97 cases of paroxetine, 18 fluoxetine, 16 sertraline, 12 citalopram, 4 venlafaxine, and 2 fluvoxamine. There were nine cohort studies analyzed. The typical neonatal syndrome consisted of CNS, motor, respiratory, and gastrointestinal signs that were mild and usually resolved within 2 weeks. Only 1 of 313 quantifiable cases involved a severe syndrome consisting of seizures, dehydration, excessive weight loss, hyperpyrexia, and intubation. There were no neonatal deaths attributable to the syndrome (35).

Possible sustained neurobehavioral outcomes beyond the neonatal period were reported in 2005 (36). Based on the previous findings that prenatally exposed newborns had reduced pain responses, biobehavioral responses to acute pain (heel lance) were prospectively studied in 2-month-old infants. The responses included facial action (Neonatal Facial Coding System) and cardiac autonomic reactivity (derived from respiratory activity and heart rate variability). Three groups of infants were formed: 11 infants with prenatal SSRI exposure alone (2 fluoxetine and 9 paroxetine), 30 infants with prenatal and postnatal (from breast milk) SSRI exposure (6 fluoxetine, 20 paroxetine, and 4

sertraline), and 22 nonexposed controls (mothers not depressed). The exposure during breastfeeding was considered to be very low. Heel lance-induced facial action increased in all three groups but was significantly lowered (blunted) in the first group. Heart rate was significantly lower in the exposed infants during recovery. Moreover, exposed infants had a greater return of parasympathetic cardiac modulation, whereas controls had a sustained sympathetic response. The findings were consistent with the patterns of pain reactivity observed in exposed newborns and suggested sustained neurobehavioral outcomes (36).

A significant increase in the risk of low birth weight (<10th percentile) and respiratory distress after prenatal exposure to SSRIs was reported in 2006 (37). The population-based study, representing all live births (N = 119,547) during a 39-month period in British Columbia, Canada, compared pregnancy outcomes of depressed mothers treated with SSRIs with outcomes in depressed mothers not treated with medication and in nonexposed controls. The severity of depression in the depressed groups was accounted for by propensity score matching (37).

A 30% incidence of SSRI-induced neonatal abstinence syndrome was found in a 2006 cohort study (38). Sixty neonates with prolonged in utero exposure to SSRIs were compared with nonexposed controls. The agents used were paroxetine (62%), fluoxetine (20%), citalopram (13%), venlafaxine (3%), and sertraline (2%). Assessment was conducted by the Finnegan score. Ten of the infants had mild and eight had severe symptoms of the syndrome. The maximum mean score in infants with severe symptoms occurred within 2 days of birth, but some occurred as long as 4 days after birth. Because of the small numbers, a dose response could only be conducted with paroxetine. Infants exposed to mean maternal doses that were <19 mg/day had no symptoms, <23 mg/day had mild symptoms, and 27 mg/day had severe symptoms (38).

A meta-analysis of clinical trials (1990–2005) with SSRIs was reported in 2006 (39). The SSRI agents included were citalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline. The specific outcomes analyzed were major, minor, and cardiac malformations and SABs. The odds ratio (OR) with 95% CI for the four outcomes were 1.394 (0.906–2.145), 0.97 (0.13–6.93), 1.193 (0.531–2.677), and 1.70 (1.28–2.25), respectively. Only the risk of SABs was significantly increased (39).

A brief 2005 report described significant associations between the use of SSRIs in the 1st trimester and congenital defects (40). The data were collected by the CDC-sponsored National Birth Defects Prevention Study in an ongoing

case–control study of birth defect risk factors. Case infants (N = 5357) with major birth defects were compared with 3366 normal controls. A positive association was found with omphalocele (N = 161; OR 3.0, 95% CI 1.4–6.1). Paroxetine, which accounted for 36% of all SSRI exposures, had the strongest association with the defect (OR 6.3, 95% CI 2.0–19.6). The study also found a significant association between the use of any SSRI and craniosynostosis (N = 372; OR 1.8, 95% CI 1.0–3.2) (40). An expanded report from this group was published in 2007 (see reference 49 below).

In a multicenter, prospective controlled study, the pregnancy outcomes of three groups of women were evaluated: (a) paroxetine 330 (286 in the 1st trimester), (b) fluoxetine 230 (206 in the 1st trimester), and (c) 1141 exposures not known to cause birth defects (41). Compared with controls, there was a higher rate of congenital defects among those exposed to paroxetine in the 1st trimester, 5.1% vs. 2.6%, relative risk (RR) 1.92, 95% CI 1.01–3.65. There also was a higher rate for cardiovascular anomalies, 1.9% vs. 0.6%, RR 3.46, 95% CI 1.06–11.42. In addition, perinatal complications were more prevalent in both SSRI groups than in controls (41).

In 1999, the Swedish Medical Birth Registry compared the use of antidepressants in early pregnancy and delivery outcomes for the years 1995–1997 (42). There were no significant differences for birth defects, infant survival, or risk of low birth weight (<2500 g) among singletons between those exposed to any depressant, SSRIs only, or non-SSRIs only, but a shorter gestational duration (<37 weeks) was observed for any antidepressant exposure (OR 1.43, 95% CI 1.14–1.80) (42). A second Registry report, published in 2006 and covering the years 1995–2003, analyzed the relationship between antidepressants and major malformations or cardiac defects (43). There was no significant increase in the risk of major malformations with any antidepressant. The strongest effect among cardiac defects was with ventricular or atrial septum defects (VSDs-ASDs). Significant increases were found with paroxetine (OR 2.22, 95% CI 1.39–3.55) and clomipramine (OR 1.87, 95% CI 1.16–2.99) (44). In 2007, the analysis was expanded to include the years 1995–2004 (44). There were 6481 women (6555 infants) who had reported the use of SSRIs in early pregnancy. The number of women using a single SSRI during the 1st trimester was 2579 citalopram, 1807 sertraline, 908 paroxetine, 860 fluoxetine, 66 escitalopram, and 36 fluvoxamine. After adjustment, only paroxetine was significantly associated with an increased risk of cardiac defects (N = 13, RR 2.62, 95% CI 1.40–4.50) or VSDs-ASDs (N = 8, RR 3.07, 95% CI 1.32–6.04). Analysis of the combined SSRI group,

excluding paroxetine, revealed no associations with these defects. The study found no association with omphalocele or craniostenosis (44).

A 2007 study evaluated the association between 1st trimester exposure to paroxetine and cardiac defects by quantifying the dose–response relationship (45). A population-based pregnancy registry was used by linking three administrative databases so that it included all pregnancies in Quebec between 1997 and 2003. There were 101 infants with major congenital defects, 24 involving the heart, among the 1403 women using only one type of antidepressant during the 1st trimester. The use of paroxetine or other SSRIs did not significantly increase the risk of major defects or cardiac defects compared with non-SSRI antidepressants. However, a paroxetine dose >25 mg/day during the 1st trimester was significantly associated with an increased risk of major defects (OR 2.23, 95% CI 1.19–4.17) and of cardiac defects (OR 3.07, 95% CI 1.00–9.42) (45).

A 2007 retrospective cohort study examined the effects of exposure to SSRIs or venlafaxine in the 3rd trimester on 21 premature and 55 term newborns (46). The randomly selected unexposed control group consisted of 90 neonates of mothers not taking antidepressants, psychotropic agents, or benzodiazepines at the time of delivery. There were significantly more premature infants among the subjects (27.6%) than in controls (8.9%), but the groups were not matched. The antidepressants, as well as the number of subjects, and daily doses (in parentheses) in the exposed group were paroxetine (46; 5–40 mg), fluoxetine (10; 10–40 mg), venlafaxine (9; 74–150 mg), citalopram (6; 10–30 mg), sertraline (3; 125–150 mg), and fluvoxamine (2; 50–150 mg). The behavioral signs that were significantly increased in exposed compared with nonexposed infants were as follows: CNS: abnormal movements, shaking, spasms, agitation, hypotonia, hypertonia, irritability, and insomnia; respiratory system: indrawing, apnea/bradycardia, and tachypnea; and other: vomiting, tachycardia, and jaundice. In exposed infants, CNS (63.2%) and respiratory system (40.8%) signs were most common, appearing during the 1st day of life and lasting for a median duration of 3 days. All of the exposed premature infants exhibited behavioral signs compared with 69.1% of exposed term infants. The duration of hospitalization was significantly longer in exposed premature compared with nonexposed premature infants (14.5 days vs. 3.7 days, respectively). In 75% of the term and premature infants, the signs resolved within 3 and 5 days, respectively. There were six infants in each group with congenital malformations, but the drugs involved were not specified (46).

A 2007 review conducted a literature search to determine the risk of major

congenital malformations after 1st trimester exposure to SSRIs and SNRIs (47). Fifteen controlled studies were analyzed. The data were adequate to suggest that citalopram, fluoxetine, sertraline, and venlafaxine were not associated with an increased risk of congenital defects. In contrast, the analysis did suggest an increased risk with paroxetine. The data were inadequate to determine the risk for the other SSRIs and SNRIs (47).

A case–control study, published in 2006, was conducted to test the hypothesis that exposure to SSRIs in late pregnancy was associated with PPHN (48). The study concept evolved from a 1996 study (see above) in which two (2.7%) newborns exposed to fluoxetine late in pregnancy had PPHN (14). A total of 1213 women were enrolled in the study, consisting of 377 cases whose infants had PPHN and 836 matched controls and their infants. Mothers were interviewed by nurses who were blinded to the hypothesis. Fourteen case infants had been exposed to an SSRI after the 20th week of gestation compared with six control infants (adjusted OR 6.1, 95% CI 2.2–16.8). The numbers were too small to analyze the effects of dosage, SSRI used, or reduction of the length of exposure before delivery. No increased risk of PPHN was found with the use of SSRIs before the 20th week or with the use of non-SSRI antidepressants at any time in pregnancy. If the relationship was causal, the absolute risk was estimated to be about 1% (48).

Two large case–control studies assessing associations between SSRIs and major birth defects were published in 2007 (49,50). The findings related to SSRIs as a group as well as to four specific agents: citalopram, fluoxetine, paroxetine, and sertraline. An accompanying editorial discussed the findings and limitations of these and other related studies (51). Details of the studies and the editorial are described in the paroxetine review (see Paroxetine).

A 16-year-old primigravida with narcolepsy, cataplexy, and glutaric aciduria type II (an autosomal recessive disorder) was treated throughout pregnancy with modafinil 200 mg/day, fluoxetine 20 mg/day, L-carnitine, and riboflavin (52). Because the episodes of narcolepsy and cataplexy increased in frequency, a cesarean section was conducted at 38 weeks' to deliver a 2.360-kg infant (sex not specified) with Apgar scores of 7, 8, and 9. No signs of withdrawal or abnormalities in vital signs or behavior were noted in the infant, who was discharged home with the mother after 3 days (52).

A prospective cohort study evaluated a large group of pregnancies exposed to antidepressants in the 1st trimester to determine if there was an association with major malformations (53). The patient population came from the Motherisk database and involved 928 cases that met their criteria. The 928 matched (for

age, smoking, and alcohol use) controls were pregnancies not exposed to antidepressants or known teratogens. In addition to the 61 fluoxetine cases, the other cases were 113 bupropion, 184 citalopram, 21 escitalopram, 52 fluvoxamine, 68 mirtazapine, 39 nefazodone, 148 paroxetine, 61 sertraline, 17 trazodone, and 154 venlafaxine. In the antidepressant group, there were 24 (2.5%) major defects compared with 25 (2.6%) in controls (odds ratio 0.9, 95% CI 0.5–1.61). There were three major anomalies in the fluoxetine group: pulmonary valve stenosis, hypospadias, and ventricular septal defect. There were no major defects in the pregnancies exposed to bupropion, escitalopram, or trazodone (53).

BREASTFEEDING SUMMARY

Fluoxetine is excreted into breast milk. A 1990 case report described a woman, 3 months postpartum, who was started on fluoxetine, 20 mg every morning, for depression (54). No drug-related adverse effects were noted in the infant by the mother or the infant's pediatrician. However, the woman's husband, also a pediatrician, thought that the nursing infant showed increased irritability during the first 2 weeks of therapy. Two months after treatment had begun, plasma and milk samples were obtained from the mother (time in relationship to the dose was not specified). Plasma concentrations of the antidepressant and its active metabolite, norfluoxetine, were 100.5 and 194.5 ng/mL, respectively. Similar measurements in the milk were 28.8 and 41.6 ng/mL, respectively. The milk:plasma ratios for the parent compound and the metabolite were 0.29 and 0.21, respectively (54).

A 1992 report described a woman treated for postpartum depression with fluoxetine, 20 mg at bedtime, 10 weeks after delivery (55). The dosing time was chosen just before the infant's longest period of sleep to lessen his exposure to the drug. After 53 days of therapy, milk and serum samples were collected 8 hours after the usual dose and 4 hours after a subsequent dose administered to approximate peak concentrations of fluoxetine. Serum concentrations of fluoxetine and the active metabolite at 4 hours were 135 and 149 ng/mL, respectively, and at 8 hours were 124 and 141 ng/mL, respectively. The variation in the milk samples was greater, with values at 4 hours of 67 and 52 ng/mL (hand-expressed foremilk), respectively, and at 8 hours of 17 and 13 ng/mL (hand-expressed hindmilk obtained after nursing), respectively. Assuming that the milk contained a steady concentration of 120 ng/mL of fluoxetine and norfluoxetine, and the infant was ingesting 150 mL/kg/day of milk, the maximum theoretical infant dose was 15–20 mcg/kg/day. No adverse

effects were observed in the nursing infant's behavior, feeding patterns, or growth during the treatment period (55).

A 1993 case study described colicky symptoms consisting of increased crying, irritability, decreased sleep, vomiting, and watery stools in a breastfed infant whose mother was taking fluoxetine, 20 mg/day (56). The mother had begun breastfeeding the infant immediately after birth and began taking fluoxetine 3 days later. The baby began to show symptoms at 6 days of age. The mother was enrolled in a study of infant crying at 3 weeks postpartum and, at 6 weeks, the infant was switched to a commercial formula for 3 weeks. The mother continued to pump her breasts during this time. She noted a marked change in the infant's behavior shortly after the change to formula feeding. The milk concentrations of fluoxetine and norfluoxetine were 69 ng/mL and 90 ng/mL, respectively. After 3 weeks of bottle-feeding, feeding with the mother's milk from a bottle was resumed; within 24 hours, the colic returned and she restarted feeding with the commercial formula. Drug levels of fluoxetine and metabolite, determined by a commercial laboratory, in the infant's serum on the 2nd day after the return to mother's milk were 340 ng/mL and 208 ng/mL, respectively. The authors associated the symptoms of colic with the presence of fluoxetine in the mother's milk (56).

The very high infant serum levels of fluoxetine and metabolite, similar to therapeutic range in adults, are difficult to explain based on the mother's low dose. A 1996 review suggested that one possible explanation was laboratory error (57).

The presence of fluoxetine and its active metabolite, norfluoxetine, was measured in the breast milk of 10 women and in serum or urine of some of the 11 (one set of twins) nursing infants (median age 185 days) (58). The women had been taking fluoxetine at an unchanged dose for 7–14 days. The mean maternal dose of fluoxetine was 0.39 mg/kg/day (range 0.17–0.85 mg/kg/day). Milk concentrations of fluoxetine, over a 24-hour interval, were 17.4–293 ng/mL, whereas those for norfluoxetine were 23.4–379.1 ng/mL. In three women, the mean milk:plasma ratios for the two agents were 0.88 (range 0.52–1.51) and 0.82 (range 0.60–1.15), respectively. Peak milk concentrations of fluoxetine occurred within 6 hours in 8 women, more than 12 hours in 2, and undetermined in 1. A plasma sample obtained from one infant contained no measurable drug or metabolite (limit of detection for both <1 ng/mL). Fluoxetine was detected in four of five infant urine samples (1.7–17.4 ng/mL) and norfluoxetine was measured in two of the five samples (10.5 and 13.3 ng/mL). Based on an ingestion of 1000 mL of milk per day, the mean infant doses of

fluoxetine and norfluoxetine were 0.077 mg/day and 0.084 mg/day, respectively, or about 10.8% of the weight-adjusted maternal dose. No adverse effects in the nursing infants, including alterations in sleeping, eating, or behavior patterns, were reported by the mothers (58).

In a 1998 case report, a 32-year-old woman with bipolar disorder took fluoxetine (20 mg/day), buspirone (45 mg/day), and carbamazepine (600 mg/day) throughout pregnancy and during the first 3 weeks postpartum (25). She reported seizure-like activity in the infant at 3 weeks, 4 months, and 5.5 months of age. Breast milk and infant serum were evaluated for the presence of fluoxetine and metabolite on postpartum days 13 and 21. On day 13, fluoxetine concentrations in breast milk were 45 ng/mL and 68 ng/mL (right and left breasts), whereas norfluoxetine levels were 68 and 57 ng/mL (right and left breasts). On day 21, the milk concentrations of the drug and metabolite were 38 and 28 ng/mL (mixed milk), respectively. The infant's serum had no detectable fluoxetine on day 13, but the level was 61 ng/mL on day 21. Norfluoxetine concentrations in infant serum on day 13 and 21 were 58 and 57 ng/mL, respectively. Maternal serum samples were not obtained for fluoxetine analysis. Similar analyses were conducted for buspirone and carbamazepine (see Buspirone and Carbamazepine for results). A neurologic examination of the infant, which included electroencephalography, was within normal limits. The authors were unable to determine the cause of the seizure-like activity, if indeed it had occurred (none of the episodes had been observed by medical personnel) (25).

Serum and milk concentrations of fluoxetine (maternal dose 20–40 mg/day) and norfluoxetine in four breastfeeding women were reported in a 1998 study (59). Maternal fluoxetine serum concentrations ranged from 71 to 250 ng/mL, whereas the levels for the metabolite were 67–177 ng/mL. Hindmilk levels of fluoxetine and norfluoxetine (always higher than foremilk) were 37–132 ng/mL and 11–74 ng/mL, respectively. Neither the parent drug nor metabolite could be detected in the serum or urine samples from the nursing infants. No neurological abnormalities were detected in the infants and all had normal mental and psychomotor performance development up to 12–13 months of age, as assessed by the Bayley Scales of Infant Development (59).

In 14 breastfeeding women receiving a mean fluoxetine dose of 0.51 mg/kg/day, the mean milk:plasma ratios for the parent drug and metabolite were 0.68 and 0.56, respectively (60). The mean total infant dose (fluoxetine plus active metabolite) was estimated to be 6.81% (range 2.15%–12%) of the weight-adjusted maternal dose. In nine infants for which plasma samples were

obtained, fluoxetine was detected in five (range 20–252 ng/mL) and norfluoxetine in seven (range 17–187 ng/mL). In eight cases, the antidepressant had also been taken during pregnancy and three of these infants had the highest plasma concentrations of fluoxetine. Two infants had colic, which had resolved in one infant before the study. Two other infants, with the highest plasma levels of fluoxetine, norfluoxetine, or both, exhibited symptoms of withdrawal consisting of uncontrollable crying, irritability, and poor feeding. In one case, however, maternal methadone use may have contributed to the symptoms (60).

An abstract of a study published in 1999 examined the effect of maternal fluoxetine therapy on the weight gain of nursing infants (61). A total of 64 women took the antidepressant during pregnancy and 26 continued the drug during breastfeeding. The other 38 women, who also breastfed their infants but who had discontinued the drug, were used as controls. Fluoxetine-exposed nursing infants had a growth curve significantly below the controls, averaging a deficit in weight gain of 392 g (95% CI –5, –780) in measurements taken between 2 weeks and 6 months of age. Although no adverse effects in the exposed nursing infants were reported by the mothers, the reduced growth was thought to be of possible clinical significance if infant weight gain was already of concern (61).

A 2001 case report described a woman who had been taking fluoxetine (40 mg/day) for 8 years, including throughout pregnancy (62). The infant was delivered at 37 weeks' gestation with a birth weight of about 2.76 kg. The infant was drowsy in the immediate postpartum period but was able to nurse. On day 3 of life, the infant was difficult to arouse, stopped rooting, closed her mouth, nursed only for a few minutes, and began to moan and grunt. On day 11, signs and symptoms included fever (102°F) and continuous moaning with an expiratory grunt; in addition, the infant was drowsy and difficult to arouse and hypotonic. An examination for sepsis was negative. Breastfeeding was stopped. The mother's serum fluoxetine and norfluoxetine levels were 453 and 422 ng/mL, respectively, whereas her milk levels were 114 and 124 ng/mL, respectively. The infant's serum levels of fluoxetine and metabolite were <40 ng/mL and 142 ng/mL, respectively. Eight days after nursing was stopped, the infant's serum levels were <40 ng/mL and 86 ng/mL, respectively. The infant recovered over the next 3 weeks (62).

A 2010 study using human and animal models found that drugs disturbing serotonin balance such as SSRIs and SNRIs can impair lactation (63). The authors concluded that mothers taking these drugs may need additional support

to achieve breastfeeding goals.

Although some of the above reports described toxicity, the long-term effects on neurobehavior and development from exposure to this potent serotonin reuptake blocker during a period of rapid CNS development have not been adequately studied. Further, the reduced weight gain identified in one study may have clinical significance in some situations. As reported by the FDA, the manufacturer was advised to revise the labeling of fluoxetine to contain a recommendation against its use by nursing mothers (64). The current labeling contains this revision (2). In contrast, the authors of a 1996 review stated that they encouraged women to continue breastfeeding while taking the drug (13). Similarly, a 1999 review of SSRI agents concluded that if there were compelling reasons to treat a mother for postpartum depression, a condition in which a rapid antidepressant effect is important, the benefits of therapy with SSRIs would most likely outweigh the risks (65). The American Academy of Pediatrics classifies the effects of fluoxetine on the nursing infant to be unknown but may be of concern (66).

FLUOXYMESTERONE

Androgenic Hormone

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Only one report describing the use of fluoxymesterone in human pregnancy has been located. Fluoxymesterone is contraindicated in pregnancy because of the risk for nonadrenal female pseudohermaphroditism (see Testosterone).

FETAL RISK SUMMARY

The androgenic hormone fluoxymesterone is indicated as replacement therapy in conditions associated with symptoms of deficiency or absence of endogenous testosterone. It is also indicated for the palliation of androgen-responsive recurrent mammary cancer. Fluoxymesterone inhibits the release of testosterone by inhibition of pituitary luteinizing hormone. Large doses may also suppress spermatogenesis by inhibiting follicle-stimulating hormone (1). The relatively low molecular weight (about 336) suggests that the drug will cross the placenta.

Fluoxymesterone (10 mg/day) was given to a 31-year-old woman in the third month of pregnancy for gigantomastia (2). "Several weeks" of therapy had no effect on the size of the breasts nor did diuretic therapy with chlorothiazide (6000 mg/day). The woman was eventually hospitalized at 6 months' gestation because of breast tissue necrosis and hemorrhage. A single IM dose of testosterone and estradiol (Deladumone) had no effect and both breasts continued to enlarge. An 8-day course of combination oral contraceptives was discontinued because of superficial thrombophlebitis in the right thigh. When the breast ulcer became infected, a bilateral simple mastectomy was performed. She eventually delivered a normal healthy, 3.8-kg male infant (2).

BREASTFEEDING SUMMARY

No reports describing the use of fluoxymesterone during human lactation have

been located. Because testosterone and its derivatives inhibit lactation (see Testosterone), fluoxymesterone is contraindicated in women who are breastfeeding.

FLUPHENAZINE

Antipsychotic

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 3rd Trimester

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Extrapyramidal and/or withdrawal have been reported when fluphenazine was used during gestation. Although one case report described multiple anomalies, most evidence suggests that phenothiazines are relatively low risk during pregnancy (see also Prochlorperazine).

FETAL RISK SUMMARY

Fluphenazine is a piperazine phenothiazine in the same group as prochlorperazine. Phenothiazines readily cross the placenta (1).

Shepard reviewed two studies, in which fluphenazine was given to pregnant rats at doses up to 100 mg/kg orally without producing adverse fetal effects (2). Pregnant mice were given fluphenazine (1 mg/kg) or diphenylhydantoin (50 mg/kg), or both, by gavage during organogenesis (3). As compared with controls, a significant reduction in fetal weight and length was observed in all treatment groups. The combination produced a significant increase in the incidence of skeletal defects (incomplete ossification of sternbrae and skull bones) and in the incidence of dilated cerebral ventricles (already increased in the fluphenazine-alone group) (3).

An apparently normal pregnancy outcome was described in a woman receiving psychotherapy and being treated with fluphenazine decanoate (2 mL IM every 3 weeks) (4). In addition, she also smoked cigarettes (up to 4 packs/day) and drank four or five cocktails each evening. She eventually delivered a 1-week postterm 3.38-kg, male infant, who developed minor extrapyramidal symptoms (or withdrawal) 4 weeks after delivery. The symptoms readily responded to oral diphenhydramine. At 2 months of age, the infant was healthy and weighed 4.66 kg. The infant boy was reported by the

mother to be doing well at 20 months of age.

A 22-year-old woman with schizophrenia was treated with chlorpromazine (up to 1200 mg/day) throughout gestation, fluphenazine decanoate (50 mg IM every 2 weeks) from the 14th week of gestation, and electroconvulsive therapy at 18 weeks (5). The fluphenazine dose was increased to 100 mg IM every 2 weeks at 24 weeks' gestation. In addition, she smoked 3–4 packs of cigarettes per day. An apparently normal, 3.53-kg male infant was delivered by cesarean section at 39 weeks, who did well during the first 3 weeks. At that time (6 weeks after the mother's last fluphenazine dose), the infant developed excessive irritability, choreiform and dystonic movements mostly in the upper limbs, jittery behavior, and hypertonicity. Two doses of diphenhydramine given on the 24th and 25th days failed to resolve the condition. Over the next few weeks, the symptoms subsided only to return on the 58th day with the same earlier intensity (5). Diphenhydramine (62.5 mg) was restarted every 6 hours with slow improvement in his condition. At 15 weeks of age, the infant's progress appeared normal. At 6 months of age, the diphenhydramine was gradually withdrawn. Follow-up at 15 months of age was normal. The authors attributed the infant's condition to fluphenazine withdrawal (5).

An infant with multiple anomalies was born to a mother treated with fluphenazine enanthate injections throughout pregnancy (6). The mother also took Debendox (see Doxylamine) during the 1st trimester. Anomalies included: ocular hypertelorism with telecanthus; cleft lip and palate; imperforate anus; hypospadias of penoscrotal type; jerky, roving eye movements; episodic rapid nystagmoid movements; rectourethral fistula; and poor ossification of frontal skull bone.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 13 newborns had been exposed to fluphenazine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). One (7.7%) major birth defect was observed (0.6 expected), a cardiovascular defect (0 expected). The number of exposures is too small for comment.

A 35-year-old woman with schizophrenia was treated throughout gestation with fluphenazine, 10 mg orally twice daily, then decreased to 5 mg orally twice daily during the 3rd trimester (7). The fluphenazine concentration in cord blood was <1.0 ng/mL. She delivered a normal, 2855-g, female infant at 39 weeks' gestation, who developed severe rhinorrhea and upper respiratory distress at 8 hours of age. Oral feedings were poor and complicated by periodic episodes of vomiting, coarse choreoathetoid movements of the arms and legs, and

intermittent arching of the body (7). Marked improvement in her symptoms occurred following a single dose of pseudoephedrine solution (0.75 mg) that was repeated once the next day. Although the infant had no further extrapyramidal symptoms, the rhinorrhea and nasal congestion persisted for 3 months.

BREASTFEEDING SUMMARY

No reports describing the use of fluphenazine during human lactation have been located. Because other phenothiazines are excreted into milk (see also Prochlorperazine), passage of fluphenazine into milk should be expected. The American Academy of Pediatrics classifies the effects of other antipsychotic phenothiazine agents (e.g., see Chlorpromazine) on the nursing infant to be unknown but may be of concern.

BREASTFEEDING RECOMMENDATION:Limited Human Data—Probably Compatible*

PREGNANCY SUMMARY

Limited reports describing the use of flurazepam in human pregnancy have been located. The effects of this drug on the fetus should be similar to other benzodiazepines (see Diazepam). Maternal use near delivery may potentially cause neonatal motor depression and withdrawal.

FETAL RISK SUMMARY

Flurazepam is a benzodiazepine used to induce sleep. No teratogenic or other adverse fetal or postnatal effects were observed in studies using rats and rabbits administered 80 mg/kg and 20 mg/kg, respectively, during various stages of gestation (1). Similarly, no reports of congenital abnormalities attributable to human exposure with flurazepam have been located. One group of investigators classified the risk to the fetus from exposure to flurazepam as “none–minimal,” but the quality of the data was judged to be “poor” (2). Studies involving other members of this class, however, have found evidence that some of these agents may cause fetal abnormalities (see Chlordiazepoxide and Diazepam).

Although published data are lacking, the molecular weight of flurazepam (about 461) suggests it is transferred to the fetus. Data from the manufacturer indicate that an active metabolite of flurazepam crosses the human placenta and may adversely affect the newborn (3). In a case cited in their product information, a woman ingested flurazepam, 30 mg nightly, for 10 days immediately preceding delivery. The newborn appeared sleepy and lethargic during the first 4 days of life. The effect was thought to be due to a long-acting metabolite, N₁-desalkylflurazepam, found in the newborn’s serum.

In a surveillance study of Michigan Medicaid recipients involving 229,101

completed pregnancies conducted between 1985 and 1992, 73 newborns had been exposed to flurazepam during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Four (5.5%) (three expected) major birth defects were observed, including (observed/expected) 2/1 cardiovascular defects, 1/0 oral clefts, and 1/0 polydactyly. These data do not support an association between the drug and congenital defects.

A brief 1982 case report described convulsions attributable to clomipramine in a newborn who was exposed to that drug and flurazepam throughout gestation (4). The 2360-g male infant was delivered vaginally at 33 weeks' gestation (the reason for the premature delivery was not stated) and had Apgar scores of 9 and 9 at 1 and 5 minutes, respectively. Convulsions, consisting of myoclonic jerks that were unresponsive to phenobarbital, started at 7 hours of age and were eventually successfully treated with IV and oral clomipramine, although the infant remained jittery. The contribution of flurazepam, which is known to cause convulsions after abrupt withdrawal following prolonged use in adults, to the seizures observed in the newborn is unknown. However, a correlation between declining serum levels of clomipramine and its active metabolite and the condition of the infant probably indicates that the seizures were not due to flurazepam.

BREASTFEEDING SUMMARY

Studies measuring the amount of flurazepam excreted into breast milk have not been located. However, the passage of this agent and its active, long-acting metabolite into milk should be expected (see also Diazepam).

The effects of exposure to benzodiazepines during breastfeeding were reported in a 2012 study (5). In a 15-month period spanning 2010–2011, 296 women called the Motherisk Program in Toronto, Ontario, seeking advice on the use of these drugs during lactation, and 124 consented to the study. The most commonly used benzodiazepines were lorazepam (52%), clonazepam (18%), and midazolam (15%). Neonatal sedation was reported in only two infants. There was no significant difference between the characteristics of these 2 and the 122 that reported no sedation in terms of maternal age, gestational age at birth, daily amount of time nursing, amount of time infant slept each day, and the benzodiazepine dose (mg/kg/day). The only difference was in the number of CNS depressants that the mothers were taking: 3.5 vs. 1.7 ($p = 0.0056$). In the two infants with sedation, one mother reported using alprazolam (two doses of 0.25 mg), sertraline (50 mg/day), and zopiclone (about 2.5 mg every 3 days), whereas the other mother took clonazepam (0.25

mg twice daily), flurazepam (1 mg/day), bupropion (1 mg/day), and risperidone (0.75 mg/day). The infant in this latter case also was exposed in utero. The investigators concluded that their results supported the recommendation that the use benzodiazepines was not a reason to avoid breastfeeding (5).

The American Academy of Pediatrics classifies the effects of lorazepam on the nursing infant as unknown but may be of concern if exposure is prolonged (6).

*Potential toxicity if combined with other CNS depressants

FLURBIPROFEN

Nonsteroidal Anti-inflammatory

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 1st and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No reports describing the use of flurbiprofen during human pregnancy have been located. Constriction of the ductus arteriosus in utero is a pharmacologic consequence arising from the use of prostaglandin synthesis inhibitors during pregnancy, as is inhibition of labor, prolongation of pregnancy, and suppression of fetal renal function (see also Indomethacin) (1). Persistent pulmonary hypertension of the newborn may occur if these agents are used in the 3rd trimester close to delivery (1,2). Women attempting to conceive should not use any prostaglandin synthetase inhibitor, including flurbiprofen, because of the findings in various animal models that indicate these agents block blastocyst implantation (3,4). Moreover, as noted below, nonsteroidal anti-inflammatory drugs (NSAIDs) have been associated with spontaneous abortions (SABs) and congenital malformations. The absolute risk for these defects, however, appears to be low.

FETAL RISK SUMMARY

Flurbiprofen is an NSAID that shares the same precautions for human pregnancy use as other NSAIDs. It is in the same subclass (propionic acids) as five other agents (fenoprofen, ibuprofen, ketoprofen, naproxen, and oxaprozin). Flurbiprofen is used in the treatment of arthritis and is available in an ocular formulation for inhibition of intraoperative miosis. No teratogenic effects were observed in mice, rats, and rabbits administered this drug during gestation (5).

Like other NSAIDs, systemic use of flurbiprofen in rats has been associated with prolonged gestation, fetal growth restriction, and decreased fetal survival (6). In one study of pregnant rats, flurbiprofen inhibition of parturition appeared to be dose-related (7).

A combined 2001 population-based, observational cohort study and a case–control study estimated the risk of adverse pregnancy outcome from the use of NSAIDs (8). The use of NSAIDs during pregnancy was not associated with congenital malformations, preterm delivery, or low birth weight, but a positive association was discovered with SABs. (A similar study, also published in 2001, failed to find a relationship, in general, between NSAIDs and congenital malformations, but did find a significant association with cardiac defects and orofacial clefts (9). In addition, a 2003 study found a significant association between exposure to NSAIDs in early pregnancy and SABs (10) (see Ibuprofen for details on these three studies).

A brief 2003 editorial on the potential for NSAID-induced developmental toxicity concluded that NSAIDs, and specifically those with greater cyclooxygenase 2 (COX-2) affinity, had a lower risk of this toxicity in humans than aspirin (11). Two reviews, both on antirheumatic drug therapy in pregnancy, recommended that if an NSAID was needed, agents with short elimination adult half-lives should be used at the maximum tolerated dosage interval, using the smallest effective dose, and that therapy should be stopped within 8 weeks of the expected delivery date (12,13). Flurbiprofen has a short plasma elimination half-life (5.7 hours), but other factors, such as its toxicity profile, need to be considered.

BREASTFEEDING SUMMARY

Very small amounts of flurbiprofen are excreted into breast milk (14,15). In 10 nursing mothers, at least 1 month postpartum, a single 100-mg oral dose of flurbiprofen was administered and milk and blood samples were obtained over a 48-hour period (14). The average peak plasma concentration (14.7 mcg/mL) occurred at 1.5 hours with a mean half-life of 5.8 hours. The average peak milk concentration was 0.09 mcg/mL with an average of 0.05% (range 0.03%–0.07%) of the maternal dose recovered in breast milk. Breastfeeding was discontinued during and after the study.

In a multiple dosing study, 12 lactating women, 3–5 days after delivery, were administered nine doses of flurbiprofen over a 3-day period (50 mg 4 times daily) (15). Paired milk and plasma samples were obtained at several times during the period and after the last dose. The mean maternal plasma half-life of the drug was 4.8 hours. Flurbiprofen milk concentrations were less than 0.05 mcg/mL in 10 of the mothers. In the remaining two mothers, only three of their milk samples contained flurbiprofen: 0.06, 0.07, and 0.08 mcg/mL. The authors concluded that these small amounts were safe for a nursing infant. The mothers

did not breastfeed their infants (15).

The small amounts of flurbiprofen recovered from transitional and mature breast milk seem to indicate that the risk posed by flurbiprofen to a nursing infant is slight, if it exists at all. One reviewer classified flurbiprofen as one of several low-risk alternatives, because of its short adult serum half-life and toxicity profile compared with other similar agents, if an NSAID was required while nursing (16). Other reviewers have also stated that flurbiprofen can be safely used during breastfeeding (17,18). Ibuprofen, another NSAID in the same subclass as flurbiprofen, is considered compatible with breastfeeding by the American Academy of Pediatrics (see Ibuprofen).

FLUTICASONE

Respiratory Drug (Corticosteroid)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Four reports totaling 201 women have described the use of fluticasone during pregnancy. No increase in the rates of embryo, fetal, or newborn toxicity were observed. Although the animal data suggest high risk, SC doses were used, resulting in much higher systemic concentrations than those obtained in humans after inhalation. Because of the initial absence of human pregnancy experience, two reviews concluded that either beclomethasone or budesonide were the inhaled corticosteroids of choice if such therapy is initiated in pregnancy (1,2). However, the new data suggest that if a nonpregnant woman has shown a good response to fluticasone, or if the agent is indicated in a pregnant woman, the drug is compatible with pregnancy.

FETAL RISK SUMMARY

Fluticasone, a synthetic trifluorinated glucocorticoid, is indicated for the maintenance treatment of asthma as a prophylactic therapy. In human lung preparations, the affinity of fluticasone for the glucocorticoid receptor is almost twice that of the active metabolite of betamethasone, and more than 3 and 18 times greater than that of budesonide and dexamethasone, respectively. Although the oral bioavailability of fluticasone is negligible (<1%), the systemic bioavailability after inhalation is high (about 30% of the dose). Peak plasma levels after an 880-mcg inhaled dose were in the range of 0.1–1.0 ng/mL. The only metabolite that has been identified in humans is relatively inactive (about 2000 times less affinity than the parent drug for the glucocorticoid receptor). Plasma protein binding of the parent compound is about 91%. Excretion is mostly in the feces with a terminal plasma elimination half-life of about 7.8 hours (3).

Reproduction studies have been conducted with SC doses in mice, rats, and rabbits. In mice and rats, SC doses approximately 0.1 and 0.5 times the maximum human daily inhalation dose based on BSA (MRHID), respectively, revealed embryonic growth restriction, omphalocele, cleft palate, and retarded cranial ossification. This toxicity was considered characteristic of potent glucocorticoid compounds as rodents may be more prone to teratogenic effects from these agents than humans (3). In male and female rats, no evidence of impaired fertility was observed with SC doses up to about 0.25 times the MRHID, but prostate weight was significantly reduced. Fluticasone was not tumorigenic in long-term studies in mice and rats, nor was it mutagenic or clastogenic in various in vitro assays. In pregnant rabbits, SC doses approximately 0.04 times the MRHID were associated with fetal weight reduction and cleft palate. Oral doses approximately 3 times the MRHID did not cause maternal toxicity or increase the incidence of external, visceral, or skeletal fetal defects. After oral doses in rats and rabbits that were about 0.5 and 3 times the MRHID, respectively, less than 0.008% of the dose crossed the placenta. However, consistent with its poor oral absorption, fluticasone was not detected in the maternal rabbit plasma (3). Although not stated, poor absorption in the rat probably also occurred.

It is not known if fluticasone can cross the human placenta. As noted above, the systemic concentrations of fluticasone after inhalation are very low. Moreover, the placenta is a rich source of enzymes that can metabolize corticosteroids (e.g., see Betamethasone, Dexamethasone, Hydrocortisone, and Prednisolone). These factors suggest that clinically significant exposure of the embryo or fetus is unlikely.

A 2004 study examined the effect of inhaled corticosteroids on low birth weight, preterm births, and congenital malformations in pregnant asthmatic patients (4). The inhaled steroids and the number of patients were beclomethasone (N = 277), fluticasone (N = 132), triamcinolone (N = 81), budesonide (N = 43), and flunisolide (N = 25). Compared with the general population, the study found no increased incidence of small-for-gestational-age infants (less than 10th percentile for gestational age), low birth weight (<2500 g), preterm births, and congenital malformations (4).

Three reports described the use of fluticasone nasal spray in 69 pregnant women, sometimes compared with placebo controls (5–7). No effects on fetal growth or pregnancy outcomes were observed in these patients. Although most synthetic corticosteroids are partially metabolized by the placental enzymes, budesonide and fluticasone were not (6).

A 2006 meta-analysis on the use of inhaled corticosteroids during pregnancy was published in 2006 (8). The analysis included five agents: beclomethasone, budesonide, flunisolide, fluticasone, and triamcinolone. The results showed that these agents do not increase the risk of major congenital defects, preterm delivery, low birth weight, and pregnancy-induced hypertension. Thus, they could be used during pregnancy (8).

BREASTFEEDING SUMMARY

No reports describing the use of fluticasone during human lactation have been located. Because of the low systemic concentrations obtained with fluticasone inhalation, and the drug's poor oral bioavailability, it is doubtful if clinically significant amounts would be ingested by a nursing infant.

FLUVASTATIN

Antilipemic Agent

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Because the interruption of cholesterol-lowering therapy during pregnancy should have no effect on the long-term treatment of hyperlipidemia, and because cholesterol and other products synthesized from cholesterol are required for fetal development, the use of fluvastatin is contraindicated during pregnancy.

FETAL RISK SUMMARY

The cholesterol-lowering, hydrophilic agent fluvastatin (a “statin”) has the same mechanism of action (i.e., inhibition of hepatic 3-hydroxy-3-methylglutaryl-coenzyme A [HMG-CoA] reductase) as other available agents in this class, atorvastatin, lovastatin, pitavastatin, pravastatin, rosuvastatin, and simvastatin (cerivastatin was withdrawn from the market in 2001).

Fluvastatin was not teratogenic in rats and rabbits at doses up to 36 and 10 mg/kg/day, respectively (1,2). Moreover, at the highest doses tested in rats for effects on fertility and reproductive performance, 20 mg/kg/day in males and 6 mg/kg/day in females, no adverse effects were observed (2). Significant maternal body weight loss and an increase in stillborns, neonatal morbidity, and maternal morbidity, however, were observed with fluvastatin doses of either 12 or 24 mg/kg/day administered to pregnant rats from the 15th day after coitus through weaning (2). The maternal morbidity was attributed to the occurrence of cardiomyopathy in the affected animals. The adverse effects of fluvastatin were lessened or prevented by the co-administration of mevalonic acid, a product produced by the enzyme HMG-CoA reductase, indicating that the toxicity was a result of inhibition of this enzyme.

Rosa (3) reported finding no recipients of this drug in his 1994 presentation on the outcome of pregnancies following exposure to anticholesterol agents. However, a 1999 case report described the pregnancy outcome of a 28-year-

old woman who had taken fluvastatin (20 mg/day) for 18 months before conception and during the first 9 weeks of pregnancy (4). The patient, who had a kidney transplantation 6 years before pregnancy, took prednisone, cyclosporine, azathioprine, cephalexin, and ranitidine throughout gestation. She delivered a healthy, 2901-g female infant at term with Apgar scores of 4 and 9 at 1 and 5 minutes, respectively. Except for transient tachypnea, no other complications were noted. At age 19 months, the infant's growth (weight, height, and head circumference all at the 50th percentile or higher) and development were normal (4).

A 2004 report described the outcomes of pregnancy that had been exposed to statins and reported to the FDA (see Lovastatin).

Among 19 cases followed by a teratology information service in England, one involved 1st trimester exposure to fluvastatin (5). The pregnancy outcome was a newborn with bradycardia and intrauterine growth restriction.

BREASTFEEDING SUMMARY

No published reports describing the use of fluvastatin during lactation have been located. The manufacturer reports that fluvastatin is present in breast milk at a milk:plasma ratio of 2 (1). Because of the potential for adverse effects in the nursing infant, the drug should not be used during lactation.

FLUVOXAMINE

Antidepressant

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 3rd Trimester

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

The limited animal and human data do not suggest a major teratogenic risk from the use of fluvoxamine. However, the above studies lack the sensitivity to identify minor anomalies because of the absence of standardized examinations. Late-appearing major defects may also have been missed because of the timing of the questionnaires. Selective serotonin reuptake inhibitor (SSRI) antidepressants, including fluvoxamine, have been associated with several developmental toxicities, including spontaneous abortions (SABs), low birth weight, prematurity, neonatal serotonin syndrome, neonatal behavioral syndrome (withdrawal), possible sustained abnormal neurobehavior beyond the neonatal period, respiratory distress, and persistent pulmonary hypertension of the newborn (PPHN).

FETAL RISK SUMMARY

Fluvoxamine is an antidepressant used in the treatment of obsessive-compulsive disorder. The mechanism of action is unknown, but the drug is an SSRI resulting in the potentiation of serotonin activity in the brain. The chemical structure of fluvoxamine is unrelated to other antidepressants.

All the antidepressant agents in the SSRI class (citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline) share a similar mechanism of action, although they have different chemical structures. These differences could be construed as evidence against any conclusion that they share similar effects on the embryo, fetus, or newborn. In the mouse embryo, however, craniofacial morphogenesis appears to be regulated, at least in part, by serotonin. Interference with serotonin regulation by chemically different inhibitors produces similar craniofacial defects (1). Regardless of the structural

differences, therefore, some of the potential adverse effects on pregnancy outcome may also be similar.

No evidence of teratogenicity was observed in reproductive studies with rats and rabbits administered oral doses approximately twice the maximum human daily dose based on BSA (MHDD) (2). Increased pup mortality at birth and decreased postnatal pup weight were seen, however, when rats were dosed at 2 and 4 times the MHDD, respectively, throughout pregnancy and weaning. These effects may have been partially due to maternal toxicity, but a direct toxic effect on the fetuses and pups could not be excluded (2).

No reports describing the transfer across the human placenta have been located. The molecular weight (about 434 for the maleate salt) is low enough that passage to the fetus should be expected.

In a 1996 descriptive case series, the European Network of the Teratology Information Services (ENTIS) prospectively examined the outcomes of 689 pregnancies exposed to antidepressants (3). Multiple drug therapy occurred in about two-thirds of the mothers. Fluvoxamine was used in 67 pregnancies. The outcomes of these pregnancies were 9 elective abortions (EABs) (1 with defect—see below), 6 SABs, 2 stillbirths, 47 normal newborns (includes 2 premature infants), 2 infants with neonatal disorders (withdrawal, cyanosis), and 2 infants with congenital defects. The three cases of defects (all exposed in the 1st trimester or longer and to multiple agents) were multicystic left kidney, right megaureter with neonatal renal insufficiency; and hydrocephaly; right diaphragmatic hernia; and agenesis of the corpus callosum (EAB) (3).

A 1998 noninterventional, observational cohort study described the outcomes of pregnancies in women who had been prescribed one or more of 34 newly marketed drugs by general practitioners in England (4). Data were obtained by questionnaires sent to the prescribing physicians one month after the expected or possible date of delivery. In 831 (78%) of the pregnancies, a newly marketed drug was thought to have been taken during the 1st trimester, with birth defects noted in 14 (2.5%) singleton births of the 557 newborns (10 sets of twins). In addition, two birth defects were observed in aborted fetuses. However, few of the aborted fetuses were examined. Fluvoxamine was taken during the 1st trimester in 21 pregnancies. The outcomes of these pregnancies included one ectopic pregnancy, five SABs, two EABs, nine normal full-term newborns, one premature delivery (twins), and three lost to follow-up. One of the EABs was for a genetic abnormality (47,XXX) (4).

A prospective, multicenter, controlled cohort study published in 1998 evaluated the pregnancy outcomes of 267 women exposed to one or more of

three SSRI antidepressants during the 1st trimester: fluvoxamine (N = 26); paroxetine (N = 97); and sertraline (N = 147) (5). The women were combined into a study group without differentiation as to the drug they had consumed. A randomly selected control group (N = 267) was formed from women who had exposures to nonteratogenic agents. The pregnancy outcomes were determined, in most cases, 6–9 months after delivery. No significant differences were measured in the number of live births, SABs or EABs, stillbirths, major malformations, birth weight, or gestational age at birth. Nine major malformations were observed in each group. The relative risk for major anomalies was 1.06 (95% confidence interval [CI] 0.43–2.62). No clustering of defects was apparent. The outcomes of women who took an antidepressant throughout gestation were similar to those who took an antidepressant only during the 1st trimester (5). All of the 267 women in the study group had taken an antidepressant during embryogenesis (6).

The effect of SSRIs on birth outcomes and postnatal neurodevelopment of children exposed prenatally was reported in 2003 (7). Thirty-one children (mean age 12.9 months) exposed during pregnancy to SSRIs (15 sertraline, 8 paroxetine, 7 fluoxetine, and 1 fluvoxamine) were compared with 13 children (mean age 17.7 months) of mothers with depression who elected not to take medications during pregnancy. All of the mothers had healthy lifestyles. The timing of the exposures was 71% in the 1st trimester, 74% in the 3rd trimester, and 45% throughout. The average duration of breastfeeding in the subjects and controls was 6.4 and 8.5 months, respectively. Twenty-eight (90%) subjects nursed their infants, 17 of who took SSRIs (10 sertraline, 4 paroxetine, and 3 fluoxetine) compared with 11 (85%) controls, three of whom took sertraline. There were no significant differences between the groups in terms of gestational age at birth, premature births, birth weight and length or, at follow-up, in sex distribution or gain in weight and length (expressed at percentage). Seven (23%) of the exposed infants were admitted to a neonatal intensive care unit (six respiratory distress, four meconium aspiration, and one cardiac murmur) compared with none of the controls (ns). Follow-up examinations were conducted by a pediatric neurologist, psychologist, and a dysmorphologist who were blinded as to the mother's medications status. The mean Apgar scores at 1 and 5 minutes were lower in the exposed group than in controls, 7.0 vs. 8.2, and 8.4 vs. 9.0, respectively. There was one major defect in each group: small asymptomatic ventricular septal defect (exposed); bilateral lacrimal duct stenosis that required surgery (control). The test outcomes for mental development were similar in the groups, but significant differences in the

subjects included a slight delay in psychomotor development and lower behavior motor quality (tremulousness and fine motor movements) (7).

A 2005 meta-analysis of seven prospective comparative cohort studies involving 1774 patients was conducted to quantify the relationship between seven newer antidepressants and major malformations (8). The antidepressants were bupropion, fluoxetine, fluvoxamine, nefazodone, paroxetine, sertraline, and trazodone. There was no statistical increase in the risk of major birth defects above the baseline of 1%–3% in the general population for any of the individual or combined studies (8).

In a 2006 report, a 33-year-old woman with severe psychotic depression was treated with fluvoxamine 200 mg/day and quetiapine 400 mg/day (9). After appropriate counseling, she continued this therapy and conceived and, after a normal pregnancy, delivered a healthy 2600-g, 49-cm-long female infant with Apgar scores of 9 and 10 at 1 and 5 minutes, respectively. The infant was developing normally at 3 months (9).

A 2003 prospective study evaluated the pregnancy outcomes of 138 women treated with SSRI antidepressants during gestation (10). Women using each agent were 73 fluoxetine, 36 sertraline, 19 paroxetine, 7 citalopram, and 3 fluvoxamine. Most (62%) took an SSRI throughout pregnancy and 95% were taking an SSRI at delivery. Birth complications were observed in 28 infants, including preterm birth (9 cases), meconium aspiration, nuchal cord, floppy at birth, and low birth weight. Four infants (2.9%) had low birth weight, all exposed to fluoxetine (40–80 mg/day) throughout pregnancy, including two of the three infants of mothers taking 80 mg/day. One infant had Hirschsprung disease, a major defect, and another had cavum septi pellucidi (neither the size of the cavum nor the SSRI agents was specified) (10). The clinical significance of the cavum septi pellucidi is doubtful as it is nearly always present at birth but resolves in the first several months (11).

Evidence for the neonatal behavioral syndrome that is associated with in utero exposure to SSRIs and serotonin and norepinephrine reuptake inhibitors (SNRIs) (collectively called serotonin reuptake inhibitors [SRIs]) in late pregnancy was reviewed in a 2005 reference (12). The report followed a recent agreement by the FDA and manufacturers for a class labeling change about the neonatal syndrome. Analysis of case reports, case series, and cohort studies revealed that late exposure to SRIs carried an overall risk ratio of 3.0 (95% CI 2.0–4.4) for the syndrome compared with early exposure. The case reports (N = 18) and case series (N = 131) involved 97 cases of paroxetine, 18 fluoxetine, 16 sertraline, 12 citalopram, 4 venlafaxine, and 2 fluvoxamine. There

were nine cohort studies analyzed. The typical neonatal syndrome consisted of CNS, motor, respiratory, and gastrointestinal signs that were mild and usually resolved within 2 weeks. Only one of 313 quantifiable cases involved a severe syndrome consisting of seizures, dehydration, excessive weight loss, hyperpyrexia, and intubation. There were no neonatal deaths attributable to the syndrome (12).

A significant increase in the risk of low birth weight (<10th percentile) and respiratory distress after prenatal exposure to SSRIs was reported in 2006 (13). The population-based study, representing all live births (N = 119,547) during a 39-month period in British Columbia, Canada, compared pregnancy outcomes of depressed mothers treated with SSRIs with outcomes in depressed mothers not treated with medication and in nonexposed controls. The severity of depression in the depressed groups was accounted for by propensity score matching (13).

A meta-analysis of clinical trials (1990–2005) with SSRIs was reported in 2006 (14). The SSRI agents included were citalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline. The specific outcomes analyzed were major, minor, and cardiac malformations, and SABs. The odds ratios (ORs) with 95% CI for the four outcomes were 1.394 (0.906–2.145), 0.97 (0.13–6.93), 1.193 (0.531–2.677), and 1.70 (1.28–2.25), respectively. Only the risk of SABs was significantly increased (14).

A brief 2005 report described significant associations between the use of SSRIs in the 1st trimester and congenital defects (15). The data were collected by the CDC-sponsored National Birth Defects Prevention Study in an on-going case–control study of birth defect risk factors. Case infants (N = 5357) with major birth defects were compared with 3366 normal controls. A positive association was found with omphalocele (N = 161; OR 3.0, 95% CI 1.4–6.1). Paroxetine, which accounted for 36% of all SSRI exposures, had the strongest association with the defect (OR 6.3, 95% CI 2.0–19.6). The study also found a significant association between the use of any SSRI and craniosynostosis (N = 372; OR 1.8, 95% CI 1.0–3.2) (15). An expanded report from this group was published in 2007 (see reference 22 below).

A 2006 report using the database (1995–2003) of the Swedish Medical Birth Registry examined the relationship between maternal use of antidepressants and major malformations and cardiac defects (16). There was no significant increase in the risk of major malformations with any antidepressant. The strongest effect among cardiac anomalies was with ventricular or atrial septum defects (VSDs-ASDs). Significant increases were found with paroxetine (OR

2.22, 95% CI 1.39–3.55) and clomipramine (OR 1.87, 95% CI 1.16–2.99 (16)). In 2007, the analysis of the Registry database was expanded to include the years 1995–2004 (17). There were 6481 women (6555 infants) who had reported the use of SSRIs in early pregnancy. The number using a single SSRI (i.e., no other SSRI or non-SSRI antidepressant) during the 1st trimester was 2579 citalopram, 1807 sertraline, 908 paroxetine, 860 fluoxetine, 66 escitalopram, and 36 fluvoxamine. Only paroxetine was significantly associated with cardiovascular effects (20 cases; OR 1.63, 95% CI 1.05–2.53). Paroxetine also had the strongest association with VSDs-ASDs, but did not reach significance (13 cases; relative risk [RR] 1.81, 95% CI 0.96–3.09). When the analysis was repeated after excluding women with body mass index >26, born outside of Sweden, or with reported subfertility (N = 405), only paroxetine was significantly associated with any cardiac defect (13 cases, RR 2.62, 95% CI 1.40–4.50) and with VSDs-ASDs (8 cases, RR 3.07, 95% CI 1.32–6.04). The RR remained significant after also excluding women who took neuroleptics, sedatives, hypnotics, folic acid, nonsteroidal anti-inflammatory agents, or anticonvulsants (N = 340). Analysis of the combined SSRI group, excluding paroxetine, revealed no associations with cardiac defects or VSDs-ASDs. The study also found no association with omphalocele or craniostenosis (17).

A 2007 study evaluated the association between 1st trimester exposure to paroxetine and cardiac defects by quantifying the dose–response relationship (18). A population-based pregnancy registry was used by linking three administrative databases so that it included all pregnancies in Quebec between 1997 and 2003. There were 101 infants with major congenital defects, 24 involving the heart, among the 1403 women using only one type of antidepressant during the 1st trimester. The use of paroxetine or other SSRIs did not significantly increase the risk of major defects or cardiac defects compared with non-SSRI antidepressants. However, a paroxetine dose >25 mg/day during the 1st trimester was significantly associated with an increased risk of major defects (OR 2.23, 95% CI 1.19–4.17) and of cardiac defects (OR 3.07, 95% CI 1.00–9.42) (18).

A 2007 retrospective cohort study examined the effects of exposure to SSRIs or venlafaxine in the 3rd trimester on 21 premature and 55 term newborns (19). The randomly selected unexposed control group consisted of 90 neonates of mothers not taking antidepressants, psychotropic agents, or benzodiazepines at the time of delivery. There were significantly more premature infants among the subjects (27.6%) than in controls (8.9%), but the groups were not matched. The antidepressants, as well as the number of

subjects and daily doses (shown in parentheses) in the exposed group were paroxetine (46; 5–40 mg), fluoxetine (10; 10–40 mg), venlafaxine (9; 74–150 mg), citalopram (6; 10–30 mg), sertraline (3; 125–150 mg), and fluvoxamine (2; 50–150 mg). The behavioral signs that were significantly increased in exposed than in nonexposed infants were as follows: CNS—abnormal movements, shaking, spasms, agitation, hypotonia, hypertonia, irritability, and insomnia; respiratory system—indrawing, apnea/bradycardia, and tachypnea; and other—vomiting, tachycardia, and jaundice. In exposed infants, CNS (63.2%) and respiratory system (40.8%) signs were most common, appearing during the first day of life and lasting for a median duration of 3 days. All of the exposed premature infants exhibited behavioral signs compared with 69.1% of exposed term infants. The duration of hospitalization was significantly longer in exposed premature than in nonexposed premature infants, 14.5 days vs. 3.7 days, respectively. In 75% of the term and premature infants, the signs resolved within 3 and 5 days, respectively. There were six infants in each group with congenital malformations, but the drugs involved were not specified (19).

A 2007 review conducted a literature search to determine the risk of major congenital malformations after 1st trimester exposure to SSRIs and SNRIs (20). Fifteen controlled studies were analyzed. The data were adequate to suggest that citalopram, fluoxetine, sertraline, and venlafaxine were not associated with an increased risk of congenital defects. In contrast, the analysis did suggest an increased risk with paroxetine. The data were inadequate to determine the risk for the other SSRIs and SNRIs (20).

A case–control study, published in 2006, was conducted to test the hypothesis that exposure to SSRIs in late pregnancy was associated with PPHN (21). A total of 1213 women were enrolled in the study, 377 cases whose infants had PPHN and 836 matched controls and their infants. Mothers were interviewed by nurses who were blinded to the hypothesis. Fourteen case infants had been exposed to an SSRI after the 20th week of gestation compared with six control infants (adjusted OR 6.1, 95% CI 2.2–16.8). The numbers were too small to analyze the effects of dosage, SSRI used, or reduction of the length of exposure before delivery. No increased risk of PPHN was found with the use of SSRIs before the 20th week or with the use of non-SSRI antidepressants at any time in pregnancy. If the relationship was causal, the absolute risk was estimated to be about 1% (21).

Two large case–control studies assessing associations between SSRIs and major birth defects were published in 2007 (22,23). The findings related to SSRIs as a group, as well as to four specific agents: citalopram, fluoxetine,

paroxetine, and sertraline. The studies found increased risks for some birth defects, but the absolute risk appeared to be small. An accompanying editorial discussed the findings and limitations of these and other related studies (24). Details of the studies and the editorial are described in the paroxetine review (see Paroxetine).

A prospective cohort study evaluated a large group of pregnancies exposed to antidepressants in the 1st trimester to determine if there was an association with major malformations (25). The patient population came from the Motherisk database and involved 928 cases that met their criteria. The 928 matched (for age, smoking, and alcohol use) controls were pregnancies not exposed to antidepressants or known teratogens. In addition to the 52 fluvoxamine cases, the other cases were 113 bupropion, 184 citalopram, 21 escitalopram, 61 fluoxetine, 68 mirtazapine, 39 nefazodone, 148 paroxetine, 61 sertraline, 17 trazodone, and 154 venlafaxine. In the antidepressant group, there were 24 (2.5%) major defects compared with 25 (2.6%) in controls (OR 0.9, 95% CI 0.5–1.61). There were two major anomalies in the fluvoxamine group: atrial septal defect and an umbilical hernia. There were no major defects in the pregnancies exposed to bupropion, escitalopram, or trazodone (25).

BREASTFEEDING SUMMARY

Fluvoxamine is excreted into human milk. A 23-year-old, 70-kg woman in her 12th postpartum week was treated for postnatal depression with fluvoxamine, 100 mg twice daily (2.86 mg/kg/day) (26). Two weeks after the start of therapy, single milk and plasma samples were obtained 5 hours after a dose and concentrations of 0.09 and 0.31 mcg/mL, respectively, were measured. It was estimated that the infant was ingesting about 0.5% of the mother's daily dose (26).

In a brief 1997 communication, plasma and breast milk samples were obtained from a breastfeeding mother 3 hours after her morning fluvoxamine dose (100 mg/day; 1.43 mg/kg/day) (27). The concentrations in the plasma and milk were 0.17 and 0.05 mcg/mL, respectively, a milk:plasma ratio of 0.29. The estimated infant dose was slightly less than 0.0075 mg/kg/day (0.5% of the mother's daily dose). The nursing infant had been exposed to the drug in milk for about 3–4 weeks when breastfeeding was discontinued. No adverse effects from the exposure were noted on infant assessments conducted up to 21 months of age (27).

A 2000 case report described a 31-year-old breastfeeding woman, 3 months postpartum, on a stable dose (100 mg twice daily) of fluvoxamine (28). Serum

and foremilk samples were collected every hour for 12 hours after a dose. The mean milk:serum ratio was 1.32. The estimated dose ingested by the nursing infant was 48 mcg/kg/day or 1.58% of the weight-adjusted maternal dose. No adverse effects or unusual behavior was noted in the nursing infant (28). Foremilk samples in women ingesting SSRI agents have been shown to contain much less drug than hindmilk because of the higher fat content of hindmilk and the lipid solubility of these drugs (see Paroxetine and Sertraline). Therefore, because only foremilk was collected from each breast, the milk:serum ratio and the actual dose ingested by the infant were probably higher.

In a second 2000 communication, a 26-year-old woman was started on fluvoxamine for severe obsessive-compulsive disorder symptoms at 19 days postpartum (29). About 8 weeks later, while on a dose of 25 mg three times daily, six breast milk (2–4 ounces) samples were collected (before each dose and before each feeding) over a 24-hour period. Blood samples were obtained from the mother and infant at the same time; 10 hours after a dose and 2–3 hours after the last feeding, respectively. Milk concentrations of fluvoxamine were 24–40 ng/mL over the collection period. Maternal and infant serum concentrations were 20 ng/mL and 9 ng/mL, respectively. The authors speculated that the atypically high infant serum concentration (45% of the mother's level) may have been related to the infant's hepatic function. The estimated maximum dose ingested by the nursing infant was 6 mcg/kg/day, or about 0.62% of the weight-adjusted maternal dose. No adverse effects or interference with normal developmental milestones up to 4 months of age was observed in the nursing infant (29).

In a 2006 case described in the Fetal Summary, a woman took fluvoxamine 200 mg/day and quetiapine 400 mg/day throughout a normal pregnancy (9). She continued this therapy while attempting to breastfeed her healthy female infant. Because of insufficient milk production, formula supplementation was required. The infant was developing normally and meeting all milestones at 3 months of age (9).

A 1999 review of SSRI agents concluded that if there were compelling reasons to treat a mother for postpartum depression, a condition in which a rapid antidepressant effect is important, the benefits of therapy with SSRIs would most likely outweigh the risks (30). However, because the long-term effects of exposure to SSRI antidepressants in breast milk on the infant's neurobehavioral development are unknown, stopping or reducing the frequency of breastfeeding should be considered if therapy with these agents is required. Avoiding nursing around the time of peak maternal concentration (about 4 hours

after a dose) may limit infant exposure. However, the long elimination half-lives of all SSRIs and their weakly basic properties, which are conducive to ion trapping in the relatively acidic milk, probably will lessen the effectiveness of this strategy. The American Academy of Pediatrics classifies fluvoxamine as a drug whose effect on a nursing infant is unknown, but may be of concern (31).

FOLIC ACID

Vitamin

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Folic acid deficiency during pregnancy is a common problem in undernourished women and in women not receiving supplements. The relationship between folic acid levels and various maternal or fetal complications is complex. Evidence has accumulated that interference with folic acid metabolism or folate deficiency induced by drugs such as anticonvulsants and some antineoplastics early in pregnancy results in congenital anomalies. Moreover, a substantial body of evidence is now available that non-drug-induced folic acid deficiency, or abnormal folate metabolism, is related to the occurrence of birth defects and some neural tube defects (NTDs). Lack of the vitamin or its metabolites may also be responsible for some cases of spontaneous abortion and intrauterine growth restriction. For other complications, it is probable that a number of factors, of which folic acid deficiency may be one, contribute to poor pregnancy outcome. To ensure good maternal and fetal health, all pregnant women should receive sufficient dietary or supplementary folic acid to maintain normal maternal folate levels.

FETAL RISK SUMMARY

Folic acid, a water-soluble B complex vitamin, is essential for nucleoprotein synthesis and the maintenance of normal erythropoiesis (1). The National Academy of Sciences' recommended dietary allowance (RDA) for folic acid in pregnancy is 0.4 mg (1). However, a recommended dietary intake of 0.5 mg/day has been proposed that would meet the needs of women with poor folate stores, those with essentially no other dietary folate, and those with multiple pregnancies (2).

Rapid transfer of folic acid to the fetus occurs in pregnancy (3–5). One investigation found that the placenta stores folic acid and transfer occurs only

after placental tissue vitamin receptors are saturated (6). Results compatible with this hypothesis were measured in a 1975 study using radiolabeled folate in women undergoing 2nd trimester abortions (7).

Folic acid deficiency is common during pregnancy (8–11). If not supplemented, maternal serum and red blood cell (RBC) folate values decline during pregnancy (8,12–16). Even with vitamin supplements, however, maternal folate hypovitaminemia may result (8). This depletion is thought to result from preferential uptake of folic acid by the fetal circulation such that at birth, newborn levels are significantly higher than maternal levels (8,15–18). At term, mean serum folate in 174 mothers was 5.6 ng/mL (range 1.5–7.6 ng/mL), whereas in their newborns, it was 18 ng/mL (range 5.5–66.0 ng/mL) (8). In an earlier study, similar serum values were measured with RBC folate decreasing from 157 ng/mL at 15 weeks' gestation to 118 ng/mL at 38 weeks (12). Folic acid supplementation prevented the decrease in both serum and RBC folate. Although supplementation is common during pregnancy in some countries, not all authorities believe this is necessary for the entire population (19,20). The main controversy is whether all women should receive supplements because of the cost involved in identifying those at risk (19), or whether supplements should be given only to those in whom a clear indication has been established (20).

The most common complication of maternal folic acid deficiency is megaloblastic anemia (9,21–30). Pancytopenia secondary to folate deficiency has also been reported during pregnancy (31). The three main factors involved in the pathogenesis of megaloblastic anemia of pregnancy are depletion of maternal folic acid stores by the fetus, inadequate maternal intake of the vitamin, and faulty absorption (27). Multiple pregnancy, hemorrhage, and hemolytic anemia hasten the decline of maternal levels (13,27). A 1969 study used 1-mg daily supplements to produce a uniformly satisfactory hematologic response in these conditions (29). In anemia associated with β -thalassemia minor, 5 mg/day of folic acid was significantly better than 0.25 mg/day in increasing predelivery hemoglobin concentrations in both nulliparous and multiparous Chinese women (32). Patients with iron deficiency, chronic blood loss, and parasitic infestation were excluded.

The proposed effects on the mother and fetus resulting from folate deficiency, not all of which appear to be related to the vitamin, can be summarized as follows:

- Fetal anomalies (NTDs; other defects)
- Placental abruption

Gestational hypertension (GHTN)

Abortions

Placenta previa

Premature delivery

Low birth weight

Fetal Anomalies (Neural Tube Defects; Other Defects)

Several investigations have suggested a relationship between folic acid deficiency and neural tube defects (NTDs). (Studies conducted with multiple vitamin products and not specifically with folic acid are described under Vitamins, Multiple.) In a randomized, double-blind trial to prevent recurrences of NTDs, 44 women took 4 mg/day of folic acid from before conception through early pregnancy (33). There were no recurrences in this group. A placebo group of 51 women plus 16 noncompliant patients from the treated group had four and two recurrences, respectively. The difference between the supplemented and nonsupplemented patients was significant ($p = 0.04$). Other researchers reported significantly lower RBC folate levels in mothers of infants with NTDs than in mothers of normal infants, but not all of the affected group had low serum folate (34). In a subsequent report by these investigators, very low vitamin B₁₂ concentrations were found, suggesting that the primary deficiency may have been due to this latter vitamin with resulting depletion of RBC and tissue folate (35). A large retrospective study found a protective effect with folate administration during pregnancy, leading to a conclusion that deficiency of this vitamin may be teratogenic (36).

Evidence was published in 1989 that low dietary intake of folic acid is related to the occurrence of NTDs (37). In this Australian population-based case-control study, 77 mothers whose pregnancies involved an isolated NTD were compared with 77 mothers of infants with other defects (control group 1) and 154 mothers of normal infants (control group 2). Free folate intake was classified into four levels (in mcg/day): 8.0–79.8, 79.9–115.4, 115.5–180.5, and 180.6–1678.0. After adjustment for potential confounding variables, a statistically significant trend for protection against an NTD outcome was observed with increasing free folate intake in comparison to both control groups: $p = 0.02$ for control group 1, and $p < 0.001$ for control group 2. The odds ratios (ORs) for the highest intake compared with the control groups were 0.31 and 0.16, respectively. When total folate intake was examined, the trends were less: $p = 0.10$ for control group 1 and $p = 0.03$ for control group 2. In an accompanying editorial comment, criticism of the above study focused on the

authors' estimation of dietary folate intake (38). The commentary cited evidence that nutrition tables are unreliable for the estimation of folate content, and that the only conclusion the study could claim was that dietary factors, but not necessarily folate, had a role in the etiology of NTDs.

A 1989 study conducted in California and Illinois examined three groups of patients to determine whether multivitamins had a protective effect against NTDs (39). The groups were composed of women who had a conceptus with an NTD (N = 571) and two control groups: those who had a stillbirth or an infant with another defect (N = 546) and women who had delivered a normal child (N = 573). In this study, NTDs included anencephaly, meningocele, myelomeningocele, encephalocele, rachischisis, iniencephaly, and lipomeningocele. The periconceptional use of multivitamins, both in terms of vitamin supplements only and when combined with fortified cereals, was then evaluated for each of the groups. The outcome of this study, after appropriate adjustment for potential confounding factors, revealed an OR of 0.95 for NTD-supplemented mothers (i.e., those who received the RDA of vitamins or more) compared with unsupplemented mothers of abnormal infants, and an OR of 1.00 when the NTD group was compared with unsupplemented mothers of normal infants. Only slight differences from these values occurred when the data were evaluated by considering vitamin supplements only (no fortified cereals) or vitamin supplements of any amount (i.e., less than the RDA). Similarly, examination of the data for an effect of folate supplementation on the occurrence of NTDs did not change the results. Thus, this study could not show that the use of either multivitamin or folate supplements reduced the frequency of NTDs. However, the investigators cautioned that their results could not exclude the possibility that vitamins might be of benefit in a high-risk population. Several reasons were proposed by the authors to explain why their results differed from those obtained in other studies: (a) recall bias, (b) a declining incidence of NTDs, (c) geographic differences such that a subset of vitamin-preventable NTDs did not occur in the areas of the current study, and (d) others had not considered the vitamins contained in fortified cereals (39). However, other researchers concluded that this study led to a null result because (a) the vitamin consumption history was obtained after delivery, (b) the history was obtained after the defect was identified, or (c) the study excluded those women taking vitamins after they knew they were pregnant (40).

In contrast to the above report, a Boston study published in 1989 found a significant effect of folic acid-containing multivitamins on the occurrence of NTDs (40). The study population comprised 22,715 women for whom complete

information on vitamin consumption and pregnancy outcomes was available. Women were interviewed at the time of a maternal serum α -fetoprotein screen or an amniocentesis. Thus, in most cases, the interview was conducted before the results of the tests were known to either the patient or the interviewer. A total of 49 women had an NTD outcome (2.2/1000). Among these, three cases occurred in 107 women with a history of previous NTDs (28.0/1000), and two were in 489 women with a family history of NTDs in someone other than an offspring (4.1/1000). After excluding the 87 women whose family history of NTDs was unknown, the incidence of NTDs in the remaining women was 44 cases in 22,093 (2.0/1000). Among the 3157 women who did not use a folic acid-containing multivitamin, 11 cases of NTDs occurred, a prevalence of 3.5/1000. For those using the preparation during the first 6 weeks of pregnancy, 10 cases occurred from a total of 10,713 women (prevalence 0.9/1000). Among mothers who, during the first 6 weeks, used vitamins that did not contain folic acid, the prevalence was three cases in 926, a ratio of 3.2/1000. When vitamin use was started in the 7th week of gestation, there were 25 cases of NTD from 7795 mothers using the folic acid-multivitamin supplements (3.2/1000; prevalence ratio 0.92) and no cases in the 66 women who started consuming multivitamins without folate. This study, then, observed a markedly reduced risk of NTDs when folic acid-containing multivitamin preparations were consumed in the first 6 weeks of gestation.

A 1989 preliminary report of a Hungarian, controlled, double-blind study evaluated the effect on congenital defects and first occurrence of NTDs of periconceptional supplementation with a multivitamin combination containing 0.8 mg folic acid compared with a trace-element supplement (controls) (41). Women were randomized to the vitamin formulation or control 1 month before through 3 months after the last menstrual period. The differences in outcome between the groups (number of subjects $N = 1302$) were not significant. Statistical significance was obtained, however, in the final report, published in 1992 (42) with an accompanying editorial (43), where pregnancy outcome was known in 2104 vitamin-supplemented cases and 2052 controls. Significantly more congenital malformations occurred in the control group (22.9/1000 vs. 13.3/1000, $p = 0.02$), including six cases of NTDs in controls compared with none in those taking vitamins ($p = 0.029$) (42). The rate of NTD occurrence in the control group corresponded to the expected rate in Hungary (41).

In 1991, the results of an 8-year study to examine the effects of folic acid supplementation, with or without other vitamins, on the recurrence rate of NTDs was published (44). This randomized, double-blind study conducted by the

British Medical Research Council (MRC) was carried out at 33 medical centers in the United Kingdom, Australia, Canada, France, Hungary, Israel, and Russia. A total of 1817 women, all of whom had a previous pregnancy affected by an NTD (anencephaly, spina bifida cystica, or encephalocele), were enrolled in the study prior to conception and randomized to one of four treatment groups: folic acid (4 mg/day) (N = 449), folic acid (4 mg/day) plus other vitamins (N = 461), other vitamins (A, D, B₁, B₂, B₆, C, and nicotinamide) (N = 453), and no vitamins (placebo capsules containing ferrous sulfate and dicalcium phosphate) (N = 454). Women with epilepsy were excluded, as were those with infants whose NTD was associated with genetic factors. Women who conceived were continued in the study until the 12th week of gestation. The study was terminated after 1195 women had a completed pregnancy where the outcome could be classified as either NTD or no NTD, because the preventive effect of folic acid was clear. Six NTDs were observed in the two folic acid groups (6/593; 10/1000) and 21 were observed in the nonfolic acid groups (21/602; 35/1000). Analysis of the data indicated that folic acid had prevented 72% of the NTD recurrences compared with other vitamins, which gave no protective effect. The benefit of folic acid was the same for anencephaly as for spina bifida and encephalocele. The study found no evidence that any other vitamin had a protective effect, nor did other vitamins enhance the effect of folic acid. Based on the results of the study, the MRC recommended that all women who have had a previous pregnancy outcome with an NTD should take folic acid supplements. The study could not determine, however, whether 4 mg/day of folic acid was required or whether a smaller dose, such as 0.36 mg, would have been equally efficacious. They speculated, however, that even small doses should have some preventive effect.

The CDC published interim recommendations for folic acid supplementation based on the MRC study, pending further research to determine the required dose, for women who have had an infant or fetus with an NTD (spina bifida, anencephaly, or encephalocele) (45): 4 mg/day of folic acid at least 4 weeks before conception through the first 3 months of pregnancy. This supplementation was not recommended for (a) women who have never had an infant or fetus with an NTD, (b) relatives of women who have had an infant or fetus with an NTD, (c) women who themselves have spina bifida, and (d) women who take valproic acid (45). Approximately 1 year later, the CDC, in conjunction with other American health agencies, published the recommendation that all women of childbearing age should consume 0.4 mg of folic acid per day either from the diet or from supplements (46). This recommendation included

women who had an NTD-affected pregnancy, unless they were planning to become pregnant. In that case, the CDC suggested that the 4-mg/day dose was still appropriate. Although the 0.4-mg dose may be as effective, the higher dose was based on a study designed to prevent NTDs, and the risks of an NTD-affected infant may be greater than the maternal risks from 4 mg/day of folic acid.

Several unanswered questions have been raised by the findings of the MRC trial, in addition to the one involving dosage, including the following: (a) How long before conception is supplementation needed (47)?, (b) What are the risks from supplementation (47–49)?, (c) If there are risks, are they the same for 4 mg and 0.4 mg (47–49)?, (d) Will the benefits of supplementation be the same for all ethnic groups, even in those with much lower prevalence rates of NTDs (47)?, (e) Will the benefits be as great for women who are not at an increased risk for producing a child with an NTD (47)?, (f) Can the required folic acid be obtained from food (47)?, (g) Is one mechanism of folic acid's action in preventing NTDs related to the correction of genetic defects, such as inborn errors of homocysteine metabolism (50)?, and (h) Is folic acid itself or its metabolite, 5-methyltetrahydrofolate (5-MTHF), the active form of the vitamin (48,49)?

Two uncontrolled trials conducted in the United Kingdom during the MRC study described above provided additional evidence that folic acid supplementation is beneficial in preventing recurrences of NTDs (51,52). Women at high-risk for recurrence, but who refused to be enrolled in the MRC trial, primarily out of fear of being placed in the placebo group, were treated with 4 mg/day of folic acid at least 1 month prior to conception through the 12th week of gestation (51). Of the 255 women supplemented, 234 achieved a pregnancy with 235 fetuses/infants (one set of twins). Two cases of NTDs were observed (spina bifida; encephalocele), a recurrence risk of 8.5/1000, approximately one-third the expected incidence of 30/1000 and nearly identical to the results in the MRC study. In the second trial, 208 high-risk women were treated similarly, but with a multivitamin preparation containing 0.36 mg of folic acid (52). Of the 194 who had delivered (14 were still pregnant), only one NTD was observed (an incidence of 5.2/1000), and that mother admitted poor compliance in taking the vitamins.

The results of three other studies, one conducted in 12 Irish hospitals beginning in 1981 (53), one in Spain between 1974 and 1990 (54), and one in the United States and Canada from 1988 through 1991 (55,56), indicated that folic acid may be protective at a much lower dosage (e.g., ≥ 0.3 mg/day) than

that used in the MRC trial. In the American/Canadian study, folic acid (the most commonly used daily dose was 0.4 mg) consumed 28 days before through 28 days after the last menstrual period decreased the risk for first occurrence of NTDs by approximately 60% (55). The investigators also found evidence that a relatively high dietary intake of folate reduced the risk of NTDs (55).

In a search for a possible mechanism of folic acid prevention of NTDs, several studies have compared the concentrations of folic acid in mothers who have produced a child with an NTD with control mothers with no history of NTDs in their infants (57–60). A brief 1991 report found no relation between NTDs and low folate levels in fetal blood, fetal red cells, or maternal blood, thus eliminating poor placental transfer of folic acid as a possible mechanism (57).

A study conducted in Dublin found no difference in serum folate or vitamin B₁₂ levels in mothers whose pregnancies ended with an NTD infant or fetus when compared with 395 normal controls (58). The serum samples were obtained during a routine screening program for rubella antibody conducted in three Dublin hospitals. After testing, the samples were frozen and then later used for this study. During the study period, 116 cases of NTDs were identified, but serum was available for only 32 of the cases: 16 with anencephalus, 15 with spina bifida, and 1 with encephalocele. In half of the cases, serum was obtained between 9 week's and 13 weeks' gestation. The mean serum folate concentrations in the cases and controls were both 3.4 ng/mL, and levels of vitamin B₁₂ were 297 and 277 pg/mL, respectively.

Another trial found significantly lower RBC folate levels in pregnancies ending with an NTD (59). This Scottish study measured vitamin levels in 20 women younger than 35 years of age who had a history of two or more NTD pregnancies. A control group of 20 women with no pregnancies ending in NTDs, but matched for age, obstetric history, and social class, was used for comparison. No significant differences between the two groups were found in assays for plasma or serum vitamin A, thiamine, riboflavin, pyridoxine, vitamin B₁₂, folate, vitamin C, vitamin E, total protein, albumin, transferrin, copper, magnesium, zinc, and white cell vitamin C. RBC folate, however, was significantly lower in the case mothers than in controls, 178 vs. 268 ng/mL ($p = 0.005$), respectively, although both were within the normal range (106–614 ng/mL). Moreover, a linear relationship was found between RBC folate and the number of NTD pregnancies. Women who had three or four such pregnancies also had the lowest concentrations of RBC folate (59). The dietary intake of folic acid was lower in the case mothers than in controls, but the difference was not statistically significant. Because the lower RBC folate levels could not be

attributed entirely to dietary intake of folic acid, the authors speculated that one factor predisposing to the occurrence of NTDs may be an inherited disorder of folate metabolism (59).

A study conducted in Finland, published in 1992, was similar in design and findings to the Dublin study described above (60). Serum samples from women who had delivered an infant with an NTD were analyzed and compared with samples from 178 matched controls. Cases of NTDs with known or suspected causes unrelated to vitamins were excluded. Maternal serum had been drawn during the first or second prenatal care appointment for reasons not related to the study, all within 8 weeks of neural tube closure, and kept frozen in a central laboratory. No statistical differences were found between case mothers and controls in serum levels of folate, vitamin B₁₂, and retinol. After adjustment, the ORs for being a case mother were 1.00 for folate, 1.05 for vitamin B₁₂, and 0.99 for retinol. Several possible explanations have been offered as to why this study was unable to find differences between case and control mothers (61): (a) Serum samples may not have been obtained early enough in pregnancy, (b) maternal serum vitamin concentrations may not be a good test of the folic acid deficiency necessary to cause NTDs, and (c), most likely, the group tested may not have been at risk to have a vitamin-sensitive NTD since the normal incidence of NTDs in the studied population is very low.

At least three publications have commented on the potential risks of high-dose folic acid supplementation (45,62,63). Megaloblastic anemia resulting from vitamin B₁₂ deficiency may be masked by folic acid doses of 4 mg/day but still allow the neurologic damage of the deficiency to progress (45,62). Responding to this, a Canadian editorial recommended that a woman's vitamin B₁₂ status be checked prior to commencing high-dose folic acid supplementation (62). A second risk identified concerned the inhibition of dihydropteridine reductase (DHPR), a key enzyme in the maintenance of tetrahydrobiopterin levels, by folic acid but not by 5-MTHF (63). Children with an inherited deficiency of this enzyme have lowered levels of dopamine, noradrenaline, serotonin, and folates in the CNS, which results in gross neurologic damage and death if untreated, thus raising the potential that high-dose folic acid could cause damage to embryonic neural tissue.

Folic acid deficiency is a known experimental animal teratogen (64). In humans, the relationship between fetal defects other than NTDs and folate deficiency is less clear. Several reports have claimed an increase in congenital malformations associated with low levels of this vitamin (9,24–26,33,36,65,66), and one study observed a significant decrease in birth defects when a

multivitamin–folic acid preparation was used before and during early gestation (42) (see details above). Other investigators have stated that maternal deficiency does not result in fetal anomalies (22,23,67–73). One study found the folate status of mothers giving birth to severely malformed fetuses to be no different from that of the general obstetric population and much better than that of mothers with overt megaloblastic anemia (67). Similar results were found in other series (71–73).

The strongest evidence for an association between folic acid and fetal defects comes from cases treated with drugs that either are folic acid antagonists or induce folic acid deficiency, although agreement with the latter is not universal (70,74,75). The folic acid antagonists, aminopterin and methotrexate, are known teratogens (see Aminopterin and Methotrexate). A very high incidence of defects resulted when aminopterin was used as an unsuccessful abortifacient in the 1st trimester. These antineoplastic agents may cause fetal injury by blocking the conversion of folic acid to tetrahydrofolic acid in both the fetus and the mother.

In contrast, certain anticonvulsants, such as phenytoin and phenobarbital, induce maternal folic acid deficiency, possibly by impairing gastrointestinal absorption or increasing hepatic metabolism of the vitamin (70,74,75). Whether these agents also induce folic acid deficiency in the fetus is less certain, because the fetus seems to be efficient in drawing on available maternal stores of folic acid. Low maternal folate levels, however, have been proposed as a mechanism for the increased incidence of defects observed in infants exposed in utero to some anticonvulsants. In a 1984 article, investigators reported research on the relationship among folic acid, anticonvulsants, and fetal defects (74). In the retrospective part of this study, a group of 24 women who were treated with phenytoin and other anticonvulsants produced 66 infants, of whom 10 (15%) had major anomalies. Two of the mothers with affected infants had markedly low RBC folate concentrations. A second group of 22 epileptic women was then given supplements of daily folic acid, 2.5–5.0 mg, starting before conception in 26 pregnancies and within the first 40 days in 6 pregnancies. This group produced 33 newborns (32 pregnancies, one set of twins) with no defects, a significant difference from the group not receiving supplementation. Negative associations between anticonvulsant-induced folate deficiency and birth defects have also been reported (70,75). Investigators studied a group of epileptic women taking anticonvulsants and observed only two defects (2.9%) in pregnancies producing a live baby, which is a rate similar to that expected in a healthy population (70). Although folate levels were not

measured in this retrospective survey, maternal folate deficiency was predicted by the authors, based on their current research with folic acid in patients taking anticonvulsants. Another group of researchers observed 20 infants (15%) with defects from 133 women taking anticonvulsants (75). No NTDs were found, but this defect is rare in Finland and an increase in the anomaly could have been missed (75). All of the women were given folate supplements of 0.1–1.0 mg/day (average 0.5 mg/day) from the 6th to 16th weeks of gestation until delivery. Folate levels were usually within the normal range (normal considered to be serum >1.8 ng/mL, RBC >203 ng/mL).

Whole embryo cultures of rats have been tested with valproic acid and folinic acid, a folic acid derivative (76). The anticonvulsant produced a dose-related increase in the incidence of NTDs that was not prevented by the addition of the vitamin. Experiments in embryonic mice, however, indicated that valproic acid-induced NTDs were related to interference with embryonic folate metabolism (77). Teratogenic doses of valproic acid caused a significant reduction in embryonic levels of formylated tetrahydrofolates and increased the levels of tetrahydrofolate by inhibition of the enzyme glutamate formyltransferase. The result of this inhibition would have serious consequences on embryonic development, including neural tube closure (77).

A review of teratogenic mechanisms involving folic acid and antiepileptic therapy was published in 1992 (78). Several studies conducted by the authors and others demonstrated that phenytoin, phenobarbital, and primidone, but not carbamazepine or valproic acid, significantly reduced serum and RBC levels of folate, and that polytherapy decreased these levels significantly more than monotherapy. Animal studies cited indicated that valproic acid disrupts folic acid metabolism, possibly by inhibiting key enzymes, rather than by lowering concentrations of the vitamin, whereas phenytoin may act on folic acid by both mechanisms (78). Data from a study conducted by the authors indicated that a significant association existed between low serum and RBC folate levels, especially <4 ng/mL, before or early in pregnancy in epileptic women and spontaneous abortions and the occurrence of congenital malformations (78). The reviewers concluded that folic acid supplementation may be effective in preventing some poor pregnancy outcomes in epileptic women.

Another 1992 report, based on the results of a 1990 workshop addressing the use of antiepileptic drugs during pregnancy, offered guidelines to counsel women with epilepsy who plan pregnancy or who are pregnant (79). Included among the guidelines was the recommendation that adequate folic acid be consumed daily, either from the diet or from supplements, to maintain normal

serum and RBC levels of folate before and during the first months of pregnancy (i.e., during organogenesis). A specific folic acid dose was not recommended.

In a 2013 case–control study from Japan covering the period 2001–2012, 360 women who had given birth to spina bifida-affected offspring were compared with 2333 women who had given birth to offspring without spina bifida (80). Four variables were significantly associated with the risk of having a newborn with spina bifida: not taking folic acid supplements (OR 2.5, 95% confidence interval [CI] 1.72–3.64, presence of spina bifida patients within third-degree relatives (OR 4.26, 95% CI 1.12–16.19), taking anticonvulsants without taking folic acid (OR 20.20, 95% CI 2.06–198.17), and low birth weight ≤ 2500 g (OR 4.21, 95% CI 3.18–5.59). In 2000, the Japanese government recommended that women planning a pregnancy should take 0.4 mg/day of folic acid. Because the prevalence rate of spina bifida, 5–6 per 10,000 total births, had not changed in 11 years, the authors recommended that mandatory food fortification with folic acid should be implemented (80).

Placental Abruption

Several articles have proposed that maternal folic acid status is associated with placental abruption (25,26,28,66,81). In a review and analysis of 506 consecutive cases of abruptio placentae, defective folate metabolism was found as a predisposing factor in 97.5%. The authors theorized that folic acid deficiency early in pregnancy caused irreversible damage to the fetus, chorion, and decidua, leading to abruption, abortion, premature delivery, low birth weight, and fetal malformations. Other studies have discovered that 60% of their patients with abruption were folate deficient, but their numbers were too small for statistical analysis (82). In other series, no correlation was found between low levels of folic acid and this complication (16,69,83).

Gestational Hypertension

A relationship between folate deficiency and GHTN is doubtful. In a study of women with megaloblastic anemia, 14% had GHTN compared with the predicted incidence of 6% for that population (22). In another report, 22 (61%) of 36 GHTN patients had folate deficiency, but the authors were unable to conclude that the association was causative (66,82). Other investigators have also failed to find a relationship between low levels of the vitamin and GHTN (23,27). In one of these studies, the incidence of GHTN in megaloblastic anemia was 12.2% compared with 14.0% in normoblastic anemia (27). A second group of investigators studied folate levels in 101 preeclamptic and 17

eclamptic women and compared them with 52 normal controls and 29 women with overt megaloblastic anemia (84). No correlation was found between levels of folic acid and the complications.

Abortions and Placenta Previa

Several papers have associated folic acid deficiency with abortion (25,26,66,78,81,85–87). The cause of some abortions, as proposed by some, is faulty folate metabolism in early pregnancy, producing irreversible injury to the fetus and placenta (81). Others have been unable to detect any significant relationship between serum and RBC folate levels and abortion (12,68,88). In a series of 66 patients with early spontaneous abortions, the incidence of folate deficiency was the same as in those with uncomplicated pregnancies (88). These researchers did find a relationship between low folic acid levels and placenta previa. However, others found no evidence of an association between folate deficiency and either abortion or antepartum hemorrhage (12).

Premature Birth and Low Birth Weight

The relationship among prematurity, low birth weight, and folic acid levels has been investigated. In one study, significantly lower folate levels were measured in the blood of low-birth-weight neonates than in that of normal-weight infants (18). The incidences of both premature delivery and infants with birth weight <2500 g were increased in folate-deficient mothers in a 1960 report (22). These patients all had severe megaloblastic anemia and a poor standard of nutrition. In a later study of 510 infants from folate-deficient mothers, 276 (54%) weighed \leq 2500 g compared with a predicted incidence of 8.6% (81). A study of women with uterine bleeding during pregnancy found a significant association between serum folate and low birth weight (86). Similarly, another study reported a significant relationship between folate levels at the end of the 2nd trimester and newborn birth weight (89). A 1992 report described the effects of supplementation with ferrous sulfate (325 mg/day) and folic acid (1 mg/day), beginning at the first prenatal visit, on infant birth weight (90). A significant association between low serum folate levels at 30 weeks' gestation and fetal growth restriction (defined as below the 15th percentile for gestational age) was discovered. Adjustment for psychosocial status, maternal race, body mass index, smoking history, history of a low-birth-weight infant, and infant gender did not change the results. In contrast, others have found no association between folic acid deficiency and prematurity (27,69,91,92) or between serum folate and birth weight (12,69,93,94).

Two reports have alluded to problems with high folic acid levels in the mother during pregnancy (95,96). An isolated case report described an anencephalic fetus whose mother was under psychiatric care (95). She had been treated with very high doses of folic acid and vitamins B₁, B₆, and C. The relationship between the vitamins and the defect is questionable. A 1984 study examined the effect of folic acid, zinc, and other nutrients on pregnancy outcome (96). Total complications of pregnancy (infection, bleeding, fetal distress, prematurity or death, pregnancy-induced hypertension, and tissue fragility) were associated with high serum folate and low serum zinc levels. The explanation offered for these surprising findings was that folate inhibits intestinal absorption of zinc, which, they proposed, was responsible for the complications. This study also found an association between low folate and abortion.

The CDC and other U.S. health agencies recommend a daily consumption of 0.4 mg of folic acid, from either the diet or supplements or both, for all women of childbearing age before the onset of pregnancy (46,97). An increased risk of adverse fetal outcome can be lowered by folic acid supplementation in at least two groups of women. Women with a history of a fetus or infant with an NTD should receive supplementation with 4 mg/day of folic acid beginning 1 month (3 months has been recommended in England [98]) before conception and continuing through the 12th week of gestation (45,98,99). Also, women receiving antiepileptic medications should receive sufficient folic acid from either the diet or supplementation or both to maintain normal serum and RBC levels of the vitamin beginning before conception and continuing through the period of organogenesis. A specific dosage recommendation has not been located for women receiving anticonvulsants, but 4 or 5 mg/day has been used.

BREASTFEEDING SUMMARY

Folic acid is actively excreted into breast milk (100–109). Accumulation of folate in milk takes precedence over maternal folate needs (100). Levels of folic acid are relatively low in colostrum but as lactation proceeds, concentrations of the vitamin rise (101–103). Folate levels in newborns and breastfed infants are consistently higher than those in mothers and normal adults (104,105). In Japanese mothers, mean breast milk folate concentrations were 141.4 ng/mL, resulting in a total intake by the infant of 14–25 mcg/kg/day (105). Much lower mean levels were measured in pooled human milk in an English study examining preterm (26 mothers, at 29–34 weeks) and term (35 mothers, at ≥39 weeks) patients (103). Preterm milk folate concentrations rose from 10.6 ng/mL (colostrum) to 30.5 ng/mL (16–196 days), whereas term milk

folate concentrations increased during the same period from 17.6 to 42.3 ng/mL.

Supplementation with folic acid is apparently not needed in mothers with good nutritional habits (103–107). Folic acid deficiency and megaloblastic anemia did not develop in women not receiving supplements even when lactation exceeded 1 year (103,104). In another study, maternal serum and RBC folate levels increased significantly after 1 mg of folic acid/day for 4 weeks, but milk folate levels remained unchanged (105). Investigators gave well-nourished lactating women a multivitamin preparation containing 0.8 mg of folic acid (106). At 6 months postpartum, milk concentrations of folate did not differ significantly from those of controls who were not receiving supplements. Other investigators measured more-than-adequate blood folate levels in American breastfed infants during the 1st year of life (107). The mean milk concentration of folate consumed by these infants was 85 ng/mL.

In patients with poor nutrition, lactation may lead to severe maternal folic acid deficiency and megaloblastic anemia (100). For these patients, there is evidence that low folate levels, as part of the total nutritional status of the mother, are related to the length of the lactation period (103). In one study, lactating mothers with megaloblastic anemia were treated with 5 mg/day of folic acid for 3 days (102). Breast milk folate rose from 7–9 ng/mL to 15–40 ng/mL 1 day after treatment began. The elevated levels were maintained for 3 weeks without further treatment. Nine lower-socioeconomic-status women were treated with multivitamins containing 0.8 mg of folic acid and were compared with seven untreated controls (108). Breast milk folate was significantly higher in the treated women. In another study of lactating women with low nutritional status, supplementation with folic acid, 0.2–10.0 mg/day, resulted in mean milk concentrations of 2.3–5.6 ng/mL (109). Milk concentrations were directly proportional to dietary intake.

Folic acid concentrations were determined in preterm and term milk in a study to determine the effect of storage time and temperature (110). Storage of milk in a freezer resulted in progressive decreases over 3 months such that the RDA of folate for infants could not be provided from milk stored for this length of time. Storage in a refrigerator for 24 hours did not affect folate levels.

The National Academy of Sciences' RDA for folic acid during lactation is 0.280 mg (1). If the lactating woman's diet adequately supplies this amount, maternal supplementation with folic acid is not needed. Maternal supplementation with the RDA for folic acid is recommended for those patients with inadequate nutritional intake. The American Academy of Pediatrics

considers maternal consumption of folic acid to be compatible with breastfeeding (111).

FOMEPIZOLE

Antidote

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: Hold Breastfeeding

PREGNANCY SUMMARY

Other than one case, no other human pregnancy experience is available. Although an assessment of the risk that this agent presents to a human embryo or fetus cannot be made, the maternal benefits should far outweigh the unknown fetal risks. Therefore, the drug should not be withheld because of pregnancy (1).

FETAL RISK SUMMARY

Fomepizole, given IV every 12 hours for ≥ 48 hours, is a competitive inhibitor of alcohol dehydrogenase, an enzyme that catalyzes the oxidation of alcohol to acetaldehyde. The enzyme also catalyzes the initial steps in the metabolism of ethylene glycol and methanol to their toxic metabolites. Fomepizole is indicated as an antidote for ethylene glycol (such as antifreeze or coolants) or methanol ingestion. It undergoes extensive metabolism to inactive metabolites. The elimination half-life has not been determined (2).

According to the manufacturer, animal reproduction studies have not been conducted with fomepizole. One source cited a 1982 abstract, however, that reported that the drug was not teratogenic in mice (3).

It is not known if fomepizole crosses the human placenta to the embryo or fetus. The very low molecular weight (about 82) suggests that the drug will cross the placenta.

Only one report describing the use of fomepizole in human pregnancy has been located. A 21-year-old woman at 11 weeks' gestation in her second pregnancy was treated with fomepizole (two doses of 15 mg IV over 30 minutes, approximately 8 hours apart) for inhalation of carburetor cleaner (4). The cleaner contained a mixture of methanol, toluene, methylene chloride, and carbon dioxide. Her history included chronic abuse of toluene and inhalants.

After release from the hospital, she was again admitted for the same problem about 6 weeks later and was treated with one dose of fomepizole. Attempts to contact the patient after discharge were unsuccessful and the eventual outcome of the pregnancy was unknown (4).

BREASTFEEDING SUMMARY

No reports describing the use of fomepizole during human lactation have been located. The very low molecular weight (about 82) suggests that the drug will be excreted into breast milk. The effects of this exposure on a nursing infant are unknown (the most common adverse effects in patients and normal volunteers were headache, nausea, dizziness, and bad taste/metallic taste [2]). Since the maternal benefits of therapy are great, breastfeeding should be temporarily discontinued, at least until the therapy is completed and the drug eliminated from the maternal system. The time required to eliminate the drug is unknown, but waiting for 24 hours would allow for nearly complete elimination if the half-life was ≥ 5 hours. Moreover, fomepizole is extensively metabolized to inactive metabolites and this will serve to lessen infant exposure. Furthermore, fomepizole is indicated as an antidote for ethylene glycol (such as antifreeze or coolants) or methanol ingestion, and these substances could be toxic to a nursing infant if they were excreted into milk.

FONDAPARINUX

Anticoagulant

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Although the human pregnancy experience with fondaparinux is limited, no reports of embryo–fetal harm have been located. Several reviews have stated that the agent is safe in pregnancy. Thus, if indicated it should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Fondaparinux is a synthetic selective inhibitor of activated factor X (Xa) that is administered by SC injection. The drug is indicated for the prophylaxis of deep vein thrombosis in patients undergoing hip fracture, hip replacement, or knee replacement surgery. Distribution to extravascular fluid is characterized as minor. The drug is extensively (at least 94%) and specifically bound to antithrombin III but not to other plasma proteins or red blood cells. The binding to antithrombin III significantly potentiates the neutralization of factor Xa by antithrombin III. Fondaparinux has no effect on thrombin or platelet function. The metabolism of fondaparinux has not been investigated, but most of a dose is excreted unchanged in the urine. The drug is contraindicated in patients weighing <50 kg because total clearance in this group is reduced by approximately 30% (1).

Reproduction studies in pregnant rats and rabbits at SC doses up to 32 and 65 times the recommended human dose based on BSA, respectively, revealed no evidence of impaired fertility or fetal harm (1).

Fondaparinux did not cross the placenta in an in vitro human dually perfused, cotyledon model using placentas from six healthy white women approximately 31 years of age (2,3). The dose tested corresponded to the therapeutic plasma concentrations observed with the recommended human dose. The

result is consistent with the high molecular weight (about 1728) and minimal extravascular distribution of fondaparinux. However, in a 2004 study of five women treated near delivery, the concentrations of fondaparinux in cord plasma were <5–40 ng/mL (4). The patient with undetectable drug had received only one dose, whereas the other four patients were at steady state with plasma levels of 255–340 ng/mL. The fetal concentrations were about 10% of the maternal levels (4).

A 31-year-old woman in her 12th week of pregnancy completely lost her vision in her right eye for 2 minutes (5). After an extensive work-up, she was diagnosed with hypereosinophilic syndrome and started on heparin and prednisone. HIT developed and her anticoagulant therapy was changed to argatroban (dose not specified). The thrombocytopenia resolved and, after 15 days, she was discharged home on fondaparinux (75 mg/day) and a tapering dose of prednisone. About 6–7 months later, she gave birth to a healthy female infant (no further details on the infant was provided) (5).

In a 2012 case report, a 33-year-old woman, with a history of hereditary antithrombin deficiency, presented at 7 weeks' gestation with a deep venous thrombosis in her left leg due to the deficiency (6). She was treated with urokinase (24,000 units/day), heparin (20,000 units/day), and antithrombin concentrate (3000 units/day). Ten days later, at 9 weeks, HIT was diagnosed; heparin was discontinued and a continuous infusion of argatroban (2.5 mcg/kg/min) was started. At 21 weeks, argatroban was stopped and fondaparinux (2.5 mg/day) was started at 24 weeks'. Argatroban (2.5–3.5 mcg/kg/min) was restarted during labor induction at 37 weeks. The patient gave birth to 2800-g male infant with Apgar scores of 9 and 10 at 1 and 5 minutes, respectively. The newborn had 14% of antithrombin activity. The mother and her newborn were discharged home 15 days later (6).

In addition to the above two reports, four other reports have described the use of fondaparinux during human pregnancy without causing embryo or fetal harm (7–10). In addition, four reviews have stated that the drug can be used safely in pregnancy (11–14).

BREASTFEEDING SUMMARY

No reports describing the use of fondaparinux during human lactation have been located. Despite the high molecular weight (about 1728), the drug may be excreted into milk. The potential effects of this exposure on a nursing infant are unknown but are probably not clinically significant.

FORMOTEROL

Respiratory Drug (Bronchodilator)

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The animal data suggest low risk, but the limited human pregnancy experience prevents a more complete assessment of the embryo–fetal risk. However, there is no published evidence that drugs in this class cause developmental toxicity (growth restriction, structural defects, functional/behavior defects, or death). β -Adrenergic agonists (e.g., see Albuterol and Terbutaline) have been used as tocolytics and inhibition of uterine contractions and labor is a potential complication. Although SC formoterol has potent tocolytic activity in rodents, this effect has not been studied in humans. Moreover, the systemic bioavailability of the drug after inhalation is probably too low to inhibit uterine activity. Of note, among the five premature births in the surveillance study, four of the women were using inhaled formoterol at the time. Other potential toxic effects of formoterol are maternal hyperglycemia (especially in diabetics) resulting in newborn hypoglycemia, and maternal pulmonary edema (especially when used with corticosteroids). Although published studies of these potential adverse effects from inhaled formoterol have not been located, the reported plasma drug concentrations appear to be too low to cause these toxicities. Because of the availability of extensive human pregnancy experience, either albuterol or salmeterol would be a better choice if a pregnant woman required an inhaled β -adrenergic bronchodilator. However, if a nonpregnant woman had a good response to inhaled formoterol, it would be reasonable to continue her on this drug during pregnancy. If formoterol is used in pregnancy, healthcare professionals are encouraged to call the toll-free number (877-311-8972) for information about patient enrollment in an Organization of Teratology Information Specialists (OTIS) study.

FETAL RISK SUMMARY

Formoterol is a potent, long-acting, selective β_2 -adrenergic agonist that acts as a bronchodilator. It is formulated as a dry powder into capsules intended for oral inhalation using the Aerolizer inhaler. Formoterol is indicated for the long-term maintenance treatment of asthma and in the prevention of bronchospasm. It also is indicated for the long-term maintenance treatment of bronchoconstriction in patients with chronic obstructive pulmonary disease (COPD), including chronic bronchitis and emphysema, and for the acute prevention of exercise-induced bronchospasm. Plasma protein binding in vitro was 61%–64% (31%–38% to albumin) over a wide range of drug concentrations. The mean plasma terminal elimination half-life after a single inhaled dose was 10 hours (1).

Reproduction studies have been conducted with formoterol in rats and rabbits. In pregnant rats, oral doses about 2000 times the maximum recommended daily inhalation dose in humans based on BSA (MRDID-BSA) or higher in late pregnancy resulted in stillbirth and neonatal mortality. These effects were not produced at doses about 70 times the MRDID-BSA. Oral doses about 70 times the MRDID-BSA or greater during organogenesis caused delayed ossification and, at 2000 times the MRDID-BSA or greater, reduced fetal weight. Oral dosing in pregnant rats and rabbits did not cause congenital malformations (1).

In long-term, high-dose studies, formoterol was carcinogenic in mice and rats. In these species, the doses used were about 25 and 45 times the human exposure based on AUC at the MRDID or higher, respectively. Formoterol was not mutagenic or clastogenic in multiple assays and did not impair fertility in rats (1).

In studies, both in vitro and in vivo, conducted in mice and rats, formoterol was a potent inhibitor of uterine contractions. The tocolytic activity of formoterol was about 1000 times that of ritodrine (2,3).

It is not known if formoterol crosses the human placenta. The molecular weight of the dihydrate fumarate salt (about 841), low protein binding, and prolonged elimination half-life suggest that the drug will pass to the embryo and/or fetus. However, the mean steady-state plasma concentrations of the drug after twice-daily dosing ranged from 4.0 to 8.8 pg/mL. Thus, very low drug concentrations will be available for placental transfer at the maternal–fetal interface.

A 2002 postmarketing surveillance study in England reported the outcomes of 34 pregnancies (33 women) exposed to formoterol (4). Most exposures (N =

31) occurred in the 1st trimester. Of these, there were 20 term live births, 5 premature births (31–36 weeks' gestation), 3 spontaneous abortions (SABs), and 3 elective pregnancy terminations. One of the premature infants had a fetal heart rate anomaly (no other information provided), and a term infant had pyloric stenosis. Formoterol treatment was ongoing in 16 of the 25 cases at the time of birth, including four of the premature births. Three women started treatment in the 2nd or 3rd trimester, and all had live term births. Exposure was uncertain in an additional pregnancy that ended in an SAB (4).

BREASTFEEDING SUMMARY

No reports describing the use of formoterol during human lactation have been located. The molecular weight of the dihydrate fumarate salt (about 841), low protein binding, and prolonged elimination half-life suggest that the drug will be excreted into breast milk. However, the very low plasma drug concentrations (4.0–8.8 pg/mL) suggest that the amount in milk will be clinically insignificant. Terbutaline, another β -adrenergic agonist, is classified by the American Academy of Pediatrics as compatible with breastfeeding (5). Thus, maternal inhalation of formoterol probably is compatible with nursing.

FOSAMPRENAVIR

Antiviral

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Although the limited human data does not allow a prediction as to the risk of fosamprenavir during pregnancy, the animal data indicate that the drug may represent a risk to the developing fetus. However, if indicated, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Fosamprenavir is a prodrug of amprenavir, an inhibitor of HIV protease. After in vivo conversion in the gut during absorption, amprenavir binds to the active site of HIV type 1 (HIV-1) protease to prevent the processing of viral Gag and Gag-Pol polyprotein precursors, resulting in the formation of immature, noninfectious viral particles. Fosamprenavir is indicated, in combination with other antiretroviral agents, for the treatment of HIV infection (1).

Fosamprenavir was not mutagenic or genotoxic in assays conducted in vitro and in vivo. The agent did not impair fertility or general reproductive performance in male and female rats treated with doses producing systemic exposures of three (males) or four (females) times the systemic exposure obtained with the maximum recommended human dose when given alone (MRHD), or similar to the systemic exposure obtained with the maximum recommended human dose when given in combination with ritonavir (MRHD-RIT) (1).

Reproduction studies have been conducted in pregnant rats and rabbits. In rats given fosamprenavir from gestational days 6–17, no major effects on embryo–fetal development were observed at doses 0.7 and 2 times the MRHD-RIT and MRHD, respectively. Dosing of female rats before and during mating, throughout gestation, and during the first six postpartum days was associated with a reduction in pup survival and body weights. An increased

incidence of abortion was observed in pregnant rabbits given fosamprenavir from gestational days 7–20 at doses 0.3 and 0.8 times the MRHD-RIT and MRHD, respectively. In contrast, amprenavir was associated with abortions and an increase in the incidence of minor skeletal variations (deficient ossification of the femur, humerus, and trochlea) in rabbits at a dose about 1/20th the human exposure obtained from the recommended dose (1).

Consistent with its molecular weight (about 506), amprenavir crosses the rat and rabbit placentas to the fetus. Amprenavir also has been shown to readily cross the ex vivo human placenta (see Amprenavir).

The Antiretroviral Pregnancy Registry reported, for the period January 1989 through July 2009, prospective data (reported before the outcomes were known) involving 4702 live births that had been exposed during the 1st trimester to one or more antiretroviral agents (2). Congenital defects were noted in 134, a prevalence of 2.8% (95% confidence interval [CI] 2.4–3.4). In the 6100 live births with earliest exposure in the 2nd/3rd trimester, there were 153 infants with defects (2.5%, 95% CI 2.1–2.9). The prevalence rates for the two periods did not differ significantly. There were 288 infants with birth defects among 10,803 live births, with exposure anytime during pregnancy (2.7%, 95% CI 2.4–3.0). The prevalence rate did not differ significantly from the rate expected in a nonexposed population. There were 98 outcomes exposed to fosamprenavir (70 in the 1st trimester and 28 in the 2nd/3rd trimesters) in combination with other antiretroviral agents. There were two birth defects (one in the 1st trimester and one in the 2nd/3rd trimester). In reviewing the birth defects of prospective and retrospective (pregnancies reported after the outcomes were known) registered cases, the Registry concluded that, except for isolated cases of neural tube defects with efavirenz exposure in retrospective reports, there was no other pattern of anomalies (isolated or syndromic) (2) (see Lamivudine for required statement).

The FDA issued a public health advisory on the association between protease inhibitors and diabetes mellitus (3). Because pregnancy is a risk factor for hyperglycemia, there was concern that these antiviral agents would exacerbate this risk. An abstract published in 2000 described the results of a study involving 34 pregnant women treated with protease inhibitors (none with fosamprenavir or amprenavir) compared with 41 controls that evaluated the association with diabetes (4). No association between protease inhibitors and an increased incidence of gestational diabetes was found.

Two reviews, one in 1996 and the other in 1997, concluded that all women currently receiving antiretroviral therapy should continue to receive therapy

during pregnancy and that treatment of the mother with monotherapy should be considered inadequate therapy (5,6). The same conclusion was reached in a 2003 review with the added admonishment that therapy must be continuous to prevent emergence of resistant viral strains (7). In 2009, the updated U.S. Department of Health and Human Services guidelines for the use of antiretroviral agents in HIV-1-infected patients continued the recommendation that therapy, with the exception of efavirenz, should be continued during pregnancy (8). If indicated, therefore, protease inhibitors, including fosamprenavir, should not be withheld in pregnancy because the expected benefit to the HIV-positive mother outweighs the unknown risk to the fetus. Pregnant women taking protease inhibitors should be monitored for hyperglycemia. The updated guidelines for the use of antiretroviral drugs to reduce perinatal HIV-1 transmission also were released in 2010 (9). Women receiving antiretroviral therapy during pregnancy should continue the therapy but, regardless of the regimen, zidovudine administration is recommended during the intrapartum period to prevent vertical transmission of HIV to the newborn (9).

BREASTFEEDING SUMMARY

No reports describing the use of fosamprenavir during lactation have been located. Amprenavir is excreted into the milk of lactating rats. In addition, the molecular weight of amprenavir (about 506) is low enough that excretion into breast milk should be expected (see Amprenavir).

Reports on the use of fosamprenavir during human lactation are unlikely because the antiviral agent is used in the treatment of HIV infection. HIV-1 is transmitted in milk, and, in developed countries, breastfeeding is not recommended (5,6,8,10–12). In developing countries, breastfeeding is undertaken, despite the risk, because there are no affordable milk substitutes available. Until 1999, no studies had been published that examined the effect of any antiretroviral therapy on HIV-1 transmission in milk. In that year, a study involving zidovudine was published that measured a 38% reduction in vertical transmission of HIV-1 infection despite breastfeeding when compared with controls (see Zidovudine).

FOSCARNET

Antiviral

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

One 1992 review suggested that foscarnet would be a first-line agent for pregnant HIV-positive patients with sight-threatening cytomegalovirus (CMV) retinitis (1). Because of the frequent occurrence of renal toxicity experienced with foscarnet in adults, however, the reviewer recommended frequent antepartum testing of the fetus and close monitoring of the amniotic fluid volume to observe for fetal renal toxicity.

FETAL RISK SUMMARY

Foscarnet has antiviral in vitro activity against all known herpes viruses, including CMV, herpes simplex virus (HSV) types 1 and 2, human herpesvirus 6, Epstein–Barr virus, and varicella–zoster virus (2). The drug is also active in vitro against HIV (3). It is used in patients with AIDS who have CMV retinitis or in immunocompromised patients with mucocutaneous acyclovir-resistant HSV infections.

Reproductive studies in pregnant rats with SC doses of 150 mg/kg/day, approximately one-eighth the estimated maximum daily human exposure based on AUC comparison, caused an increase in the frequency of skeletal malformations or variations. Administration to pregnant rabbits with 75 mg/kg/day, approximately one-third the human dose (AUC comparison), produced similar skeletal defects or variations. In addition, dose-related genotoxic effects were seen in two in vitro tests and in one in vivo test in mice (2).

It is not known if foscarnet crosses the human placenta. The molecular weight (about 300 for the sodium salt) is low enough that passage to the fetus should be expected.

Only one report describing the use of foscarnet during human pregnancy has

been located. A 21-year-old woman at 18 weeks' gestation was treated with an 8-day course of IV foscarnet (total dose 43.8 g) for severe, genital acyclovir-resistant HSV type 2 (3). The patient also had a 3-year history of HIV disease that was being treated with saquinavir, lamivudine, and zidovudine. After discharge from the hospital, repeat cultures yielded HSV type 2 sensitive to acyclovir and she was treated with oral doses of this antiviral agent for the remainder of her pregnancy. She underwent a cesarean section at term to deliver a healthy, HIV-negative, female infant who was developing normally at 1 year of age. The authors, citing information received from the manufacturer, briefly reviewed two other cases of IV foscarnet therapy. In one case, a HIV-negative woman with acyclovir-resistant HSV encephalitis and retinitis had been treated with foscarnet (60 mg/kg IV every 8 hours) for 17 days starting at 32 weeks' gestation. She eventually delivered a healthy infant at term. The second case involved a HIV-positive patient who was treated with foscarnet (40 mg/kg IV every 8 hours) for genital HSV type 2 beginning at 29 weeks' gestation. No further information was available on this case (3).

BREASTFEEDING SUMMARY

No reports describing the use of foscarnet during human lactation have been located. Because excretion into human milk most likely occurs, and because of the potentially severe toxicity that might occur in a nursing infant, women receiving foscarnet should not breastfeed.

FOSFOMYCIN

Antibiotic

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

The lack of teratogenicity in animals and the apparently safe use of fosfomycin during human pregnancy appear to indicate that the drug presents a low risk, if any, to the fetus.

FETAL RISK SUMMARY

Fosfomycin is a synthetic, broad-spectrum, bactericidal phosphonic acid antibiotic given as a single 3-g oral dose of the trometamol salt for the treatment of uncomplicated urinary tract infections (acute cystitis) in women (1). Outside of the United States, other salt forms (calcium salt for oral administration, disodium salt for IM or IV dosing) are also available. Following absorption, fosfomycin tromethamine is rapidly converted to the free acid, fosfomycin.

Studies in male and female rats found no effect on fertility or impairment of reproductive performance (1). No teratogenic effects were observed in pregnant rats administered doses up to 1000 mg/kg/day, about 9 and 1.4 times the human dose based on body weight and BSA (HD), respectively (1). In pregnant rabbits, fetotoxicity was observed at doses up to 1000 mg/kg/day, about 9 and 2.7 times the HD, respectively, a maternally toxic dose in the rabbit.

The placental transfer of fosfomycin, following a single 1-g IM dose (14–20 mg/kg), was studied in a group of women at term in active labor (2). Samples of maternal and fetal blood were obtained before delivery at 30, 90, and 120–210 minutes after the dose in 7, 8, and 7 women, respectively. Mean maternal blood concentrations of fosfomycin at the three time intervals were 14.24, 23.32, and 15.86 mcg/mL, respectively, whereas those in the fetal blood were 1.58, 5.35, and 11.5 mcg/mL, respectively. Another report found that the drug

crossed the placenta, resulting in detectable concentrations in amniotic fluid and cord blood in three women (3).

Although the above studies were conducted with IM dosing, the results appear to be comparable with those expected after oral dosing. The mean maximum maternal serum concentration of fosfomycin, after a single 3-g oral dose of fosfomycin tromethamine under fasting conditions, was 26.1 mcg/mL within 2 hours (1). As should be expected because of the normal physiologic changes that occur during gestation, pregnant women will have lower peak levels. In four pregnant women at 28–32 weeks' gestation after a single 3-g oral dose, the mean peak serum level at 2 hours was 20.5 mcg/mL (4).

A number of reports have described the use of fosfomycin during human pregnancy. Although appropriate precautions had been taken to exclude and prevent pregnancies during clinical trials, three women conceived shortly after enrolling and all received a single 3-g oral dose of fosfomycin (H.A. Schneier, personal communication, Forest Laboratories, 1997). The dose was apparently consumed about 3 days before conception in one case, 8 days after the last menstrual period (probably before conception) in a second, and 14 days after the last menstrual period (assumed to be around the time of conception) in a third. The first woman was lost to follow-up and the other two delivered healthy male newborns who were developing normally at 3 years of age.

In a case of stillbirth reported by the manufacturer to the FDA, the mother was hospitalized following a car accident and approximately 10 days later received a single 3-g oral dose of fosfomycin for a urinary tract infection (H.A. Schneier, personal communication, Forest Laboratories, 1997). About 5 days later, ultrasound demonstrated no fetal heartbeat and an induced abortion was performed. The cause of death was thought to be caused by progressive multiple placental infarctions and fetal hypotrophy.

Several published reports have studied the efficacy and safety of oral fosfomycin during pregnancy (4–15). The drug has been used in all trimesters of pregnancy without apparent harm to the fetus or newborn.

A 1998 noninterventional observational cohort study described the outcomes of pregnancies in women who had been prescribed ≥ 1 of 34 newly marketed drugs by general practitioners in England (16). Of 1067 exposed pregnancies, fosfomycin was taken during the 1st trimester in two, both concluding with normal, full-term infants.

BREASTFEEDING SUMMARY

No reports describing the use of fosfomycin during human lactation have been

located. However, consistent with the molecular weight (about 259), the drug is excreted into colostrum and breast milk (3). In two women, the average colostrum and milk concentrations were 4.8 and 3.6 mcg/mL, respectively (colostrum:plasma and milk:plasma ratios 0.07). The risk to a nursing infant from this exposure is unknown, but modification of the infant's bowel flora may occur.

FOSINOPRIL

Antihypertensive

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of fosinopril in human pregnancy have been located. The 1st trimester experience with other angiotensin-converting enzyme (ACE) inhibitors does not suggest a risk of major anomalies. The use of this drug during the 2nd and 3rd trimesters may cause teratogenicity and severe fetal and neonatal toxicity. Fetal toxic effects may include anuria, oligohydramnios, fetal hypocalvaria, intrauterine growth restriction (IUGR), prematurity, and patent ductus arteriosus. Anuria-associated anhydramnios/oligohydramnios may produce fetal limb contractures, craniofacial deformation, and pulmonary hypoplasia. Severe anuria and hypotension, resistant to both pressor agents and volume expansion, may occur in the newborn following in utero exposure to valsartan. Newborn renal function and blood pressure should be closely monitored.

FETAL RISK SUMMARY

Fosinopril is an ACE inhibitor. In reproduction studies in rats at doses about 80–250 times the maximum recommended human dose based on body weight (MRHD), three similar orofacial malformations and one fetus with situs inversus were observed (1). No teratogenic effects were observed in rabbits at a dose up to 25 times the MRHD (1).

A retrospective study using pharmacy-based data from the Tennessee Medicaid program identified 209 infants, born between 1985 and 2000, who had 1st trimester exposure to ACE inhibitors (2). Infants of mothers with evidence of diabetes, either before or during pregnancy, were excluded, as were those exposed to angiotensin-receptor antagonists (ARBs), ACE inhibitors, or other antihypertensives beyond the 1st trimester, and those

exposed to known teratogens. Two comparison groups, those taking other antihypertensives (N = 202) and those taking no antihypertensives (N = 29,096), were formed. The number of major birth defects in each of the three groups was 18 (8.6%), 4 (2%), and 834 (2.9%), respectively. Compared with the no antihypertensives group, exposure to ACE inhibitors was associated with a significantly increased risk of major defects (relative risk [RR] 2.71, 95% confidence interval [CI] 1.72–4.27). When the analysis was conducted by the type of defect, the highest rates were with cardiovascular defects, 9, 2, and 294 respectively, RR 3.72, 95% CI 1.89–7.30, and with CNS defects, 3, 0, and 80, respectively, RR 4.39, 95% CI 1.37–14.02. The major defects observed in the subject group were as follows: atrial septal defect (N = 6) (includes three with pulmonic stenosis and/or three with patent ductus arteriosus (PDA), renal dysplasia (N = 2), PDA alone (N = 2), and one each of ventricular septal defect, spina bifida, microcephaly with eye anomaly, coloboma, hypospadias, intestinal and choanal atresia, Hirschsprung disease, and diaphragmatic hernia (2). In an accompanying editorial, it was noted that neither previous reports of 1st trimester exposure to ACE inhibitors nor the animal studies had observed an increased risk of birth defects (3). It also was noted that no mechanism for ACE inhibitor-induced teratogenicity was known. A subsequent communication raising concerns about the validity of the study in terms of adequate exclusion of diabetes, charting and coding errors in busy medical practices, and the effects of maternal obesity (4) was addressed by the investigators (5).

ACE inhibitors are human teratogens when used in the 2nd and 3rd trimesters, producing fetal hypocalvaria and renal defects. The cause of the defects and other toxicity is thought to be related to fetal hypotension and decreased renal blood flow. The compromise of the fetal renal system may result in severe, and at times fatal, anuria, both in the fetus and in the newborn. Anuria-associated oligohydramnios may produce pulmonary hypoplasia, limb contractures, PDA, craniofacial deformation, and neonatal death (6,7). Prematurity, IUGR, and severe neonatal hypotension may also be observed. Two reviews of fetal and newborn renal function indicated that both renal perfusion and glomerular plasma flow are low during gestation and that high levels of angiotensin II may be physiologically necessary to maintain glomerular filtration at low perfusion pressures (8,9). Fosinopril prevents the conversion of angiotensin I to angiotensin II and, thus, may lead to in utero renal failure. Since the primary means of removal of the drug is renal, the impairment of this system in the newborn prevents elimination of the drug, resulting in prolonged hypotension. Newborn renal function and blood pressure should be closely

monitored. If oligohydramnios occurs, stopping fosinopril may resolve the problem but may not improve infant outcome because of irreversible fetal damage (6). In those cases in which fosinopril must be used to treat the mother's disease, the lowest possible dose should be used, combined with close monitoring of amniotic fluid levels and fetal well-being. Guidelines for counseling exposed pregnant patients have been published and should be of benefit to health professionals faced with this task (6,10).

A 2012 review of the use of ACE inhibitors and ARBs in the 1st trimester concluded that there may be an elevated teratogenic risk, but the risk appeared to be related to other factors (11). The factors that typically coexist with hypertension in pregnancy included diabetes, advanced maternal age, and obesity.

BREASTFEEDING SUMMARY

No published reports describing the use of fosinopril during lactation have been located. The manufacturer states that the drug can be detected in milk after a daily dose of 20 mg given for 3 days (1). Although the effects of this exposure on a nursing infant are unknown, the American Academy of Pediatrics classifies two other similar agents (see Captopril and Enalapril) as compatible with breastfeeding.

FOSPROPOFOL

Hypnotic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of fospropofol in human pregnancy have been located. The agent is converted to its active metabolite propofol for which there is limited human pregnancy experience but not in the first half of gestation. Although the animal data suggest low risk, human data are required for a complete assessment of the embryo–fetal risk. As with propofol, use of the prodrug near birth may cause transient depression of the newborn (see Propofol).

FETAL RISK SUMMARY

Fospropofol is a prodrug that is metabolized by alkaline phosphatases to propofol, which undergoes further metabolism. It is indicated for monitored anesthesia care sedation in adult patients undergoing diagnostic or therapeutic procedures. The mean elimination half-life of fospropofol is 0.88 hours, whereas the mean elimination half-life of propofol from fospropofol is 1.13 hours. Both fospropofol and its active metabolite propofol are highly plasma protein bound (about 98%) primarily to albumin (1).

Reproduction studies have been conducted in rats and rabbits. In these species, doses up to 0.6 and 1.7 times, respectively, the anticipated human dose for a 16-minute procedure based on BSA (HD) revealed no evidence of embryo–fetal harm or impaired fertility. In rats, the highest doses caused significant maternal toxicity, whereas in rabbits all doses caused significant maternal toxicity. When rats were given doses up to 0.2 times the HD from gestation day 7 through lactation day 20, no clear treatment-related effects on growth, development, behavior (passive avoidance and water maze), or fertility and mating capacity of the offspring were noted (1).

Long-term studies for carcinogenicity have not been conducted with fospropofol. The drug was not genotoxic in two assays, with or without metabolic activation. However, in a third assay, fospropofol was mutagenic in the presence of metabolic activation but the finding was thought to have been an artifact of the culture conditions (1).

It is not known if fospropofol crosses the human placenta. The molecular weight (about 332 for the disodium salt form) is low enough, but the extensive plasma protein binding and relatively short elimination half-life suggest that transfer will be limited. However, the active metabolite propofol does cross, with an umbilical vein:maternal vein ratio of 0.7 (see Propofol).

BREASTFEEDING SUMMARY

No reports describing the use of fospropofol during human lactation have been located. The molecular weight (about 332 for the disodium salt form) is low enough for excretion, but the extensive plasma protein binding and relatively short elimination half-life should limit the amount in milk. Small amounts of the active metabolite propofol are excreted into colostrum and milk following use of the agent for the induction and maintenance of maternal anesthesia during cesarean delivery (see Propofol).

FROVATRIPTAN

Antimigraine

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of frovatriptan in human pregnancy have been located. The animal data suggest low risk, but an assessment of the actual risk cannot be determined until human pregnancy experience is available. Although a 2008 review of triptans in pregnancy found no evidence for teratogenicity, the data did suggest a possible increase in the rate of preterm birth (1).

FETAL RISK SUMMARY

Frovatriptan is an oral selective serotonin (5-hydroxytryptamine [5-HT]) receptor agonist that has high affinity for 5-HT_{1B} and 5-HT_{1D} receptors. The drug is closely related to almotriptan, eletriptan, naratriptan, rizatriptan, sumatriptan, and zolmitriptan. It is indicated for the acute treatment of migraine with or without aura in adults. Protein binding is minimal (about 15%). Several metabolites have been identified, but only one has affinity, lower than frovatriptan, for the 5-HT_{1B/1D} receptors. The mean terminal elimination half-life of frovatriptan is about 26 hours (2).

Reproduction studies have been conducted in rats and rabbits. In rats, frovatriptan was given during organogenesis at oral doses ranging from 130 to 1300 times the maximum recommended human dose based on BSA (MRHD). Dose-related increases were found in the incidences of dilated ureters, unilateral and bilateral pelvic cavitation, hydronephrosis, and hydroureters. The renal effects were thought to be consistent with a slight delay in fetal maturation. A no-effect dose for this toxicity was not established. Skeletal variations (incomplete ossification of the sternbrae, skull, and nasal bones) were observed at all doses. In pregnant rabbits, oral doses up to 210 times the

MRHD during organogenesis revealed no effects on fetal development (2).

It is not known if frovatriptan or its less active metabolite crosses the human placenta to the fetus. The molecular weight of the parent compound (about 243 for the free base) is low enough that passage to the fetus should be expected. In addition, the minimal protein binding and prolonged elimination half-life suggest that the drug will be available for transfer at the maternal:fetal interface.

BREASTFEEDING SUMMARY

No reports describing the use of frovatriptan during human lactation have been located. The molecular weight (about 243 for the free base), low plasma protein binding (about 15%), and prolonged elimination half-life (about 26 hours) suggest that the drug will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown, but using an antimigraine agent with a shorter half-life should be considered.

FURAZOLIDONE

Anti-infective

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports linking the use of furazolidone with congenital defects have been located.

FETAL RISK SUMMARY

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 132 of whom had 1st trimester exposure to furazolidone (1). No association with malformations was found. Theoretically, furazolidone could produce hemolytic anemia in a glucose-6-phosphate dehydrogenase-deficient newborn if given at term. Placental passage of the drug has not been reported.

BREASTFEEDING SUMMARY

No reports describing the use of furazolidone during human lactation have been located.

FUROSEMIDE

Diuretic

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Administration of furosemide during pregnancy does not significantly alter amniotic fluid volume (1). Serum uric acid levels, which are increased in toxemia, are further elevated by furosemide (2). No association was found in a 1973 study between furosemide and low platelet counts in the neonate (3). Unlike the thiazide diuretics, neonatal thrombocytopenia has not been reported for furosemide.

FETAL RISK SUMMARY

Furosemide is a potent diuretic. The drug has caused maternal deaths and abortions in rabbits at doses 2, 4, and 8 times the maximum recommended human dose of 600 mg/day (4).

An increase in the incidence and severity of hydronephrosis (distention of the renal pelvis and in some cases of the ureters) has also been observed in the offspring of mice and rabbits (4). Wavy ribs and some skeletal defects have been observed in the offspring of rats given furosemide during organogenesis (5). These effects appeared to be caused directly or indirectly by the diuretic action of the drug.

Cardiovascular disorders, such as pulmonary edema, severe hypertension, or congestive heart failure, are probably the only valid indications for this drug in pregnancy. Furosemide crosses the placenta (6). Following oral doses of 25–40 mg, peak concentrations in cord serum of 330 ng/mL were recorded at 9 hours. Maternal and cord levels were equal at 8 hours. Increased fetal urine production after maternal furosemide therapy has been observed (7,8). Administration of furosemide to the mother has been used to assess fetal kidney function by provoking urine production, which is then visualized by ultrasonic techniques (9,10). Diuresis was found more often in newborns

exposed to furosemide shortly before birth than in controls (11). Urinary sodium and potassium levels in the treated newborns were significantly greater than in the nonexposed controls.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 350 newborns had been exposed to furosemide during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 18 (5.1%) major birth defects were observed (15 expected). Specific data were available for six defect categories, including (observed/expected) 2/4 cardiovascular defects, 1/1 oral clefts, 0/0 spina bifida, 1/1 polydactyly, 1/1 limb reduction defects, and 3/1 hypospadias. Only with the latter defect is there a suggestion of an association, but other factors, including the mother's disease, concurrent drug use, and chance, may be involved.

In the 2nd and 3rd trimesters, furosemide has been used for edema, hypertension, and toxemia of pregnancy without causing fetal or newborn adverse effects (1,12–33). One case report described the use of oral furosemide throughout gestation for the treatment of Gordon's syndrome (short stature, defective dentition, hyperkalemic hyperchloremic acidosis, and chronic hypertension) (34). A cesarean section at 32 weeks' gestation gave birth to an 1100-g female infant with Apgar scores of 8 and 9. Except for respiratory distress due to prematurity and hyperkalemia that required treatment, the infant did well.

Many investigators now consider diuretics contraindicated in pregnancy, except for patients with cardiovascular disorders, since they do not prevent or alter the course of toxemia and they may decrease placental perfusion (35–38). A 1984 study determined that the use of diuretics for hypertension in pregnancy prevented normal plasma volume expansion and did not change perinatal outcome (39). Thus, diuretics are not recommended for the treatment of gestational hypertension and/or preeclampsia because of the maternal hypovolemia characteristic of these conditions.

BREASTFEEDING SUMMARY

Furosemide is excreted into breast milk (4,40). No reports of adverse effects in nursing infants have been found. Thiazide diuretics have been used to suppress lactation (see Chlorothiazide).

G

GABAPENTIN

Anticonvulsant

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

A 2005 report of gabapentin monotherapy raises concerns of drug-induced developmental toxicity (1). Although limited, other studies involving monotherapy have not confirmed these findings. Moreover, a 2012 review concluded that the available data were not sufficient to determine whether or not exposure to gabapentin was harmful to the fetus (2). Because the agent is often combined with other anticonvulsants, the actual cause of a defect may be obscured. If a woman's condition requires gabapentin, the benefits of therapy to her appear to outweigh the potential risks to her embryo and/or fetus. A 2009 review on the treatment of cluster headache in pregnancy and lactation concluded that, if indicated, gabapentin was the drug of choice (3).

FETAL RISK SUMMARY

Gabapentin (Neurontin) is an anticonvulsant used as adjunctive therapy for the treatment of partial seizures in patients with epilepsy (4,5). The drug also is indicated for the management of postherpetic neuralgia in adults (5). Gabapentin enacarbil (Horizant) is a prodrug that undergoes extensive first-pass hydrolysis by enterocytes and to a lesser extent in the liver to form gabapentin so that blood levels are low and transient ($\leq 2\%$ of gabapentin plasma levels) (6). The prodrug is indicated for the treatment of moderate-to-severe restless legs syndrome (6). Gabapentin has been used off-label for

multiple other conditions, including migraine and chronic headache, bipolar disorder, peripheral neuropathy, diabetic neuropathy, complex regional pain syndrome, attention deficit disorder, trigeminal neuralgia, periodic limb movement disorder of sleep, and alcohol withdrawal syndrome (7).

Fetotoxicity in mice exposed during organogenesis to maternal oral doses of about 1–4 times the maximum recommended human dose based on BSA (MRHD) was characterized by delayed ossification of bones in the skull, vertebrae, forelimbs, and hindlimbs. The no-effect dose in mice was about half of the MRHD. Delayed ossification was also observed in rats exposed in utero to 1–5 times the MRHD. Hydroureter or hydronephrosis was observed in rat pups exposed in utero during organogenesis and during the perinatal and postnatal periods after similar doses. The causes of the urinary tract anomalies were unclear. The no-effect dose in rats during organogenesis was approximately equal to the MRHD in the teratogenicity study. When compared with controls, exposure to gabapentin during organogenesis did not increase congenital malformations, other than hydroureter or hydronephrosis in rats, in mice, rats, and rabbits at 4, 5, or 8 times, respectively, the MRHD. In rabbits, doses less than about ¼ to 8 times the MRHD caused an increased incidence of postimplantation fetal loss (5).

Animal reproduction studies have been conducted with gabapentin enacarbil (6). In rats and rabbits given the drug throughout organogenesis, increased embryo–fetal mortality and decreased fetal body weights were observed. The no-effect dose in rats and rabbits was about 3 and 16 times, respectively, the recommended human dose of 600 mg/day based on BSA (RHD). When rats were dosed throughout pregnancy and lactation, decreased growth and survival were noted. The no-effect dose was about three times the RHD (6).

Both gabapentin and gabapentin enacarbil were carcinogenic (pancreatic acinar cell adenomas and carcinomas) in rats, but assays for mutagenicity were negative. No adverse effects on fertility were observed with either agent (5,6).

Consistent with its low molecular weight (about 171), absence of metabolism and plasma protein binding, gabapentin crosses the placenta. In a 2005 study involving six women, the mean cord:maternal plasma concentration ratio was 1.7 (range 1.3–2.1) (8). The drug declined in the neonates with an estimated half-life of 14 hours.

No cases of fetal or newborn adverse outcomes were reported to the FDA through 1996 (F. Rosa, personal communication, FDA, 1996).

A 2005 abstract reported 62 pregnancy outcomes after exposure to

gabapentin, lamotrigine, or topiramate (1). The study included a blinded dysmorphology examination. Thirty women used gabapentin, one of whom delivered an infant with a major malformation: pyloric stenosis with bilateral fifth finger clinodactyly and prominent epicanthal folds (mother treated for seizures with monotherapy). Two of the 13 infants that were examined by a dysmorphologist had anticonvulsant facies (one monotherapy and the other combined with carbamazepine). In addition, two had neurologic abnormalities: failure to gaze up (sunsetting), opisthotonus, frontal bossing, medial flare of the eyebrows, and small for gestational age (mother treated for depression with gabapentin, doxepin, clonazepam, nefazodone, and zolpidem); sunsetting and metopic ridge (mother treated for chronic fatigue and fibromyalgia with gabapentin, lorazepam, and fluoxetine). Although they were not conclusive, the findings suggested reason for concern with gabapentin, as well as the same phenotype that has been observed with older anticonvulsants (1).

In a brief 1995 communication, a newborn exposed to gabapentin and carbamazepine during pregnancy had a cyclops holoprosencephaly (no nose and one eye) (9). Of the seven suspected cases of holoprosencephaly described in this report, five involved the use of carbamazepine (two cases of monotherapy and three of combined therapy). Because of the lack of family histories, an association with familial holoprosencephaly or maternal neurologic problems could not be excluded (9).

The Lamotrigine Pregnancy Registry, an ongoing project conducted by the manufacturer, was first published in January 1997 (10). The final report was published in July 2010. The Registry is now closed. Among 32 prospectively enrolled pregnancies exposed to gabapentin and lamotrigine, with or without other anticonvulsants, 27 were exposed in the 1st trimester, resulting in 25 live births without defects, 1 spontaneous abortion (SAB), and 1 birth defect. There were five exposures in the 2nd/3rd trimester resulting in live births without defects (10).

A 1998 noninterventional observational cohort study described the outcomes of pregnancies in women who had been prescribed ≥ 1 of 34 newly marketed drugs by general practitioners in England (11). Data were obtained by questionnaires sent to the prescribing physicians 1 month after the expected or possible date of delivery. In 831 (78%) of the pregnancies, a newly marketed drug was thought to have been taken during the 1st trimester with birth defects noted in 14 (2.5%) singleton births of the 557 newborns (10 sets of twins). In addition, two birth defects were observed in aborted fetuses. However, few of the aborted fetuses were examined. Gabapentin was taken during the 1st

trimester in 17 pregnancies. The outcomes of these pregnancies included 2 SABs, 4 elective abortions (EABs), and 11 normal newborns (1 premature) (11). Although no congenital malformations were observed, the study lacked the sensitivity to identify minor anomalies. Late-appearing major defects may also have been missed due to the timing of the questionnaires.

A 1996 review reported 16 pregnancies exposed to gabapentin from preclinical trials and postmarketing surveillance (12). The outcomes of these pregnancies included five EABs, one ongoing pregnancy, seven normal infants, and three infants with birth defects. No specific information was provided on the defects other than that there was no pattern of malformation and all had been exposed to polytherapy for epilepsy (12).

A 2002 review concluded that gabapentin could be used for chronic headache during early pregnancy but not later because of concerns about delaying fetal bony growth plate development (13). The reason for this concern was not stated, but the animal data above may have influenced the conclusion. In a 2002 report of a postmarketing surveillance study in England, there were no congenital anomalies in the 11 infants of women who used gabapentin in the 1st trimester (14).

Results from the Neurontin Pregnancy Registry were reported in 2003 (15). There were 51 fetuses, including 3 sets of twins, from 39 women with epilepsy and other disorders. At conception, 17 were taking gabapentin alone, 30 were taking it with other antiepileptic drugs, and 4 were not receiving gabapentin. At delivery, the numbers were 19, 21, and 4, respectively. There were six SABs and one EAB. Among the 44 live births, there were 2 (4.5%) major anomalies: hypospadias (gabapentin plus valproate) and single kidney (gabapentin alone, changed to phenobarbital at 16 weeks'). There also was one (2.3%) minor defect (defect of left external ear canal and two small skin tags on the jaw). The outcomes were comparable to the risk of major (4%–8%) defects in infants of epileptic mothers and the risk of minor (3%–10%) defects in the general population (15).

The United Kingdom Epilepsy and Pregnancy Register prospective study reported the malformation risks of antiepileptic drugs (AEDs) (16). Among the 3607 cases, there were 31 pregnancies (excludes an unspecified number of pregnancy losses with no major defects) exposed to gabapentin monotherapy. There was one major anomaly (type not specified). Compared to no exposure to AED, the adjusted odds ratio was 1.76, 95% confidence interval 0.22–14.49 ($p = 0.596$) (16).

A brief report described the use of gabapentin in seven women with

hyperemesis gravidarum (17). Therapy was started at a mean gestational age of 8 weeks and discontinued at a median gestational age of 21 weeks (range 10–25 weeks). The mean dose was 1843 mg (range 1200–3000 mg). Two birth defects were observed: hydronephrosis and tethered spinal cord. The latter defect occurred in an infant conceived by in vitro fertilization, a process known to increase the risk of congenital defects (17).

A study published in 2009 examined the effect of AEDs on the head circumference in newborns (18). Significant reductions in mean birth-weight-adjusted mean head circumference (bw-adj-HC) was noted for monotherapy with carbamazepine and valproic acid. No effect on bw-adj-HC was observed with gabapentin, phenytoin, clonazepam, and lamotrigine. A significant increase in the occurrence of microcephaly (bw-adj-HC smaller than 2 standard deviations below the mean) was noted after any AED polytherapy but not after any monotherapy, including carbamazepine and valproic acid. The potential effects of these findings on child development warrant study (18).

A 2013 prospective cohort study compared the outcomes of 223 pregnancies exposed to gabapentin (average dose 1000 mg/day, range 100–4800 mg/day combined with other drugs) with 223 pregnancies not exposed to gabapentin or known teratogens (19). Indications for use of gabapentin were known in 207 cases: epilepsy (34%), pain (90%), and psychiatric conditions (22%). In the two groups, there was no statistical difference in the number of major malformations 7 (4.1%) vs. 5 (2.5%), SABs 22 (9.8%) vs. 17 (7.6%), stillbirths 2 (1.1%) vs. 0, or IUGR 6 (3.5%) vs. 4 (1.9%). Statistically significant outcomes were found for live births (76.2% vs. 90%), EABs (13% vs. 2.2%), preterm birth (10.5% vs. 3.9%), and low (<2500 g) birth weight (10.5% vs. 4.4%). The seven infants with major malformations were exposed to gabapentin and other drugs in the 1st trimester. The defects were ventricular septal defect (2 infants); anencephaly; macrocephaly, micrognathism, and cutis marmorata; pyloric stenosis; bilateral varus clubfoot; and cryptorchidism. Although the authors noted the small size of their study, and the absence of a comparative group with other antiepileptic drugs, they concluded that gabapentin did not appear to increase the risk for major malformations (19).

A 27-year-old woman was diagnosed about 2 months before pregnancy with stiff person syndrome (Moersche-Woltman syndrome) (20). She was treated with gabapentin (2700 mg/day), diazepam (30 mg/day), and a prednisone taper. When pregnancy was diagnosed, diazepam was discontinued but, without the drug, her muscle spasms increased and baclofen (30 mg/day) was started. The patient was able to wean down her medications in the 2nd and 3rd

trimesters (specific details not provided). Labor commenced at about 40 weeks' while still on gabapentin and baclofen. A cesarean section was conducted because of fetal repetitive late decelerations to deliver a 3230-g female infant with Apgar scores of 5 and 8 at 1 and 5 minutes, respectively. The infant, discharged home on day 4, was doing well (age assumed to be 6 weeks) (20).

BREASTFEEDING SUMMARY

Consistent with its low molecular weight (about 171) and lack of plasma protein binding, gabapentin is excreted breast milk. A 2005 study described the use of gabapentin during pregnancy in five women, three of whom breastfed their infants (7). One infant was born at 33 weeks', but all five had normal Apgar scores. No congenital defects were noted in the five infants. In the three women who breastfed, their doses were 600, 1800, and 2100 mg/day, respectively. Milk and plasma sampling occurred on postpartum days 21, 16, and 97, respectively. Infant plasma levels of gabapentin after completion of nursing were 1.3, 1.5, and 1.9 μM , respectively, and the milk:plasma ratios were 1.0, 1.3, and 0.8, respectively. The estimated infant dose as a percentage of the mother's weight-adjusted dose was 1.3%–3.8% (not specified by infant) (7).

In a 2006 case report, a 34-year-old mother had been taking gabapentin 600 mg three times daily (36.7 mg/kg/day) and amitriptyline 2.5 mg/day for 6 weeks while nursing her male infant (21). On the date the milk samples were obtained, her infant was 1.6 months old and weighed 3.1 kg. The milk:plasma ratio was 0.86 and the relative infant was 2.34% of the mother's weight-adjusted dose. The plasma concentration in the infant (0.4 mg/L) was about 6% of the mother's plasma concentration. No adverse effects were noted in the infant, who was doing well (21).

GADOBENATE DIMEGLUMINE

Diagnostic Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Gadolinium-based contrast agents are complexes with chelating agents that lower the potential toxicity in patients receiving the agents by preventing the cellular uptake of free gadolinium. The complexes cross the placenta to the fetus and are excreted by the fetal kidneys into the amniotic fluid, where they remain for long periods. The complexes themselves are relatively nontoxic, but dissociation may occur to release free gadolinium into the amniotic fluid where it could expose fetal lungs and gut. Presently, the risk of gadolinium-induced toxicity in the fetus is unknown but may be harmful (1–3). A concern has been raised for a risk of gadolinium-induced nephrogenic systemic fibrosis (3). The American College of Radiology recommends that these agents should not be routinely used in pregnancy and, if such use is indicated, a written informed consent be obtained from the patient (1). The guidelines of the Contrast Media Safety Committee of the European Society of Urogenital Radiology and a review article recommend that gadolinium-based contrast media may be used in pregnancy if such use is important to the mother's health (4,5).

FETAL RISK SUMMARY

Gadobenate dimeglumine, a paramagnetic agent, is a complex formed between a chelating agent and a paramagnetic ion, gadolinium. It is in the same subclass of gadolinium-based contrast agents as gadodiamide, gadofosveset trisodium, gadopentetate dimeglumine, gadoteridol, and gadoversetamide. Gadobenate dimeglumine is given IV for magnetic resonance imaging (MRI) of the central nervous system in adults. Neither metabolism nor plasma protein binding of the agent has been detected. The mean elimination half-life is about

1–2 hours (6).

Reproduction studies have been conducted in rats and rabbits. In rats, no evidence of teratogenicity, other developmental toxicities (i.e., birth, survival, growth, development, and fertility of the next generation), or maternal toxicity at a daily IV dose that was three times the human dose based on BSA (HD). Teratogenicity (microphthalmia/small eye and/or focal retinal fold in three fetuses from three litters) was observed in rabbits given a daily IV dose during organogenesis that was six times the HD. A dose that was 10 times the HD resulted in increased intrauterine deaths (6).

Long-term studies to evaluate the potential for carcinogenicity have not been conducted. Assays for mutagenicity and chromosome aberrations assay were negative. No effect on male and female rat fertility was observed with daily IV doses up to three times the HD. A dose five times the HD caused irreversible toxicity in male rat reproductive organs. These effects were not observed in dog and monkey studies with doses up to about 11 and 10 times, respectively, the HD (6).

BREASTFEEDING SUMMARY

Although no reports describing the administration of gadobenate dimeglumine during human lactation have been located, reviewers consider gadolinium contrast media to be compatible with breastfeeding because of the very small amounts excreted into milk and potentially being absorbed by a nursing infant (2–4). The American Academy of Pediatrics classifies gadopentetate dimeglumine as compatible with breastfeeding (7) (see Gadopentetate Dimeglumine).

GADOBUTROL

Diagnostic (Radiopaque Agent)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of gadobutrol in human pregnancy have been located. Gadolinium-based contrast agents are complexes with chelating agents that lower the potential toxicity in patients receiving the agents by preventing the cellular uptake of free gadolinium. The complexes cross the placenta to the fetus and are excreted by the fetal kidneys into the amniotic fluid, where they remain for long periods. The complexes themselves are relatively nontoxic, but dissociation may occur to release free gadolinium into the amniotic fluid, where it could expose fetal lungs and gut. Presently, the risk of gadolinium-induced toxicity in the fetus is unknown but may be harmful (1–3). A concern has been raised for a risk of gadolinium-induced nephrogenic systemic fibrosis (3). The American College of Radiology recommends that these agents should not be routinely used in pregnancy and, if such use is indicated, a written informed consent be obtained from the patient (1). The guidelines of the Contrast Media Safety Committee of the European Society of Urogenital Radiology and a review article recommend that gadolinium-based contrast media may be used in pregnancy if such use is important to the mother's health (4,5).

FETAL RISK SUMMARY

Gadobutrol, a gadolinium-based contrast agent, is a paramagnetic macrocyclic administered for magnetic resonance imaging (MRI). It is indicated for IV use in diagnostic MRI in adults and children 2 years of age or older to detect and visualize areas with disrupted blood–brain barrier and/or abnormal vascularity of the central nervous system. The agent does not display any particular protein binding and is not metabolized. The mean terminal half-life is 1.81 hours

(6).

Reproduction studies have been conducted in rats, rabbits, and monkeys. In rats, maternally toxic doses that were 12 times the human equivalent dose based on BSA (HED) caused retardation of the embryo development and embryolethality. Similar toxicity, but without evidence of maternal toxicity, occurred in rabbits at doses that were 8 times the HED. In rabbits, the toxicity occurred despite minimal placental transfer (0.01% of the dose detected in the fetuses). In monkeys, gadobutrol was not teratogenic but was embryolethal when given IV during organogenesis in doses up to 8 times the recommended single human dose based on BSA. However, pregnant animals received repeated daily doses so their exposure was much higher than that obtained with the standard single dose in humans (6).

Studies for carcinogenicity have not been conducted. Multiple assays for mutagenicity were negative. No effect on fertility and general reproductive performance was observed in male and female rats (6).

It is not known if gadobutrol crosses the human placenta. However, other gadolinium-based contrast agents cross (see Gadobenate Dimeglumine and other agents in this subclass) and exposure of the embryo–fetus should be expected with gadobutrol. The molecular weight (about 605) and the terminal half-life are consistent with placenta transfer.

BREASTFEEDING SUMMARY

No reports describing the use of gadobutrol during human lactation have been located. However, the molecular weight (about 605) and terminal half-life (1.81 hours) suggest that the drug will be excreted into breast milk. Although there are no reports, reviewers consider gadolinium contrast media to be compatible with breastfeeding because of the very small amounts excreted into milk and potentially being absorbed by a nursing infant (2–4). The American Academy of Pediatrics classifies gadopentetate dimeglumine as compatible with breastfeeding (7) (see Gadopentetate Dimeglumine).

GADODIAMIDE

Diagnostic Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Available gadolinium-based contrast agents are complexes with chelating agents that lower the potential toxicity in patients receiving the agents by preventing the cellular uptake of free gadolinium. The complexes cross the placenta to the fetus and are excreted by the fetal kidneys into the amniotic fluid, where they remain for long periods. The complexes themselves are relatively nontoxic, but dissociation may occur to release free gadolinium into the amniotic fluid, where it could expose fetal lungs and gut. Presently, the risk of gadolinium-induced toxicity in the fetus is unknown but may be harmful (1–3). A concern has been raised for a risk of gadolinium-induced nephrogenic systemic fibrosis (3). The American College of Radiology recommends that these agents should not be routinely used in pregnancy and, if such use is indicated, a written informed consent be obtained from the patient (1). In addition, the guidelines of the Contrast Media Safety Committee of the European Society of Urogenital Radiology and a review article recommend that gadolinium-based contrast media may be used in pregnancy if such use is important to the mother's health (4,5).

FETAL RISK SUMMARY

Gadodiamide, a paramagnetic agent, is a complex formed between a chelating agent and a paramagnetic ion, gadolinium. It is in the same subclass of gadolinium-based contrast agents as gadobenate dimeglumine, gadofosveset trisodium, gadopentetate dimeglumine, gadoteridol, and gadoversetamide. Gadodiamide is indicated for IV use in magnetic resonance imaging (MRI) to visualize lesions with abnormal vascularity (or those thought to cause abnormalities in the blood–brain barrier) in the brain (intracranial lesions), spine,

and associated tissues. It is also indicated for IV administration to facilitate the visualization of lesions with abnormal vascularity within the thoracic (noncardiac), abdominal, and pelvic cavities, and the retroperitoneal space. Neither metabolism nor plasma protein binding has been detected. The elimination half-life is about 78 minutes (6).

Reproduction studies have been conducted in rats and rabbits. Increased incidences of flexed appendages and skeletal malformations were observed in rabbits given a daily IV dose for 13 days during gestation that was about 0.6 times the human dose (HD) based on mmol/m². The skeletal malformations may have due to maternal toxicity (reduced body weight). Neither fetal abnormalities nor maternal toxicity were observed in rats at a daily IV dose given for 10 days during gestation that was 1.3 times the HD based on mg/m² (6).

Long-term studies to evaluate the potential for carcinogenicity have not been conducted. Assays for mutagenicity and chromosome aberrations assay were negative. No effect on male and female rat fertility was observed with a low IV dose given three times weekly (6).

BREASTFEEDING SUMMARY

Although no reports describing the administration of gadodiamide during human lactation have been located, reviewers consider gadolinium contrast media to be compatible with breastfeeding because of the very small amounts excreted into milk and potentially being absorbed by a nursing infant (2–4). The American Academy of Pediatrics classifies gadopentetate dimeglumine as compatible with breastfeeding (7) (see Gadopentetate Dimeglumine).

GADOFOSVESET

Diagnostic Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Available gadolinium-based contrast agents are complexes with chelating agents that lower the potential toxicity in patients receiving the agents by preventing the cellular uptake of free gadolinium. The complexes cross the placenta to the fetus and are excreted by the fetal kidneys into the amniotic fluid, where they remain for long periods. The complexes themselves are relatively nontoxic, but dissociation may occur to release free gadolinium into the amniotic fluid, where it could expose fetal lungs and gut. Presently, the risk of gadolinium-induced toxicity in the fetus is unknown but may be harmful (1–3). A concern has been raised for a risk of gadolinium-induced nephrogenic systemic fibrosis (3). The American College of Radiology recommends that these agents should not be routinely used in pregnancy and, if such use is indicated, a written informed consent be obtained from the patient (1). In addition, the guidelines of the Contrast Media Safety Committee of the European Society of Urogenital Radiology and a review article recommend that gadolinium-based contrast media may be used in pregnancy if such use is important to the mother's health (4,5).

FETAL RISK SUMMARY

Gadofosveset, a paramagnetic agent, is a complex formed between a chelating agent and a paramagnetic ion, gadolinium. It is in the same subclass of gadolinium-based contrast agents as gadobenate dimeglumine, gadodiamide, gadopentetate dimeglumine, gadoteridol, and gadoversetamide. Gadofosveset trisodium is indicated for use as a contrast agent in magnetic resonance angiography (MRA) to evaluate aortoiliac occlusive disease in adults with known or suspected peripheral vascular disease. It binds reversibly to serum

albumin, resulting in longer time in the vascular system than non-protein-binding contrast agents. Metabolism has not been detected and the mean elimination half-life is about 16 hours (6).

Reproduction studies have been conducted in rats and rabbits. In rats and rabbits, daily doses up to about 11 and 21.5 times, respectively, the human dose based on BSA (HD) did not cause fetal anomalies. In both species, the highest dose caused maternal toxicity. In rabbits, a daily dose 3 times the HD caused increased postimplantation loss, resorptions, and dead fetuses (6).

Long-term studies to evaluate the potential for carcinogenicity have not been conducted. Assays for mutagenicity and chromosome aberrations assay were negative. Male and female rat fertility was not impaired with daily doses up to 8.3 times the HD given for 4 and 2 weeks, respectively (6).

BREASTFEEDING SUMMARY

Although no reports describing the administration of gadofosveset during human lactation have been located, reviewers consider other gadolinium-based contrast media to be compatible with breastfeeding because of the very small amounts excreted into milk and potentially being absorbed by a nursing infant (2–4). The American Academy of Pediatrics classifies gadopentetate dimeglumine as compatible with breastfeeding (7) (see Gadopentetate Dimeglumine). However, gadofosveset has a much longer elimination half-life (16 hours) than other gadolinium-based contrast agents and, even though the agent is bound to albumin, the binding is reversible. Until human data are available, withholding breastfeeding for 24 hours or longer should lessen the amount available for excretion into breast milk.

GADOPENTETATE DIMEGLUMINE

Diagnostic Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Available gadolinium-based contrast agents are complexes with chelating agents that lower the potential toxicity in patients receiving the agents by preventing the cellular uptake of free gadolinium. The complexes cross the placenta to the fetus and are excreted by the fetal kidneys into the amniotic fluid, where they remain for long periods. The complexes themselves are relatively nontoxic, but dissociation may occur to release free gadolinium into the amniotic fluid, where it could expose fetal lungs and gut. Presently, the risk of gadolinium-induced toxicity in the fetus is unknown but may be harmful (1–3). A concern has been raised for a risk of gadolinium-induced nephrogenic systemic fibrosis (3). The American College of Radiology recommends that these agents should not be routinely used in pregnancy and, if such use is indicated, a written informed consent be obtained from the patient (1). In addition, the guidelines of the Contrast Media Safety Committee of the European Society of Urogenital Radiology and a review article recommend that gadolinium-based contrast media may be used in pregnancy if such use is important to the mother's health (4,5).

FETAL RISK SUMMARY

Gadopentetate dimeglumine, a paramagnetic agent, is a complex formed between a chelating agent and a paramagnetic ion, gadolinium. It is in the same subclass of gadolinium-based contrast agents as gadobenate dimeglumine, gadodiamide, gadoversetamide, and gadoteridol. Gadopentetate dimeglumine is indicated for use with magnetic resonance imaging (MRI) in adults, and pediatric patients (2 years of age and older) to visualize lesions with abnormal vascularity in the brain (intracranial lesions), spine, and associated tissues. It also is indicated for use with MRI in adults and pediatric patients (2 years of

age and older) to facilitate the visualization of lesions with abnormal vascularity in the head, neck, and body (excluding the heart). Neither metabolism nor plasma protein binding has been detected. The mean elimination half-life is 1.6 hours (6).

Reproduction studies have been conducted in rats and rabbits. Although no congenital malformations were observed, daily IV doses in these species that were 7.5–12.5 times the human dose based on body weight (HD) resulted in slight retardation of development. Doses that were 2.5 times the HD did not cause this effect (6). The contrast agent crosses the placenta to the fetus in rabbits (7).

Long-term studies for carcinogenicity potential have not been conducted. The drug was not mutagenic or clastogenic in several assays. High doses impaired fertility in male and female rats, including dose-related irreversible toxicity of male rat reproductive organs (6).

In a 1997 report, 11 women at 16–37 weeks' gestation underwent gadolinium-enhanced MRI for suspected uterine or placental abnormalities (8). The placentas were rapidly and intensely enhanced immediately after administration of the contrast agent. Three patients were in the 2nd trimester and eight were in the 3rd trimester. All infants were healthy at birth (8).

A 1992 case report described the inadvertent IV bolus administration of gadopentetate dimeglumine (0.2 mmol/kg) to a woman with multiple sclerosis shortly after conception (9). Her last menstrual period had occurred 23 days before the MRI procedure, thus giving her an estimated gestational length of 9 days. Because this was before the period of organogenesis, the authors of the report concluded that the most likely adverse effect would have been an early spontaneous abortion, rather than congenital malformations. A normal pregnancy occurred, however, terminating in the delivery of a healthy baby girl at 39 weeks' gestation. The infant was developing normally at 3 months of age (9).

A 1993 report described two women at 3 and 5 months' gestation, respectively, who were given the contrast agent for MRI diagnosis of Crohn's disease (10). Both patients delivered healthy infants at term.

Eleven women with symptomatic hydronephrosis at 19–34 weeks' underwent gadolinium-enhanced (gadopentetate dimeglumine) MRI excretory urography (11). There were no adverse effects of the procedure in the pregnancies. All of the infants had good Apgar scores, none had a birth weight below the third centile adjusted for gestational age and sex, and one had an umbilical hernia.

A prospective cohort study, conducted by a teratology information service in

Italy, described the outcomes of 26 women who had an MRI with gadopentetate dimeglumine immediately before or after conception (12). Two cases were exposed preconceptional (4 and 12 days after the last menstrual period) and 24 were exposed at about a mean 30 days after the last menstrual period. Because of the short half-life of the agent, all of the exposures occurred before organogenesis. The outcomes were two spontaneous abortions (SABs), one elective abortion (mother taking valproic acid), two infants with low birth weight, and one infant with a congenital anomaly (hemangiomas; mother exposed at 31 days). No information was available on the two SABs. The 23 live births were all at term (12).

BREASTFEEDING SUMMARY

Gadopentetate dimeglumine is excreted into breast milk. A woman breastfeeding her infant was given the contrast agent 13 weeks after birth (13). Small amounts of the drug were found in her milk at 2, 11, 17, and 24 hours with a cumulative amount of 1.60 mcg-mols (0.023% of the administered dose).

A 2000 study described the excretion of gadopentetate dimeglumine into the breast milk of 19 women (14). One woman who was undergoing MRI received 0.2 mmol/kg IV (15 mmol), but the other 18 women received 0.1 mmol/kg (mean 5.9 mmol). Breastfeeding was stopped for at least 24 hours. The cumulative amount of drug excreted into milk over 24 hours was 0.57 μ mol (range 0.05–3.0 μ mol). This amount was a mean 0.009% (range 0.001% to 0.04%) of the mother's dose. Because the amount excreted into milk would be far less than the recommended IV dose for neonates (200 μ mol/kg), and because very little of orally administered gadopentetate dimeglumine is absorbed systemically, the authors concluded that waiting 24 hours to resume breastfeeding was not warranted (14). An editorial also concluded that waiting 24 hours was not required because of the small amounts in milk and the safety profile of the contrast agent in infants and children (15). The American Academy of Pediatrics classifies gadopentetate dimeglumine as compatible with breastfeeding (16), as do other reviewers (2–4).

GADOTERIDOL

Diagnostic Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Available gadolinium-based contrast agents are complexes with chelating agents that lower the potential toxicity in patients receiving the agents by preventing the cellular uptake of free gadolinium. The complexes cross the placenta to the fetus and are excreted by the fetal kidneys into the amniotic fluid, where they remain for long periods. The complexes themselves are relatively nontoxic, but dissociation may occur to release free gadolinium into the amniotic fluid, where it could expose fetal lungs and gut. Presently, the risk of gadolinium-induced toxicity in the fetus is unknown but may be harmful (1–3). A concern has been raised for a risk of gadolinium-induced nephrogenic systemic fibrosis (3). The American College of Radiology recommends that these agents should not be routinely used in pregnancy and, if such use is indicated, a written informed consent be obtained from the patient (1). In addition, the guidelines of the Contrast Media Safety Committee of the European Society of Urogenital Radiology and a review article recommend that gadolinium-based contrast media may be used in pregnancy if such use is important to the mother's health (4,5).

FETAL RISK SUMMARY

Gadoteridol, a paramagnetic agent, is a nonionic complex formed between a chelating agent and a paramagnetic ion, gadolinium. It is in the same subclass of gadolinium-based contrast agents as gadobenate dimeglumine, gadodiamide, gadofosveset trisodium, gadopentetate dimeglumine, and gadoversetamide. Gadoteridol is indicated for use in MRI in adults and children over 2 years of age to visualize lesions with abnormal vascularity in the brain (intracranial lesions), spine, and associated tissues. It also is indicated for use

in MRI in adults to visualize lesions in the head and neck. It is not known if gadoteridol is metabolized or if it binds to plasma proteins. The elimination half-life is about 1.57 hours (6).

Reproduction studies have been conducted in rats and rabbits. In rats, a daily IV dose given for 12 days during gestation that was six times the human dose based on mmol/m² (HD) doubled the incidence of postimplantation loss. This dose and a daily dose that was 40% lower given for 12 days caused an increase in spontaneous locomotor activity in rat offspring. In rabbits, an increase in the incidence of spontaneous abortions and early delivery was noted at a dose that was seven times the HD (6).

Studies to evaluate the potential for carcinogenicity or potential effects on fertility have not been conducted. Assays for mutagenicity and chromosome aberrations assay were negative. No effect on male and female rat fertility was observed with a low IV dose given three times weekly (6).

BREASTFEEDING SUMMARY

Although no reports describing the administration of gadoteridol during human lactation have been located, reviewers consider gadolinium contrast media to be compatible with breastfeeding because of the very small amounts excreted into milk and potentially being absorbed by a nursing infant (2–4). The American Academy of Pediatrics classifies gadopentetate dimeglumine as compatible with breastfeeding (7) (see Gadopentetate Dimeglumine).

GADOVERSETAMIDE

Diagnostic Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Available gadolinium-based contrast agents are complexes with chelating agents that lower the potential toxicity in patients receiving the agents by preventing the cellular uptake of free gadolinium. The complexes cross the placenta to the fetus and are excreted by the fetal kidneys into the amniotic fluid, where they remain for long periods. The complexes themselves are relatively nontoxic, but dissociation may occur to release free gadolinium into the amniotic fluid, where it could expose fetal lungs and gut. Presently, the risk of gadolinium-induced toxicity in the fetus is unknown but may be harmful (1–3). A concern has been raised for a risk of gadolinium-induced nephrogenic systemic fibrosis (3). The American College of Radiology recommends that these agents should not be routinely used in pregnancy and, if such use is indicated, a written informed consent be obtained from the patient (1). In addition, the guidelines of the Contrast Media Safety Committee of the European Society of Urogenital Radiology and a review article recommend that gadolinium-based contrast media may be used in pregnancy if such use is important to the mother's health (4,5).

FETAL RISK SUMMARY

Gadoversetamide, a paramagnetic agent, is a complex formed between a chelating agent (versetamide) and a paramagnetic ion (gadolinium). It is in the same subclass of gadolinium-based contrast agents as gadobenate dimeglumine, gadodiamide, gadofosveset trisodium, gadopentetate dimeglumine, and gadoteridol. Gadoversetamide is indicated for use with magnetic resonance imaging (MRI) in patients with abnormal blood–brain barrier or abnormal vascularity of the brain, spine, and associated tissues. The

agent also is indicated for use with MRI to provide contrast enhancement and facilitate visualization of lesions with abnormal vascularity in the liver in patients who are highly suspect for structural abnormalities of liver on computed tomography. Neither metabolites nor plasma protein binding has been detected. The mean elimination half-life is about 104 ± 20 minutes (6).

Reproduction studies have been conducted in rats and rabbits. In rats, daily IV doses given for 5 weeks (including gestation) that were equal to the human dose based on BSA (HD) reduced neonatal weights from birth through weaning. A dose 0.2 times the HD did not cause the effect. Neither dose was maternal toxic. A daily IV dose given on gestational days 7–17 that was 10 times the HD did cause maternal toxicity, as well as reduced mean fetal weight, abnormal liver lobation, delayed ossification of sternebrae, and delayed behavioral development (startle reflex and air rights reflex). These effects were not observed with doses that were equal to the HD. In rabbits, daily IV doses given during gestational days 6–18 that were 1 and 4 times the HD caused forelimb flexures and cardiovascular changes (malformed thoracic arteries, a septal defect, and abnormal ventricle) in fetuses. These effects were not observed at doses that were 0.3 times the HD. Maternal toxicity was not observed at any dose (6).

Long-term studies to evaluate the potential for carcinogenicity have not been conducted. Genotoxicity assays were negative but a chromosome aberration assay was positive. In fertility studies, daily IV doses given for 4 and 7 weeks that were 6 and 4 times the HD, respectively, caused irreversible toxicity in male rat reproductive organs and impaired fertility. These effects were not observed with a dose equal to the HD, nor were they observed in similar studies conducted in dogs. In a rat single-dose study, no adverse effects were seen on the male reproductive system 24 hours and 14 days after doses that were 1–25 times the HD (6).

BREASTFEEDING SUMMARY

Although no reports describing the administration of gadoversetamide during human lactation have been located, reviewers consider gadolinium contrast media to be compatible with breastfeeding because of the very small amounts excreted into milk and potentially being absorbed by a nursing infant (2–4). The American Academy of Pediatrics classifies gadopentetate dimeglumine as compatible with breastfeeding (7) (see Gadopentetate Dimeglumine).

GALANTAMINE

Cholinesterase Inhibitor (CNS Agent)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of galantamine in human pregnancy have been located. Because of its indication, such reports should be rare. Moreover, the animal data suggest that the risk to the embryo and/or fetus is low. Therefore, inadvertent exposure to galantamine during pregnancy should not be a reason for pregnancy termination.

FETAL RISK SUMMARY

Galantamine is a reversible cholinesterase inhibitor that is indicated for the treatment of mild-to-moderate dementia of the Alzheimer's type. The metabolites are apparently inactive. Plasma protein binding is low (18%) and the plasma elimination half-life is about 7 hours (1).

Reproduction studies have been conducted in rats and rabbits. In rats, a dose three times the maximum recommended human dose based on BSA (MRHD) given for 14 days before mating through organogenesis caused a slight increase in skeletal variations. No major malformations were observed with a dose seven times the MRHD. When rats were given doses three and seven times the MRHD from the beginning of organogenesis through postpartum day 21, pup weights were decreased. However, no other adverse effects on postnatal development were observed. The above doses also caused slight maternal toxicity. No impairment of fertility was observed in female rats given doses up to seven times the MRHD for 14 days or in male rats for 60 days before mating. In rabbits, doses up to 32 times the MRHD during organogenesis revealed no evidence of teratogenicity (1).

It is not known if galantamine crosses the human placenta. The molecular weight (about 287 for the free base), low plasma protein binding, and the

moderately long plasma elimination half-life suggest that the drug will cross to the embryo and/or fetus.

BREASTFEEDING SUMMARY

No reports describing the use of galantamine during human lactation have been located. Because of its indication, such reports should be rare. The molecular weight (about 287 for the free base), its low plasma protein binding (18%), and moderately long plasma elimination half-life (about 7 hours) suggest that galantamine will be excreted into breast milk. The effects of this exposure on a nursing infant are unknown.

GALSULFASE

Endocrine/Metabolic Agent (Enzyme)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data —Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of galsulfase in human pregnancy have been located. The animal data in two species suggest low risk. Because Maroteaux-Lamy syndrome is a debilitating chronic disease, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Galsulfase is a purified human enzyme that is produced by DNA technology. It is a glycoprotein that is given as weekly IV infusions. Galsulfase is indicated for patients with mucopolysaccharidosis VI (MPS VI; Maroteaux-Lamy syndrome) to improve walking and stair-climbing capacity. In 13 patients with MPS VI the medium half-life at weeks 1 and 24 were 9 and 26 minutes, respectively (1).

Reproduction studies have been conducted in rats and rabbits. In these species, IV doses up to about 0.5 and 0.97 times, respectively, the recommended human dose of 1 mg/kg based on BSA (RHD) revealed no evidence of impaired fertility or harm to the fetus (1).

Long-term studies in animals for carcinogenicity and mutagenicity have not been conducted. In male and female rats, an IV dose that was about 0.5 times the RHD had no effect on fertility and reproductive performance (1).

It is not known if galsulfase crosses the human placenta. The molecular weight (about 56,000) and brief half-life suggest that exposure of the embryo or fetus will be minimal, if it occurs at all.

Pregnant women treated with this agent are encouraged to enroll in the MPS VI Clinical Surveillance Program by calling 800-983-4587 (1).

BREASTFEEDING SUMMARY

No reports describing the use of galsulfase during lactation have been located. The molecular weight (about 56,000) and brief half-life (9–26 minutes) suggest that excretion into breast milk will be minimal, if it occurs at all. Moreover, as a glycoprotein, the agent would most likely be digested in the infant's gut.

GANCICLOVIR

Antiviral

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential
Toxicity

PREGNANCY SUMMARY

Cytomegalovirus (CMV) is the most common cause of congenital viral infection in the United States, infecting 0.2%–2.2% of all liveborn infants (1). Approximately 40% of primary CMV infections occurring during pregnancy will result in transplacental passage of the virus to the fetus. A relatively small percentage of these infants, however, will exhibit structural damage, such as symmetric growth restriction, hepatosplenomegaly, chorioretinitis, microphthalmia, cerebral calcification, hydrocephaly, and microcephaly. Some infants infected in utero will develop later toxicity as evidenced by deafness (CMV is the leading cause of congenital hearing loss), mental retardation, and impaired psychomotor development (1). The effectiveness of ganciclovir in preventing or ameliorating these effects is unknown. Only six cases of its use in human pregnancy are known. No adverse effects attributable to ganciclovir were apparent in the five cases with outcome details, although one infant had a positive CMV urine culture without signs or symptoms of infection. Long-term evaluation of three of the four exposed infants for late-appearing toxicity has not been reported. The fourth infant was developing normally at 3 years of age (2). Because of the potential for fetal toxicity and the known toxic effects in animals, some investigators have recommended that ganciclovir should only be used during pregnancy for life-threatening disease or in immunocompromised patients with major CMV infections, such as retinitis (3–5). The only approved indications for ganciclovir are for the treatment of CMV retinitis or prevention of CMV disease in immunocompromised patients or in solid organ transplant recipients (3). However, based on the above cases and avoiding the 1st trimester, if possible, the use of ganciclovir to prevent or treat fetal infection might be reasonable.

FETAL RISK SUMMARY

Ganciclovir, a synthetic nucleoside analog that inhibits replication of herpes viruses, is used in the treatment of CMV retinitis and other viral infections.

The drug is embryotoxic in mice and rabbits, causing fetal resorption in at least 85% of animals exposed to two times the human dose based on AUC (HD). Month-old male offspring of female mice administered 1.7 times HD before and during gestation and during lactation had hypoplastic testes and seminal vesicles and pathologic changes in the nonglandular region of the stomach. In pregnant rabbits given doses two times the HD, fetal effects included growth restriction and teratogenicity (cleft palate, anophthalmia/microphthalmia, aplastic kidneys and pancreas, hydrocephaly, and brachygnathia) (3).

Ganciclovir is both carcinogenic and mutagenic in mice (3). Moreover, inhibition of spermatogenesis has been observed in mice and dogs. One study using cultured fetal rat hepatocytes, however, found little or no toxic effects, in terms of cell growth and cell membrane permeability, of high concentrations (0.5–30 mcg/mL) of ganciclovir (6).

Passage of ganciclovir across the perfused human placenta has been reported (4,6). In a 1993 report, ganciclovir was found initially to concentrate on the maternal placental surface and then to cross passively, without metabolism, to the fetus (6). In a second study, ganciclovir and acyclovir were discovered to cross the placenta in approximately similar amounts by simple diffusion (4).

Six reports (three unpublished) have described the use of ganciclovir during human pregnancy (2,7,8). In the first case, a 31-year-old woman received a renal transplant approximately 3 weeks after her last menstrual period (LMP) (8 and 10 days after unprotected intercourse) (7). Medications related to maintaining the transplant included methylprednisolone tapered to prednisone, azathioprine, and cyclosporine. Other drugs added shortly after surgery were trimethoprim, nifedipine, and acyclovir. Her worsening hypertension was controlled with nifedipine. Six weeks after surgery (9 weeks after her LMP), she developed CMV infection that was treated with IV ganciclovir (2.5 mg/kg twice daily) for 2 weeks and a single dose of IV CMV hyperimmune globulin. CMV cultures were negative after treatment and remained so throughout the remainder of the pregnancy. A normal 2640-g male infant was born at 38 weeks' gestation with Apgar scores of 9 and 9 at 1 and 5 minutes, respectively. Placental villitis consistent with CMV was noted and the infant had a positive CMV urine culture, but he remained healthy and was developing

normally at 18 months of age (7).

The second case involved a 29-year-old who was a CMV-negative woman and who had received a CMV-positive liver transplant (8). She became pregnant 5 months after the transplant. She received oral ganciclovir (3 g/day), tacrolimus, and prednisone before conception and throughout the 1st trimester. Ganciclovir was discontinued when pregnancy was diagnosed at 3 months' gestation. Steroid-induced hyperglycemia was not observed, but worsening preeclampsia and fetal distress resulted in delivery at 30 weeks' gestation of a 790-g female infant with Apgar scores of 4 and 7 at 1 and 5 minutes, respectively. No malformations were observed and, except for her small size and mild respiratory problems, she did well and was discharged home on day 50 of life. The author also mentioned three other, unpublished, ganciclovir-treated pregnancies that had been reported to the manufacturer. One patient had been lost to follow-up, one had been treated with IV ganciclovir during the last 4 weeks of pregnancy, and one had been treated with oral ganciclovir at 14–18 weeks' gestation. The two pregnancies with known outcomes resulted in normal infants (8).

A 2005 report described the use of ganciclovir to treat CMV infection in a fetus at 22 weeks' gestation (2). The mother had received a renal transplant before pregnancy and had been treated for CMV infection subsequent to a blood transfusion. Although the mother had no signs or symptoms of infection, an amniocentesis at 21–4/7 weeks' gestation suggested fetal CMV infection. Oral ganciclovir 3 g/day was started at 22 weeks'. At 25 weeks, a repeat amniocentesis revealed that the CMV–DNA level had decreased to within the negative range. The minimum inhibitory concentration for CMV was 3 μM , whereas the amniotic fluid concentration of ganciclovir was 14.5 μM . A cesarean section at 36 weeks' delivered a healthy female infant with no signs or symptoms of CMV infection. At 3 years of age, the child had no signs of neurological, ophthalmological, or developmental abnormalities (2).

BREASTFEEDING SUMMARY

No reports describing the use of ganciclovir during lactation have been located. Because of the potential for serious toxicity in a nursing infant, mothers taking ganciclovir should probably not breastfeed. However, the drug has been used in newborns. The pharmacokinetics of ganciclovir in newborns with congenital cytomegalovirus infections has been reported (9).

GARLIC

Herb

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Ingestion of garlic as a food flavoring appears to be safe during pregnancy. The herb has been used since ancient times and its use is so common that it is doubtful that it presents any risk to the embryo or fetus. Some components of garlic do cross the placenta to the fetus, as shown by detection of a garlic odor in the amniotic fluid and on the newborn's breath. The use of high-dose garlic during gestation is not common and apparently has not been reported. Moreover, the lack of standardization of therapeutic garlic preparations would make any such study suspect unless analysis of the chemical constituents of the actual product used in the study was also reported. The complete lack of data on the outcome of animal or human pregnancies after high-dose garlic does not allow any assessment of its fetal risk. At least one source considers the use of large amounts of garlic during pregnancy to be contraindicated because of the potential for inducing menstruation or uterine contractions (1).

FETAL RISK SUMMARY

Allium sativum L. (Family, Alliaceae), better known as garlic, is a perennial bulb used as a food flavoring. In much higher doses, the herb has been used for medicinal purposes since ancient times. The medicinal parts of garlic are the whole fresh bulb, the dried bulb, and the oil. Studies have demonstrated antibacterial, antimycotic, lipid-lowering, and platelet aggregation inhibition properties. Garlic may prolong bleeding and clotting time and enhance fibrinolytic activity. The average daily doses for medicinal indications are 4 g of fresh garlic, 8 mg of essential oil, and one or two fresh garlic cloves (1–5).

The primary chemical constituents of garlic are the alliin (alkylcysteine sulfoxides), in particular the odorless, colorless amino acid, alliin (S-allyl-L-cysteine sulfoxide). This amino acid, which has no pharmacologic activity, is

converted by the enzyme, allinase (released from neighboring vascular bundle sheath cells by cutting or crushing the bulb) to allicin (diallyl-disulfide-mono-S-oxide, but also known as diallyl thiosulfinate responsible for the pungent characteristic garlic odor), a sulfur-containing volatile oil. The unstable allicin then undergoes further changes to two major products, diallyldisulfide (a predominant compound in garlic breath) and diallyltrisulfide, and several minor products, cycloalliin, vinyl dithiins, ajoene (4,5,9, trithiadodeca-1,6,11-triene 9-oxide), and methylallyltrisulfide (2–5).

Depending on the method of preparation, commercial garlic products may vary widely in their content of allicin, especially those in oil (4). In some cases, no detectable levels of allicin were found. A 1992 study that evaluated 18 garlic preparations of the approximate 70 that were commercially available in Germany found that only five had an allicin content equivalent to 4 g of fresh garlic, the average daily dose required for therapeutic effects. The other 13 products were considered “expensive placebos” because they had no pharmacologic activity (4).

Korean garlic juice was administered to rats to investigate whether it would protect against embryotoxicity induced by maternal ingestion of methylmercuric chloride (6). Analysis of Korean garlic juice indicated that it contained several types of free amino acids, including (numbers in parentheses is the number of amino acids for each type) neutral (N = 7), sulfur-containing (N = 3), acidic (N = 2), basic (N = 2), imino acid (N = 1), and aromatic acid (N = 3) with a total content of approximately 55 mg/mL. The pregnant rats were given 20 mg of methylmercuric chloride on gestational day 7 and then treated with either 0.5 or 1.0 g/kg Korean garlic juice or saline. A fourth group of rats was not treated with mercury or garlic juice. Korean garlic juice was effective, in a dose-related manner, in preventing or reversing the toxicity of organic mercury in terms of increasing maternal and fetal body weights, increasing fetal survival, and decreasing mercury levels in the organs and blood of dams and fetuses. The investigators concluded that the effects of Korean garlic juice were most likely due to the thiol groups found on several of the amino acids that resulted in chelation of the mercury, thereby protecting essential maternal and fetal enzyme systems (6).

Some of the chemical components apparently cross the placenta of animals and humans. In fetal sheep, the taste system develops between 50 and 100 days after conception (7). To determine if garlic crosses the sheep placenta, sheep were administered 6 mL of Egyptian garlic oil by gavage on approximately day 110 of gestation. A sensory panel of 16 judges, selected

because of demonstrated ability to detect dilute concentrations of garlic in water, was used to determine if the odor was present in allantoic and amniotic fluid, fetal blood, and maternal blood. Samples were drawn at 0, 50, 100, and 150 minutes after the maternal dose. Paired samples (treated and untreated) were presented to each judge. Garlic odor was detected in amniotic fluid at 100 and 150 minutes and in allantoic fluid, fetal blood, and maternal blood at 50, 100, and 150 minutes (7). In a brief letter, one correspondent said the odor of garlic had been noted on the breath of some human newborns (8). In a 1995 study, a sensory panel of 13 judges, screened for normal olfactory function, smelled paired samples of amniotic fluid from 10 women (9). At 48 minutes before amniocentesis in the 2nd trimester, five of the women received capsules containing the essential oil of garlic and five received placebo capsules containing lactose. The odor of garlic was judged stronger in four of the five women who had ingested the capsules with garlic. Therefore, this study demonstrated that components of garlic were transferred across the placenta and altered the odor of amniotic fluid (9). Although the specific components of garlic in the amniotic fluid were not identified, allicin (diallyl thiosulfinate) and at least one of its degradation products (diallyldisulfide) were most likely present because these are responsible for the characteristic odor of garlic (see above).

Two brief reports by a group of investigators in London stated that garlic might have benefits in preventing preeclampsia and intrauterine growth restriction (IUGR) (10,11). In an in vitro experiment, the investigators added increasing concentrations of garlic extract to a homogenate of human placental villous tissue to demonstrate a dose-related increase in nitric oxide synthase (enzyme that produces nitric oxide) activity (10). Because both calcium-dependent and calcium-independent nitric oxide synthase activities are decreased in preeclampsia and IUGR, the researchers speculated that garlic might be beneficial in these vascular conditions. In the second study, also using human placental villous tissue, both garlic extract and perchloric acid-treated garlic extract (allicin-negative) were shown to have cyclooxygenase inhibitor activity similar to that of aspirin (11).

BREASTFEEDING SUMMARY

Garlic ingestion by a lactating woman may impart garlic odor to her milk. The clinical significance of occasional garlic odor in milk appears to relate only to the amount of time the infant will be attached to the breast and this effect will disappear if the mother ingests the herb frequently.

At least some garlic constituents are excreted into breast milk. A 1994 study

in lactating mice evaluated the effects on xenobiotic metabolizing enzymes in mouse pups from garlic administered to the mother (12). The lactating mice received either 200 or 400 mg/kg of crushed fresh garlic diluted in a volume of 0.1 mL of water for 14 or 21 days postpartum. Significant hepatic enzyme changes were measured in both the dams and pups, but the clinical significance of the changes is unknown.

Eight women, all exclusively breastfeeding their 3- to 4-month old infants, were the subject of a study published in 1991 examining the effect of garlic on the odor of breast milk and the nursing's behavior (13). None of the women was a regular user of garlic and their consumption of other sulfur-containing foods was limited before and during the study. In addition to breastfeeding, milk samples were also collected from the women every hour for 4 hours. They were given either placebo or garlic (1.5 g of garlic extract) capsules on alternate days. A sensory panel of 11 judges, all screened for normal olfactory function, were able consistently to detect the odor of garlic from paired samples of expressed milk (treated and untreated) with a peak effect at 2 hours. It also appeared that the nursing infants detected the garlic odor because when the mother had ingested garlic capsules, the infants attached to the breast for significantly longer periods and sucked more. Although not significant, the infants also tended to consume more milk, but consumption may have been limited by the amount of milk available to the infant (13). A subsequent study confirmed that infants remained attached to the breast longer than usual when their mothers started taking garlic but that this effect disappeared with continued garlic ingestion (14).

The clinical significance of the above investigations is unknown. A review on the effect of various flavors in milk concluded that it was not known whether flavors such as garlic in milk had any effect on the subsequent development of food habits or willingness to accept new foods at weaning or later in life (15).

GATIFLOXACIN

Ophthalmic (Anti-infective)

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of ophthalmic gatifloxacin during human pregnancy have been located. The risk to an embryo or fetus appears to be nil because serum concentrations after ophthalmic use were below the lower limit of quantification. The oral and IV formulations have been withdrawn and only the ophthalmic preparation is available.

FETAL RISK SUMMARY

Gatifloxacin is a synthetic, broad-spectrum, fluoroquinolone antibacterial agent. It is in the same anti-infective class as ciprofloxacin, enoxacin, gemifloxacin, levofloxacin, lomefloxacin, moxifloxacin, norfloxacin, ofloxacin, sparfloxacin, and trovafloxacin. In an escalated dosing regimen up to 2 drops 8 times daily for 3 days, serum gatifloxacin concentrations were below the lower limit of quantification (5 ng/mL) (1).

In reproduction studies with rats and rabbits, oral doses up to about 1000 times the maximum recommended ophthalmic dose (MROD) were not teratogenic. In rats, skeletal/craniofacial anomalies or delayed ossification, atrial enlargement, and reduced fetal weight were observed in fetuses at about 3000 times the MROD. In a perinatal/postnatal study, increased postimplantation loss and neonatal/perinatal death were observed at a dose that was about 4000 times the MROD (1).

It is not known if gatifloxacin crosses the human placenta. Although the molecular weight of the hydrate (about 402) is low enough, serum concentrations are below the lower limit of quantification. Thus, clinically significant exposure of the embryo and/or fetus should not occur.

BREASTFEEDING SUMMARY

No reports describing the use of gatifloxacin in human lactation have been located. Because serum concentrations are below the lower limit of quantification (5 ng/mL), clinically significant amounts of gatifloxacin are not expected in breast milk.

GEFITINIB

Antineoplastic (Tyrosine Kinase Inhibitor)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

One report describing the use of gefitinib in the 2nd and 3rd trimesters has been located. There was developmental toxicity (growth restriction and death) in two animal species, but the very limited human pregnancy experience prevents a more complete assessment of the embryo–fetal risk.

FETAL RISK SUMMARY

Gefitinib is an oral epidermal growth factor receptor tyrosine kinase inhibitor. It is in the same subclass as several other agents (see Appendix). It is indicated as monotherapy for the continued treatment of patients with locally advanced or metastatic non-small-cell cancer after failure of other chemotherapies. Gefitinib is extensively metabolized and one of the metabolites is partially active. The elimination half-life of gefitinib is about 48 hours. Plasma protein binding to albumin and α -1 glycoprotein is 90% (1).

Reproduction studies have been conducted in rats and rabbits. Pregnant rats were treated from the beginning of organogenesis to the end of weaning with daily doses (5 mg/kg) that were about one-fifth the recommended human dose based on BSA (RHD), there was a decrease in the number of pups born alive. When the dose was increased to 20 mg/kg, the effect was more severe with more pups dying soon after birth. The no-effect dose was 1 mg/kg. In pregnant rabbits, a dose about twice the RHD caused reduced fetal weight (1). No mention of maternal toxicity was made in any of the animal studies.

Carcinogenicity studies have not been conducted with gefitinib. Genotoxicity studies in several tests were negative (1).

It is not known if gefitinib crosses the human placenta. After a single dose of

5 mg/kg (about one-fifth the RHD), gefitinib crossed the rat placenta (1). The molecular weight (about 447) and long elimination half-life suggest that gefitinib also will cross the human placenta.

A 2011 case report described a 38-year-old woman at 26 weeks' gestation who was diagnosed with lung cancer (2). The woman had never smoked. She was initially treated with erlotinib 100 mg/day and then changed about 2 weeks later to gefitinib 250 mg/day. Gefitinib was continued through the remainder of her pregnancy. At 36 weeks', she gave birth to a healthy 2.08-kg infant with an Apgar score of 9 at 1 minute. The baby weighed 2.98 kg 6 weeks later (2).

BREASTFEEDING SUMMARY

No reports describing the use gefitinib during human lactation have been located. The molecular weight (about 447) and long elimination half-life suggest that gefitinib will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown, but could be serious. In adults, the most common adverse effects were diarrhea, rash, acne, dry skin, nausea, and vomiting. Until human data are available, the safest course is to not breastfeed while taking gefitinib.

GEMCITABINE

Antineoplastic (Antimetabolite)

PREGNANCY RECOMMENDATION: Contraindicated—1st Trimester

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Two case reports have described the use of gemcitabine in the 2nd trimester. One of the reports speculated that two unusual complications (chronic lung disease and excessive lung excretions) might have been related to the therapy. The animal data suggest risk. Gemcitabine is indicated for the treatment of cancers with a high mortality, often in combination with other antineoplastics. Nevertheless, the maternal benefit appears to outweigh the unknown fetal risk, but avoiding organogenesis is a reasonable option.

FETAL RISK SUMMARY

Gemcitabine is a nucleoside analog antineoplastic. It is classified as an antimetabolite in the subclass of pyrimidine analogs. Other antineoplastic agents in the subclass are capecitabine, cytarabine, floxuridine, and fluorouracil. Gemcitabine is indicated in combination with carboplatin for ovarian cancer, with paclitaxel for breast cancer, and with cisplatin for non-small-cell lung cancer. It also is indicated for locally advanced or metastatic adenocarcinoma of the pancreas. Gemcitabine is metabolized intracellularly to the active diphosphate and triphosphate nucleosides. Gemcitabine triphosphate can be extracted from peripheral blood mononuclear cells and has a half-life of the terminal phase from these cells of 1.7–19.4 hours. An inactive metabolite is found in the plasma. The half-lives of gemcitabine in women 29 and 45 years of age were 49 and 57 minutes, respectively. Plasma protein binding is negligible (1).

Reproduction studies have been conducted in mice and rabbits. In mice, gemcitabine was embryotoxic, causing cleft palate and incomplete ossification at doses about 1/200th of the recommended human dose based on BSA (RHD). This dose was also maternally toxic. Fetotoxicity or embryoletality was

observed at about 1/1300th of the RHD (1). A 1993 study in mice that was conducted by the manufacturer expanded on the maternal and developmental toxicities noted above (2). In rabbits, embryotoxicity (decreased fetal viability, reduced live litter sizes, and developmental delays) and fetotoxicity (fused pulmonary artery and absence of the gall bladder) at doses about 1/600th of the RHD (1).

Carcinogenesis studies have not been conducted with gemcitabine. The drug was associated with mutagenic and clastogenic effects in some assays. Effects on the fertility of male mice were noted at a dose 1/700th of the RHD, consisting of hypospermatogenesis, decreased fertility, and decreased implantations. The fertility of female mice was not affected at doses up to about 1/200th of the RHD (1).

It is not known if gemcitabine crosses the human placenta. The molecular weight (about 264 for the free base) and negligible plasma protein binding suggest that the drug will cross the placenta. However, the very short plasma elimination half-life of the drug should reduce the amount reaching the embryo–fetus.

A 2008 report described the use of gemcitabine, docetaxel, and cisplatin in a woman who had lung cancer with brain metastases and an unrecognized pregnancy (3). Very early in gestation, she underwent craniotomy with tumor removal, followed by whole brain irradiation. Starting at 9 weeks' gestation, she was treated with four cycles of docetaxel and cisplatin (days 1 and 8) every 3 weeks. At 19 weeks', therapy was changed to gemcitabine and cisplatin (days 1 and 8) at 3-week intervals for two cycles. About 2 months after the last dose, her pregnancy was diagnosed. A cesarean section was performed at 33 weeks to deliver a normal, 1490-g female infant (normal karyotype 46, XX) with Apgar scores of 8, 9, and 10 at 1, 5, and 10 minutes, respectively, and normal blood counts. An extensive examination of the infant failed to find any abnormalities. She was developing normally at 10 months of age (3).

In a second case, a 38-year-old woman was treated for lung cancer at 25 weeks' gestation with gemcitabine (1000 mg/m² on day 1 and 8) and carboplatin AUC 5 (day 1) (4). She gave birth by an elective cesarean section at 28 4/7 weeks to a baby girl with Apgar scores of 7 and 9 at 1 and 5 minutes, respectively. The infant had multiple complications secondary to prematurity. The authors speculated that two unusual features, chronic lung disease and excessive secretions from her lungs, might have been related to either the chemotherapy or an effect of the malignancy itself. At 8 months of age, the infant had been weaned off of oxygen therapy and her

neurodevelopment was age-appropriate (4).

Occupational exposure of the mother to antineoplastic agents during pregnancy may present a risk to the fetus. A position statement from the National Study Commission on Cytotoxic Exposure and a research article involving some antineoplastic agents are presented in the monograph for cyclophosphamide (see Cyclophosphamide).

BREASTFEEDING SUMMARY

It is not known if gemcitabine is excreted into human breast milk. The molecular weight (about 264 for the free base) and negligible plasma protein binding suggest that the drug will be excreted into milk, but the very short elimination half-life (49–57 minutes) should mitigate the amount entering milk. However, the cytotoxicity of the drug and its use in combination with other antineoplastics strongly suggests that women being treated with gemcitabine should not breastfeed.

GEMFIBROZIL

Antilipemic Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

The animal data suggest risk, but the limited human pregnancy experience prevents a more complete assessment of the embryo–fetal risk. Teratogenic effects secondary to the drug have not been observed in the few case reports. Because the drug is used for a severe maternal condition, it should not be withheld, if indicated, because of pregnancy, but starting therapy after the 1st trimester should be considered.

FETAL RISK SUMMARY

Gemfibrozil is a lipid-regulating agent. It is indicated as adjunctive therapy to diet for treatment of adult patients with very high serum triglyceride levels who present a risk of pancreatitis and who do not respond adequately to a determined dietary effort. The drug is extensively metabolized to multiple metabolites, one of which may be active (see reference 9). Gemfibrozil is highly bound to plasma proteins but may be displaced by other drugs. The plasma half-life is 1.5 hours following multiple doses (1).

Reproductive tests have been conducted in rats and rabbits. In male and female rats, gemfibrozil was tumorigenic (benign liver nodules, liver carcinoma, and benign Leydig cell tumors) at 0.2 and 1.3 times the human exposure based on AUC. Treatment of female rats before and during gestation with 0.6 and 2 times the human dose based on BSA (HD) produced dose-related decreases in the conception rate, birth weight, and pup growth during lactation, and increased skeletal variations. Anophthalmia was observed rarely. The highest dose also resulted in an increased rate of stillbirths. Pregnant rabbits given 1 and 3 times the HD during organogenesis had a decreased litter size and, at the highest dose, an increased incidence of parietal bone variations (1). Two

other studies have found no evidence of reproductive or teratogenic effects in rats and rabbits (2, 3).

It is not known if gemfibrozil crosses the human placenta during early pregnancy. The molecular weight (about 250) suggests that the drug will cross to the embryo–fetus. Although the extensive metabolism, high plasma protein binding, and short half-life should limit the exposure, the drug and an active metabolite cross near term (see reference 9).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 8 newborns had been exposed to gemfibrozil during the 1st trimester and 7 in the 2nd or 3rd trimester (4). One defect, a structural brain anomaly, was observed in an infant delivered from a mother who took the agent after the 1st trimester. In a separate case included in this report, an infant with Pierre Robin syndrome, suspected of being associated with 1st trimester exposure to gemfibrozil, was reported retrospectively to the FDA. The syndrome (cleft palate–micrognathia–glossoptosis) was most likely due to autosomal recessive inheritance (4).

A 1992 report described the use of gemfibrozil starting at 20 weeks' gestation in a 33-year-old woman with eruptive xanthomas (5). The patient had a similar condition in her first pregnancy that included hypertriglyceridemia, fulminant pancreatitis, and acute respiratory distress syndrome (5). A dose of 600 mg 4 times daily for 2 months lowered the triglyceride level from 7530 to 4575 mg/dL, and the total cholesterol level from 1515 to 1325 mg/dL, but the xanthomas persisted throughout her pregnancy. A healthy, term infant (birth weight and sex not specified) was eventually delivered (5).

A 1999 case report described the use of gemfibrozil 600 mg twice daily in a 22-year-old woman for severe acute pancreatitis due to hypertriglyceridemia throughout pregnancy (except for gestational week 11) (6). After treatment in the hospital, she did well during the remainder of her pregnancy without a recurrence of her pancreatitis or other complications. She gave birth to a full-term, healthy, male infant (no other details on the infant were given) (6).

A 29-year-old woman with lipotrophic diabetes mellitus was treated throughout gestation with gemfibrozil 600 mg twice daily (7). The lipotrophic diabetes was thought to be consistent with congenital partial lipodystrophy (Kobberling-Dunnigan syndrome). At 37 weeks' gestation, labor was induced and she gave birth to a 2800-g female infant with Apgar scores of 7 and 8. No other information about the infant was provided (7).

A 18-year-old woman with familial chylomicronemia syndrome had lipoprotein lipase deficiency and hypertriglyceridemia since birth (8). During pregnancy,

she was managed with a very-low-fat diet and, in the 3rd trimester, with gemfibrozil. Because of a risk for pancreatitis, labor was induced at 38 weeks' and she gave birth to a healthy 2.77-kg male infant. No details on the infant were given (8).

A 23-year-old woman with primary lipoprotein lipase deficiency was managed with a low-fat diet throughout gestation (9). In week 29, gemfibrozil 600 mg/day was started and increased to 900 mg/day a week later. A second episode of pancreatitis prompted labor induction at 35 weeks and a female infant (about 2355 g) with a 5-minute Apgar of 9 was delivered vaginally. Analysis of the cord blood revealed similar concentrations of gemfibrozil and its active metabolite in both umbilical vein and artery at levels within the normal reference for adults. The infant was intubated for 48 hours for respiratory distress. The mother and her daughter were both healthy and doing well 11 years later (9).

BREASTFEEDING SUMMARY

No reports describing the use of gemfibrozil during lactation have been located. The molecular weight (about 250) suggests that the drug will be excreted into milk. However, the extensive metabolism, high plasma protein binding, and short half-life (1.5 hours) should limit the exposure. Nevertheless, there is a potential for severe toxicity in a nursing infant and the drug should probably not be used during breastfeeding.

GEMIFLOXACIN

Anti-infective (Quinolone)

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of gemifloxacin during human pregnancy have been located. The animal toxicity (fetal growth restriction) observed at exposures close to those obtained in humans should be considered before this agent is used in pregnant women. Moreover, some reviewers have concluded that all fluoroquinolones should be considered contraindicated in pregnancy (e.g., see Ciprofloxacin and Norfloxacin) because safer alternatives are usually available.

FETAL RISK SUMMARY

Gemifloxacin is a synthetic, broad-spectrum, fluoroquinolone antibacterial agent. It is in the same anti-infective class as ciprofloxacin, enoxacin, gatifloxacin, levofloxacin, lomefloxacin, moxifloxacin, norfloxacin, ofloxacin, sparfloxacin, and trovafloxacin. Gemifloxacin is available in an oral formulation. Gemifloxacin and its metabolites are primarily eliminated in the feces (about 61%), with the remainder excreted in the urine (about 36%). Plasma protein binding ranges from 55% to 73% and the elimination half-life is about 7 hours (range 4–12 hours) (1).

Reproduction studies have been conducted with gemifloxacin in mice, rats, and rabbits. Fetal growth restriction was observed in all three species given doses resulting in exposures, based on AUC, that were two-, four-, and three-fold greater, respectively, than those obtained in women given oral doses of 325 mg (HD). The growth restriction appeared to be reversible in rats, but this was not studied in mice and rabbits. In rats, a dose eight times the HD not only caused fetal brain and ocular malformations but also caused maternal toxicity. The no-observed-effect-level (NOEL) in pregnant animals was about 0.8–3 times the HD (1).

It is not known if gemifloxacin crosses the human placenta. The molecular weight of the mesylate salt (about 485), plasma protein binding (55%–73%), and elimination half-life (about 7 hours) suggest that passage to the fetus should be expected.

BREASTFEEDING SUMMARY

No reports describing the use of gemifloxacin in lactating humans have been located. The molecular weight (about 485), plasma protein binding (55%–73%), and elimination half-life (about 7 hours) suggest that the drug will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown. However, other fluoroquinolones are classified by the American Academy of Pediatrics as compatible with breastfeeding (see Ciprofloxacin).

GEMTUZUMAB OZOGAMICIN

[Withdrawn from the market. See 9th edition.]

GENTAMICIN

Antibiotic (Aminoglycoside)

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Gentamicin is used frequently in pregnancy to treat maternal infections. Developmental toxicity has not been associated with this agent.

FETAL RISK SUMMARY

Gentamicin is an aminoglycoside antibiotic. The antibiotic did not impair fertility or cause fetal harm in rats and rabbits (1). Not surprisingly, gentamicin produces dose-related nephrotoxicity in fetal rats (2–4). High doses (110 mg/kg/day SC) of gentamicin during gestation have also been shown to produce significant and persistent increases in the blood pressure, as well as nephrotoxicity, in exposed rat offspring (5).

Gentamicin rapidly crosses the placenta into the fetal circulation and amniotic fluid (6–15). Following 40- to 80-mg IM doses given to patients in labor, peak cord serum levels averaging 34%–44% of maternal levels were obtained at 1–2 hours (6,9,13,14). Following a single 80-mg IM injection before delivery, mean peak amniotic fluid concentrations (5.17 mcg/mL) occurred at 8 hours (14). No toxicity attributable to gentamicin was seen in any of the newborns. Patients undergoing 1st and 2nd trimester abortions were given 1 mg/kg IM (10). Gentamicin could not be detected in their cord serum before 2 hours. Amniotic fluid levels were undetectable at this dose up to 9 hours after injection. Doubling the dose to 2 mg/kg allowed detectable levels in the fluid in one of two samples 5 hours after injection.

The pharmacokinetics of gentamicin in 23 women with pyelonephritis at a mean gestational age of 21.8 weeks was described in 1994 (16). Similar to that observed in postpartum women, standard weight-adjusted doses of gentamicin produced low, subtherapeutic serum levels in most of the women.

A brief study published in 2000 compared gentamicin serum levels in infants of women who had received the antibiotic IV (240-mg single daily dose vs. 80

mg 3 times daily) during labor (17). In the single daily dose group (N = 11), all of the mothers had received one dose a mean 5.12 hours before delivery, whereas in the divided-dose group (N = 10), 9 of 10 mothers received one dose a mean 4.72 hours before delivery. The mean serum levels in the newborn infants were 1.94 and 0.98 mcg/mL, respectively (p = 0.01). There was no correlation between the infant's serum level and the time interval from the mother's dose (17). Based on their analysis, the authors concluded that the divided-dose regimen was best for women in labor (17).

In an abstract published in 1997, women undergoing mid-trimester terminations received gentamicin either as a 10-mg intra-amniotic infusion (N = 16) or a single 80-mg IV dose (18). Low median gentamicin plasma levels were measured in the mothers and fetuses after the intra-amniotic dose: 0.28 mcg/mL in the mothers and 0.4 mcg/mL in the fetuses. In contrast, the median amniotic fluid concentration, 46 mcg/mL, was sustained for >24 hours. After IV dosing, amniotic fluid concentrations were low throughout the study (median 0.35 mcg/mL). The authors concluded that intra-amniotic infusions of gentamicin were a safe method to administer the antibiotic without reaching toxic levels in the mother or the fetus (18).

Intra-amniotic instillations of gentamicin were given to 11 patients with premature rupture of the membranes (19). Ten patients received 25 mg every 12 hours and one received 25 mg every 8 hours, for a total of 1–19 doses per patient. Maternal gentamicin serum levels ranged from 0.063 to 6 mcg/mL (all but one were <0.6 mcg/mL and that one was believed to be caused by error). Cord serum levels varied from 0.063 to 2 mcg/mL (all but two were <0.6 mcg/mL). No harmful effects were seen in the newborns after prolonged exposure to high local concentrations of gentamicin.

Only one report linking the use of gentamicin to congenital defects has been located. A 34-year-old woman, who was not known to be pregnant at the time, received a 10-day course of gentamicin (300 mg/day) in gestational week 7 (20). The appropriateness of this dose cannot be determined because the mother's height and weight and renal function were not given. The mother was also treated with prednisolone (50 mg/day for 5 days) for an "allergic reaction" to the antibiotic. She delivered an apparently healthy, 2950-g (6 pounds 8 ounces) male infant at 37 weeks' gestation. His growth after birth was less than the 5th percentile and, at 4.5 years of age, the child was evaluated for short stature (<5th percentile). At this time, he was noted to have impaired renal function. Ultrasound examination revealed small kidneys, both <5th percentile for age, with increased echotexture, markedly decreased

corticomedullary differentiation, and small bilateral cysts. Although the exact cause of the renal cystic dysplasia was unknown, and a potential genetic defect could not be excluded, the authors speculated, on the basis of animal studies, that the combination of gentamicin and prednisolone had induced the abnormal nephrogenesis.

Gentamicin, in combination with ampicillin (N = 62), was compared with two groups of women treated with cefazolin (N = 58) or ceftriaxone (N = 59) in a randomized trial of the treatment of acute pyelonephritis in pregnancy (21). The mean gestational age at the start of therapy was 14 to 15 weeks. There were no significant differences among the three groups in clinical or pregnancy outcomes. The pregnancy outcomes included gestational age at delivery, preterm delivery, birth weight, neonatal intensive care admission, and length of stay in the neonatal intensive care if admitted (21).

The population-based dataset of the Hungarian Case-Control Surveillance of Congenital Abnormalities, covering the period of 1980–1996, was used to evaluate the teratogenicity of aminoglycoside antibiotics (parenteral gentamicin, streptomycin, tobramycin, and oral neomycin) in a study published in 2000 (22). A case group of 22,865 women who had fetuses or newborns with congenital malformations were compared with 38,151 women who had no newborns with structural defects. A total of 38 cases and 42 controls were treated with aminoglycosides. There were 19 women in the case and control groups, 0.08% and 0.05%, respectively, treated with gentamicin (odds ratio 1.7, 95% confidence interval 0.9–3.2). A case–control pair analysis for the 2nd and 3rd months of gestation also failed to show a risk for teratogenicity. The investigators concluded that there was no detectable teratogenic risk for structural defects for any of the aminoglycoside antibiotics (22). Although it was not investigated in this study, they also concluded that the risk of deafness after in utero aminoglycoside exposure was small.

Ototoxicity, which is known to occur after gentamicin therapy, has not been reported as an effect of in utero exposure. However, eighth-cranial nerve toxicity in the fetus is well known following exposure to other aminoglycosides (see Kanamycin and Streptomycin) and may potentially occur with gentamicin. Gentamicin and vancomycin, both of which can cause ototoxicity and nephrotoxicity, have been used together during pregnancy without apparent harm to the fetus or newborn (see Vancomycin).

Potential of $MgSO_4$ -induced neuromuscular weakness has been reported in a neonate exposed during the last 32 hours of pregnancy to 24 g of $MgSO_4$ (23). The depressed infant was treated with gentamicin for sepsis at 12 hours

of age. After the second dose, the infant's condition worsened with rapid onset of respiratory arrest. Emergency treatment was successful, and no lasting effects of the toxic interaction were noted.

BREASTFEEDING SUMMARY

Small amounts of gentamicin are excreted into breast milk and absorbed by the nursing infant. In a reference published in 1994, 10 women, who had just delivered term infants, were administered antibiotic prophylaxis with gentamicin (80 mg IM 3 times daily) (24). On the 4th day of a 5-day therapy course, milk and serum samples were obtained. The mean maternal serum levels of gentamicin at 1 and 7 hours after a dose were 3.94 and 1.02 mcg/mL, respectively. Mean milk levels at 1, 3, 5, and 7 hours after a dose were 0.42, 0.48, 0.49, and 0.41 mcg/mL, respectively, providing mean milk:plasma ratios at 1 and 7 hours of 0.11 and 0.44, respectively. The infants were allowed to breastfeed 1 hour after a dose and serum samples were collected 1 hour later. Five of the 10 infants had detectable (>0.27 mcg/mL) gentamicin serum levels with a mean level of 0.41 mcg/mL.

In a case report, a nursing infant developed two grossly bloody stools while his mother was receiving gentamicin and clindamycin (25). The condition cleared rapidly when breastfeeding was discontinued. Although both antibiotics are known to be excreted into milk, the cause of the infant's diarrhea cannot be determined with certainty. The American Academy of Pediatrics classifies gentamicin as compatible with breastfeeding (26).

GENTIAN VIOLET

Disinfectant/Anthelmintic

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 40 of whom had 1st trimester exposure to gentian violet (1). Evidence was found to suggest a relationship to malformations based on defects in 4 patients. Independent confirmation is required to determine the actual risk.

BREASTFEEDING SUMMARY

No reports describing the use of gentian violet during human lactation have been located.

GINGER

Herb

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

There is no evidence of ginger-induced developmental toxicity. The herb has been used safely as an antiemetic for nausea and vomiting of pregnancy.

FETAL RISK SUMMARY

The rhizome of the perennial plant, ginger (*Zingiber officinale*), is used as a dried powdered spice in foods and as a natural medicine for its alleged carminative, cardiotoxic, antithrombotic, antibacterial, antioxidant, antitussive, antiemetic, stimulant, antihepatotoxic, anti-inflammatory, antimutagenic, diaphoretic, diuretic, spasmolytic, immunostimulant, and cholagogue actions (1). The active ingredients in ginger are thought to be primarily a class of structurally cardiotoxic compounds called gingerols. Other pharmacologically active compounds that have been identified in ginger include shogaol, dehydrogingerdiones, gingerdiones, and zingerone. Some of these ingredients inhibit prostaglandin synthetase (cyclooxygenase) but, in some cases, this activity may be confined only to fresh ginger (1).

In a reproduction study, ginger tea (20 or 50 g/L) was given to rats during organogenesis (days 6–15) via their drinking water (2). The lower concentration (20 g/L) was equivalent to the ginger tea consumed by humans (2). No maternal toxicity or teratogenicity was seen, but early embryonic loss was double that of the controls ($p < 0.05$) at both doses. In addition, surviving fetuses, especially females, were significantly heavier than controls and had more advanced skeletal growth (2). Another rat study used a patented standardized ethanol extract of *Z. officinale* (EV.EXT 33) to administer doses up to 1000 mg/kg/day during organogenesis (3). Compared with a control group, no embryo toxicity, teratogenicity, or treatment-related adverse effects

were observed in the pregnant rats or their offspring.

Several authors have commented on or reported, with mixed results, studies examining the antiemetic properties of ginger in nonpregnant patients (4–10), and a review of this topic was published in 2000 (11). The oral dose in the studies varied from 1 to 2 g/day of the powdered root or rhizome. Although the exact mechanism of action is unknown, it appears to be a local effect in the gastrointestinal tract rather than a central action (7,10). The effect may be mediated by antagonism of gastrointestinal 5-hydroxytryptamine (serotonin) to prevent stimulation of the vagus nerve and, thus, the vomiting center (8,10). One author commented that ginger has been long used in Chinese herbal or folk medicine for the treatment of pregnancy-induced nausea and vomiting (5).

The efficacy of ginger as an antiemetic in pregnancy was studied in a double-blind, randomized, cross-over trial involving women with hyperemesis gravidarum (12). All the subjects had been admitted to a hospital with hyperemesis and if their symptoms persisted for more than 2 days, they were enrolled in the study after giving informed consent. A total of 27 women at a mean gestational age of about 11 weeks completed the study. The women were administered either powdered root of ginger (1 g/day) or placebo for 4 days, then nothing for 2 days, then given the alternate agent for 4 days. More patients stated a preference for ($p = 0.003$), and had greater relief from their symptoms ($p = 0.035$), with ginger than with placebo. No maternal adverse effects were observed. The pregnancy outcomes were one spontaneous abortion in the 12th week of gestation, one elective abortion for reasons other than nausea and vomiting, and 25 normal living infants. The mean gestational age at delivery was 39.9 weeks (range 36–41 weeks) with a mean birth weight of 3585 g (range 2450–5150 g). All had Apgar scores of 9–10 at 5 minutes, and none had a congenital abnormality (12).

In a comment relating to the above study, one author urged caution in the use of ginger during pregnancy, citing ginger's action as a thromboxane synthetase inhibitor, which, theoretically, could affect testosterone-receptor binding and result in adverse sex-steroid differentiation of the fetal brain (13). Although the author's research failed to find evidence of toxicity due to ginger, he recommended that it not be used in pregnancy until this effect was studied. No published reports to refute or support this alleged effect, however, have been located.

A 2001 randomized, double-masked study also evaluated the effect on ginger on nausea and vomiting of pregnancy (14). Ginger 1 g/day was compared with placebo for 4 days starting at a mean gestational age of about

10 weeks. Ginger resulted in a significant decrease in the severity of nausea and vomiting. No adverse effects on pregnancy outcome were detected (14).

The result of a prospective study of women consuming ginger in the 1st trimester for nausea and vomiting was reported in 2003 (15). The pregnancy outcomes of the exposed women were compared with a control group who were exposed to nonteratogenic drugs that were not antiemetics. The outcomes in the 187 ginger-exposed subjects were 3 spontaneous abortions, 1 elective abortion (Down's syndrome), 2 stillbirths, and 181 live births. Three liveborn infants had birth defects: ventricular septal defect, right lung abnormality, and a kidney abnormality (pelviectasis). In addition, a female child was later diagnosed with idiopathic central precocious puberty at 2 years of age. The mean birth weight was 3542 g and the mean gestational age at birth was 39 weeks. Except for the fact that more control infants weighed <2500 g, the outcomes between the groups did not differ significantly. Sixty-six women rated the effectiveness of ginger in controlling nausea and vomiting. On a 10-point scale (0 being no effect and 10 the best effect), the mean score was 3.3 (within the "mild effect" range) (15).

A 2004 randomized, controlled trial was conducted in women <16 weeks' gestation (16). Women were treated for 3 weeks with either ginger (N = 146) (1.05 g/day) or vitamin B6 (N = 145) (75 mg/day) and the efficacy of the treatments was measured at 7, 14, and 21 days. The median gestational age at the start of the study in the two groups was 8.5 and 8.6 weeks, respectively. There was no difference between the groups, averaged over time, in reducing nausea, retching, or vomiting. There also was no difference in the pregnancy outcomes, except that the ginger group had slightly more live births (16).

BREASTFEEDING SUMMARY

No studies describing the use of ginger during lactation have been located. It is unlikely, however, that small doses of ginger, such as those used as a spice, would affect a nursing infant. The effects, if any, of the higher doses used as an antiemetic are also unknown, but they are probably of little consequence to the infant. The oral bioavailability of ginger and its active ingredients, however, has not been studied in animals or humans.

GINKGO BILOBA

Herb

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of ginkgo biloba during human pregnancy have been located. No mutagenicity in animals or human sperm was observed and no teratogenicity occurred in one animal species, but the data and details of the animal studies are very limited. Moreover, a large number of chemicals have been identified from this herb and none has undergone rigorous reproductive testing. However, because ginkgo is an ancient herb and its use is widespread, it is doubtful that a major teratogenic effect or other significant reproductive toxicity would have escaped notice. More subtle or low-incidence effects, however, including structural and behavioral teratogenicity, the induction of abortions, and infertility may have escaped detection, and further study is required before human reproductive risk or safety can be assessed.

Because of the uncertainties described above, various sources can be found that either state there are no restrictions against its use in pregnancy (1) or that the herb is contraindicated during gestation (2–4). The safest course is to avoid ginkgo products during pregnancy.

FETAL RISK SUMMARY

Ginkgo biloba (scientific name) is a popular herbal preparation. The dioecious ginkgo tree may live as long as several 100–1000 years. It is the sole survivor of the family Ginkgoaceae, which dates back >200 million years. The tree, which may grow to a height of 30–40 m (approximately 98–131 feet), has fan-shaped leaves and is indigenous to China, Japan, and Korea (2,3,5). Commercial plantations of ginkgo trees in the United States, however, are pruned to shrub height to allow mechanical picking of the leaves (6).

The medicinal parts of ginkgo are the fresh and dried leaves, and the seeds separated from their fleshy outer layer (5). Ginkgo leaf extract, however, is the most commonly used form of this herb (3). Numerous uses have been recommended for the various IV (not available in United States) and oral preparations of ginkgo leaf extract, some of which are symptomatic relief of organic brain syndrome (e.g., cerebral insufficiency, anxiety and stress, memory impairment, headache, and dementias), intermittent claudication and other circulatory disorders, asthma, and vertigo and tinnitus of vascular origin (1–3,5,6).

Ginkgo seed, although not commercially available in the United States, is used orally as an antitussive and expectorant, as an aid for digestion, to prevent drunkenness, in asthma and bronchitis, and for genitourinary complaints. Topical uses include scabies and skin sores. Roasted seeds with the pulp removed are eaten for food in Japan and China (3).

The content of active compounds in ginkgo leaves may vary widely depending on the season (2,7). Seasonal and other factors, such as location and method of harvest, may result in variance as much as 300% in the concentrations of active compounds (7). Ginkgo leaf extract is prepared using an acetone–water extraction process and subsequent purification steps without adding concentrates or isolated ingredients (1,3,5,6). A number of chemical constituents have been identified in the extract (percentages refer to German Commission E standards): 22%–27% flavanone glycosides (flavonoids consisting of monosides, biosides, and triosides of quercetin, kaempferol, isorhamnetins, and 3'-O-methylmyristicins); 5%–7% terpene lactones (terpenoids) (2.8%–3.4% ginkgolides A, B, C, and M [trilactonic diterpenes], 2.6%–3.2% bilobalide [trilactone sesquiterpene]); and <5 ppm of ginkgolic acids (1–3,5,6). Other chemical constituents found in the leaf before processing, in addition to those identified in the extract, include amino acid 6-hydroxykynurenic acid, bioflavonoids (dimeric bioflavones: amentoflavone, bilobetin, ginkgetin, isoginkgetin, 5-methoxybilobetin, sciadopitysin) (about 40 different bioflavonoids have been identified), terpene lactone (ginkgolide J), steroids (sitosterol, stigmasterol), polyprenols, organic acids (shikimic, vanillic, ascorbic, p-coumaric), benzoic acid derivatives, carbohydrates, straight-chain hydrocarbons, alcohol, ketones, and 2-hexenol (2). A 1993 reference detailed the chemical structures of the active ingredients (flavonoids and terpene lactones) (8).

The seed contains 38% carbohydrate, 4% protein, and <2% fat (2). This part of the tree is not marketed in the United States, but may contaminate other

ginkgo products (9). Chemicals found in the seed are alkaloids (e.g., ginkgotoxin), amino acids, cyanogenetic glycosides, and long-chain phenols (e.g., anacardic acid, bilobol, and cardanol) (2).

Reproduction studies in animals have revealed no mutagenic or teratogenic effects. No teratogenicity was observed in pregnant rats given oral doses up to 1600 mg/kg/day (2).

In a sperm penetration assay, zona-free hamster oocytes were incubated for 1 hour with two concentrations of ginkgo, 0.1 and 1.0 mg/mL, dissolved in HEPES-buffered synthetic human tubal fluid (modified HTF) (10). Fresh human donor sperms was suspended in the modified HTF and then mixed with the oocytes for 3 hours. Modified HTF served as the control. At the 0.1 mg/mL concentration, three of nine oocytes were penetrated, whereas at 1.0 mg/mL, zero (0 of 8) penetration occurred. The decrease in penetration was not associated with a decrease in sperm motility. In the second part of the study, sperms were incubated with the herbal solutions for 7 days. Neither concentration caused significant sperm DNA denaturation or mutation of a selected sperm sentinel gene (BRCA1 exon 11 gene), but the higher concentration reduced sperm viability compared with controls. Extrapolation of these data to the reproductive risk of ginkgo in males is difficult, in part because the concentration of the herb in semen or sperm has not been studied (10). Moreover, although the doses used in this study are small fractions of the actual recommended human dose, usually expressed in milligrams of ginkgo, no published evidence indicates that the adverse effects observed have occurred in vivo.

Although some ginkgo preparations may be standardized, the standardization of any herbal product as to its constituents, concentrations, and the presence of contaminants is generally lacking. Consumption of these products during pregnancy may result in fetal exposure to unintended chemicals and doses.

BREASTFEEDING SUMMARY

No reports describing the use of ginkgo biloba during lactation have been located. Although one source states that there are no restrictions to its use during lactation (1), other sources consider the use of the herb during lactation to be contraindicated (2–4). The latter course is the safest because of the large number of chemical compounds in the herb and the absence of information on the effects of exposure to these substances in a nursing infant.

GINSENG

Herb

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Ginseng is an ancient popular herb that is used extensively throughout the world. The reproductive effects of the herb in pregnant animals, except in one case, have not been studied. Similarly, only one small study has investigated its effect in human pregnancy, but the study did not mention if birth defects were observed. As with most herbal preparations, there appears to be little or no quality control in the production of commercial products, and mislabeling of these products is probably common. Ginseng is known to act on multiple organ systems. Depending on the product ingested and the dose and duration of use, the herb can produce clinically significant adverse reactions in nonpregnant patients. Hypertension and hypoglycemia have been reported with ginseng (1). These effects could complicate pregnancies with hypertensive disorders or diabetes. However, because ginseng has been used in medicine for more than 2000 years and its current use is widespread, it is doubtful if it causes major birth defects or other clinically significant developmental toxicity. More subtle or low-incidence effects, however, including structural and behavioral teratogenicity, the induction of abortions, and infertility, may have escaped detection. Further study using products identified by chemical analysis is required before human reproductive risk or safety can be assessed.

FETAL RISK SUMMARY

Ginseng is a plant that is found throughout the world. The root is considered the most important part of the plant because it contains the pharmacologically active ginsenosides. Ginseng has been used in medicine for >2000 years. The herb is promoted as having multiple pharmacologic effects, including

adaptogenic, CNS, cardiovascular, endocrine, ergogenic, antineoplastic, and immunomodulatory effects. It is available as fresh or dried roots, extracts, solutions, tablets, sodas, teas, chewing gum, cigarettes, and candy (1–3).

Although the name ginseng (common names, if given, shown in parentheses) commonly refers to *Panax quinquefolius* L. (American or Canadian ginseng) or *P. ginseng* C.A. Meyer (Asian, Chinese, Korean, or Oriental ginseng; red ginseng [steamed]), one source listed seven other recognized medicinal ginsengs (1). They are *P. japonicus* var *bipinnatifidus*, *P. japonicus* C.A. Meyer (Japanese, Chikusetsu, or zhu je ginseng), *P. japonicus* var *major*, *P. notoginseng* (Western or Five-fingers ginseng; Sang; San-chi; Tien-chan or tienqi ginseng), *P. pseudoginseng* subsp. *himalaicus* (Himalayan ginseng), *P. pseudoginseng* var *major* (Zhuzishen), and *P. vietnamensis* Ha et Grushv. (Vietnamese ginseng) (1).

A 1994 letter stated that there were eight species and three varieties of genus *Panax* in the Northern Hemisphere (4). The eight species were ginseng, *quinquefolium*, *notoginseng*, *pseudoginseng*, *zingigerensis*, *trifolus*, *stipuleanatus*, and *japonicus*. The varieties of *P. japonicus* were identified as var *major*, var *angustifolius*, and var *bipinnatifidus*.

Ginseng products are commercially available as food flavorings and herbal medicines. Although the minor constituents of ginseng listed below might have some role, the principal pharmacologically active ingredients of ginseng appear to be a group of steroid-like compounds linked to sugars, called saponins (ginsenosides) (1). At least 13 major saponins, as well as numerous minor glycosides, have been identified. Minor constituents include volatile oils, β -elemine, sterols, acetylenes, polysaccharides, starch, flavonoids, peptides, various B-complex vitamins, minerals, enzymes, and choline (1). Xanthines (e.g., caffeine, theophylline, and theobromine), produced by the plant, may also be present in various concentrations and may contribute to the pharmacologic action of the product (1).

The actual amount of ginsenosides in commercial preparations varies widely. This variance partially reflects poor quality control, but may also depend on the species, age of the root, location, season of harvest, and preservation or curing method (1). In addition, products sold as ginseng may actually contain no ginsenosides (2,5). For example, other herbal species that do not contain ginsenosides are also called “ginseng,” such as Siberian ginseng (*Eleutherococcus senticosus*; active constituents are eleutherosides) and Brazilian ginseng (*Pfaffia paniculata*) (6). In addition, Chinese silk vine (*Periploca sepium*), an herb that contains cardiac glycosides but no

ginsenosides, is a common substitute for Siberian ginseng (7).

A reproduction study with rats was conducted with an extract (G115) of Oriental ginseng (*P. ginseng*) (8). Two generations of rats, male and female, were fed a diet supplemented with ginseng extract at doses of 1.5, 5, or 15 mg/kg/day or a control diet. No differences in treatment-related effects were observed between the groups in terms of body weights, food consumption, hematologic and clinical chemical data. In addition, no differences were noted in ophthalmic, gross and histopathologic examinations, or in autopsies (8).

Ginseng (*P. ginseng*) was used as a fetal protectant in a study involving rats given hexavalent chromium throughout gestation (9). Hexavalent chromium, the most toxic form of chromium for the embryo and fetus, was fed to two groups of female rats in their drinking water. In one of the groups, ginseng (20 mg/kg/day) was also given. A third group received ginseng only, whereas a control group received neither agent. The rats receiving chromium plus ginseng had significantly better pregnancy outcomes than those receiving only chromium in terms of increased maternal weight gain, fewer pre- and postimplantation losses, resorptions, and stillbirths, and lower rates of visceral and skeletal anomalies (9).

The effects of American ginseng (*P. quinquefolium*) on male copulatory behavior have been studied in rats (10). Doses of 10–100 mg/kg/day given for 28 days significantly stimulated copulatory behavior. In comparison with controls, no effects were noted on plasma luteinizing hormone or testosterone levels, or on sex organs, but plasma prolactin concentrations were significantly decreased in ginseng-treated animals (10).

Three brief reports have described an estrogen-like effect (11) and vaginal bleeding (12,13) in three postmenopausal women taking ginseng (*P. ginseng* in two; unknown source in one).

A 30-year-old woman took an herbal preparation alleged to be pure Siberian ginseng (1300 mg/day—twice the manufacturer's recommended dose) throughout pregnancy and during the first 2 weeks of breastfeeding (14). In late pregnancy, she had repeated occurrences of premature uterine contractions. She also thought that the hair growth on her head, face, and pubic region had increased and was thicker. The term, 3.3-kg male infant had thick black hair in the pubic region and over the entire forehead, and swollen, red nipples (14). The mother stopped breastfeeding 2 weeks postpartum on medical advice because she did not want to stop taking the herb. At 7.5 weeks of age, the infant's weight (5.8 kg) and length (60.6 cm) were above the 97th percentile, but the pubic and forehead hair, which had begun to fallout at 2 weeks, was

scant. A physical examination revealed testes that were enlarged (volume = 3 mL) but were otherwise normal. In addition, there was no evidence of adrenogenital syndrome because the serum concentrations of 17-hydroxyprogesterone, testosterone, and cortisol were within normal ranges. The investigators noted that ginseng increases testosterone levels in male rats and testes growth in rabbits, and could significantly increase corticotropin and corticosteroid levels. Therefore, they concluded that the product she was taking might have caused the hirsutism in the mother and infant and the infant's excessive weight gain (14).

In response to the above case, a representative for a government agency argued that the cited animal studies involving ginseng had no relevance because the active constituents of Siberian ginseng were eleutherosides that are completely different from ginsenosides (15). In reply, one of the investigators stated that they had recently given the woman doses either of her Siberian ginseng or placebo in a double-blind manner. Her testosterone levels were undetectable when she was taking the herb and normal when she received placebo. The investigator hypothesized that the product she was taking contained a compound that suppressed, but acted like, endogenous testosterone (16). In the last correspondence on this case, three bulk lots of powder supposedly containing Siberian ginseng were obtained from the manufacturer of the product taken by the woman. The lot dates overlapped the period of her pregnancy. Chemical analysis revealed that the powder was actually Chinese silk vine (*P. sepium*), the bark of which contains cardioactive glycosides (17). Inadvertent substitution of Chinese silk vine for Siberian ginseng had occurred previously and may have resulted because of confusion surrounding the Chinese names of the herbs (17).

A brief 1991 correspondence compared the outcomes of 88 Asian women who had taken ginseng during pregnancy with 88 matched controls who had not taken the herb (18). No statistically significant differences were found in the mode of delivery, birth weight, low birth weight (<2500 g), preterm delivery (<37 weeks), low Apgar scores (<7), and stillbirths or neonatal deaths. Regarding pregnancy complications, there were no differences in the incidence of gestational diabetes, or antepartum or postpartum hemorrhage, but significantly more controls than subjects had preeclampsia (1 vs. 8; $p < 0.02$). No mention was made of congenital malformations in either group (18).

BREASTFEEDING SUMMARY

No studies describing the use of ginseng during human lactation have been

located. Confusion has arisen over the actual identity of commercial products (see above) and without chemical analysis, the actual herb ingested is uncertain. Ginseng can affect multiple organ systems in users and, potentially, could adversely affect a nursing infant if the ginsenosides (active constituents) were excreted into breast milk. However, it is doubtful if ginseng has caused clinically significant effects in nursing infants because of its ancient and widespread use. Although more subtle effects on a nursing infant could have been missed, the proven benefits of breastfeeding may outweigh the unknown risk from exposure to the active and inactive constituents of ginseng. Women taking this herb and nursing should be informed of this uncertainty.

GLATIRAMER

Immunologic Agent (Immunosuppressive)

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably
Compatible

PREGNANCY SUMMARY

The use of glatiramer during pregnancy appears to be low risk. In addition, the benefits of the drug in reducing the number of relapses of multiple sclerosis appear to outweigh the potential, but unknown risks to the embryo–fetus. If indicated, glatiramer should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Glatiramer (copolymer-1) is an immunosuppressant agent given by SC injection to reduce the frequency of relapses in patients with relapsing–remitting multiple sclerosis, including patients who experienced a first clinical episode and have features consistent with multiple sclerosis. It is the acetate salts of synthetic polypeptides containing four naturally occurring amino acids: L-glutamic acid, L-alanine, L-lysine, and L-tyrosine. Chemically, glatiramer is a designated L-glutamic acid polymer with L-alanine, L-lysine, and L-tyrosine, acetate (salt).

A substantial fraction of the dose is hydrolyzed locally, but some may enter the systemic circulation intact (1).

Reproduction studies during organogenesis have been conducted in rats and rabbits at SC doses up to 18 and 36 times the human dose of 20 mg based on BSA (HD), respectively. No adverse fetal effects were observed in either species. Pregnant rats were also given glatiramer at doses up to about 18 times the HD from gestational day 15 and throughout lactation. No significant effects were observed on delivery or pup growth or development.

Long-term studies for carcinogenesis in mice and rats were negative, as were assays for mutagenesis or clastogenic effects. In fertility and reproductive performance studies in rats at SC doses up to 18 times the HD, no adverse

effects were observed on reproductive or developmental parameters (1).

It is not known if glatiramer crosses the human placenta to the fetus. The average molecular weight of glatiramer acetate is 5000–9000, suggesting that it does not cross by simple diffusion.

A prospective observational cohort study from a Teratology Information Service in Berlin compared the pregnancy outcomes of four groups: exposure to glatiramer (N = 31) or interferon (N = 69) (either beta-1a (N = 48) or beta-1b (N = 21), women with multiple sclerosis not exposed to these agents (N = 64), and a healthy comparative group (N = 1556) (2). Spontaneous abortions (SABs), all within the expected range, in the four groups were 3.9%, 11.7%, 9.8%, and 9.1%, respectively. The higher rate in the interferon group was due to a 27.8% rate in the beta-1b subgroup. Major birth defects occurred in two exposed to glatiramer, none in the interferon group, three in the multiple sclerosis group, and 23 of the healthy controls. In the glatiramer-exposed group, club feet occurred in a term infant who was exposed until gestational week 6. The second defect in the glatiramer group was a complex heart defect diagnosed by ultrasound. The mother in this case had received the drug until gestational week 13. She also had received moxifloxacin for 1 day and levofloxacin for 5 days in week 6, as well as IV glucocorticoids for 3 days for relapse. Her pregnancy was electively terminated. The male fetus had a complete atrioventricular canal (grade III) with a normal karyotype. In all groups, the mean birth weights were within the normal range (>3200 g) but were significantly lower in the interferon group. The birth weights also were significantly lower in mothers who had relapsed. The authors concluded that neither glatiramer or interferon was a major risk for developmental toxicity (2).

A 2010 study reported the pregnancy outcomes of 13 women (14 newborns—one set of twins) with multiple sclerosis (3). Glatiramer was used throughout gestation in nine cases, discontinued early (weeks 4 or 5) in gestation in three cases, and discontinued at 19 weeks in one case. There were no birth defects in the 14 newborns (3).

A brief 2011 report described three women with multiple sclerosis who received glatiramer throughout gestation (4). The pregnancy outcomes were compared with seven women with more complicated (increased relapses) multiple sclerosis who were treated with interferon beta-1a throughout gestation. Birth weight was lower in the glatiramer group, 3142 g vs. 3444 g, but the glatiramer group was born earlier (38.3 vs. 39.7 weeks). In the glatiramer group, a male infant had hypospadias that required surgical correction. In the interferon group, a male infant had a valvular stenosis of the

pulmonary artery (4).

In a 2012 study from Germany, pregnancy outcomes in women with multiple sclerosis were compared in three groups: glatiramer (N = 41), interferon beta (N = 78), and pregnancies not exposed to these agents (N = 216) (5). There were no differences between the groups in terms of birth weight, body length, gestational age at birth, and preterm birth. Congenital anomalies were observed in two infants in the glatiramer group (defect of urinary bladder and hip dysplasia), three in the interferon group (ventricular septal defect [VSD], valvular stenosis of the pulmonary artery, and hip dysplasia), and seven in the control group (5).

A 2012 study from Italy evaluated the pregnancy outcomes in 423 cases where the mother had multiple sclerosis (6). In the prospective observational multicenter study, 17 were exposed to glatiramer, 88 to interferon beta, and 318 nonexposed. Glatiramer was not associated with a higher frequency of SAB or other negative pregnancy and fetal outcomes (6).

BREASTFEEDING SUMMARY

Because of the high molecular weight (about 5000–9000), it is doubtful if unmetabolized glatiramer is excreted into breast milk. In a 2010 report described above, 8 of 13 mothers receiving glatiramer chose to breastfeed their infants (3). The duration of nursing was 1 day to 6 months, but only two breastfed for a significant period (2 and 6 months). No other information was provided.

Three mothers who taken glatiramer throughout pregnancy continued the therapy during exclusive breastfeeding for 6 months (4). None of the infants had noticeable problems.

In the above study from Germany, 170 of 335 women throughout all three groups breastfed exclusively (5). Significantly reduced relapse rates of multiple sclerosis during the first 3 months occurred compared with nonexclusive breastfeeding or nonbreastfeeding women ($p < 0.0001$).

GLIMEPIRIDE

Antidiabetic Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

One report describing the use of glimepiride during human pregnancy has been located. Insulin is the treatment of choice for pregnant diabetic patients because, in general, other hypoglycemic agents do not provide adequate glycemic control. Moreover, insulin, unlike most oral agents, does not cross the placenta to the fetus, thus eliminating the additional concern that the drug therapy itself will adversely affect the fetus. Carefully prescribed insulin therapy provides better control of the mother's glucose, thereby preventing the fetal and neonatal complications that occur with this disease. High maternal glucose levels, as may occur in diabetes mellitus, are closely associated with a number of maternal and fetal adverse effects, including fetal structural anomalies if the hyperglycemia occurs early in gestation. To prevent this toxicity, the American College of Obstetricians and Gynecologists recommends that insulin be used for types 1 and 2 diabetes occurring during pregnancy and, if diet therapy alone is not successful, for gestational diabetes (1,2).

FETAL RISK SUMMARY

Glimepiride is a second-generation sulfonylurea in the same class as glipizide and glyburide (see also Glipizide and Glyburide). It is used as an adjunct to diet and exercise, either alone or in combination with other oral agents, in the treatment of type 2 diabetes (non-insulin-dependent diabetes mellitus). It has also been used in combination with insulin when diet, exercise, and an oral hypoglycemic have not controlled hyperglycemia.

Reproduction studies in animals have been conducted with glimepiride. No teratogenic effects were observed in rats and rabbits given doses up to

approximately 4000 and 60 times, respectively, the maximum recommended human dose based on BSA (MRHD). However, in some studies, rat pups, nursing from mothers given high doses of glimepiride during pregnancy and lactation, developed skeletal deformities consisting of shortening, thickening, and bending of the humerus during the postnatal period. Moreover, fetotoxicity (intrauterine death) occurred in both rats and rabbits at 50 and 0.1 times, respectively, the MRHD. The fetotoxicity, which has also been observed with other sulfonylureas, occurred only at doses that produced maternal hypoglycemia and was thought to be due to that effect. No effect on the fertility of male and female rats was noted at doses up to 4000 times the MRHD (3).

It is not known if glimepiride crosses the placenta, but the molecular weight (about 491) is low enough that transfer to the fetus should be expected. Hypoglycemia in the newborn may occur if glimepiride is taken close to delivery.

A 2005 case report described the pregnancy outcome of a 33-year-old woman treated with glimepiride for type 2 diabetes mellitus in the first 8 weeks of an unplanned pregnancy (4). Other diseases in the patient were hypertension, hypercholesterolemia, and morbid obesity that were treated with orlistat, ramipril, thiocolchicoside (a muscle relaxant), simvastatin, metformin, ciprofloxacin, and aspirin. When pregnancy was diagnosed at 8 weeks, all medications were stopped, and she was started on methyldopa and insulin. She gave birth at 38 weeks to a 3.470-kg female infant with Apgar scores of 5 and 7 at 1 and 5 minutes, respectively. No minor or major malformations were observed in the infant (4).

BREASTFEEDING SUMMARY

No reports describing the use of glimepiride during human lactation have been located. The relatively low molecular weight (about 491) suggests that the drug will be excreted into breast milk. Because neonatal hypoglycemia is a potential effect, women taking glimepiride should consider changing to insulin therapy while nursing.

GLIPIZIDE

Antidiabetic Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Although the use of glipizide may be beneficial for decreasing the incidence of fetal and newborn morbidity and mortality in developing countries where the proper use of insulin is problematic, insulin is still the treatment of choice for this disease during pregnancy. Moreover, insulin, unlike glipizide, does not cross the placenta, which eliminates the additional concern that the drug therapy itself is adversely affecting the fetus. Carefully prescribed insulin therapy will provide better control of the mother's blood glucose, thereby preventing the fetal and neonatal complications that occur with this disease. High maternal glucose levels, as may occur in diabetes mellitus, are associated with a number of maternal and fetal adverse effects, including fetal structural anomalies if the hyperglycemia occurs early in gestation. To prevent this toxicity, the American College of Obstetricians and Gynecologists recommends that insulin be used for types 1 and 2 diabetes occurring during pregnancy and, if diet therapy alone is not successful, for gestational diabetes (1,2). If glipizide is used during pregnancy, therapy should be changed to insulin. If glipizide is continued, it should be stopped before delivery (the exact time before delivery is unknown) to lessen the possibility of prolonged hypoglycemia in the newborn.

FETAL RISK SUMMARY

Glipizide is an oral sulfonylurea agent, structurally similar to glyburide that is used for the treatment of adult-onset diabetes mellitus. It is not the treatment of choice for the pregnant diabetic patient.

Reproductive studies in male and female rats showed no effect on fertility.

Mild fetotoxicity (type not specified) was observed at all doses tested in rats and was thought to be caused by the hypoglycemic action of glipizide. No teratogenic effects were observed in rats or rabbits (3).

A 1994 report described the in vitro placental transfer, using a single cotyledon human placenta, of four oral hypoglycemic agents (4). As expected, molecular weight was the most significant factor for drug transfer, with dissociation constant (pK_a) and lipid solubility providing significant additive effect. The cumulative percentage placental transfer at 3 hours of the four agents and their approximate molecular weights (shown in parentheses) were tolbutamide (270) 21.5%, chlorpropamide (277) 11.0%, glipizide (446) 6.6%, and glyburide (494) 3.9% (4).

A 1984 source cited a study that described the use of glipizide in four diabetic patients from the 32nd week of gestation through delivery (5). No adverse effects in the fetuses were observed.

A study published in 1995 assessed the risk of congenital malformations in infants of mothers with non-insulin-dependent diabetes during a 6-year period (6). Women were included in the study if, during the first 8 weeks of pregnancy, they had not participated in a preconception care program and then had been treated either with diet alone (group 1), diet and oral hypoglycemic agents (predominantly chlorpropamide, glyburide, or glipizide) (group 2), or diet and exogenous insulin (group 3). The 302 women eligible for analysis gave birth to 332 infants (5 sets of twins and 16 with two or three separate singleton pregnancies during the study period). A total of 56 (16.9%) infants had one or more congenital malformations, 39 (11.7%) of which were classified as major anomalies (defined as those that were either lethal, caused significant morbidity, or required surgical repair). The major anomalies were divided among those involving the CNS, face, heart and great vessels, gastrointestinal, genitourinary, and skeletal (includes caudal regression syndrome) systems. Minor anomalies included all of these, except those of the CNS, and a miscellaneous group composed of sacral skin tags, cutis aplasia of the scalp, and hydroceles. The number of infants in each group and the number of major and minor anomalies observed were group 1—125 infants, 18 (14.4%) major, 6 (4.8%) minor; group 2—147 infants, 14 (9.5%) major, 9 (6.1%) minor; and group 3—60 infants, 7 (11.7%) major, 2 (3.3%) minor. There were no statistical differences among the groups. Six (4.1%) of the infants exposed in utero to oral hypoglycemic agents and four other infants in the other two groups had ear anomalies (included among those with face defects). Other than the incidence of major anomalies, two other important findings of this study were

(1) the independent associations between the risk of major anomalies (but not minor defects) and poor glycemic control in early pregnancy and (2) a younger maternal age at the onset of diabetes. Moreover, the study did not find an association between the use of oral hypoglycemics during organogenesis and congenital malformations, in that the observed anomalies appeared to be related to poor maternal glycemic control (6).

BREASTFEEDING SUMMARY

Nondetectable levels of glipizide were reported in three of four milk samples from two women nursing their infants (7). The two women were on a steady-state dose of glipizide (5-mg immediate-release tablet every morning for 6 and 15 days). In one woman, the peak milk concentration (3 hours after dose) was 0.20 mcg/mL and the trough level was nondetectable (detection limit 0.08 mcg/mL). In the second woman, both the peak and trough samples had nondetectable glipizide levels. Blood glucose levels were normal in both of the exclusively breastfed infants (7).

GLUCAGON

Antidote

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

The limited animal and human pregnancy data suggest that the embryo and/or fetal risks from glucagon are very low or negligible. Apparently, the drug does not cross the placenta.

As with all antidotes, maternal treatment usually is paramount. Thus, in cases of severe hypoglycemia, when IV glucose cannot be administered, glucagon should not be withheld because of concern for embryo–fetal safety. The maternal consequences of withholding treatment might place the pregnancy at far greater risk than the undocumented risk from the drug.

FETAL RISK SUMMARY

Glucagon is a single-chain polypeptide hormone produced by recombinant DNA technology that is identical to human glucagon. Glucagon increases blood glucose by stimulating hepatic glycogenolysis and relaxes smooth muscle of the gastrointestinal tract. It also is used as an antidote for β -blocker overdose. Glucagon must be given parenterally because it is destroyed in the gastrointestinal tract and is not active when taken orally. The polypeptide contains 29 amino acid residues with a molecular weight of 3483. Glucagon treats severe hypoglycemia by the conversion of liver glycogen to glucose. It is also indicated as a diagnostic aid in the radiologic examination of the gastrointestinal tract when diminished intestinal motility is advantageous. The hormone is extensively metabolized in the liver, kidney, and plasma and has a very short elimination half-life (range 8–18 minutes) (1).

Reproduction studies have not been conducted with recombinant glucagon, but have been performed with animal-source glucagon. In rats, doses up to 40 times the human dose based on BSA revealed no evidence of impaired fertility or fetal harm (1).

An in vitro mouse study examined the effect of glucagon and other metabolic factors (insulin, β -hydroxybutyrate, and acetoacetate) on the preimplantation development of mouse embryos (2). Glucagon, as well as the other factors, demonstrated a statistically significant dose-related inhibition of blastocyst development when cultured over 72 hours. However, the relationship of the observed embryotoxicity to a typical human clinical exposure is doubtful.

The metabolic response to glucagon injections (1 mcg/kg to 1 mg/kg) was studied in chronically catheterized fetal lambs near term (3). A significant hyperglycemia occurred within 15–30 minutes but, in contrast to neonatal lambs, did not induce a significant ketogenesis.

In a 1992 study, no effects on renal function were observed in near-term fetal sheep administered pharmacologic doses of glucagon (0.5 mcg/kg/min) for 1.5 hours (4). However, a significant increase in fetal heart rate, without changes in arterial pressure, was noted.

Glucagon does not cross the placenta in sheep or humans (5–8). In an experiment with pregnant sheep at term, no transfer of radioiodine-labeled glucagon was detected either from the mother to the fetus or from the fetus to the mother (5). A 1972 human study failed to find evidence of glucagon placental transfer in three mothers at term (6). Similarly, in an in vitro study using human chorion, no transfer of glucagon to the fetal side was detected (7). In a 1976 study, 15 women received a 1-mg IV dose of glucagon within 40 minutes of delivery (8). Compared with 47 control subjects, no change in glucagon concentrations in umbilical cord blood was observed, suggesting a lack of significant placental transfer.

A 1987 study reported the outcomes of seven pregnant women who had received glucagon for severe hypoglycemia on 12 occasions during pregnancy (9). In each case, a single 1-mg dose was given SC or IM by a spouse or other family member, resulting in glucose levels of 100–200 mg/dL within 30 minutes in 11 cases. In one case, the woman did not respond and required IV glucose in the emergency room. Although the gestational timing of the glucagon doses was not given, all of the infants survived and had normal Apgar scores at birth (9).

Glucagon was used as an antidote in a pregnant woman who had taken a massive overdose (15.2 g) of the β -blocker, metoprolol (10). At 20 weeks' gestation, the woman ingested 152 100-mg tablets in a suicide attempt. She suffered cardiac arrest in the hospital. Despite prolonged, but successful, cardiopulmonary resuscitation, she remained in severe cardiogenic shock with low systolic blood pressure. When the nature of the ingestion was learned, the

woman was given glucagon 1-mg IV. Her condition markedly improved after the glucagon, but intrauterine fetal death had occurred and an induced abortion was performed 10 days later (10).

A 2003 review on the effects of antidotes in pregnancy concluded that there was probably no teratogenic risk because of the endogenous nature of glucagon (11). However, doses >1 mg in human pregnancy have not been reported.

BREASTFEEDING SUMMARY

No reports describing the use of glucagon during lactation have been located. It is doubtful if such reports would be forthcoming because of the nature of its indications (severe hypoglycemia; antidote; diagnostic agent) and its very short elimination half-life (8–18 minutes). Moreover, even if the high molecular weight (3483) polypeptide hormone were excreted into milk, it would be broken down to its constituent amino acids or fragments thereof in the infant's digestive tract. Thus, the risk to a nursing infant appears to be negligible.

GLUCARPIDASE

Antidote

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of glucarpidase in human or animal pregnancy have been located, but such reports are unlikely because of the drug's indication. The use of methotrexate in pregnancy is contraindicated (see Methotrexate). However, if the drug was used because a pregnant woman inadvertently received methotrexate, the benefit–risk ratio might favor glucarpidase.

FETAL RISK SUMMARY

Glucarpidase is a carboxypeptidase produced by recombinant DNA technology. The enzyme is a homodimer protein that converts methotrexate to its inactive metabolites. It is indicated for the treatment of toxic plasma methotrexate concentrations ($>1 \mu\text{mol/L}$) in patients with delayed methotrexate clearance due to impaired renal function. The metabolism and plasma protein binding data were not specified, but the elimination half-life is 9 hours (1).

Reproduction studies in animals have not been conducted. Neither have studies been conducted for carcinogenic and mutagenic potential, and studies for impairment of fertility.

It is not known if glucarpidase crosses the human placenta. The molecular weight (83,000) suggests that the protein will not cross to the embryo–fetus, at least early in gestation.

BREASTFEEDING SUMMARY

No reports describing the use of glucarpidase during human lactation have been located. The molecular weight (83,000) suggests that the protein will not be excreted into mature milk, but might be excreted during the colostrum phase.

However, reports of its use during breastfeeding are unlikely because of its indication. Methotrexate is contraindicated during breastfeeding (see Methotrexate).

GLUCOSAMINE

Dietary Supplement

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Except for the one study, no reports describing the use of glucosamine in human pregnancy have been located. The very limited animal data suggest low risk, but the human data are too limited to determine the risk of glucosamine in pregnancy. However, glucosamine is an endogenous substance widely found in human tissues, so the embryo–fetus must synthesize it during development. Moreover, the availability of free glucosamine to cross the placenta also is apparently very limited. Therefore, the planned or inadvertent use of glucosamine during gestation does not appear to represent a clinically significant risk of embryo–fetal harm.

FETAL RISK SUMMARY

Glucosamine, an amino-sugar, is an endogenous substance found in chitin, glycoproteins, and glycosaminoglycans (formerly known as mucopolysaccharides). It not only is derived from marine exoskeletons but also is prepared synthetically. Endogenous glucosamine is involved in the process of cartilage tissue formation and is present in tendons and ligaments. Commercial formulations of glucosamine, sometimes in combination with chondroitin or manganese, are used to treat osteoarthritis and other inflammatory conditions (1–4). The drug is available in oral, injectable (intra-articular, IM, and IV), and topical formulations, but only the oral form is available in the United States (2,3,5). Oral bioavailability (26%) is limited by hepatic metabolism, whereas IM bioavailability is 96%. After absorption, glucosamine is incorporated into plasma proteins, and the elimination half-life is 57–70 hours (5). No official standards regulate glucosamine production in the United States, so the actual dose taken

cannot be accurately determined.

In a 1956 study, no teratogenicity was observed in mice and rabbits (6). However, glucosamine has been suspected of inhibiting protein, RNA, and DNA synthesis (1). The clinical significance of this is unknown.

It is not known if glucosamine crosses the animal or human placenta. The molecular weight (about 179) and prolonged plasma protein elimination half-life suggest that the drug will cross to the embryo–fetus. However, unbound glucosamine is concentrated in articular cartilage and free drug is undetectable in the plasma (3). Therefore, it appears that free drug at the maternal:fetal interface is very limited and that little, if any, glucosamine would be available to cross the placenta.

A 2005 abstract cited data from an ongoing study involving the exposure of pregnant patients to glucosamine (7). Of the 55 women in the study, outcome data were available for 34 pregnancies (20 pregnancies ongoing; 1 case no data provided): 33 livebirths (2 sets of twins) and 3 spontaneous abortions. A male infant had a scrotal hernia, which was repaired surgically (7). The timing of the exposures, doses, and other information were not provided in this brief abstract.

Concern has been expressed that glucosamine might alter glucose metabolism (1–5). A 2006 review, however, concluded that the agent could be used in some patients without affecting glucose control, but data in diabetic patients were limited (8). Because pregnancy is a state of insulin resistance, pregnant women with diabetes should be monitored closely for changes in glucose control.

BREASTFEEDING SUMMARY

No reports describing the use of glucosamine during human lactation have been located. The molecular weight (about 179) and prolonged plasma protein elimination half-life suggest that the drug could be excreted in breast milk. However, unbound glucosamine is undetectable in the plasma (3). Therefore, it appears that little, if any, drug will be excreted into milk, and its use during lactation probably is compatible.

GLYBURIDE

Antidiabetic Agent

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

The evidence suggests that glyburide may be an acceptable alternative to insulin in gestational diabetes, but the risk factors for failure need to be considered in the decision to use the oral agent. Glyburide also may be beneficial for decreasing the incidence of fetal and newborn morbidity and mortality in developing countries and in some populations where the proper use of insulin is problematic. Moreover, either the agent does not cross the placenta in detectable amounts or is actively transported back to the mother. In either case, neonatal hypoglycemia secondary to glyburide appears to be a low risk. Insulin is the treatment of choice for diabetic types 1 and 2. For non-insulin-dependent diabetics (type 2), close control of the mother's blood glucose with insulin, preferably starting before conception, will help to prevent the fetal and neonatal complications that occur with this disease. High maternal glucose levels, as may occur in diabetes mellitus, are associated with a number of maternal and fetal adverse effects, including fetal structural anomalies if the hyperglycemia occurs early in gestation. To prevent this toxicity, the American College of Obstetricians and Gynecologists recommends that insulin be used for types 1 and 2 diabetes occurring during pregnancy and, if diet therapy alone is not successful, for gestational diabetes (1,2).

FETAL RISK SUMMARY

Glyburide is a second-generation, oral sulfonylurea agent, structurally similar to acetohexamide and glipizide that is used for the treatment of adult-onset diabetes mellitus. It is not the treatment of choice for the pregnant diabetic patient. Glyburide is metabolized to inactive metabolites. The decrease in glyburide serum levels is biphasic with a terminal half-life of about 10 hours (3).

No fetotoxicity or teratogenicity was observed in pregnant mice, rats, and rabbits fed large doses of the agent (4). In pregnant rats, glyburide crossed the placenta to the fetus (fetal:maternal ratio 0.541) in amounts similar to diazepam (fetal:maternal ratio 0.641) (5).

In studies using in vitro techniques with human placentas, only relatively small amounts of glyburide were observed to transfer from the maternal to the fetal circulation (6–11), and the use of placentas from diabetic patients (7) or with high glucose concentrations (8) did not change the amounts transferred. Concentrations used on the maternal side of the perfused placenta model were approximately 800 ng/mL, much higher than the average peak serum level of 140–350 ng/mL obtained after a single 5-mg oral dose (9). Transport of the drug to the fetal side of the placenta was 0.62% at 2 hours.

The in vitro placental transfer, using a single cotyledon human placenta, of four oral hypoglycemic agents has been described (10). As expected, molecular weight was the most significant factor for drug transfer, with the dissociation constant (pK_a) and lipid solubility providing a significant additive effect. The cumulative percentage placental transfer at 3 hours of the four agents and their approximate molecular weights (shown in parentheses) were tolbutamide (270) 21.5%, chlorpropamide (277) 11.0%, glipizide (446) 6.6%, and glyburide (494) 3.9% (10). In a study using similar in vitro techniques with human placentas, glyburide did not increase glucose transfer to the fetus or affect the placental uptake of glucose (11).

A commentary in 2001 considered several factors (pK_a , molecular weight, lipid solubility, elimination half-life, and protein binding) that could limit glyburide from crossing the placenta (12). The short elimination half-life (4 hours) and extensive protein binding (99.8%) were thought to be the major determinants limiting transplacental transfer (12).

A 2006 study using an in vitro perfused human placental cotyledon reported evidence of active glyburide transport from the fetal to the maternal side (13). The transfer was against a concentration gradient, as the initial fetal:maternal concentration ratio was 0.92 and then decreased over 3 hours to 0.31. The investigators concluded that this was the first direct evidence of active transport from the fetus to the mother of any medicinal drug used during pregnancy (13).

A 1991 report described the outcomes of pregnancies in 21 non-insulin-dependent diabetic women who were treated with oral hypoglycemic agents (17 sulfonylureas, 3 biguanides, and 1 unknown type) during the 1st trimester (14). The duration of exposure was 3–28 weeks, but all patients were changed to insulin therapy at the first prenatal visit. Forty non-insulin-dependent diabetic

matched women served as a control group. Eleven (52%) of the exposed infants had major or minor congenital malformations compared with 6 (15%) of the controls. Moreover, ear defects, a malformation that is observed, but uncommonly, in diabetic embryopathy, occurred in six of the exposed infants and in none of the controls. Two of the infants with defects (anencephaly; ventricular septal defect) were exposed in utero to glyburide during the first 10 and 23 weeks of gestation, respectively, but these and the other malformations observed, with the possible exception of the ear defects, were thought to be related to poor blood glucose control during organogenesis. The cluster of ear defects, however, suggested a drug effect or synergism between the drug and lack of metabolic control in the mother. Sixteen live births occurred in the exposed group compared with 36 in the control group. The groups did not differ in the incidence of hypoglycemia at birth (53% vs. 53%), but 3 of the exposed newborns (not exposed to glyburide) had severe hypoglycemia lasting 2, 4, and 7 days, even though the mothers had not used oral hypoglycemics close to delivery. This was attributed to irreversible β -cell hyperplasia that may have been increased by exposure to oral hypoglycemics. Hyperbilirubinemia was noted in 10 (67%) of 15 exposed newborns compared to 13 (36%) of controls ($p < 0.04$), and polycythemia and hyperviscosity requiring partial exchange transfusions were observed in 4 (27%) of 15 exposed vs. 1 (3.0%) control ($p < 0.03$) (1 exposed infant was not included in these data because of delivery after completion of study) (14).

The use of glyburide in all phases of human gestation has been reported in other studies (15–19). In these studies, glyburide (glibenclamide) was either used alone or combined with the oral antihyperglycemic agent, metformin (see Metformin). Neonatal hypoglycemia (blood glucose < 25 mg/dL) was present in 4 of 15 (27%) newborns who were exposed to glyburide during gestation (16,17). This adverse effect was 3.5 times that observed in a group of newborns whose mothers were treated with insulin. Moreover, in one newborn, the hypoglycemia persisted for more than 48 hours (16).

A study published in 1995 assessed the risk of congenital malformations in infants of mothers with non-insulin-dependent diabetes (NIDDM) over a 6-year period (20). Women were included in the study if, during the first 8 weeks of pregnancy, they had not participated in a preconception care program and then had been treated either with diet alone (group 1), diet and oral hypoglycemic agents (predominantly chlorpropamide, glyburide, or glipizide) (group 2), or diet and exogenous insulin (group 3). The 302 women eligible for analysis gave birth to 332 infants (5 sets of twins and 16 with two or three separate singleton

pregnancies during the study period). A total of 56 (16.9%) of the infants had one or more congenital malformations, 39 (11.7%) of which were classified as major anomalies (defined as those that were either lethal, caused significant morbidity, or required surgical repair). The major anomalies were divided among those involving the central nervous system, face, heart and great vessels, gastrointestinal, genitourinary, and skeletal (includes caudal regression syndrome) systems. Minor anomalies included all of these, except those of the central nervous system, and a miscellaneous group composed of sacral skin tags, cutis aplasia of the scalp, and hydroceles. The number of infants in each group and the number of major and minor anomalies observed were group 1—125 infants, 18 (14.4%) major, 6 (4.8%) minor; group 2—147 infants, 14 (9.5%) major, 9 (6.1%) minor; and group 3—60 infants, 7 (11.7%) major, 2 (3.3%) minor. There were no statistical differences among the groups. Six (4.1%) of the infants exposed in utero to oral hypoglycemic agents and four other infants in the other two groups had ear anomalies (included among those with face defects). Another important finding of this study was the independent association between the risk of major anomalies and poor glycemic control in early pregnancy. The study did not find an association between the use of oral hypoglycemics during organogenesis and congenital malformations because the observed anomalies appeared to be related to poor maternal glycemic control (20).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 37 newborns had been exposed to glyburide during the 1st trimester (F. Rosa, personal communication, FDA, 1993). One (2.7%) major birth defect was observed (two expected), which was a cardiovascular defect (0.4 expected). No anomalies were observed in five other categories of defects (oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available.

A study published in 2000 compared the pregnancy outcomes in gestational diabetic women with singleton pregnancies who were randomly assigned to treatment with glyburide or insulin (21). A majority of the women (83%) were Hispanic, mostly Mexican American. The study was not blinded. The goals of treatment were the achievement of a mean glucose concentration of 90–105 mg% and fasting, preprandial, and postprandial glucose levels of 60–90, 80–95, and <120 mg%, respectively. A total of 404 women were enrolled, 201 in the glyburide group and 203 in the insulin group. The mean pretreatment glucose concentrations, fasting, preprandial, and postprandial concentrations,

and the glycosylated hemoglobin's in the glyburide and insulin groups were 114 vs. 116 mg%, 104 vs. 108 mg%, 104 vs. 107 mg%, 130 vs. 129 mg%, and 5.7% vs. 5.6%, respectively. These results are indicative of mild hyperglycemia. There were no significant differences between the groups in terms of any characteristic, including the gestational age at start of therapy and at delivery. The mean doses of glyburide and insulin were 9 mg/day and 85 units/day, respectively. Eight (4%) of the women randomized to glyburide failed to achieve good glycemic control and were changed to insulin. During treatment, the mean blood glucose concentrations and the mean fasting, preprandial, and postprandial values did not differ significantly between the glyburide and insulin groups. Nor was there a difference in the mean glycosylated hemoglobin values, 5.5% vs. 5.4%, respectively, measured late in the 3rd trimester. In 12 randomly selected women a mean 8 hours after the last dose, the glyburide maternal serum concentrations ranged from 50 to 150 ng/mL, whereas glyburide was undetectable in cord serum. No significant differences were measured between the groups in terms of neonatal features, metabolic outcomes, or perinatal mortality (21). An accompanying editorial explored the strengths and limitations of the study (22).

Several reports and an editorial have studied (23–27) or discussed (28) the use of glyburide for the treatment of gestational diabetes not controlled by diet. The studies reported favorable control of glucose levels with relatively few patients requiring a change to insulin therapy. However, in one study, glyburide-treated women had an increased risk of preeclampsia and their infants were more likely to require phototherapy for hyperbilirubinemia (25). Several risk factors have been identified that were predictors of glyburide failure: higher mean glucose values on glucose challenge test and more likely to have a test value ≥ 200 mg/dL (26); and diagnoses of diabetes earlier in gestation (23 vs. 28 weeks') of older age (34 vs. 29 years) and multiparity, and with higher fasting glucoses (>110 mg/dL) (27).

BREASTFEEDING SUMMARY

Nondetectable levels of glyburide in breast milk were reported in a 2005 study involving 11 lactating women, 3 of whom were nursing infants (29). The analysis of glyburide in milk was conducted at two different laboratories. Of eight nonbreastfeeding subjects, six received a single 5- mg dose and two received a single 10-mg dose. Glyburide was not detected in the milk of these cases (detection limit 0.005 mcg/mL). Three breastfeeding women on a steady-state dose of glyburide (5 mg every morning for 4–7 days) also had nondetectable

peak (4 hours post-dose) and trough glyburide levels in their milk (detection limit 0.080 mcg/mL). Blood glucose levels were normal in two of the breastfed infants (not determined in the third infant because supplements were being given) (29).

GLYCERIN

Laxative

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Only one report describing the use of glycerin in human pregnancy has been located. The near absence of human pregnancy experience prevents a full assessment of the embryo–fetal risk.

FETAL RISK SUMMARY

In a 2013 case report, a 24-year-old woman at 22 weeks' gestation was treated with 6 weeks of meropenem (3 g/day) and cefotaxime (2 g/day) for a brain abscess (1). Glycerin (20 g/day) was given to reduce intracranial pressure. She responded well to the therapy. At term, she gave birth to a normal 2890-g female infant (1).

BREASTFEEDING SUMMARY

No data are available.

GLYCOPYRROLATE

Parasympatholytic (Anticholinergic)

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Glycopyrrolate is an anticholinergic agent. Although the data are very limited, there is no evidence that drugs in this class cause developmental toxicity.

FETAL RISK SUMMARY

In pregnant sheep, the transfer of glycopyrrolate (0.025 mg/kg) across the placenta was significantly less than that of atropine (0.05 mg/kg) (1). No change in maternal or fetal arterial pressure, fetal heart rate, or beat-to-beat variability was observed. In pregnant dogs, the placental passage of glycopyrrolate was again significantly less than that of atropine (2).

In a large prospective study, 2323 patients were exposed to this class of drugs during the 1st trimester, only 4 of whom took glycopyrrolate (3). A possible association was found between the total group and minor malformations.

Glycopyrrolate has been used before cesarean section to decrease gastric secretions (4–7). Maternal heart rate, but not blood pressure, was increased. Uterine activity increased as expected for normal labor. Fetal heart rate and variability were not changed significantly, confirming the limited placental transfer of this quaternary ammonium compound. No effects in the newborns were observed.

In a 1999 double-blind, randomized, controlled study, women were treated with either glycopyrrolate (N = 24) or placebo (N = 25) immediately before induction of subarachnoid anesthesia for elective cesarean section to determine if the drug reduced the incidence and severity of nausea (8). Glycopyrrolate reduced the frequency ($p = 0.02$) and severity ($p = 0.03$) of nausea. It also

reduced the severity of hypotension as evidenced by reduced ephedrine requirements ($p = 0.02$). There was no difference in Apgar scores between the two groups (8).

A 2011 study was conducted to determine if glycopyrrolate prevents bradycardia in women receiving spinal anesthesia for cesarean section (9). In the double-blind, placebo-controlled study, 34 patients received glycopyrrolate and 35 received saline. Bradycardia (heart rate $<60/\text{min}$) occurred in none of the glycopyrrolate patients and in six of the placebo group ($p = 0.02$) (9).

Glycopyrrolate has been recommended as the anticholinergic of choice during anesthesia for electroconvulsive therapy in pregnant patients (10).

BREASTFEEDING SUMMARY

No reports describing the use of glycopyrrolate during human lactation have been located (see also Atropine).

GOLDENSEAL

Herb

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity (High or Frequent Doses)

PREGNANCY SUMMARY

Goldenseal and its active isoquinoline alkaloids, hydrastine and berberine, should be avoided in pregnancy because they can stimulate uterine contractions and induce labor. Although dosage information and clinical reports are lacking, goldenseal has been used traditionally as an abortifacient. Nevertheless, goldenseal preparations have been available for centuries, and the absence of reports describing human pregnancy toxicity suggests low risk, at least from usual doses. However, the safest course is to avoid this herb in pregnancy, especially high doses and/or frequent use.

FETAL RISK SUMMARY

The perennial herb, goldenseal is found in the woods of the Ohio River valley and other locations in the northeastern United States. It also is grown commercially in Washington State, New York, North Carolina, and Canada (1). Goldenseal has been used for hundreds of years and is one of the five top-selling herbal products in the United States (2). The principal active components, found in the roots, include the isoquinoline alkaloids (range of concentrations) hydrastine (1.5%–4%) and berberine (0.5%–6%). Other alkaloids with apparently less activity include canadine (tetrahydroberberine), palmatine, and berberastine. For goldenseal, the typical daily doses for tablets and capsules is 0.75–3.4 g/day, 0.9–3 mL of fluid extract, 6–12 mL of tincture, and 1.5–3 g of dried root as a decoction (1,2).

Goldenseal is a component of many over-the-counter products, such as dietary supplements, digestive aids, eardrops, cold/flu and allergy remedies, and laxatives. The herb or individual alkaloids have been used for their antimicrobial, antidiarrheal, anti-inflammatory, antiproliferative, cardiovascular,

ophthalmic, immunostimulant, and other effects, but controlled trials are lacking. Moreover, the alkaloids are poorly absorbed when taken orally (1,2).

Reproduction studies have been conducted in rats and mice (3–8). In pregnant rats, a daily oral dose that was 65 times the human dose based on body weight was given on gestation days 1–8 or 8–15 (3). Compared with controls, there was no increase in pre- or postimplantation losses, no change in fetal weight, and no difference in the incidence of external or internal malformations. In a separate study, rat embryos were explanted on gestation day 10.5 and cultured with increasing concentrations (0.5–6 $\mu\text{L}/\text{mL}$) of goldenseal extract for 26 hours in rat serum. Compared with nonexposed embryos, growth restriction and embryotoxicity were observed in a dose-dependent manner beginning at 1 $\mu\text{L}/\text{mL}$. The different results observed were thought to be due to the poor oral absorption of goldenseal. Because goldenseal is unlikely to be absorbed to the same extent as the concentrations used in the in vitro study, the authors thought that the herb, at the prescribed human dose, would not cause human embryo toxicity (3).

In a series of studies conducted by the National Toxicology Program, no developmental toxicity was observed in pregnant rats and mice at doses that were less than the maternal toxic dose (4–9).

It is not known if the active isoquinoline alkaloids of goldenseal cross the human placenta. The molecular weights of two alkaloids, berberine (about 353) and canadine (about 339), are low enough to cross. However, the poor systemic bioavailability after recommended oral doses suggests that little will reach the maternal circulation and be available to expose the embryo–fetus. Higher doses, however, may result in greater bioavailability and, consequently, greater embryo–fetal exposure.

Hydrastine and berberine are known to be uterine stimulants (1,2). Although published clinical trials are lacking, herbs containing these constituents have been used traditionally as abortifacients (2). The dose required for this effect has not been published.

BREASTFEEDING SUMMARY

No reports describing the use of goldenseal or its active constituents during lactation have been located. Systemic absorption is poor after ingestion of recommended doses, so the amount of alkaloids in milk is most likely very low. High or frequent doses, however, might result in systemic concentrations and excretion into breast milk. Berberine, one of the active isoquinoline alkaloids of goldenseal, is known to displace bilirubin from albumin in animal studies,

resulting in increased serum total and direct bilirubin concentrations (2). The risk of this for a nursing infant is unknown but probably low if the mother is ingesting low, infrequent doses of goldenseal. However, high doses or frequent use of goldenseal, or use of the specific alkaloids, could place the infant at risk of icterus or jaundice. Until human data are available, the safest course is to avoid goldenseal or its active alkaloids while breastfeeding (10).

GOLD SODIUM THIOMALATE

Immunologic Agent (Antirheumatic)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Although gold compounds apparently do not pose a major risk to the fetus, the clinical experience is limited and long-term follow-up studies of exposed fetuses have not been reported.

FETAL RISK SUMMARY

Gold sodium thiomalate is indicated in the treatment of active rheumatoid arthritis. Teratogenic effects were observed in rats and rabbits given SC doses 140 and 175 times the usual human dose, respectively, during organogenesis (1). In rats, the defects were hydrocephaly and microphthalmia, whereas those in rabbits were limb malformations and gastroschisis.

Gold compounds have been used for the treatment of maternal rheumatoid arthritis and other conditions in a small number of pregnancies (2–7). One review noted that several pregnant patients had been treated with gold salts without harmful effects observed in the newborns (2). In a Japanese report, 119 patients were treated during the 1st trimester with gold, 26 of whom received the drug throughout pregnancy (3). Two anomalies were observed in the newborns—a dislocated hip in one infant and a flattened acetabulum in another—but the association with the therapy is unknown. A German case history involved a woman who received her last injection of gold for chronic polyarthritis in the 3rd week of pregnancy (4). A growth-restricted, 1750-g female infant was delivered at 40 weeks' gestation. Other than the low birth weight, no other abnormalities were noted in the infant, whose development during the next 2 years was normal. In another case, a woman had been treated with gold sodium thiomalate (sodium aurothiomalate) for 2 years immediately prior to pregnancy, receiving her last dose when several weeks

pregnant (5). No adverse effects in the newborn were mentioned.

Gold compounds cross the placenta. A patient who had received a total dose of 570 mg of gold sodium thiomalate from before conception through the 20th week of gestation elected to terminate her pregnancy (6). No obvious fetal abnormalities were observed, but gold deposits were found in the fetal liver and kidneys. A second patient received monthly 100-mg injections of gold throughout pregnancy (7). The last dose, given 3 days prior to delivery, produced a cord serum concentration of 2.25 mcg/mL, 57% of the simultaneous maternal serum level. No anomalies were observed in the infant.

BREASTFEEDING SUMMARY

Gold is excreted in milk (5,8–10). A woman received a total aurothioglucose dose of 135 mg in the postpartum period (8). Gold levels in two milk samples collected a week apart were 8.64 and 9.97 mcg/mL, respectively. The validity of these figures has been challenged on a mathematical basis, so the exact amount excreted is open to question (9). In addition, the timing of the samples in relation to the dose was not given. Of interest, however, was the demonstration of gold levels in the infant's red blood cells (0.354 mcg/mL) and serum (0.712 mcg/mL) obtained on the same date as the second milk sample. The author speculated that this unexpected oral absorption may have been the cause of various unexplained adverse reactions noted in nursing infants of mothers receiving gold injections, such as rashes, nephritis, hepatitis, and hematologic abnormalities (8).

Another report described a lactating woman who was treated with 50 mg of gold sodium thiomalate weekly for 7 weeks after an initial 20-mg dose (total dose 370 mg) (10). Milk and infant urine samples collected 66 hours after the last dose yielded gold levels of 22 and 0.4 ng/mL, respectively. Repeat samples collected 7 days after an additional 25-mg dose produced milk and urine levels of 40 and <0.4 ng/mL, respectively. Three months after cessation of therapy, transient facial edema was observed in the nursing infant, but it was not known whether this was related to the maternal gold administration (10).

In a 1986 report, two women were given IM injections of gold sodium thiomalate (5). One patient received 20 mg on day 1 followed by 50 mg on day 3. Milk concentrations rose from a low of 17 ng/mL (1.4% of simultaneous maternal serum) 10 hours after the first dose to a peak of 153 ng/mL (approximately 4.6% of maternal serum) 22 hours after the second dose. The second patient received three doses of the gold salt consisting of 10 mg on day 1, 20 mg on day 8, and 20 mg on day 12. The peak milk concentration, 185

ng/mL (10.4% of maternal serum), occurred 3 hours after the third dose. The levels of gold in the milk of both patients increased steadily over the sampling periods. The investigators estimated that the nursing infant would receive about 20% of the maternal dose (5).

Three studies have described the excretion of gold into breast milk, with milk concentrations in two of the studies similar in magnitude. Gold absorption by the nursing infant has been documented. Although adverse effects have been suggested, a direct cause-and-effect relationship has not been proven. At least one set of investigators cautioned that, due to the prolonged maternal elimination time after gold administration and the potential for toxicity in the infant, nursing should be avoided (5). However, the American Academy of Pediatrics classifies gold salts as compatible with breastfeeding (11).

GOLIMUMAB

Immunologic Agent (Immunomodulator)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk Contraindicated (if combined with methotrexate)

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible Contraindicated (if combined with methotrexate)

PREGNANCY SUMMARY

No reports describing the use of golimumab in human pregnancy have been located. The animal data from one species suggest that the embryo–fetal risk is low. However, the lack of human pregnancy experience prevents a full assessment of the risk. There is some similarity between the action of immunomodulators with antitumor necrosis factor alpha (TNF α) activity and the human teratogen thalidomide, a drug that also decreases the activity of TNF α (see Thalidomide). However, decreased production of TNF α may not be a primary cause of the teratogenicity of thalidomide. Theoretically, TNF α antagonists could interfere with implantation and ovulation, but this has not been shown clinically (1). If golimumab is indicated in a pregnant woman, she should be informed of the absence of human pregnancy data. Moreover, until adequate human data are available, the safest course is to avoid the drug during organogenesis (20–55 days after conception or 34–69 days from the first day of the last menstrual period).

FETAL RISK SUMMARY

Golimumab is a human IgG1k monoclonal antibody that blocks human TNF α . TNF α is a pro-inflammatory cytokine with a central role in inflammatory processes. Golimumab is in the same subclass of immunomodulators as adalimumab, certolizumab pegol, etanercept, and infliximab that block TNF. It is indicated, in combination with methotrexate, for the treatment of adult patients with moderately to severely active rheumatoid arthritis. Golimumab also is indicated, either alone or with methotrexate, for the treatment of adult patients with active psoriatic arthritis and, alone for the treatment of adult patients with active ankylosing spondylitis. The median terminal half-life is about 2 weeks (2).

Reproduction studies have been conducted in monkeys. Pregnant monkeys were given twice-weekly SC doses during the 1st trimester that were up to 300 times the maximum recommended human dose based on weight. No evidence of maternal or fetal harm or developmental defects was observed. The drug crossed the placenta as indicated by its presence in umbilical cord blood obtained at the end of the 2nd trimester. When monkeys were given twice-weekly SC doses during the 2nd and 3rd trimesters, no evidence of maternal or neonatal harm was noted. The doses produced maternal and neonatal exposures that were 860 and 310 times, respectively, the maximal steady state human blood levels. This exposure during pregnancy and lactation had no effect on the development and maturation of the immune system in offspring (2,3).

Studies for neither carcinogenicity nor mutagenicity have been conducted with golimumab. A study in mice using an analogous anti-mouse TNF α antibody showed no impairment of fertility (2).

It is not known if golimumab crosses the human placenta. The molecular weight (about 150,000–151,000) is high, but immunoglobulin G crosses the placenta late in pregnancy (see Immune Globulin Intravenous). Placental transfer of IgG was a function of dose, as well as gestational age. Moreover, golimumab crossed to the fetus in monkeys and, because the placentas in monkeys are similar to those in humans, the antibody should be expected to cross to the human fetus.

BREASTFEEDING SUMMARY

No reports describing the use of golimumab during human lactation have been located. It is not known if the antibody is excreted into breast milk. The molecular weight (about 150,000–151,000) is high, but the terminal half-life is very long (about 2 weeks). Because immunoglobulins are excreted into milk, exposure of a nursing infant should be expected. The effect of this exposure is unknown, but serious infections have been observed in human adults treated with golimumab. However, exposure during lactation had no effect on the development and maturation of the immune system in monkey offspring (3). Nevertheless, if a woman elects to nurse her infant while receiving this agent, close observation of the infant for signs and symptoms of infection should be considered.

GRANISETRON

Antiemetic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Three reports describing the use of granisetron during human gestation have been located. Because of the indication for this drug, the opportunity for fetal exposure appears to be minimal.

FETAL RISK SUMMARY

Granisetron is an antiemetic used for the prevention of nausea and vomiting in patients receiving cancer chemotherapy. The drug is a selective 5-hydroxytryptamine₃ (5-HT₃)-receptor antagonist with little or no affinity for other serotonin receptors (1). No evidence of an effect on plasma prolactin concentrations has been found in clinical studies.

Reproductive studies at doses up to 146 and 96 times, respectively, the recommended human dose based on BSA in pregnant rats and rabbits found no evidence of impaired fertility or harm to the fetus (1). Shepard reviewed three studies conducted in rats and rabbits before and after conception or in the perinatal and postnatal periods that found no adverse fetal effects or drug-related effects on behavior (2).

It is not known whether granisetron crosses the placenta to the fetus. The molecular weight (about 349) is low enough that passage to the fetus should be expected.

Granisetron has been used to prevent vomiting during cesarean section (3) and with chemotherapy in the 3rd trimester (4,5). No fetal or newborn complications related to the antiemetic were reported.

BREASTFEEDING SUMMARY

No reports describing the use of granisetron during lactation have been located. The indication for granisetron therapy, however, suggests that the opportunities for use of the drug during lactation are minimal. Because of its low molecular weight (about 349), transfer into breast milk should be expected.

GRISEOFULVIN

Antifungal

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although the animal reproductive data suggest risk, the human pregnancy experience is too limited for a complete assessment of the embryo–fetal risk. However, griseofulvin is best avoided during organogenesis because the use of an antifungal agent is seldom essential during this time.

FETAL RISK SUMMARY

Griseofulvin is a fungistatic antibiotic derived from a species of *Penicillium*. The drug is tumorigenic, embryotoxic, and teratogenic in some species of animals. Chronic oral exposure to griseofulvin in several strains of mice has induced hepatic and thyroid tumors (1). Hepatic tumors were also induced by relatively low weekly SC doses in mice during the first 3 weeks of life (1). Multiple malformations, including defects of the eye, skeleton, urogenital tract, and the central nervous system, were observed in fetuses of pregnant rats injected with 50–500 mg/kg on days 11–14 of gestation (2). Daily doses of 1250–1500 mg/kg (about 60–75 times the usual human dose) on days 6 through 15 of gestation in rats produced tail defects and occasional exencephaly (2). Because of the animal toxicity, at least one publication suggested that it not be given during pregnancy (3).

Human placental transfer of griseofulvin has been demonstrated at term (4).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 34 newborns had been exposed to griseofulvin during the 1st trimester (F. Rosa, personal communication, FDA, 1993). One (2.9%) major birth defect was observed (one expected). No anomalies were observed in six defect categories (cardiovascular defects, oral clefts, spina bifida, polydactyly, limb reduction

defects, and hypospadias) for which specific data were available. The number of exposures is too small to draw any conclusions.

A possible interaction between oral contraceptives and griseofulvin has been reported in 22 women (5). The study described transient intermenstrual bleeding in 15 women, amenorrhea in 5, and unintended pregnancies in 2.

In a report from the FDA, two sets of conjoined twins were observed in a sample of >20,000 birth defect cases with 1st trimester drug exposure (6). The first case involved female twins conjoined at the head and chest (craniothoracopagus syncephalus), and the second involved male dicephalic twins joined in the thorax and lumbar areas with a single seven-chamber heart. In both cases, the mothers had taken griseofulvin during early pregnancy. Fission with twinning is normally completed by the 20th day after ovulation, and thus, the cause of conjoined twinning would have to be present prior to this time (6). In both cases, maternal griseofulvin use was the only drug exposure (of those drugs under surveillance by the FDA). Because the incidence of conjoined twins is rare (approximately 1 in 50,000 births) and thoracopagus is even less common (1 in 250,000), the authors concluded that the cases provided evidence for an association with griseofulvin (6). The FDA investigators also examined other data on 1st trimester griseofulvin exposure involving 55,736 deliveries from one geographic area between 1980 and 1983 (6). Of these cases, griseofulvin was taken during the first 3 months by 37 mothers, two of whom delivered infants with birth defects: one with a congenital heart defect and the other with an unknown defect. The incidence of 5.4% (2 of 37) was approximately the incidence in the total sample. However, in 4264 women with spontaneous or threatened abortion diagnoses, 7 had been prescribed the drug during the preceding 3 months, a relative risk of 2.5 (95% confidence interval 1.01–6.1) (6).

Prompted by the above report, investigators in two other countries reported data from their respective congenital anomaly registries (7,8). One of these, from Hungary, found 39 sets of conjoined twins in a sample of more than 100,000 cases of congenital anomalies observed between 1970 and 1986 (griseofulvin was marketed in Hungary in 1970) (7). None of the mothers of the 39 conjoined twins took griseofulvin. The prevalence of conjoined twins in Hungary is approximately 1 in 60,000 births (7). The investigators also reported data from their case–control surveillance system for the period 1980–1984 (7). Of 6786 congenital anomaly cases, 2 were exposed to griseofulvin—one infant with a heart defect was exposed during the 2nd and 3rd months, and one infant with pyloric stenosis was exposed during the 1st month. Three exposures

occurred in the 10,962 matched controls, all in the late 2nd and 3rd trimesters.

The second report involved data from the International Clearinghouse for Birth Defects Monitoring Systems (8). None of the 47 sets of conjoined twins in more than 3 million births had been exposed to griseofulvin. Thus, neither of these reports was able to support the FDA report of an association between griseofulvin and the rare defect.

A 2003 review concluded that griseofulvin was contraindicated in pregnancy because of a high risk of teratogenicity and the availability of safer alternatives (9). In contrast, a 2004 report of a population-based case-control study did not detect a teratogenic risk of oral griseofulvin treatment during pregnancy (10). The data for this study came from the Hungarian Case-Control Surveillance of Congenital Anomalies in 1980–1996 and the Hungarian Congenital Abnormalities Registry for 1970–2002. The control group was composed of 38,151 pregnant women who gave birth to normal infants compared with 22,843 case women who had fetuses or newborns with birth defects. Griseofulvin was used in 7 (0.03%) of the cases and 24 (0.06%) of the controls. No teratogenic potential was found by a comparison of the expected and observed number of different congenital anomalies. In addition, there were 55 conjoined twins and none had been exposed to griseofulvin (10).

BREASTFEEDING SUMMARY

No reports describing the use of griseofulvin during lactation have been located. Because of the potential for toxicity in a nursing infant, the use of griseofulvin during breastfeeding does not appear to be warranted.

GUAIFENESIN

Respiratory Drug (Expectorant)

Pregnancy Recommendation: Compatible

Breastfeeding Recommendation: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The available pregnancy data do not support an association between guaifenesin and developmental toxicity.

FETAL RISK SUMMARY

The Collaborative Perinatal Project monitored 197 mother–child pairs with 1st trimester exposure to guaifenesin (1, p. 478). An increase in the expected frequency of inguinal hernias was found. For use anytime during pregnancy, 1336 exposures were recorded (1, p. 442). In this latter case, no evidence for an association with malformations was found. In another large study in which 241 women were exposed to the drug during pregnancy, no strong association was found between guaifenesin and congenital defects (2).

A 1981 report described a woman who consumed, throughout pregnancy, 480–840 mL/day of a cough syrup (3). The potential maximum daily doses based on 840 mL of syrup were 16.8 g of guaifenesin, 5.0 g of pseudoephedrine, 1.68 g of dextromethorphan, and 79.8 mL of ethanol. The infant had features of the fetal alcohol syndrome (see Ethanol) and displayed irritability, tremors, and hypertonicity. It is not known whether guaifenesin or the other drugs, other than ethanol, were associated with the adverse effects observed in the infant.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 141 newborns had been exposed to guaifenesin during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Nine (6.4%) major birth defects were observed (6 expected), including two cardiovascular defects (1.4 expected). No anomalies were observed in five other categories of defects (oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available. An additional 1338 newborns were exposed to the general

class of expectorants during the 1st trimester with 63 (4.7%) major birth defects observed (57 expected). Specific malformations were (observed/expected) 9/13 cardiovascular defects, 0/2 oral clefts, 1/1 spina bifida, 7/4 polydactyly, 1/2 limb reduction defects, and 3/3 hypospadias. These data do not support an association between either guaifenesin or the general class of expectorants and congenital defects.

BREASTFEEDING SUMMARY

No reports describing the use of guaifenesin during lactation have been located.

GUANABENZ

[Withdrawn from the marker. See 9th edition.]

GUANADREL

[Withdrawn from the market. See 9th edition.]

GUANETHIDINE

Sympatholytic (Antihypertensive)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although most reports of guanethidine have not been associated with drug-induced adverse fetal or newborn outcome, only three cases of 1st trimester exposure have been described. Two of these were reported in a surveillance study, in which one malformed infant was delivered from a group of 13 women who took miscellaneous antihypertensives. Thus, the data are too limited to assess the safety of the drug during early human pregnancy. Moreover, the use of this potent antihypertensive has been supplanted by the use of safer, more effective agents for pregnant women. Because of this, it probably should be considered as a drug of last choice during pregnancy (1).

FETAL RISK SUMMARY

Guanethidine is a peripherally acting, antiadrenergic agent used in the treatment of hypertension. In nonpregnant adults, the drug is often combined with diuretics. Because orthostatic hypotension resulting from adrenergic inhibition and unopposed parasympathetic function is a common problem with this agent, its usefulness in the pregnant patient is markedly reduced (1–4).

In a reproduction study in pregnant rats, guanethidine 10 mg/kg/day (average human dose <1.0 mg/kg/day) produced no adverse effects in the offspring (5). Guanethidine was listed in a later reference as a drug that causes maternal death before any effect on the fetus is observed (6). Without citing details, another publication cited guanethidine as a drug capable of producing embryopathy (i.e., death or malformation or both) in laboratory animals (7).

Guanethidine neurotoxicity has been observed in newborn rats and mice that were given the drug early in postnatal life (8,9). In one study, newborn rats

were given guanethidine (50 mg/kg SC) once daily for 5 days starting on postnatal day 2 (8). In contrast to adult rats, a possible drug-induced delay in cellular proliferation resulting in initially low brain weights occurred that was thought to be related to passage of guanethidine into the brain because of immature function of the neonatal blood–brain barrier (8). An earlier study found a dysfunctional blood–brain barrier in newborn mice, but not in adult mice, when administration of guanethidine caused a long-lasting reduction in brain catecholamine (norepinephrine and dopamine) levels (9). It is not known if these neurotoxicities would have occurred in the animal fetuses from exposure to the much smaller amounts of drug that would have presumably resulted after placental transfer.

No studies relating to the placental transfer of guanethidine in animals or humans have been located. The commercially available form of the drug, guanethidine monosulfate, has a molecular weight of about 296, which is low enough that passage to the embryo and fetus in measurable amounts should occur.

Several reports have described the use of guanethidine during all phases of human pregnancy (10–16). The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 13 of whom had 1st trimester exposure to a miscellaneous group of antihypertensives, 2 of which were exposed to guanethidine (10). There was 1 infant with a malformation from the total group of 13.

Three references described the use of guanethidine during the 3rd trimester for the treatment of preeclampsia (11–13). Although the outcomes of many of these pregnancies were poor, including fetal death, they appeared to be related to the severity of the mother’s disease rather than to the drug therapy. In a fourth reference, the use of guanethidine, tolazoline, phentolamine, and methyldopa for severe hypertension of pregnancy was curtailed over a 3-year period in favor of reserpine and phenoxybenzamine because the authors concluded that the latter two agents gave better control of hypertension, improvement of renal function, and greater predictability of results (14). No fetal or newborn adverse effects were mentioned. A fifth reference also concluded that guanethidine was not an effective antihypertensive, in comparison to other available agents, for the treatment of severe hypertension presenting late in pregnancy (15).

A 1977 report described a 29-year-old woman who was treated with guanethidine (10 mg/day) and hydrochlorothiazide (50 mg twice daily) for hypertension during the first 12 weeks of pregnancy (16). This therapy was

stopped, and she was eventually diagnosed with pheochromocytoma that was resected during delivery of a healthy, full-term, 5400-g female infant. The infant was alive and well at 8 years of age.

BREASTFEEDING SUMMARY

The manufacturer states that very small amounts of guanethidine are excreted into milk (17), but published reports describing the use of guanethidine during lactation have not been located. The molecular weight (about 296) of the commercially available form guanethidine monosulfate suggests that the drug will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown.

GUANFACINE

Sympatholytic (Antihypertensive)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although the limited human pregnancy data for guanfacine have not shown developmental toxicity, if an antihypertensive is indicated, agents with greater pregnancy experience should be used.

FETAL RISK SUMMARY

Guanfacine is a centrally acting antihypertensive agent. The drug did not produce reproductive dysfunction or adverse fetal effects in rats and rabbits given doses 70 and 20 times the maximum recommended human dose (MRHD). At doses 200 and 100 times the MRHD, respectively, increased fetal mortality and maternal toxicity were observed (1).

Although guanfacine crosses the placenta in animals (1,2), this has not been studied in humans. The molecular weight (about 247 for the free base) is low enough that exposure of the embryo and fetus should be expected.

The manufacturer is aware of two unreported cases of exposure during pregnancy that resulted in the birth of healthy infants (A.H. Robins Company, personal communication, 1987). A third patient, who was participating in a clinical trial of the drug for the treatment of hypertension, became pregnant during treatment (3). Guanfacine therapy was discontinued at approximately 8 weeks of gestation. She subsequently delivered a healthy male infant.

Guanfacine is not approved for the treatment of preeclampsia, but one study has been located that describes the use of the agent for this purpose. A 1980 German report summarized the use of guanfacine for the treatment of hypertension secondary to preeclampsia in 30 women (4). The gestational ages of the women at the time of treatment were not specified. Therapy was administered for 16–68 days with doses ranging from 1 to 4 mg/day (mean

dose approximately 2 mg/day). Mean systolic blood pressures (supine/standing) before treatment were about 160/164 mmHg compared with 136/139 mmHg just before parturition. Mean diastolic pressures (supine/standing) before treatment and just before delivery were 105/106 and 88/92 mmHg, respectively. No significant changes in fetal heart rate were observed during the trial. Six infants were growth restricted, but this was probably secondary to the maternal hypertension. No drug-induced adverse effects were observed in any of the infants, and all were developing normally on follow-up (duration of follow-up not specified).

BREASTFEEDING SUMMARY

No reports describing the use of guanfacine during human lactation have been located. The molecular weight (about 247 for the free base) is low enough that excretion into human milk should be expected. The effect of this exposure on a nursing infant is unknown. Guanfacine reduces serum prolactin concentrations in some patients and, theoretically, could cause inhibition of milk secretion.

H

HALOPERIDOL

Antipsychotic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although the animal data suggest moderate risk, the limited human pregnancy experience with haloperidol prevents a more complete assessment of embryo–fetal risk. Neonatal tardive dyskinesia may be an uncommon complication of exposure throughout gestation. There does not appear to be an increased risk of major congenital defects, but there were three cases of limb defects after 1st trimester haloperidol exposure and a fourth case after exposure to a drug in the same class (penfluridol). This potential association requires further study. Until such data are available, avoiding 1st trimester exposure, if possible, should be considered.

FETAL RISK SUMMARY

Haloperidol, a butyrophenone, is indicated for the management of manifestations of psychotic disorders (e.g., schizophrenia) and Tourette's disorder. It is available in both oral and IM formulations (1).

Animal reproductive studies with haloperidol in mice, rats, rabbits, and dogs have not revealed a teratogenic effect attributable to this tranquilizer. In rodents, doses 2–20 times the usual maximum human dose (oral or parenteral) were associated with an increased incidence of resorption, reduced fertility, delayed delivery, and pup mortality (1,2). With single injections up to maternal toxic levels in hamsters, haloperidol was associated with fetal mortality and dose-related anomalies (3). Exposure of male rats in utero to haloperidol

throughout most of gestation had no effect on typical parameters of adult sexual activity other than subtle changes involving ultrasonic vocalization (4).

Consistent with the molecular weight (about 376), haloperidol crosses the human placenta. In a 2007 study, 13 women taking a staple dose (mean 2.2 mg/day) of haloperidol for a mean 22 weeks before delivery had maternal and cord concentrations of the drug determined at birth (5). The cord blood concentration was 65.5% of the maternal concentration. The mean Apgar scores were 7.4 and 8.9 at 1 and 5 minutes, respectively. There were four neonatal complications (two cardiovascular, 1 respiratory, and 1 hypotonia; complications were not further described). No infants were admitted to the neonatal intensive care unit (5).

A 31-year-old woman with atypical psychosis was treated with oral haloperidol 3 mg/day and biperiden 3 mg/day at 36 weeks' (6). As her condition worsened, her doses were increased to IM 5 mg twice daily for each drug. At about 38 weeks', 3.5 hours after a dose of both drugs, she gave birth to a healthy 3260-g male infant with Apgar scores of 9 and 9. At delivery, maternal plasma concentrations of haloperidol and biperiden were 10.2 and 4.4 ng/mL, whereas in the newborn they were 4.6 ng/mL and not detectable, respectively (6).

Three reports have described limb defects in three infants after 1st trimester exposure to haloperidol (7–9). In one of these cases, high doses (15 mg/day) were used (8). Defects were observed in two infants: ectromelia (phocomelia) in one infant (7), and multiple upper- and lower-limb defects and an aortic valve defect in the other (8). The infant in the latter case died.

The third case was identified in a 2005 international prospective cohort study that compared 215 pregnancies exposed to either haloperidol (N = 188) or penfluridol (N = 27) (a butyrophenone antipsychotic not available in the United States) with 631 controls (9). The pregnancy outcomes were determined by telephone interviews and/or mailed questionnaires. In 161 pregnancies, exposure occurred in the 1st trimester, 136 to haloperidol and 25 to penfluridol. The median doses for haloperidol were oral 5 mg/day (2.25–10 mg) or parenteral 100 mg/4 weeks. There were no statistical differences between the butyrophenone and control groups in terms of spontaneous abortions (8.8% vs. 5.5%), ectopic pregnancies (0.5% vs. 0.2%), stillbirths (0 vs. 0.2%), or major malformations (3.4% vs. 3.8%). Significant differences were observed in the rates of elective terminations (8.8% vs. 3.8%), preterm births (13.9% vs. 6.9%), birthweight (3155 vs. 3370 g), birthweight of full-term infants (3250 vs. 3415 g), and cesarean section delivery (25.5% vs. 16.3%). There were

three major defects in pregnancies exposed to haloperidol in the 1st trimester: absent left fourth finger, common wrist (carpal) of left first and second fingers; carbamazepine syndrome, developmental delay, congenital heart defect (also exposed to carbamazepine); and ventricular septal defect (also exposed to perphenazine). The haloperidol doses in the three cases were 12.5 mg IM every 4 weeks, 150 mg IM every month, and 10 mg/day orally. There was one major defect with 1st trimester exposure to penfluridol (oral 20 mg/ week): upper limb reduction defect and foot deformity. The small size of the study prevented excluding a possible association between butyrophenones and limb defects (9). Of interest, though, other studies have not observed limb defects in haloperidol-exposed pregnancies (10–14).

In 98 of 100 patients treated with haloperidol for hyperemesis gravidarum in the 1st trimester, no effects were produced on birth weight, duration of pregnancy, sex ratio, or fetal or neonatal mortality, and no malformations were found in abortuses, stillborn, or liveborn infants (10). Two of the patients were lost to follow-up. In 31 infants with severe reduction deformities born over a 4-year period, none of the mothers remembered taking haloperidol (11). Haloperidol has been used for the control of chorea gravidarum and manic-depressive illness during the 2nd and 3rd trimesters (15,16). During labor, the drug has been administered to the mother without causing neonatal depression or other effects in the newborn (12).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 56 newborns had been exposed to haloperidol during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Three (5.4%) (two expected) major birth defects were observed, two of which were cardiovascular defects (0.6 expected). No anomalies were observed in five other defect categories (oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available.

A 1989 report described a case of withdrawal emergent syndrome, a subtype of tardive dyskinesia, in a newborn infant who had been exposed to oral haloperidol (2–6 mg/day) throughout gestation (17). The mother had been treated with haloperidol for schizophrenia, but she stopped the drug 2 weeks before delivery at 38 weeks' gestation. The male infant (weight not given except as "appropriate for gestational age") had Apgar scores of 8 and 9 at 1 and 5 minutes, respectively. One hour after delivery, he became irritable and developed continuous tongue thrust. In addition, poor suck resulting in difficult feeding, vomiting, abdominal posturing of the hands, and tremors of the trunk

and extremities were noted. By 8 days of age, all of the signs had resolved except for the tongue thrusting. This symptom continued to persist at 6 months of age, but otherwise, his development and examination were normal (17). A second, similar case of tardive dyskinesia was described in a 2003 case report (18). The mother had been treated for schizophrenia with haloperidol 200 mg IM every 2 weeks throughout gestation. She received her last dose 3 weeks before delivery of an infant (sex and weight not given) with Apgar scores of 9 and 9 at 1 and 5 minutes, respectively. The newborn was noted to be jittery and developed diarrhea and metabolic acidosis. Irritability increased over the next 8 days when tonic-clonic movements in all extremities were noted (seizures were excluded by an electroencephalogram) as well as tongue thrusting and torticollis. Treatment with clonazepam resolved the condition and the infant was discharged home at 21 days of age (18).

Premature labor, loss of fetal cardiac variability and acceleration, an unusual fetal heart rate pattern (double phase baseline), and depression at birth (Apgar scores of 4 and 7 at 1 and 5 minutes, respectively) were observed in a comatose mother and her infant after an acute overdose of an unknown amount of haloperidol and lithium at 31 weeks' gestation (19). Because of progressive premature labor, the 1526-g female infant was delivered about 3 days after the overdose. The lithium concentrations of the maternal plasma, amniotic fluid, and cord vein plasma were all >4 mmol/L (severe toxic effect >2.5 mmol/L), whereas the maternal level of haloperidol at delivery was about 1.6 ng/mL. The effects observed in the fetus and newborn were attributed to cardiac and cerebral manifestations of lithium intoxication. No follow-up on the infant was reported (19).

BREASTFEEDING SUMMARY

Haloperidol is excreted into breast milk. In a patient receiving an average of 29.2 mg/day, a milk level of 5 ng/mL was detected (20). When the dose was decreased to 12 mg, a level of 2 ng/mL was measured. In a second patient taking 10 mg daily, milk levels up to 23.5 ng/mL were found (21). A milk:plasma ratio of 0.6–0.7 was calculated. No adverse effects were noted in the nursing infant.

In a 1985 report, the haloperidol milk concentration was 1.7 ng/mL 3 hours after an unspecified dose (total daily dose 6 mg but the number of doses per day not specified) and 12 days after birth (6). However, the mother had not been breastfeeding and attempts had been made to halt milk production.

A 1992 reference measured haloperidol in the breast milk of three women

receiving chronic therapy (22). The maternal doses were 3, 4, and 6 mg/day, and the corresponding haloperidol concentrations in their milk were 32, 17, and 4.7 ng/mL, respectively. The patient receiving 6 mg/day, but with the lowest milk concentration, was thought to be noncompliant with her therapy. No mention of nursing infants was made (22).

A study published in 1998 described 12 mothers who breastfed their infants while taking haloperidol, chlorpromazine, or trifluoperazine for bipolar depression (3 cases), manic disorder (1 case), schizo-affective disorder (5 cases), or schizophrenia (3 cases) (23). Haloperidol doses were 1–40 mg/day. The ages of the nursing infants at the start of therapy were 1–18 weeks. Using an enzyme immunoassay technique, the range of concentrations in fore-milk and hind-milk were <10–988 and 23–140 ng/mL, respectively, whereas the range of ratios of fore-milk and hind-milk to maternal plasma were 0.8–5.2 and 1.7–8.0, respectively. Plasma concentrations of haloperidol in the four nursing infants who were tested were 0.8, 1.2 and 2.1, 6.8, and 8.0 ng/mL, respectively. Two of the samples (6.8 and 8.0 ng/ mL) were in the adult range. In addition, the urine of all seven infants tested contained haloperidol (1.6–7.9 ng/mL). The maximum infant dose ingested was 3% of the weight-adjusted maternal dose. As assessed using the Bayley Scales of Infant Development, all three of the infants whose mothers were taking both haloperidol (20–40 mg/day) and chlorpromazine (200–600 mg/day) showed a decline in mental and psychomotor development from the first (at 1–4 months of age) to the second assessment (at 12–18 months of age). Because of this decline, the investigators concluded that breastfeeding might not be best if a breastfeeding mother is taking neuroleptics, either alone or in combination, at the upper end of their recommended dose ranges (23).

The American Academy of Pediatrics classifies haloperidol as an agent whose effect on the nursing infant is unknown but may be of concern (24).

HALOTHANE

General Anesthetic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Halothane has demonstrated teratogenicity and toxicity in some animal studies, but this may have occurred at maternally toxic doses. The potential for long-term behavioral teratogenicity in animals or humans has not been adequately studied but such studies are needed. The anesthetic does not appear to cause human structural anomalies nor does it appear to be related to embryotoxicity (e.g., abortions), but this is based on limited 1st trimester experience. Others also have reached this same conclusion (1). In addition, general anesthesia usually involves the use of multiple pharmacologic agents which complicates attempts at fetal risk assessment. In the past, halothane frequently was used during delivery for analgesia and anesthesia. This use does not appear to affect the newborn any differently than use of other general anesthetic agents does. The uterine effects of halothane (relaxation and increased blood loss) also appear to be similar to those of other agents in this class. All anesthetic agents can cause depression in the newborn that may last for 24 hours or more. The potential reproductive toxicity (spontaneous abortion and infertility) of occupational exposure to halothane has not been adequately studied.

FETAL RISK SUMMARY

Halothane, a nonflammable, volatile liquid administered via vaporizer, is indicated for the induction and/or maintenance of anesthesia during surgery. It is a fluorinated inhalation anesthetic agent that was the first such agent in a class that now includes desflurane, enflurane, isoflurane, methoxyflurane, and sevoflurane. Halothane has a high blood–gas partition coefficient (2.5)

compared with other anesthetics in this class (2). The agent has been used in obstetric anesthesia since the 1950s.

In a 1968 reproduction study, pregnant rats were administered a subanesthetic mixture of 0.8% halothane in 25% oxygen–nitrogen for 12 hours at different stages of gestation (3). Higher incidences of lumbar ribs, vertebral anomalies, and fetal resorptions were observed. An abstract published the same year described the effects on pregnant mice exposed to either 1% or 1.5% halothane for 3 hours during organogenesis (4). An increased incidence of cleft palate, limb hematomas, and ossification defects in the limbs was observed.

An increased incidence of resorptions, as well as decreased fetal weight and length, was observed in pregnant hamsters exposed on the 9th, 10th, or 11th day of gestation to a mixture of 0.6% halothane and 60% nitrous oxide (5). In contrast, subanesthetic concentrations of halothane (50–3200 ppm) administered to rats on days 8–12 of pregnancy did not increase fetal death and resorption rates, growth restriction, or frequency of skeletal anomalies (6). Skeletal variations and ossification defects were observed in all groups but were not dose-related.

In a 1978 study, male and female mice were exposed to subanesthetic and anesthetic concentrations of halothane before mating (5–7 days/week for 9 weeks), then the females were exposed daily throughout gestation (7). Halothane exposures ranged from 0.025 to 4.0 minimum alveolar anesthetic concentration (MAC) hours/day. (Note: MAC is the concentration that causes immobility in 50% of patients exposed to a noxious stimulus such as a surgical incision; it represents the ED₅₀ (8).) Maternal (decreased weight gain), fetal (decreased weight and length), and neonatal (decreased early postnatal weight gain) toxicity were observed at ≥ 0.4 MAC hours/day. At 1.2 MAC hours/day, the pregnancy rate, implantation rate, and number of live fetuses per litter were all significantly decreased, but the percentage of resorptions and postnatal offspring survival were not altered. The smallest dose at which toxicity was observed was estimated to be 40 times greater than the level of occupational exposure in unscavenged operating rooms (7). Two studies of similar design using subanesthetic mixtures of halothane and nitrous oxide found a decrease in ovulation and implantation and a slight decrease in fetal growth (9,10). No increase in resorptions or major defects was observed in either study. However, cytogenetic damage to bone marrow and spermatogonial cells were noted after prolonged exposure (9,10).

High subanesthetic concentrations of halothane or halot hane plus nitrous

oxide resulted in fetal growth restriction in pregnant rats, but did not increase fetal death or congenital malformations (11). Another study in rats also found no minor or major congenital defects using 0.75 MAC of halothane (0.8%) for 6 hours/day for 3 consecutive days at different intervals during gestation (12).

A 1999 study examined the effects on mice exposed to 1.2 MAC of halothane (1.5%) before and during gestation (13). The dose was equivalent to that used clinically. Treatment before gestation had no effect on fertility or the number of live young delivered. Compared with controls, there were an increased number of offspring deaths before weaning, and the immune response of the offspring was impaired. The clinical significance of the impairment was unknown (13).

The effects of halothane on growing neural tips (growth cones) in the forebrains of neonatal rat pups were described in a 1993 report (14). The pups were exposed to three concentrations of halothane (0.5%, 0.75%, and 1.0%) over a 6-hour period on postnatal day 1. A dose–response chart on the activity of a growth cone enzyme (protein kinase C [PKC]) was found, with the lowest concentration having no effect on the enzyme. The 1.0% concentration, however, reduced the activity to about 71%. The 0.75% dose also reduced the PKC activity but to a lesser degree. The authors thought that the reduced enzyme activity could be related to long-term morphologic or behavioral neuroabnormalities in the pups (14).

The molecular weight (about 197) suggests that halothane will cross the placenta to the embryo and fetus. In agreement, research has demonstrated the rapid uptake of halothane by the fetus (15). Two reviews have concluded that, in general, inhalational anesthetic agents are freely transferred to fetal tissues (1,16), and in most cases, the maternal and fetal blood concentrations are approximately equivalent (16). Lower levels were reported in a 1977 study in which 15 women undergoing cesarean section received 0.65% halothane combined with 50% nitrous oxide in oxygen (17). The umbilical vein:maternal artery ratio at delivery was 0.35. The ratio in a second group of 15 women who received the anesthetic mixture with 0.2% halothane was 0.51. The time from start of halothane to delivery was about 10.5 minutes in both groups.

Pregnant women, at least in early gestation, require less halothane for anesthesia than nonpregnant women. A 1996 study compared eight women scheduled for pregnancy termination at 8–13 weeks' gestation with eight nonpregnant women undergoing laparoscopic sterilization (18). In pregnant women the median MAC of 0.58 volume% (range 0.53–0.58) was less than that in nonpregnant women, 0.75 volume% (range 0.70–0.78; $p = 0.0005$). The

percentage decrease (95% confidence interval) for pregnant women was 27% (20%–27%). Similar results were found with enflurane (18).

Halothane and similar anesthetic agents (e.g., isoflurane and enflurane) have a relaxant effect on the pregnant uterus (2,19–24). This effect has been known since the 1950s and was considered one reason to avoid using halothane during routine, uncomplicated obstetric procedures (2,19). A 1970 study using low concentrations (0.5% or 0.8%) found no increase in blood loss at cesarean section (23). However, it was recognized that decreasing uterine tone could result in increased postpartum hemorrhage. Indeed, a 1989 review concluded that halothane, isoflurane, and enflurane all increased blood loss through a dose-related depression of uterine activity (24). In agreement with the dose-related uterine effects, a 1991 reviewer thought that low halothane concentrations ($\leq 0.5\%$) were not associated with an increased risk of uterine hemorrhage (25). In the 1970 study cited above, the 0.8% concentration of halothane was associated with an increased incidence of maternal hypotension, most likely secondary to compression of the inferior vena cava by the uterus and vasodilatation (23). However, uterine blood flow is maintained during maternal hypotension because of uterine artery dilation (24). In addition, low concentrations of halothane (0.25%–0.5%) did not depress the neonatal cardiac or respiratory systems (24).

Halothane was once frequently prescribed for both vaginal and cesarean deliveries (17,20,26,27). For example, one hospital conducted 2500 vaginal deliveries over a 6-year period with a combination of halothane, nitrous oxide, and oxygen (20). The decline in obstetric use was probably due to the availability of agents with reduced solubility in blood (e.g., see Desflurane and Isoflurane) and the recognition that general anesthesia can cause depression in the newborn.

Several studies have documented decreased initial Apgar scores in newborns following cesarean section under general anesthesia (17,23,26–28). Because the halothane concentrations often were subanesthetic and combined with nitrous oxide, it was not always clear whether the depression was secondary to a specific agent or the combination. In one study, reducing the amount of nitrous oxide from 75% to 50% and adding 0.5% halothane substantially improved the Apgar scores at 2 minutes (23). In an earlier study that combined halothane anesthesia with succinylcholine, reducing the halothane dose markedly improved the condition of the newborns as measured by Apgar scores (26). Another study found no difference in Apgar scores between groups given 0.3%–0.5% halothane combined with either 40% or 25%

nitrous oxide (27). In a direct comparison between 0.5% halothane and 0.75% isoflurane, both combined with 50% nitrous oxide, the isoflurane group required significantly less succinylcholine, recovered faster from anesthesia, and had less uterine relaxation and bleeding (28). The mean Apgar scores were significantly higher at 1 minute in the isoflurane group (7.4 vs. 6.7) but were similar at 5 minutes (8.9 vs. 8.8).

A 1989 study compared 0.5% halothane, 0.5% isoflurane, and 1.0% isoflurane (N = 20 in each group) during cesarean section delivery (29). No differences among the groups were observed in the incidence of low 1-minute Apgar scores or in the Neurologic and Adaptive Capacity Scores (NACS) at 15 minutes, 2 hours, and 24 hours. The percentage of infants who scored 35–40 on the NACS was similar in the three groups (29). A small 1983 study compared the neonatal outcomes in four groups (10 patients each) of women receiving general anesthesia for cesarean section: 50% nitrous oxide and 50% oxygen either alone or combined with 0.5% halothane, 1.0% enflurane, or 0.75% isoflurane (30). There were no differences among the groups in low Apgar scores at 1 and 5 minutes, neonatal neurobehavioral assessment 2–4 hours after delivery, or maternal or umbilical blood–gas analysis at delivery. A randomized study examined the effects of halothane (N = 32) and isoflurane (N = 34) (both at 0.7 MAC) on newborn Apgar scores and acid–base status after anesthesia for emergency cesarean section (31). There were no statistically significant differences in the percentage of infants with low Apgar scores (<7) at 1 and 5 minutes. Similarly, there were no significant differences in the hydrogen ion concentration, partial pressure of carbon dioxide, partial pressure of oxygen, or base deficit in blood samples from umbilical arteries and veins (31).

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 25 of whom had 1st trimester exposure to halothane (32). Two children had unspecified malformations, but there was no evidence of an association between halothane and the defects (32). A 1965 report on fetal hazards of surgery during pregnancy described the outcomes of 20 women who were administered general anesthesia (halothane plus nitrous oxide) during pregnancy (7, 9, and 4 women in the 1st, 2nd, and 3rd trimesters, respectively) (33). One unspecified birth defect was observed (timing of exposure not specified).

A possible association between surgery in the 1st trimester and neural tube defects (NTD) was published in 1990 (34). Using data from Swedish health care registries, investigators studied 2252 infants whose mothers had surgery

during the 1st trimester. Six of the infants had NTD (expected 2.5), one of whom was thought to have Meckel's syndrome. An additional infant had a diagnosis of hydranencephaly, but the autopsy report indicated that the diagnosis was uncertain and it may have been a very large encephalocele. In the total group, 572 had operations during the period of neural tube closure (gestational weeks 4 and 5). Mothers of five of the six infants with NTD (expected 0.6) had surgery during this period, but only one had been exposed to halothane (in combination with nitrous oxide). The mother of the hydranencephaly case had surgery in gestational week 8 and was exposed to halothane in combination with thiopental and succinylcholine. The authors could not determine whether the findings represented a causal association with surgery or just a random occurrence (34).

Chronic occupational exposure to anesthetic gases in operating rooms during pregnancy has raised concerns that such exposure could cause spontaneous abortions (35,36). The principal concern relates to unscavenged environments in which high concentrations of halothane (0.001% or 10 ppm) and nitrous oxide (0.03% or 300 ppm) had been measured (35). Lower concentrations of halothane also have been reported near the anesthesiologist (1–26 ppm) and the surgeon (1–2 ppm) (37). A 1988 review cited a number of studies investigating the possible association between occupational exposure to anesthetic gases and adverse pregnancy outcomes (15). The reviewer concluded that serious methodological weaknesses in these studies precluded arriving at a firm conclusion, but a slightly increased risk of miscarriage was a possibility. However, there was no evidence of an association between occupational exposure and congenital anomalies (15).

A review published in 1991 briefly evaluated the possibility that some drugs and environmental agents could cause behavioral teratogenicity (38). Anesthetics (e.g., halothane) were listed as "suspected" human behavioral teratogens apparently based solely on animal studies. However, specific data for any anesthetic agent, including halothane, were not cited.

A 2004 study, however, found a significant association between maternal occupational exposure to waste anesthetic gases during pregnancy and developmental deficits in their children, including gross and fine motor ability, inattention/hyperactivity, and IQ performance (see Nitrous Oxide).

A 1993 study evaluated the effect of halothane anesthesia for fetal surgery in pregnant ewes (39). Compared with ketamine, halothane decreased fetal cardiac output and placental blood flow. An increase in total vascular resistance, highest in the placenta, resulted in the shunting of blood away from

the placenta (39). The combination of these effects resulted in depressed respiratory gas exchange. The investigators concluded that halothane was a poor anesthetic for fetal surgery (39).

BREASTFEEDING SUMMARY

Halothane is excreted into breast milk (40–42). Breast milk samples were collected on 2 days from a lactating anesthesiologist while she was working (40). The milk concentrations of 2 ppm were consistent with the concentrations at the anesthesiologist's face in the operating room. Because respiratory excretion of halothane by operating room personnel continues for ≤ 72 hours, the authors thought that the trace milk concentrations would be detectable for a similar period of time (40).

No reports measuring the amount of halothane excreted in milk of patients who have received halothane anesthesia have been located. Of interest, a 1993 reference stated that respiratory excretion of halothane in patients may occur for ≤ 20 days after exposure and that trace amounts of halothane should be expected in milk during that interval (41). One review considered the potential amounts in milk after halothane anesthesia, when nursing was feasible, to be negligible (42). The American Academy of Pediatrics classifies halothane as a drug that usually is compatible with breastfeeding (43).

HEMIN

Hematopoietic

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Animal reproduction studies have not been conducted with hemin and there is only one report on its use in human pregnancy. The citations below, however, suggest that hemin has been used more frequently in pregnant women. The primary embryo or fetal risk from hemin appears to be from the transmission of viruses or other agents from a hemin-induced maternal infection or from a hemin-induced maternal adverse reaction (e.g., thrombocytopenia or coagulopathy). Therefore, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

The enzyme inhibitor hemin (previously known as hematin) limits the hepatic and/or marrow synthesis of porphyrin. It is indicated for the amelioration of recurrent attacks of acute intermittent porphyria that are temporally related to the menstrual cycle (1). Hemin is an iron molecule derived from human red blood cells. Although multiple steps have been taken to lessen the chance of blood-borne infection, a risk still exists for the transmission of infectious agents, such as viruses, and for the agent that causes Creutzfeldt-Jacob disease (1).

Reproduction studies in animals have not been conducted. It is not known if hemin can cross the human placenta to the fetus. As a natural constituent of human blood, it is unlikely that clinically significant amounts would cross to the fetal compartment.

A 1989 review summarized the prevalence, genetics, biochemistry, classification, and the treatment of acute intermittent porphyria (2). The authors also cited evidence that female hormones affect the onset and expression of the disease. Before an understanding of the disease and improved prenatal

care were achieved, porphyria was associated with significant maternal mortality and poor pregnancy outcome (2). Although the authors did not specifically state that hemin treatment was indicated during pregnancy, they did state that patients with acute attacks should be hospitalized for symptomatic treatment. They also noted that treatment with hemin could shorten the duration of the attack and reduce its severity (2).

Earlier, a brief response to a question concerning porphyria and pregnancy hinted at the potential severity of this disease. The author, although noting the lack of information relating to the potential to cause adverse pregnancy outcomes, still recommended hematin therapy for an acute porphyric attack before considering termination of pregnancy (3). Responding to this recommendation, another author suggested that glucose infusions were safer and expressed concern that the anticoagulant effect of hemin could jeopardize a pregnancy (4). However, hemin was not thought to have a clinically significant anticoagulant effect at low doses and was indicated in pregnancy if glucose infusions were not effective in reversing the disease process (5).

A 34-year-old woman, in the 1st or 2nd month of pregnancy, was treated with hematin, 3 mg/kg/day administered as an IV infusion for 5 days, for an exacerbation of acute intermittent porphyria (6). A second IV infusion course, 1.5 mg/kg/day for 2 weeks, was started 41 days after the first course. No adverse fetal effects of the exposure were noted and the woman eventually delivered a healthy, 2570-g male infant at 39 weeks' gestation. At follow-up, no evidence of porphyria was noted in the 5-year-old child (6).

A 1984 study investigated the effect of hematin on bilirubin binding (7). Cord blood of newborn infants with ABO hemolytic disease was thought to contain endogenous hematin, which could increase the risk of kernicterus. In an in vitro experiment, hematin was added to bilirubin-enriched cord blood and was found to have a significant adverse effect on bilirubin binding. However, the high concentrations required were not physiologic and, thus, were not thought to have clinical significance for infants with ABO-isoimmune hemolysis (7).

A 2010 review of the treatment of acute intermittent porphyria in pregnancy concluded that although the available information was limited, hemin could be safely given in pregnancy (8).

BREASTFEEDING SUMMARY

No reports describing the use of hemin during lactation have been located. Hemin is an enzyme inhibitor that is derived from human red blood cells. It is doubtful if hemin is excreted in milk but even if small amounts were excreted,

they would be digested in the infant's gut.

HEPARIN

Anticoagulant

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No reports linking the use of heparin during gestation with developmental toxicity have been located. Because heparin probably does not cross the placenta, other fetal complications are related to the severe maternal disease necessitating anticoagulant therapy.

FETAL RISK SUMMARY

Hall et al. (1) reviewed the use of heparin and other anticoagulants during pregnancy (167 references) (see also Coumarin Derivatives). They concluded from the published cases in which heparin was used without other anticoagulants that significant risks existed for the mother and fetus and that heparin was not a clearly superior form of anticoagulation during pregnancy. Nageotte and coworkers (2) analyzed the same data to arrive at a different conclusion.

| | Hall | Nageotte |
|---|------|----------------|
| Total number of cases | 135 | 120 |
| Term liveborn—no complications | 86 | 86 |
| Premature—survived without complications | 19 | 19 |
| Liveborn—complications (not specified) | 1 | 1 |
| Premature—expired | | |
| Heparin therapy appropriate ^a | 10 | 5 |
| Heparin therapy not appropriate ^a | | 4 ^b |

^aAppropriateness as determined by current standards.

^bHypertension of pregnancy (4).

^cTricuspid atresia (1).

^dHypertension of pregnancy (6); proliferative glomerulonephritis (1).

By eliminating the 15 cases in which maternal disease or other drugs were the most likely cause of the fetal problem, the analysis of Nageotte and coworkers results in a 13% (15 of 120) unfavorable outcome vs. the 22% (30 of 135) of Hall and associates. This new value appears to be significantly better than the 31% (133 of 426) abnormal outcome reported for coumarin derivatives (see Coumarin Derivatives). Furthermore, in contrast to coumarin derivatives in which a definite drug-induced pattern of malformations has been observed (fetal warfarin syndrome), heparin has not been related to congenital defects nor does it cross the placenta (3–5). Consequently, the mechanism of heparin's adverse effect on the fetus, if it exists, must be indirect. Hall and coworkers theorized that fetal effects may be caused by calcium (or other cation) chelation resulting in the deficiency of that ion(s) in the fetus. A more likely explanation, in light of the report of the Nageotte group, is severe maternal

disease that could be relatively independent of heparin. Thus, heparin appears to have major advantages over oral anticoagulants as the treatment of choice during pregnancy (6–13).

A retrospective study, published in 1989, lends support to the argument that heparin therapy is safe for the mother and fetus (14). A total of 77 women were treated with heparin during 100 pregnancies. In 98 pregnancies, therapy was administered for the prevention or treatment of venous thromboembolism; in 2 pregnancies treatment was because of prosthetic heart valves. In comparison with normal pregnancies, no difference was seen in the treated mothers in terms of prematurity, spontaneous abortions, stillbirths, neonatal deaths, or congenital malformations (6). Two bleeding episodes occurred, but there were no symptomatic thrombotic events.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 65 newborns had been exposed to heparin during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Seven (10.8%) major birth defects were observed (three expected). Specific data were available for six defect categories, including (observed/expected) 4/0.6 cardiovascular defects, 0/0 oral clefts, 0/0 spina bifida, 1/0 polydactyly, 0/0 limb reduction defects, and 1/0 hypospadias. The data for total malformations and for cardiovascular defects are suggestive of possible associations, but other factors, most likely the mother's disease, but also possibly concurrent drug therapy and chance, are probably involved.

Long-term heparin therapy during pregnancy has been associated with maternal osteopenia (15–19). Both low-dose (10,000 U/day) and high-dose heparin have been implicated, but the latter is more often related to this complication. One study found bone demineralization to be dose related, with more severe changes occurring after long-term therapy (>25 weeks) and in patients who had also received heparin in a previous pregnancy (18). The significant decrease in 1,25-dihydroxyvitamin D levels measured in heparin-treated pregnant patients may be related to the pathogenesis of this adverse effect (16,17). Similar problems have not been reported in newborns.

BREASTFEEDING SUMMARY

Heparin is not excreted into breast milk because of its high molecular weight (15,000) (20). Moreover, it is not absorbed after oral administration.

HEROIN

Narcotic Agonist Analgesic

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

In the United States, heroin exposure during pregnancy is confined to illicit use as opposed to in other countries, such as Great Britain, where the drug is commercially available. The documented fetal toxicity of heroin derives from the illicit use and resulting maternal–fetal addiction. In the form available to the addict, heroin is adulterated with various substances (such as lactose, glucose, mannitol, starch, quinine, amphetamines, strychnine, procaine, or lidocaine) or contaminated with bacteria, viruses, or fungi (1,2). Maternal use of other drugs, abuse and nonabuse, is likely. It is, therefore, difficult to separate entirely the effects of heroin on the fetus from the possible effects of other chemical agents, multiple diseases with addiction, and life-style. However, there are data that morphine, which is closely related to heroin, and other opioids are human teratogens (see Morphine).

FETAL RISK SUMMARY

Heroin rapidly crosses the placenta, entering fetal tissues within 1 hour of administration. Withdrawal of the drug from the mother causes the fetus to undergo simultaneous withdrawal. Intrauterine death may occur from meconium aspiration (3,4).

Assessment of fetal maturity and status is often difficult because of uncertain dates and an accelerated appearance of mature lecithin:sphingomyelin ratios (5).

Until recently, the incidence of congenital anomalies was not thought to be increased (6–8). Current data, however, suggest that a significant increase in major anomalies can occur (9). In a group of 830 heroin-addicted mothers, the incidence of infants with congenital abnormalities was significantly greater than in a group of 400 controls (9). Higher rates of jaundice, respiratory distress

syndrome, and low Apgar scores were also found. Malformations reported with heroin are multiple and varied with no discernible patterns of defects (6–13). In addition, all of the mothers in the studies reporting malformed infants were consuming numerous other drugs, including drugs of abuse.

Characteristics of the infant delivered from a heroin-addicted mother may include the following (14):

Accelerated liver maturity with a lower incidence of jaundice (8,15)

Lower incidence of hyaline membrane disease after 32 weeks' gestation (5,16)

Normal Apgar scores (6)

(Note: The findings of Ostrea and Chavez (9) are in disagreement with the above statements.)

Low birth weight; up to 50% weigh less than 2500 g

Small size for gestational age

Narcotic withdrawal in about 85% (58%–91%): symptoms (hyperactivity, respiratory distress, fever, diarrhea, mucus secretion, sweating, convulsions, yawning, and face scratching) apparent usually within the first 48 hours, with some delaying up to 6 days; incidence is directly related to daily dose and length of maternal addiction (7,8)

Meconium staining of amniotic fluid

Elevated serum magnesium levels when withdrawal signs are present (up to twice normal)

Increased perinatal mortality; rates up to 37% in some series (13)

Random chromosomal damage was significantly higher when Apgar scores were 6 or less (12,17). However, only one case has appeared relating chromosomal abnormalities to congenital anomalies (12). The clinical significance of this is doubtful. The lower incidence of hyaline membrane disease may be caused by elevated prolactin blood levels in fetuses of addicted mothers (18).

Long-term effects on growth and behavior have been reported (19). As compared with controls, children aged 3–6 years delivered from addicted mothers were found to have lower weights, lower heights, and impaired behavioral, perceptual, and organizational abilities.

BREASTFEEDING SUMMARY

Heroin crosses into breast milk in sufficient quantities to cause addiction in the infant (20). A milk:plasma ratio has not been reported. Previous investigators

have considered breastfeeding as one method for treating the addicted newborn (21). However, the American Academy of Pediatrics classifies heroin abuse as a contraindication to breastfeeding (22).

HETACILLIN

[Withdrawn from the market. See 8th edition.]

HEXACHLOROPHENE

Anti-infective

PREGNANCY RECOMMENDATION: Compatible (Topical; Excludes Mucous Membranes)

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

One report has suggested that heavy use of hexachlorophene during the 1st trimester may cause birth defects in exposed offspring, but several criticisms have been directed at this study on methodological grounds. Moreover, in nonprimate animal species, only very high levels (i.e., that approached maternal toxicity) of hexachlorophene are teratogenic. These considerations, coupled with the absence of confirming reports in humans, suggest a lack of an association between routine handwashing with hexachlorophene and human congenital malformations. Because of other toxicities, use of the antiseptic on mucous membranes, such as in the vagina, or on injured skin should be avoided.

FETAL RISK SUMMARY

Hexachlorophene, a polychlorinated biphenol compound, is a topical antiseptic used primarily as a surgical hand scrub and as a bacteriostatic skin cleanser. Although no longer recommended, hexachlorophene has also been used as a douching agent and in feminine hygiene sprays. The drug is rapidly absorbed systemically following topical administration to injured skin, but percutaneous absorption also occurs across intact skin (1–3). Because of very rapid absorption, hexachlorophene should not be used on mucous membranes or injured skin (1,2).

Blood concentrations of the anti-infective have been documented in premature and full-term newborns who were bathed with hexachlorophene and in adults after chronic handwashing (3). CNS toxicity has been observed following the topical use of hexachlorophene in burn patients and after intravaginal application (3).

Hexachlorophene crosses the human placenta (4,5). Newborn whole cord

blood concentrations in one study ranged from 0.003 to 0.182 mcg/g with a mean of 0.022 mcg/g (1 mcg/g = 1 ppm) (4). The source of the drug was thought to be from vaginal sprays used by the mothers and from preparation of the skin immediately before delivery. In a second study, a commercially available 3% emulsion of hexachlorophene was used as antiseptic lubricant for vaginal examinations during labor (5). At delivery, detectable maternal serum concentrations of the drug occurred in 12 of 28 women (range 0.142–0.942 mcg/mL) and in the whole cord blood of 9 of 28 newborns (range 0.177–0.617 mcg/mL). Because of the potential for toxicity, the authors recommended the use of alternative lubricants.

A number of studies have examined the reproductive toxicity of hexachlorophene in various animal species (6–14). A marked reduction in the sperm count was observed in male rats administered a single oral dose of 125 mg/kg (6). In pregnant rats, dose-related teratogenicity was demonstrated following acute and chronic oral dosing (6–9). No malformations resulted with relatively low doses (6–8), but high maternal doses were associated with cleft palate (8) and with microphthalmia, anophthalmia, and rib anomalies (9). Intravaginal administration of hexachlorophene in pregnant rats resulted in frequent microphthalmia, anophthalmia, wavy ribs, and less frequently, cleft palate in the offspring (10,11). Blood concentrations were 6–10 times higher after vaginal or oral administration than after dermal application (11). Oral doses of 6 mg/kg/day in pregnant rabbits produced defects of the ribs in a small percentage of exposed fetuses, indicating a minimal teratogenic response (9).

Three studies have described the distribution of hexachlorophene in the fetuses of pregnant mice, rats, and monkeys (12–14). In fetal mice, the drug selectively accumulated in the brain, optic vesicles, and neural tube in early gestation (12). During late gestation, high fetal concentrations were measured in the blood, liver, and intestine. A similar pattern of distribution during gestation was described in fetal monkeys (13). In both mice and monkeys, a partial blood–brain barrier was demonstrated to hexachlorophene in term fetuses (12,13). Hexachlorophene crossed the placenta in pregnant rats after both oral and dermal administration with concentrations detected in the placenta, amniotic fluid, and fetus (14).

Only one study has associated the routine use of hexachlorophene with human teratogenicity (15). The results of the investigation were summarized as a news item in a medical journal approximately a year before publication of the original study (16). In a retrospective analysis of the pregnancy outcomes

among nurses who had washed their hands with hexachlorophene during the 1st trimester, 25 severe malformations were observed in 460 neonates (15). No major congenital defects were observed among 233 newborns delivered from similarly employed mothers who did not use hexachlorophene. The exposed nurses had worked at one of six Swedish hospitals between 1969 and 1975 and had washed their hands 10–60 times per day with either a 0.5% or 3% hexachlorophene liquid soap. Three of the hospitals also used a 0.3% or 0.5% hexachlorophene hand cream. Among the exposed group, 46 newborns, in addition to the 25 with major defects, had minor malformations for a total of 71 affected infants (15.4%). The major malformations included cleft lip and/or palate, microphthalmia, anal atresia and hypospadias, cystic kidneys, esophageal atresia and kidney defects, limb reductions, diaphragmatic hernia, neural tube defects, pulmonary stenosis, and cardiac defects. Minor malformations included dislocations of the hip, undescended testes, polydactyly, various foot anomalies, and mild cardiac defects. Eight (3.4%) minor malformations were observed in the control group.

Criticisms of this study on methodological grounds have been published (17,18). Most of the hexachlorophene-exposed nurses were selected because of an infant malformation, not on the basis of exposure to the drug, thus leading to a higher rate of malformations in the exposed group. The selection of the control group was also criticized and was considered, at least on statistical grounds, not to be representative of random selection (17). Concern was expressed over the identification of the minor defects and how diligently these defects were searched for at the various hospitals (18). Furthermore, another study evaluated delivery data on women working in Swedish hospitals from 1973 to 1975 and compared them with births in the general Swedish population during the same period (19). A cluster of malformed infants was found during 1973–1974 that was similar to that observed in the report associating defects with hexachlorophene. However, the rates of perinatal deaths and congenital malformations did not differ between 3007 infants born to women heavily exposed to hexachlorophene in 31 hospitals and 1653 infants born to women working in 18 hospitals where the antiseptic was not used at all or was used only sporadically (19).

BREASTFEEDING SUMMARY

Hexachlorophene has been measured in breast milk following the presumed use of the antiseptic as a nipple wash between nursings (20). The specific history of hexachlorophene use by the women was not available. Six samples of milk

were found to have a range of hexachlorophene levels from trace (<2 ppb) to 9.0 ppb (1 ng/g = 1 ppb). The authors concluded that the low milk concentrations of hexachlorophene found in their study were not a risk to a nursing infant. The American Academy of Pediatrics has not found any reports describing signs or symptoms in a nursing infant or effect on lactation after use of the drug but notes that nipple washing with hexachlorophene may contaminate the milk (21).

HOMATROPINE

Parasympatholytic (Anticholinergic)

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The limited human experience and absence of animal reproductive data prevent an assessment of the embryo–fetal risk. In general, however, anticholinergics are not thought to present a clinically significant risk of developmental toxicity (see also Atropine).

FETAL RISK SUMMARY

Homatropine is an anticholinergic agent. The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 26 of whom used homatropine in the 1st trimester (1, pp. 346–353). For use anytime during pregnancy, 86 exposures were recorded (1, p. 439). Only for anytime use was a possible association with congenital defects discovered. In addition, when the group of parasympatholytics was taken as a whole (2323 exposures), a possible association with minor malformations was found (1, pp. 346–353).

BREASTFEEDING SUMMARY

No reports describing the use of homatropine during human lactation have been located (see also Atropine).

HYDRALAZINE

Antihypertensive

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 3rd Trimester

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports linking the use of hydralazine with congenital defects have been located. However, fetal toxicity has been associated with use of the drug in the 3rd trimester.

FETAL RISK SUMMARY

In England, hydralazine is the most commonly used antihypertensive agent in pregnant women (1). Neonatal thrombocytopenia and bleeding secondary to maternal ingestion of hydralazine have been reported in three infants (2). In each case, the mother had consumed the drug daily throughout the 3rd trimester. This complication has also been reported in series examining severe maternal hypertension and may be related to the disease rather than to the drug (3,4).

Hydralazine readily crosses the placenta to the fetus (5). Serum concentrations in the fetus are equal to or greater than those in the mother.

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 8 of whom had 1st trimester exposure to hydralazine (6, p. 372). For use anytime during pregnancy, 136 cases were recorded (6, p. 441). No defects were observed with 1st trimester use. There were eight infants born with defects who were exposed in the 2nd or 3rd trimester. This incidence (5.9%) is greater than the expected frequency of occurrence, but the severe maternal disease necessitating the use of hydralazine is probably responsible. Patients with preeclampsia are at risk for a marked increase in fetal mortality (7–10).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 40 newborns had been exposed to hydralazine during the 1st trimester (F. Rosa, personal

communication, FDA, 1993). One (2.5%) major birth defect was observed (two expected), a hypospadias (none expected).

A number of studies involving the use of hydralazine either alone or in combination with other antihypertensives have found the drug to be relatively safe for the fetus (4,7–17). Fatal maternal hypotension has been reported in one patient after combined therapy with hydralazine and diazoxide (18).

In a woman with chronic hypertension maintained on methyldopa, an increase in blood pressure at about 35 weeks' gestation prompted the addition of hydralazine, 25 mg twice daily, to the treatment regimen (19). Fetal premature atrial contractions were diagnosed 1 week later, but tachyarrhythmias, which can be initiated by premature atrial contractions, were not observed (19). Hospitalization with bed rest allowed the patient's blood pressure to decline enough to discontinue hydralazine therapy. Within 24 hours of stopping hydralazine, the fetal arrhythmia resolved. The infant was delivered at 38 weeks and cardiac evaluation after discharge at 3 days indicated a regular heart rate.

A syndrome resembling lupus erythematosus was diagnosed in a 29-year-old woman treated with IV hydralazine during the 28th week of pregnancy (20). The patient received 425 mg during a 6-day period for the treatment of hypertension. IV methyldopa was administered on the 6th day of therapy. Labor was induced for fetal distress and a 780-g growth-restricted male infant was delivered vaginally. The infant expired at 36 hours of age secondary to cardiac tamponade induced by 7 mL of clear sterile transudate in the pericardial space. Lupus-like symptoms consisting of macular rash, arthralgia, and bilateral pleural effusion developed in the mother on the 5th day of hydralazine therapy and gradually resolved after discontinuance of the drug and delivery. The findings of pericardial effusion and cardiac tamponade in the infant were also thought to represent clinical evidence of a lupus-like syndrome (20). The symptoms in both the mother and fetus were attributed to hydralazine sensitivity resulting in the induction of a lupus-like syndrome.

BREASTFEEDING SUMMARY

Hydralazine is excreted into breast milk (5). In one patient treated with 50 mg 3 times daily, the milk:plasma ratio 2 hours after a dose was 1.4. This value is in close agreement with the predicted ratio calculated from the pK_a (21). The available dose of hydralazine in 75 mL of milk was estimated to be 13 mcg (5). No adverse effects were noted in the nursing infant from this small concentration. The American Academy of Pediatrics classifies hydralazine as

compatible with breastfeeding (22).

HYDROCHLOROTHIAZIDE

Diuretic

See Chlorothiazide.

HYDROCODONE

Narcotic Agonist Analgesic, Respiratory Drug (Antitussive)

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

The National Birth Defects Prevention Study discussed below found evidence that opioid use during organogenesis is associated with a low absolute risk of congenital birth defects. Interestingly, this supports the FDA data also presented below. Similar to other opioid analgesics, the use of hydrocodone late in pregnancy has the potential to cause respiratory depression and withdrawal in the newborn (see also Codeine).

FETAL RISK SUMMARY

Hydrocodone is a centrally acting narcotic agent that is related to codeine. It is combined with other drugs for use as an analgesic or as an antitussive. In a reproductive study in hamsters, a single SC injection (102 mg/kg) during the critical period of CNS organogenesis produced malformations (cranioschisis and various other lesions) in 3.4% of the offspring (1). Because of its narcotic properties, withdrawal could theoretically occur in infants exposed in utero to prolonged maternal ingestion of hydrocodone.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 332 newborns had been exposed to hydrocodone during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 24 (7.2%) major birth defects were observed (14 expected), 5 of which were cardiovascular defects (3 expected). No anomalies were observed in five other defect categories (oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available. The total number of malformations is suggestive of a possible association but other factors, including the mother's disease, concurrent drug use, and chance, may be involved.

At a 1996 meeting, data on 118 women using hydrocodone (N = 40) or

oxycodone (N = 78) during the 1st trimester for postoperative pain, general pain, or upper respiratory infection were matched with a similar group using codeine for these purposes (2). Six (5.1%) of the infants exposed to hydrocodone or oxycodone had malformations, an odds ratio of 2.61 (95% confidence interval 0.6–11.5) (p = 0.13). There was no pattern evident among the six malformations (2).

Results of a National Birth Defects Prevention Study (1997–2005) were published in 2011 (3). This population-based case–control study examined the association between maternal use of opioid analgesics and >30 types of major structural birth defects. In 17,449 case mothers, therapeutic opioid use was reported by 454 (2.6%) compared with 134 (2.0%) of 6701 control mothers. Indications for use of opioid analgesics were surgical procedures (41%), infections (34%), chronic diseases (20%), and injuries (18%). Dose, duration, and frequency were not evaluated. The exposure period evaluated was from 1 month before to 3 months after conception. Limiting the exposure period to the first 2 months after conception produced similar results. Infants with >1 defect were included in multiple birth defect categories. The following opioids were included (number of cases for each agent not specified): codeine, hydrocodone, hydromorphone, fentanyl, meperidine, methadone, morphine, oxycodone, pentazocine, propoxyphene, and tramadol. The birth defect, total number, number exposed, and the adjusted odds ratio (aOR) with 95% confidence interval (CI) were as follows:

| Birth Defect | Total | Cases | aOR (95% CI) |
|--|-------|-------|---------------|
| Spina bifida | 718 | 26 | 2.0 (1.3–3.2) |
| <i>Any heart defect</i> (20 types) | 7724 | 211 | 1.4 (1.1–1.7) |
| Atrioventricular septal defect | 175 | 9 | 2.4 (1.2–4.8) |
| Teratology of Fallot | 672 | 21 | 1.7 (1.1–2.8) |
| Conotruncal defect | 1481 | 41 | 1.5 (1.0–2.1) |
| Conoventricular septal defect | 110 | 6 | 2.7 (1.1–6.3) |
| Left ventricular outflow tract obstruction defect | 1195 | 36 | 1.5 (1.0–2.2) |
| Hypoplastic left heart syndrome | 357 | 17 | 2.4 (1.4–4.1) |
| Right ventricular outflow tract obstruction defect | 1175 | 40 | 1.6 (1.1–2.3) |
| Pulmonary valve stenosis | 867 | 34 | 1.7 (1.2–2.6) |
| Atrial septal defect (ASD) | 511 | 17 | 2.0 (1.2–3.6) |
| Ventricular septal defect + ASD | 528 | 17 | 1.7 (1.0–2.9) |
| Hydrocephaly | 301 | 11 | 2.0 (1.0–3.7) |
| Glaucoma/anterior chamber defects | 103 | 5 | 2.6 (1.0–6.6) |
| Gastroschisis | 726 | 26 | 1.8 (1.1–2.9) |

The authors speculated that the activity of opioids and their receptors as growth regulators during development of the embryo might be a mechanism to explain the above findings. The exposure data were obtained by retrospective maternal self-report; the authors acknowledged that recall bias and misclassification might have affected their results. They concluded that the absolute risk was a modest absolute increase above the baseline risk for birth defects (3).

BREASTFEEDING SUMMARY

A mother, breastfeeding her third infant, experienced severe pain from cracked nipples associated with a fungal infection (4). She had successfully breastfed her two previous infants for 1–2 years. At about 3 weeks postpartum, because acetaminophen alone or combined with codeine had not been successful in controlling her pain, she was started on hydrocodone/acetaminophen (10/650

mg/tablet) two tablets every 4 hours. Good analgesia was obtained, but both the mother and infant were “groggy and sleepy most of the day.” After 24 hours, the mother decreased the dose to 1 tablet every 3–5 hours alleviating the symptoms in her and the infant. She eventually discontinued the drug combination completely after 3 weeks. The fungal infection was successfully treated with long-term (30 days) oral fluconazole (4). Although hydrocodone milk concentrations were not measured, it is obvious that sufficient amounts were excreted into milk to cause marked sedation in the infant. Such excretion is consistent with the molecular weight (about 381) of hydrocodone.

Severe apnea, requiring mouth-to-mouth resuscitation, intubation, and IV naloxone, developed in a 5-week old, 3.8-kg breastfed infant (5). The mother had been prescribed methadone and hydrocodone/acetaminophen (doses not specified) for migraine headaches and had taken these agents before breastfeeding the infant. The infant’s urine drug screen was positive for opioids. It could not be determined if the infant toxicity was due to methadone, hydrocodone, or a combination of the two agents (5).

A 2007 study reported milk concentrations of hydrocodone in two women (6). In the first case, a 22-year-old, 63.6-kg woman was treated during the 3rd trimester with hydrocodone/acetaminophen two tablets every 3–4 hours to control headaches caused by left-sided temporal schwannoma (skull-based tumor). She continued the analgesic combination after delivery at 35 weeks’ gestation. On postpartum day 7, the patient underwent a craniotomy to remove the tumor and was continued on 5 mg of hydrocodone/acetaminophen one to two tablets every 4 hours as needed. She received 105 mg hydrocodone over 81 hours. During that time, an electric pump was used to obtain breast milk for her infant. The milk hydrocodone concentrations were 8.6–127.3 mcg/L with the levels dependent upon the mother’s dose and the time interval from the last dose. The average milk concentration, based on AUC, was 57.2 mcg/L. The infant dose, if exclusively breastfed, was 8.58 mcg/kg/day, or 3.1% of the mother’s weight-adjusted dose. In the second case, a 22-year-old, 73.5-kg woman at 16 days postpartum was admitted to the hospital for treatment of mastitis and urosepsis. In addition to antibiotics, she received hydrocodone/acetaminophen (5/500 mg) every 6 hours, but only took three doses (15 mg hydrocodone) over a 24-hour period. Milk was obtained as in the first case. Milk concentrations of the opioid were 5.2–47.2 mcg/L depending on the time from the last dose. The average milk concentration, based on AUC, was 20.4 mcg/L. The infant dose, if exclusively breastfed, was 3.07 mcg/kg/day, or 3.7% of the mother’s weight-adjusted dose (6).

In their comments, the authors noted that although the infant doses relative to their mother's weight-adjusted dose were nearly the same (3.1% vs. 3.7%), the absolute infant doses were much different (8.58 vs. 3.07 mcg/kg/day) (6). Because the infants were not hospitalized, the authors could not determine if either infant experienced an adverse reaction. However, toxicity would have been more likely in the first infant because of the higher dose.

In a 2011 study, 30 postpartum women received hydrocodone–acetaminophen for pain while fully breastfeeding their infants (7). The study period averaged 55.3 hours (range 16.9–84.1 hours). The average milk concentration of hydrocodone was 14.2 mcg/L. The infant dose as a percentage of the mother's weight-adjusted dose was 1.6% (range 0.2%–9%). Hydromorphone, a metabolite of hydrocodone, was detected in 12 of the 30 women. The total median opiate dosage from breast milk was 0.7% (range 0.1%–9.9%) of the therapeutic dose for older infants. The infants were not followed for evidence of adverse effects (7).

Occasional doses of hydrocodone probably represent a minimal risk for a nursing infant, but higher or frequent maternal dosing may cause toxicity. Regardless, mothers taking hydrocodone products while breastfeeding should observe their infants for breathing difficulty, sedation, excessive sleepiness, gastrointestinal effects, and changes in feeding patterns.

HYDROCORTISONE

Corticosteroid

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Hydrocortisone and its inactive precursor, cortisone, appear to present a small risk to the human fetus. These corticosteroids produce dose-related teratogenic and toxic effects in genetically susceptible experimental animals consisting of cleft palate, cataracts, spontaneous abortion, intrauterine growth restriction (IUGR), and polycystic kidney disease. Although the large amount data do not support these effects in the great majority of human pregnancies, adverse outcomes have been observed and may have been caused by corticosteroids. Moreover, the decrease in birth weight and a small increase in the incidence of cleft lip with or without cleft palate is supported by large epidemiologic studies. In addition, cataracts, resulting from a toxicity observed in humans administered the drug directly, have been reported in human offspring exposed in utero, but a causal relationship to maternal corticosteroid use is less certain. Because the benefits of corticosteroids appear to far outweigh the fetal risks, these agents should not be withheld if the mother's condition requires their use. The mother, however, should be informed of the risks so that she can actively participate in the decision on whether to use these agents during her pregnancy.

FETAL RISK SUMMARY

Hydrocortisone (Cortisol; Compound F) is a corticosteroid secreted by the adrenal cortex. An inactive precursor, cortisone (Compound E), is also secreted by the adrenal cortex and is converted by reduction, primarily by the liver, to hydrocortisone (1). Hydrocortisone is used for various indications. Physiologic doses are used to treat adrenal hormone deficiency, and higher, pharmacologic amounts for the anti-inflammatory and immunosuppressant

properties and other effects.

Multiple studies have described the effects of hydrocortisone or cortisone on the pregnancy outcomes of experimental animals (2–14). In five different strains of pregnant mice administered a daily IM dose of cortisone ranging from 0.625 to 10.0 mg for 4–5 days, a dose-related and strain-related incidence of cleft palate and resorption were observed (2). Depending on the day of gestation that treatment started, the percentage of young with cleft palate ranged from 2.9% to 79.1%. (Pups with cleft lip and palate similar to the spontaneous defects that sometimes occur in untreated pups were excluded (2).) In contrast, no cases of cleft palate were observed in the young from control mice injected with an inert cortisone-free vehicle. Other anomalies observed in the offspring of treated groups included marked IUGR, shortening of the head and mandible, and spina bifida.

In a continuation of the above work, this same research group studied the effects on pregnant mice of a daily 2.5-mg IM cortisone dose given for 4 consecutive days beginning on gestational days 7 through 18 (3). The maximum percentage of litters resorbed occurred on day 7 (88%) and declined thereafter as the gestational age increased at the first dose. Depending on the mother's genotype, the 4-day cortisone treatment beginning on gestational day 11 resulted in an incidence of cleft palate in the offspring varying from 4% to 100%. Much of this and earlier experiments were reviewed by these investigators in a 1957 paper (4).

Hydrocortisone was shown to produce an incidence of cleft palate in mice offspring similar to cortisone (95%) in genetically susceptible pregnant mice treated with 2.5 mg/day IM for 4 days starting on the 10th or 11th gestational day (5). No other gross external malformations were observed in the offspring.

The effect of cortisone treatment in mice on litter size, birth weight, cleft palate, gestation length, and spontaneous cleft lip (with or without palate) has been investigated (6). Litter size was reduced only if treatment was begun before the 12th gestational day, whereas birth weight was primarily reduced (mean reduction 31.2%) by treatment after this time. Cortisone administration had no effect on mean gestation length or on the frequency of spontaneous cleft lip but did induce cleft palate in some offspring. A 1998 correspondence reiterated the negative effect of cortisone on intrauterine growth that was found in this study (7).

The teratogenic potency of three corticosteroids to produce cleft palate in mice was the subject of a study published in 1965 (8). Therapeutically equivalent IM doses of hydrocortisone (4 mg), prednisolone (1 mg), or

dexamethasone (0.15 mg) were administered to pregnant mice (weight 20 to 25 g) on gestational days 11 through 14. After exclusion of offspring with spontaneous cleft lip and palate, the frequency of cleft palate with the three agents was 18%, 77%, and 100%, respectively (8). In another study, cleft palate (palatoschisis) and cataract were frequently observed in the offspring of pregnant mice (weight 20 g) administered 1 mg of hydrocortisone SC for 2–4 days between gestational days 9 and 16 (9). Resorption of part or all of the litters was common.

One study investigated the effect of IM cortisone, 1–5.7 mg/kg/day administered for 1–33 days, on reproduction in rabbits (10). Gross congenital anomalies were not seen in offspring that survived, but IUGR was evident in some. Further, a marked increase in fetal and neonatal death was observed. In a later study, pregnant rabbits received IM cortisone, 25 or 30 mg (approximately 7–8 mg/kg/day), for 4 days beginning on gestational day 14 or 15 (11). (Total gestation time in rabbits is 31–34 days (12)) Seventeen of the 35 embryos had a cleft palate, including 9 of the 12 born dead. Embryos with cleft palate, living or stillborn, usually weighed less than their siblings. In addition, two of the seven exposed litters were completely resorbed. All 36 offspring from nonexposed controls were born alive without cleft palate.

Reduced lung and body weights were observed in rabbit fetuses given a 2-mg IM injection of hydrocortisone on gestational day 24 (13). Treated fetuses also had fewer lung cells as indicated by decreased DNA per lung. The deficiencies in the number of lung cells and the weights of lung and body recovered within 30 days of birth. In a 1979 study, hydrocortisone, 57 mg/kg/day intraperitoneal on day 12 or 15 of gestation, had no effect on the development of brain monoamine cell bodies or the arrival of axon terminals in the regions where the synapses form (14).

A study published in 1991 demonstrated that a single 250 mg/kg SC dose of hydrocortisone in pregnant mice on gestational days 11 through 17 could induce polycystic kidney disease in the fetus (15). (Total gestation time in mice is 18–20 days (12).) The highest incidence of the defect occurred after exposure on gestational day 12, corresponding to the expected onset of metanephric renal differentiation in the fetal mouse (15).

Hydrocortisone and cortisone cross the human placenta to the fetus (16–19). Six pregnant women, immediately before an elective cesarean section at term, received a continuous IV infusion of a mixture of radioactive-labeled hydrocortisone and cortisone (16). By measurement of the hormones in the mothers and newborns, the investigators demonstrated that most (about 75%)

of the hydrocortisone in the fetus was endogenous, whereas most of the cortisone was from the mother. Two other studies described low transfer of hydrocortisone to the fetus because of placental metabolism (17,18). The placenta is a rich source of the enzyme 11 β -ol-dehydrogenase which can convert hydrocortisone to cortisone, the biologically inactive 11-ketosteroid (17,18). In an in vivo experiment, radioactive-labeled IV hydrocortisone was administered to five women immediately before an elective abortion at 13–18 weeks' gestation (17). The concentrations of hydrocortisone and cortisone in umbilical cord serum and the placenta exhibited similar patterns: about 15% for hydrocortisone and 85% for cortisone, indicating that most of hydrocortisone crossing the placenta had been converted to cortisone (17). Using a perfused human placenta, one investigation discovered that the percentage of hydrocortisone converted to cortisone in three different perfusion mediums was 73% (buffer), 85% (1% human serum albumin), and 78% (washed calf red blood cells) (18).

In a 1982 report, researchers measured the concentration of hydrocortisone in the cord blood of 71 premature infants (mean gestational age 32.5 weeks) after administration of the drug in an attempt to prevent respiratory distress syndrome (RDS) (19). The mothers received an IV dose of 100 mg, followed by 100 mg IM every 8 hours up to a total of 400 mg. The infants were delivered between 6 minutes and 85 hours after the first dose. The peak cord blood concentration (32 mcg/100 mL) occurred approximately 1 hour after a dose, representing a 3.8-fold increase over endogenous levels (8.5 mcg/100 mL). Nearly all of the exogenous hydrocortisone was cleared between doses as indicated by the elimination half-life of about 2 hours (19).

Hydrocortisone is frequently prescribed during human pregnancy and case reports and other references have described the use of this agent or its precursor, cortisone, during pregnancies that produced an infant with a congenital malformation. In most cases, however, a relationship between the drug and the outcome cannot be determined.

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, of whom 21 and 34 infants, respectively, were exposed in the 1st trimester to hydrocortisone and cortisone (20, pp. 388–400). Three of the infants exposed in utero to hydrocortisone had a major malformation (relative risk [RR] 2.79), whereas one infant had a defect following exposure to cortisone (RR 0.46) (type of defect not specified). There were 74 exposures to hydrocortisone anytime during pregnancy with three malformed infants (RR 1.70) (20, p. 443). Although the number of exposures is limited, no evidence of an association with

congenital malformations was found with these data (20, p. 398).

Several case reports have described congenital anomalies in newborns exposed to corticosteroids with and without other drug exposures (21–25). Some of these cases are included in the review discussed below (26). A brief 1953 correspondence describes four infants with defects (club foot, coarctation of the aorta, cataract, and hypospadias) who were delivered to mothers treated during the 1st trimester with cortisone for nausea and vomiting (21). Microcephaly was noted in a newborn whose mother was treated with two 100-mg IV doses of hydrocortisone and a single IM dose of procaine penicillin at about the 8th week of gestation (22). A male cyclops with a single orbit containing one eyeball with two corneas and two irides was described in a 1973 publication (23). The mother had been treated with “high doses” (specifics not given) of cortisone, procaine penicillin, and sodium salicylate at about 4 weeks fetal age for symptoms of diarrhea, fever, and a maculopapular rash. The infant died 5 minutes after birth. In addition to the cyclops, the nose was absent and the ears were low set, and at autopsy, the brain was found to be small and severely malformed. Although the mother had a positive rubella titer, a definite diagnosis of rubella could not be made (23). Moreover, the defects noted in the infant were not consistent with those required for a diagnosis of congenital rubella syndrome (see Vaccine, Rubella). Two malformed infants, one with gastroschisis and the other with hydrocephalus, were briefly noted in a 1965 reference (24). The mothers had used cortisone (doses not specified) throughout their pregnancies for ulcerative colitis and severe asthma, respectively. Bilateral nuclear cataract was diagnosed in a male infant who had been exposed to prednisone (15–60 mg/day) throughout gestation for maternal Crohn’s disease (25). In addition, “high-dose” (amount not specified) cortisone had been given during the 6th month of gestation.

A brief 1995 article reviewed the available literature to assess whether the use of corticosteroids (hydrocortisone, cortisone, prednisone, prednisolone, or dexamethasone) during the first 70 days after human conception was teratogenic (26). The disorders treated were mainly systemic lupus erythematosus, asthma, and infertility. From 18 case reports, the researchers identified 26 exposed pregnancies of which 7 (27%) ended with malformed offspring. Four (57%) of the anomalies were cleft palate (three of these cases are described below in references 27–29) and the other three were bilateral nuclear cataract, gastroschisis, and hydrocephalus. Although the number of infants with congenital defects is much higher than expected, the authors thought it likely that they represented reporting bias. In addition, they reviewed

17 reported series of 457 mothers exposed to the corticosteroids during the 1st trimester. In this group, 16 (3.5%) of the offsprings, an incidence close to that expected, had malformations. Of these, two had cleft palate (0.2 expected based on population frequency). The other defects were anencephaly (N = 2), clubfoot (N = 3), dislocated hip (N = 1), coarctation of the aorta (N = 2; 1 with a positive family history), transposition of the great vessels (N = 1; with a positive family history), cataract (N = 2; 1 with a positive family history), hypospadias (N = 2), and undescended testis (N = 1). Other adverse effects including stillbirth, neonatal death, prematurity, and low birth weight accounted for 21% of the outcomes, but the authors were unable to separate the effect of the drug treatment from the disease process itself. They concluded that there was little teratogenic risk, if any, from the use of corticosteroids in human pregnancy (26).

The first reported case of cleft palate in an infant delivered from a woman treated with cortisone was published in 1956 (27). A 30-year-old woman with idiopathic steatorrhea was administered oral cortisone, 100 mg 3 times daily, beginning on the 38th day of pregnancy. Therapy was gradually tapered and then discontinued about 9 weeks later when pregnancy was diagnosed. The woman eventually delivered a term stillborn male child with a cleft palate. The cause of death was thought to be intrauterine anoxia. A second case was also reported in 1956 (28). A woman with disseminated lupus erythematosus was treated throughout her pregnancy with oral cortisone (100 mg/day) and tolazoline (400 mg/day). She delivered a premature, growth-restricted 2 pound 11 ounce (about 1.22 kg) male infant between 35 and 36 weeks' gestation. The infant, who died of pneumonia 14 days after birth, had a cleft palate but no other malformations were observed at autopsy. A 1962 paper mentioned an infant with a cleft palate whose mother had taken 62.5 mg/day of cortisone during the first 6 months of pregnancy (29).

A 1960 reference cited pregnancy outcome data from 31 reports totaling 260 pregnancies exposed to pharmacologic doses of cortisone or its analogs (30). The outcomes included 8 stillborn, 1 abortion, 15 premature infants, and 7 newborns with various disorders, 1 of which involved transient adrenocortical failure. (Disorders in the other six were not specified.) The authors did not attempt to list the type or frequency of congenital defects, stating only that most "... showed no malformations." They did, however, mention four cases of cleft palate (two from their series and two from unpublished data) in infants exposed to large doses of corticosteroids during the 1st trimester (30).

Data from the MADRE (Malformation Drug Exposure Surveillance) project

were published in 1994 (31). This large surveillance study, a part of the International Clearinghouse for Birth Defects Monitoring Systems, compared congenital malformations with 1st trimester drug exposures from six countries (Australia, France, Israel, Italy, Japan, and South America) during a 2-year period (1990–1991) (31). A total of 1448 infants with birth defects were studied. Most of the programs, however, did not report abortions. Moreover, individual drugs were not identified but were grouped into 45 pharmacologic classes. The maternal drug exposure history was determined by interview in the postpartum period. Of interest, seven infants with facial clefts (cleft lip N = 5, cleft lip and palate N = 2) were exposed to systemic corticosteroids (odds ratio [OR] 3.16; 95% confidence interval [CI] 1.08–7.91; p = 0.04). The authors noted that the association may have occurred by chance (31).

The MADRE database again was used in a 2003 case–control study (32). The time interval for data collection was 13 years (1990–2002) and included 11,150 reported congenital malformations (included live births, stillbirths, and induced abortion) with 1st trimester drug exposure. For the present study, cases were defined as infants with cleft lip and/or palate and exposure to systemic corticosteroids during the 1st trimester. Controls were defined as infants with any other birth defect. There were nine cases of cleft lip or cleft palate (OR 2.10, 95% CI 1.03–4.26). Two of the cases were cleft palate only (OR 1.17, 95% CI 0.28–4.92) and seven were cleft lip with or without cleft palate (OR 2.59, 95% CI 1.18–5.67). Because of a decreasing trend of the number of cases per year and animal data, the results were thought to suggest a possible interaction with environmental pesticides (32).

The case–control study, Spanish Collaborative Study of Congenital Malformations, surveying more than 1.2 million infants born live from 1976 to 1995 was published in 1995 (33). The study's purpose was to determine if the occurrence of nonsyndromic cleft lip (with or without cleft palate) was related to 1st trimester exposure to systemic corticosteroids. Three control groups were used: (a) paired controls, (b) controls born at the same hospital ± 45 days of the case's birth date, and (c) malformed infants without oral clefts. Statistical analysis was employed to control for four potential confounding factors: (a) maternal smoking; (b) maternal hyperthermia; (c) first-degree malformed relatives with cleft lip with or without cleft palate; and (d) 1st trimester drug exposure to anticonvulsants, benzodiazepines, metronidazole, or sex hormones. A total of 1184 case infants were identified with nonsyndromic oral clefts, 5 (0.42%) of whom were exposed during the 1st trimester to corticosteroids. Among the 31,752 control infants, 36 (0.11%) had been exposed to

corticosteroids during the 1st trimester. None of the 5 case infants had been exposed to known teratogens or known risk factors for oral clefts during the 1st trimester. Based on four cases (a case of cleft soft palate was excluded), there was an increased risk of cleft lip (with or without cleft palate) following 1st trimester exposure to systemic corticosteroids (OR 6.55; 95% CI 1.44–29.76; $p = 0.015$) (32). Control of the four confounding factors made the association slightly stronger (OR 6.64; 95% CI 1.46–30.18; $p = 0.014$). The corticosteroids identified in these four cases were hydrocortisone (N = 1; 40 mg/day throughout pregnancy), prednisone (N = 2; 15–30 mg/day during 1st trimester), and triamcinolone (N = 1; 8 mg/day during 2nd month) (33).

Another large case–control study of the teratogenic potential of oral and topical corticosteroids involving 1,923,413 total births from 1980 to 1994 was conducted with the Hungarian Case–Control Surveillance of Congenital Abnormalities and published in 1997 (34). Among the 20,830 malformed case infants, 322 (1.55%) were exposed to systemic corticosteroids (all oral except for 4 who received parenteral doses) during the 1st trimester compared with 503 (1.41%) (all oral except for 3 who received parenteral doses) of the 35,727 normal control infants ($p = 0.19$). A corticosteroid ointment was used in 73 (0.35%) of the cases and in 118 (0.33%) of the controls ($p = 0.69$). A corticosteroid spray was used by 8 case mothers (0.04%) and 11 controls (0.03%) ($p = 0.63$), but the offspring from those mothers were excluded from the detailed analysis because of the small numbers. The indications for systemic corticosteroids during the 1st trimester were primarily for asthma, hay fever, rheumatoid disorders, and subfertility, whereas the ointments were used for skin diseases. Most of the systemic exposures in both cases and controls were to dexamethasone and prednisolone. None of the patients in either group received systemic hydrocortisone and only 15 cases and 22 controls received systemic cortisone. Hydrocortisone ointment was used by 24 case mothers and 32 controls. No association between the rate of different abnormalities and the use of corticosteroids (oral and ointment) in the 2nd and 3rd months of gestation or during the 1st trimester was found based on the analysis of the case–control pairs. In the 1st gestational month, three cases with cleft lip (with or without cleft palate) (OR 5.88, 95% CI 1.70–20.32) and multiple defects (OR 4.88, 95% CI 1.41–16.88) were observed. However, exposures that occurred only during the 1st gestational month (the 1st half of this month is before conception and the other half involves the processes of preimplantation and implantation) cannot cause defects because this time is before the critical period for induction of congenital malformations (34).

In a case–control study published in 1999, the California Birth Defects Monitoring Program evaluated the association between selected congenital anomalies and the use of corticosteroids 1 month before to 3 months after conception (periconceptual period) (35). Case infants or fetal deaths diagnosed with orofacial clefts, conotruncal defects, neural tubal defects (NTD), and limb anomalies were identified from a total of 552,601 births that occurred from 1987 through the end of 1989. Controls, without birth defects, were selected from the same database. Following exclusion of known genetic syndromes, mothers of case and control infants were interviewed by telephone, an average of 3.7 years (cases) or 3.8 years (controls) after delivery, to determine various exposures during the periconceptual period. The number of interviews completed were orofacial cleft case mothers (N = 662, 85% of eligible), conotruncal case mothers (N = 207, 87%), NTD case mothers (N = 265, 84%), limb anomaly case mothers (N = 165, 82%), and control mothers (N = 734, 78%) (34). Orofacial clefts were classified into four phenotypic groups: isolated cleft lip with or without cleft palate (ICLP, N = 348), isolated cleft palate (ICP, N = 141), multiple cleft lip with or without cleft palate (MCLP, N = 99), and multiple cleft palate (MCP, N = 74). A total of 13 mothers reported using corticosteroids during the periconceptual period for a wide variety of indications. Six case mothers of ICLP and 3 of ICP used corticosteroids (unspecified corticosteroid, N = 1; prednisone, N = 2; cortisone, N = 3; triamcinolone acetonide, N = 1; dexamethasone, N = 1; and cortisone plus prednisone, N = 1). One case mother of an infant with NTD used cortisone and an injectable unspecified corticosteroid, and three controls used corticosteroids (hydrocortisone, N = 1; and prednisone, N = 2). The OR for corticosteroid use and ICLP was 4.3 (95% CI 1.1–17.2), whereas the OR for ICP and corticosteroid use was 5.3 (95% CI 1.1–26.5). No increased risks were observed for the other anomaly groups. Commenting on their results, the investigators thought that recall bias was unlikely because they did not observe increased risks for other malformations, and it was unlikely that the mothers would have known of the suspected association between corticosteroids and orofacial clefts (35).

A 2002 study, using data from a Danish prescription database and a birth registry, examined the relationship between topical corticosteroids and low birth weight, malformations, and preterm delivery (36). The pregnancy outcomes of 363 women, who had received prescriptions for the drugs 30 days before conception and/or during pregnancy, were compared with 9263 controls, who had received no prescriptions at all. The incidence of birth defects in 170

pregnancies with 1st trimester exposure was 1.8% (3 of 170) and in controls was 3.6%. The defects in the exposed group were clubfoot, flat foot, and metatarsus varus. For use anytime in pregnancy, no associations were found with low birth weight and preterm delivery. Stratification by corticosteroid strength (weak to very strong) did not change any of the results (36).

In a 2004 report, the Israeli Teratogen Information Service prospectively collected and followed 311 pregnancies exposed to systemic corticosteroids (37). The pregnancy outcomes, in terms of major congenital defects, of exposed and 790 controls did not differ significantly (4.6% vs. 2.6%). There were no cases of oral clefts in the exposed group. However, significant differences were observed in the rates of spontaneous abortion (11.5% vs. 7.0%) and preterm births (22.7% vs. 10.8%). Moreover, exposed infants had a lower median birth weight (3080 vs. 3290 g) and were born at an earlier median gestational age (39 vs. 40 weeks). The study had a power to find a 2.5-fold increase in the overall rate of major congenital defects (37).

Hydrocortisone was only partly successful in an attempt to prevent in utero virilization by adrenal suppression of a female fetus with congenital adrenal hyperplasia (21-hydroxylase deficiency) (38). A daily oral dose of 40 mg was started at 9.4 weeks' gestation and increased to 50 mg/day during mid-pregnancy. At delivery, low amniotic fluids of estriol suggested only partial suppression of the fetal adrenal glands. The infant had moderate virilization as indicated by clitoral hypertrophy and slight posterior fusion. In contrast, dexamethasone was used successfully in a second mother (see Dexamethasone). The failure of hydrocortisone to prevent virilization was probably a result of the lower placental transfer and adrenal suppression potency compared with dexamethasone (38).

Hydrocortisone has been used in attempts to enhance fetal lung maturation and, thus, prevent RDS (18,39–48). This therapy is relatively nontoxic to the fetus. However, hydrocortisone is no longer used for this purpose because very large doses are required to overcome placental metabolism and relatively short half-life of the corticosteroid in the fetus. Compared with a corticosteroid frequently used to prevent RDS (betamethasone 24 mg/treatment course), at least a 2000 mg/treatment course of hydrocortisone would have to be administered to achieve therapeutically equivalent results (48).

Both hydrocortisone and cortisone have been used to treat pregnancy-induced severe nausea and vomiting (i.e., hyperemesis gravidarum (21,49,50)). Although this therapy appears to be successful, its risks, especially in the 1st trimester (e.g., see reference 21), indicate that corticosteroids should not be

used as primary therapy.

Hydrocortisone and other systemic and inhaled corticosteroids are frequently prescribed to control the symptoms of severe asthma during pregnancy (51–57). Most authorities believe that these agents are relatively safe in pregnancy and that their benefit to both the mother and her pregnancy clearly outweigh the potential risks to the fetus (51–56). One author, however, suggested caution in their use around the time of palate closure and in women with a family history of cleft lip (with or without cleft palate) (51). A recent study of 824 pregnant asthmatic patients matched with 678 controls (all singleton pregnancies in both groups) found no significant relationship between major congenital malformations and 1st trimester exposure to corticosteroids (oral, inhaled, or intranasal) (53). However, significant associations were found between corticosteroid use and preeclampsia (exposed 11.4% vs. controls 7.1%, $p = 0.014$), preterm birth (exposed 6.4% vs. controls 3.8%, $p = 0.048$), and low birth weight (exposed 6.0% vs. controls 3.3%, $p = 0.032$) (53). Other references have reported IUGR as a complication of systemic corticosteroids (54–56). The latter reference quantified the impaired fetal growth as about a 300- to 400-g decrease in birth weight (56).

BREASTFEEDING SUMMARY

Trace amounts of endogenous hydrocortisone (cortisol) are excreted into breast milk (57,58). The amount of the corticosteroid in milk varies from 0.2 to 32 ng/mL with the highest mean concentrations (25.5 ng/mL) measured in colostrum during late pregnancy (58). The concentration of hydrocortisone in colostrum averages 7.5% of the plasma level.

No reports describing the excretion of exogenous hydrocortisone or cortisone into human milk have been located. It is unlikely, however, that these agents pose a risk to a nursing infant. Prednisone, a corticosteroid more potent than hydrocortisone, is excreted in trace amounts into milk and is classified as compatible with breastfeeding (see Prednisone). Moreover, a 1997 review stated that corticosteroids have been used safely during lactation (54).

HYDROMORPHONE

Narcotic Agonist Analgesic

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

The National Birth Defects Prevention Study discussed below found evidence that opioid use during organogenesis is associated with a low absolute risk of congenital birth defects. In addition, withdrawal could occur in infants exposed in utero to prolonged maternal ingestion of hydromorphone. Use of the drug in pregnancy is primarily confined to labor. Respiratory depression in the neonate similar to that produced by meperidine or morphine should be expected (1) (see also Codeine).

FETAL RISK SUMMARY

Hydromorphone, an opioid analgesic, is a hydrogenated ketone of morphine. The drug is extensively metabolized in the liver to apparently inactive metabolites. It also is a metabolite of hydrocodone. Plasma protein binding of hydromorphone is low (about 8%–19%) and the elimination half-life is dose-dependent (about 2.6–2.8 hours) (2).

Results of a National Birth Defects Prevention Study (1997–2005) were published in 2011 (3). This population-based case–control study examined the association between maternal use of opioid analgesics and >30 types of major structural birth defects. In 17,449 case mothers, therapeutic opioid use was reported by 454 (2.6%) compared with 134 (2.0%) of 6701 control mothers. Indications for use of opioid analgesics were surgical procedures (41%), infections (34%), chronic diseases (20%), and injuries (18%). Dose, duration, and frequency were not evaluated. The exposure period evaluated was from 1 month before to 3 months after conception. Limiting the exposure period to the first 2 months after conception produced similar results. Infants with >1 defect were included in multiple birth defect categories. The following opioids were included (number of cases for each agent not specified): codeine,

hydrocodone, hydromorphone, fentanyl, meperidine, methadone, morphine, oxycodone, pentazocine, propoxyphene, and tramadol. The birth defect, total number, number exposed, and the adjusted odds ratio (aOR) with 95% confidence interval (CI) were as follows:

| Birth Defect | Total | Cases | aOR (95% CI) |
|--|-------|-------|---------------|
| Spina bifida | 718 | 26 | 2.0 (1.3–3.2) |
| <i>Any heart defect (20 types)</i> | 7724 | 211 | 1.4 (1.1–1.7) |
| Atrioventricular septal defect | 175 | 9 | 2.4 (1.2–4.8) |
| Teratology of Fallot | 672 | 21 | 1.7 (1.1–2.8) |
| Conotruncal defect | 1481 | 41 | 1.5 (1.0–2.1) |
| Conoventricular septal defect | 110 | 6 | 2.7 (1.1–6.3) |
| Left ventricular outflow tract obstruction defect | 1195 | 36 | 1.5 (1.0–2.2) |
| Hypoplastic left heart syndrome | 357 | 17 | 2.4 (1.4–4.1) |
| Right ventricular outflow tract obstruction defect | 1175 | 40 | 1.6 (1.1–2.3) |
| Pulmonary valve stenosis | 867 | 34 | 1.7 (1.2–2.6) |
| Atrial septal defect (ASD) | 511 | 17 | 2.0 (1.2–3.6) |
| Ventricular septal defect + ASD | 528 | 17 | 1.7 (1.0–2.9) |
| Hydrocephaly | 301 | 11 | 2.0 (1.0–3.7) |
| Glaucoma/anterior chamber defects | 103 | 5 | 2.6 (1.0–6.6) |
| Gastroschisis | 726 | 26 | 1.8 (1.1–2.9) |

The authors speculated that the activity of opioids and their receptors as growth regulators during development of the embryo might be a mechanism to explain the above findings. The exposure data were obtained by retrospective maternal self-report; the authors acknowledged that recall bias and misclassification might have affected their results. They concluded that the

absolute risk was a modest absolute increase above the baseline risk for birth defects (3).

BREASTFEEDING SUMMARY

Hydromorphone is excreted into breast milk (4). Eight healthy lactating women were given a single dose of 2-mg hydromorphone by nasal spray and serial blood and milk samples were collected over 24 hours. Infants were not allowed to nurse during the study. Little of the drug was found in milk fat (skim milk:whole milk ratio 0.98). The milk:plasma ratio was about 2.6 and the estimated infant dose (based on 150 mL/kg/day) was 0.67% of the mother's weight-adjusted dose (3).

The effect of these amounts, if any, on a nursing infant are unknown but appear to be clinically insignificant. However, further study, especially with multiple dosing, is warranted (see also Hydrocodone).

HYDROQUINONE

Dermatologic Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

In a 1998 study, approximately 45% of a dose from a 24-hour application of 2% topical hydroquinone cream was absorbed into the systemic circulation (1). In one of two animal species studied, an increased incidence of structural anomalies was noted but only at a maternal toxic dose. The difference between the oral doses used in animals and the topical human dose in terms of systemic exposure (i.e., AUC) is unknown. However, since the difference should be large, the animal data appear to suggest low risk. Moreover, the nearly complete absence of reported human pregnancy experience, combined with the expected frequent use in pregnancy, provides some reassurance that topical hydroquinone is not associated with embryo or fetal toxicity. Although more data are needed, the use of hydroquinone in pregnancy probably is low risk, but one review concluded that it was best to minimize exposure because of the amounts absorbed into the systemic circulation (2).

FETAL RISK SUMMARY

Hydroquinone, usually in combination with a sunscreen agent, is used topically to produce reversible depigmentation of the skin (3–5). Hydroquinone also occurs naturally in leaves, bark, and fruit of a number of plants and in some insects, and has several industrial uses (6). It is structurally related to monobenzene. Two commercial preparations (EpiQuin Micro and Claripel) are indicated for the gradual treatment of ultraviolet-induced dyschromia and discoloration resulting from the use of oral contraceptives, pregnancy, hormone replacement therapy, or skin trauma (3,4). A third product (Glyquin XM) is indicated for the gradual bleaching of hyperpigmented skin conditions such as

chloasma, melasma, freckles, senile lentigines, and other unwanted areas of melanin hyperpigmentation (5). Hydroquinone is a strong base (pK_a 9.96) (3).

Animal reproductive tests have not been conducted with topical hydroquinone (3–5). However, oral doses of the drug have been tested in pregnant animals (6–8). In a rat study, gavage doses ≤ 300 mg/kg/day during organogenesis caused no adverse effects on reproductive indices (i.e., pregnancy rate, numbers of corpora lutea, implantation sites, preimplantation and postimplantation losses, early and late resorptions, viable fetuses, fetal sex ratio, and gravid uterine weights) (7). However, the highest dose did cause maternal toxicity (slightly reduced body weight) and an associated small decrease in mean fetal weight. Common vertebral variations also were observed in the fetuses at the highest dose. The no-observable-effect level (NOEL) for both maternal and developmental toxicity was 100 mg/kg/day (7). In a two-generation rat study, no evidence of impaired fertility or embryo–fetal harm was observed at oral doses up to 150 mg/kg/day given before and throughout gestation (6).

In a study with pregnant rabbits, gavage doses of 75 and 150 mg/kg/day during organogenesis were associated with maternal toxicity (reduced food consumption and/or body weight) (8). The NOEL for maternal toxicity was 25 mg/kg/day. At 150 mg/kg/day, in the presence of maternal toxicity, nonsignificant increases in the incidences of fetal ocular and minor skeletal malformations (microphthalmia, vertebral/rib defects, angulated hyoid arch) were observed. The NOEL for developmental toxicity was 75 mg/kg/day (8).

The relationship of the systemic hydroquinone exposures resulting from the oral doses used in these studies to the human systemic exposure resulting from topical application is not known. However, even though the amount absorbed systemically by the animals is unknown, the exposures most likely are significantly higher than those that humans experience from topical use.

It is not known if hydroquinone crosses the human placenta. The molecular weight (about 110) is low enough for passive diffusion. Because it is a strong base, most of the drug that reaches the systemic circulation should be in the ionized state.

In a 1996 study, a combination of glycolic acid and hydroquinone was used, but the outcomes of the pregnancy cases were not specified (9). The treatment of hyperpigmentation disorders, including melasma (also known as the “mask of pregnancy”), typically involves women of reproductive age (9–15). Hydroquinone is the most commonly used agent for melasma (16,17). Other topical agents in addition to glycolic acid, such as antioxidants, tretinoin, and

fluocinolone (a corticosteroid), are sometimes combined with hydroquinone to increase the efficacy of melasma treatment (14,15). The use of topical tretinoin in pregnancy is controversial and best avoided (see Tretinoin [Topical]).

BREASTFEEDING SUMMARY

No reports describing the use of topical hydroquinone during lactation have been located. It is not known if hydroquinone is excreted into breast milk. The molecular weight (about 110) is low enough but, because it is a strong base, most of the compound, if it reaches the systemic circulation, would be in the ionized state and not available for excretion into milk. The potential effects on a nursing infant appear to be negligible.

HYDROXYCHLOROQUINE

Antimalarial/Immunologic Agent (Antirheumatic)

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Hydroxychloroquine does not appear to pose a significant risk to the fetus, especially with lower doses. No reports of retinal or ototoxicity after in utero exposure have been located. The CDC has stated that hydroxychloroquine may be used during pregnancy for antimalarial prophylaxis since, in prophylactic doses, the agent has not been shown to be harmful to the fetus (1,2). The adult antimalarial prophylactic dose is 400 mg/week (3). The use of higher doses for prolonged periods, such as those used for systemic lupus erythematosus (SLE), acute attacks of malaria, and rheumatoid arthritis, probably represents an increased fetal risk, but the magnitude of this increase is unknown. At least one source has recommended that the use of hydroxychloroquine for rheumatoid arthritis or SLE be avoided during pregnancy (4), but recent reports (5–7) do not support this conclusion. Moreover, stopping therapy when a pregnancy became known would not, as discussed below, stop exposure of the embryo–fetus to the drug, but could increase the risk because of a lupus flare. If hydroxychloroquine is used in pregnancy for the treatment of rheumatoid arthritis, health care professionals are encouraged to call the toll-free number (877-311-8972) for information about patient enrollment in the Organization of Teratology Information Specialists (OTIS) Rheumatoid Arthritis study.

FETAL RISK SUMMARY

Hydroxychloroquine is used for the treatment of malaria, SLE, and rheumatoid arthritis. A 1988 review described several references relating to animal studies with the closely related agent, chloroquine (4). In pregnant mice, rats, rabbits,

and monkeys, chloroquine crosses the placenta to the fetus. In fetal mice and monkeys, the drug accumulates for long intervals, ≤ 5 months in mice, in the melanin structures of the eyes and inner ears (3,4). Teratogenicity studies with chloroquine using monkeys have not been published. However, in rats, only high doses were teratogenic, producing skeletal and ocular defects (4). In pregnant mice, chloroquine alone was not teratogenic, but in combination with radiation, a significant increase in cleft palates and tail anomalies was observed. No similar data are available for hydroxychloroquine.

Published data relating to the use of hydroxychloroquine during human pregnancy are scarce but do not indicate that the drug poses a significant risk to the fetus. The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 2 of whom had 1st trimester exposure to hydroxychloroquine (8). Neither child had a congenital malformation. A 1974 reference reported no abnormalities in a fetus after a therapeutic abortion at 14 weeks' gestation (9). The fetus had been exposed to the antimalarial agent, 200 mg twice daily, since the time of conception. Examination of the temporal bones, the embryonal precartilage, the anlagen of the auditory ossicles, and the membranous labyrinth demonstrated a normal 14-week stage of development, indicating an apparent lack of drug-induced ototoxicity in this fetus (9). A short 1983 communication described the use of 200 mg/day of hydroxychloroquine during the first 16 weeks of gestation for the treatment of maternal discoid lupus erythematosus (10). A male infant was eventually delivered who was alive and well at 2 years of age.

The use of hydroxychloroquine during 27 pregnancies in 23 women with mild to moderate SLE was described in a 1995 abstract (5). In 17 of the pregnancies, the drug was used at a dose of 200–400 mg daily throughout gestation. The outcomes of these cases included 2 miscarriages, 2 perinatal deaths, 1 infant with congenital heart block (in a Ro-positive mother), and 12 normal newborns. In six other pregnancies, hydroxychloroquine was started after conception, three during the 1st trimester. In the remaining three cases, therapy was stopped after diagnosis of pregnancy, resulting in a worsening of the disease and higher doses of prednisolone, and pregnancy termination in one because of severe renal lupus. No fetal or newborn adverse effects related to hydroxychloroquine were observed. A follow-up of 20 newborns for ≥ 3 years found that all were healthy. The authors concluded that hydroxychloroquine was safe in pregnancy, and because of the risk of lupus flare, discontinuing therapy during pregnancy represented a greater danger to the fetus (5).

Other investigators have reached similar conclusions as to the safety of

hydroxychloroquine in the treatment of SLE during pregnancy (6,7). These authors described nine pregnancies (plus seven from an earlier paper) in which hydroxychloroquine (200 mg/day) was used throughout gestation without producing congenital malformations. In the present series of nine pregnancies, five newborns were delivered preterm and four at term. Long-term follow-up of the children exposed in utero has been normal. Because of the very long elimination half-life of the drug from maternal tissues (weeks to months), the authors concluded that discontinuing the drug when pregnancy was known would not eliminate fetal exposure but could jeopardize the pregnancy from a lupus flare (6,7).

The use of hydroxychloroquine as an antimalarial, instead of chloroquine, has been recommended because of the belief that hydroxychloroquine is less toxic (4). However, few data are available to substantiate this practice, either in terms of congenital malformations or in optic or otic toxicity. From published reports of fetal exposure to either chloroquine or hydroxychloroquine, one source cited an incidence of 7 infants with congenital anomalies from 188 live births—a rate of 4.5% (4). This value is within the expected 3%–6% incidence of congenital malformations in a nonexposed population.

BREASTFEEDING SUMMARY

Two reports have described the excretion of small amounts of hydroxychloroquine into breast milk. A 27-year-old woman was treated with hydroxychloroquine, 400 mg (310 mg base) each night, for an exacerbation of lupus erythematosus (11). She had been breastfeeding her infant for 9 months. No mention of the infant's condition or of the presence of toxic effects was made by the authors of this report. Milk samples were collected 2.0, 9.5, and 14.0 hours after one dose and 17.7 hours after a second dose. Milk concentrations of hydroxychloroquine base at the 4 times were 1.46, 1.09, 1.09, and 0.85 mcg/mL, respectively. A maternal blood sample was collected 15.5 hours after the first dose. Hydroxychloroquine base concentrations in whole blood and plasma were 1.76 and 0.20 mcg/mL, respectively. The authors estimated that the infant was consuming, based on 1000 mL of milk, a daily dose of 1.1 mg hydroxychloroquine base, or approximately 0.35% of the mother's daily dose (11).

Much lower milk concentrations of drug were obtained from a 28-year-old woman who was being treated with hydroxychloroquine, 200 mg twice daily, for rheumatoid arthritis (12). Treatment had been stopped for 6 months during pregnancy and then restarted 2 months later because of arthritis relapse. A

total of 3.2 mcg of the drug was recovered from her milk over a 48-hour interval, representing 0.0005% of the mother's dose. The highest milk concentration of the agent, 10.6 ng/mL, was found in the 39–48-hour sample. It was not stated whether the infant was allowed to breastfeed.

Because of the slow elimination rate and the potential for accumulation of a toxic amount in the infant, breastfeeding during daily therapy with hydroxychloroquine should be undertaken cautiously (11–13). The administration of once-weekly doses, such as those used for malaria prophylaxis, would markedly reduce the amount of drug available to the nursing infant and, consequently, produce a much lower risk of accumulation and toxicity. Although breastfeeding during maternal malarial prophylaxis is not thought to be harmful, the amount of hydroxychloroquine in milk is insufficient to provide protection against malaria in the infant (10). The American Academy of Pediatrics classifies the drug as compatible with breastfeeding (14).

HYDROXYPROGESTERONE

Progestogenic Hormone

PREGNANCY RECOMMENDATION: Human Data Suggest Risk (0–16 Weeks), Compatible (After 16 Weeks)

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Hydroxyprogesterone (17 α -hydroxyprogesterone [17 α -HP]) is efficacious and safe for the prevention of preterm labor when it is used after 16 weeks' gestation. Use before this carries a small risk of female masculinization and hypospadias and/or ambiguous genitals in males. Development of the phallus occurs between the 7th and 16th week of gestation (1). Use of 17 α -HP after this point cannot cause hypospadias because the urethral groove has fused. Because several issues still exist, including long-term safety and the ideal progesterone formulation (e.g., progesterone vs. 17 α -HP; and dosage), the American College of Obstetricians and Gynecologists (ACOG) recommended in 2008 that the use of progesterone supplementation should be restricted to women with a singleton pregnancy and a prior spontaneous preterm birth due to spontaneous preterm labor or premature rupture of membranes (2).

FETAL RISK SUMMARY

17 α -HP is not available commercially in the United States but is prepared by some compounding pharmacies. It is a naturally occurring metabolite of progesterone (3).

The Collaborative Perinatal Project monitored 866 mother–child pairs with 1st trimester exposure to progestational agents (including 162 with exposure to 17 α -HP) (4, pp. 389, 391). An increase in the expected frequency of cardiovascular defects and hypospadias was observed for both estrogens and progestogens (4, p. 394; 5). Reevaluation of these data in terms of timing of exposure, vaginal bleeding in early pregnancy, and previous maternal obstetric history, however, failed to support an association between female sex

hormones and cardiac malformations (6).

Dillon reported six infants with malformations exposed to 17α -HP during various stages of gestation (7,8). The congenital defects included spina bifida, anencephalus, hydrocephalus, tetralogy of Fallot, common truncus arteriosus, cataract, and ventricular septal defect. Complete absence of both thumbs and dislocated head of the right radius in a child has been associated with 17α -HP (8). However, the use of diazepam in early pregnancy and the lack of similar reports make an association doubtful.

In 2000, Schardein (9) reviewed the risk of progestogens for female masculinization and male feminization after 1st trimester use. He cited seven cases of female masculinization with 17α -HP. Although admitting that the relationship between progestogens and male feminization was still tenuous, among 78 cases there were 7 cases of hypospadias and/or ambiguous genitals associated with 17α -HP and 2 cases of hypospadias with progesterone (9).

A 1985 study described 2754 offspring born to mothers who had vaginal bleeding during the 1st trimester (10). Of the total group, 1608 of the newborns were delivered from mothers treated during the 1st trimester with either oral medroxyprogesterone (20–30 mg/day), 17-hydroxyprogesterone (500 mg/week by injection), or a combination of the two. Medroxyprogesterone was used exclusively in 1274 (79.2%) of the study group. The control group consisted of 1146 infants delivered from mothers who bled during the 1st trimester but who were not treated. There were no differences between the study and control groups in the overall rate of malformations (120 vs. 123.9/1000, respectively) or in the rate of major malformations (63.4 vs. 71.5/1000, respectively) (10). Another 1985 study compared 988 infants exposed in utero to various progesterones with a matched cohort of 1976 unexposed controls (11). No association between the use of progestins, primarily progesterone and 17α -HP, and fetal malformations was discovered.

Developmental changes in the psychosexual performance of boys have been attributed to in utero exposure to 17α -HP (12). The mothers received an estrogen–progestogen regimen for their diabetes. Hormone-exposed males demonstrated a trend to have less heterosexual experience and fewer masculine interests than controls (12).

A number of studies have reported the use of 17α -HP during pregnancy or its benefits to prevent premature labor (13–30). The hormone is not effective in twin pregnancies (3,22). A 2005 meta-analysis of randomized controlled trials of progestational agents, most of which (80%) involved 17α -HP, concluded that these agents reduced the incidence of preterm birth and low-birth-weight

newborns (31). In another 2005 review, the clinical use of 17 α -HP for the prevention of preterm delivery and its safety was summarized (3). No increase in the incidence of fetal adverse effects has been observed. The evidence supports the use of 17 α -HP (250 mg IM every week) beginning as soon as possible after 16 weeks' gestation and continuing to 36 weeks' (3).

17 α -HP also has been used in early gestation to prevent spontaneous abortion, but the results have been mixed (32,33).

BREASTFEEDING SUMMARY

No reports describing the use of 17 α -HP during human lactation have been located. Because of its use for the prevention of preterm birth, it is doubtful if such reports will ever be available. However, progesterone is classified as compatible with breastfeeding (34).

HYDROXYUREA

Antineoplastic

PREGNANCY RECOMMENDATION: Limited Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although hydroxyurea is teratogenic in animals, almost all reported human pregnancy exposures have resulted in normal outcomes. In some of cases, however, hydroxyurea was discontinued very early in gestation or started after organogenesis. The available data prevent a better assessment of the embryo–fetal risk. In addition, although many children exposed in utero have had normal growth and development during their first few years, longer evaluation periods are warranted because the drug might be a human carcinogen. Nevertheless, if the drug is indicated, it should not be withheld because of pregnancy, but avoiding organogenesis would be best.

FETAL RISK SUMMARY

Hydroxyurea is an antineoplastic agent that causes cytotoxic and cytoreductive effects. It is indicated to reduce the frequency of painful crises and to reduce the need for blood transfusions in adult patients with sickle cell anemia with recurrent moderate to severe painful crises. It undergoes partial metabolism. Hydroxyurea is presumed to be a human carcinogen (1). The drug is also used for other indications as discussed below.

Hydroxyurea is teratogenic in several animal species including mice, hamsters, cats, miniature swine, dogs, and monkeys at doses within onefold of the human dose based on BSA (1). Shepard (2) reviewed nine studies describing the effects of this agent on the embryos and fetuses of various animal species. Anomalies observed included defects of the CNS, palate, and skeleton, depressed DNA synthesis, extensive cell death in limb buds and CNS, impaired postnatal learning, and decreased body and brain growth (rats); beak defects (chick embryos); and neural tube and cardiac defects (hamsters) (2). A

1999 report, evaluating the combined prenatal toxicity of hydroxyurea and 6-mercaptopurine riboside in mice, determined that the NOAEL (no-observed-adverse-effect level) of a single, intraperitoneal dose of hydroxyurea administered on day 11 of gestation was 250 mg/kg (3). An increase in gross structural abnormalities was observed at the 300- and 350-mg/kg dose levels.

A number of reports have described the use of hydroxyurea in human pregnancy (4–27). Two women, both with acute myelocytic leukemia, were treated with five-drug chemotherapy regimens at 17 and 27 weeks' gestation, respectively (4). In both cases, hydroxyurea (8 mg) was given as an initial, single IV dose. One woman underwent an elective abortion (EAB) of a grossly normal fetus 4 weeks after the start of chemotherapy. The second patient delivered a premature infant at 31 weeks with no evidence of birth defects, again 4 weeks after the start of therapy. Follow-up at 13.5 months revealed normal growth and development (4).

A 1991 report described the use of hydroxyurea, 0.5–1.0 g/day, throughout gestation in a woman with chronic myelocytic leukemia (CML) (5). A spontaneous vaginal delivery at 36 weeks' gestation resulted in the birth of a normal, healthy 2670-g male infant with normal blood counts. The infant's growth and development have been normal through 26 months of age (5). A subsequent brief report described a similar patient treated with 1–3 g/day orally before and throughout gestation (6). Hydroxyurea therapy was stopped (to prevent a potential cytopenia in the fetus) 1 week before a planned cesarean section at 38 weeks' gestation. A healthy 3100-g male infant was delivered, without evidence of hematologic abnormalities, whose growth and development remain normal at 32 months of age (6). A 1992 report listed a pregnant woman with CML who was treated in the 1st trimester with hydroxyurea and three other agents (7). She elected to terminate her pregnancy.

Several other studies have reported on the use of hydroxyurea for CML during pregnancy (8–14). A 1992 publication described two women who were treated before and throughout gestation with oral doses of 1.5 g/day (8). Eclampsia developed at 26 weeks' gestation in one woman resulting in the delivery of a stillborn male fetus without gross abnormalities who had a normal phenotype. The second patient had a vaginal delivery at 40 weeks of a healthy 3.2-kg male infant with normal phenotype. No follow-up evaluation of the infant was mentioned (8). The clinical course of a pregnant woman with CML was discussed in a 1993 report (9). She required 1.5–3 g/day during pregnancy for her disease. At 37 weeks' gestation, she delivered a healthy baby girl who had

normal blood counts and no evidence of congenital defects (9). A second 1993 report described a woman with CML treated unsuccessfully with interferon alfa before pregnancy and then with hydroxyurea (10). At the patient's request, all therapies were stopped before conception. Hydroxyurea therapy (dose not specified) was reinstated during the 2nd trimester and continued until 1 month before the delivery of a normal, term, 3.4-kg male infant. The infant was developing normally at approximately 11 months of age (10). In another case, a woman received hydroxyurea, 1.5–2.5 g/day, throughout gestation and delivered a term, 3.44-kg female infant who was normal at age 6 weeks (11). In a 2011 case report, the therapy of a 24-year-old patient with CML was changed at 10 weeks' from imatinib to hydroxyurea. She was maintained on the agent (2.0–2.5 g/day) for the remainder of her pregnancy (12). A healthy 2.5-kg female baby was born at 37 weeks. At 1-year follow-up, her growth and development were normal. In a 2006 report, a woman was treated for chronic-phase CML with imatinib before and during the first 6 weeks of gestation until her pregnancy was diagnosed (13). Therapy was stopped until the completion of the 1st trimester, at which time hydroxyurea was started. At 30 weeks', a fetal ultrasound revealed a meningocele and 4 weeks later the woman delivered a dead fetus. The defect was thought to have been caused by imatinib (13). A brief 2009 case report described the outcome of a 34-year-old woman with CML who was treated with imatinib (400 mg/day) during the first 4 months of an unplanned pregnancy (14). When pregnancy was diagnosed, imatinib was stopped and hydroxyurea was started. At 37 weeks', she delivered a healthy 3.12-kg infant with Apgar scores of 9 and 10. The child was doing well at 26 months of age (14).

A 1994 report described a woman with primary thrombocythemia who had lost two previous pregnancies from stillbirths (15). She was treated with hydroxyurea (1–2 g/day) before and during the first 6 weeks of her third pregnancy. She delivered a healthy male infant at 35 weeks' gestation. Two other publications have also reported the use of hydroxyurea in pregnant women with essential thrombocythemia (16,17). In one case, the dose and exposure time were not specified but the pregnancy was electively terminated due to maternal complications (15). In the other case, 0.5–1.0 g/day was used from 18 to 28 weeks' gestation and a healthy male infant was delivered at 37 weeks' gestation (17).

In another 1994 case report, a 28-year-old woman, known to have familial myeloproliferative syndrome, was treated successfully for essential thrombocythemia (ET) with hydroxyurea and aspirin with disappearance of her

neurologic symptoms (18). After about 9–10 months of treatment, she was found to be pregnant and all therapy was stopped. About 2–3 months later, her symptoms reappeared and she was treated with interferon alpha and aspirin the remainder of pregnancy. At term, she gave birth to a growth-restricted baby with multiple malformations (ambiguous genitalia, hemivertebrae D6 to D10 with 11 pairs of ribs, and secondary scoliosis) (no other details on the baby were provided) (18).

A 1995 study described the outcomes of 34 pregnancies in 18 women with ET (19). Only one of the pregnancies was treated with hydroxyurea and that pregnancy was terminated by an EAB. In a 2001 study, 43 pregnancies occurred in 20 patients with ET but only were treated with hydroxyurea (20). The pregnancy outcome was “successful” (no further details given). A 2011 report described the pregnancy outcome of a 42-year-old woman with ET who had been treated with hydroxyurea and aspirin during the first 5 months of gestation (21). At term, she delivered a normal 2.7-kg male infant with Apgar scores of 8 and 9.

Four reports have described the use of hydroxyurea for the management of sickle cell disease in pregnant women (22–25). In a study published in 1995, three women conceived while receiving the drug (22). All stopped the therapy when pregnancy was diagnosed. One delivered a normal, full-term infant, and two had EABs. A 1999 report described one woman with sickle cell disease who had received hydroxyurea (1 g/day) and folic acid (5 mg/day) for 3 years before pregnancy (23). She discontinued hydroxyurea when pregnancy was confirmed at 9 weeks’ gestation and delivered a normal male 3.24-kg baby at 39 weeks’ with Apgar scores of 8 and 10 at 1 and 5 minutes, respectively. The infant was developing normally at 15 months. Another 1999 publication reported two pregnancies that were exposed to hydroxyurea very early in gestation (24). Both women were being treated for sickle cell disease with the drug (1 and 0.5 g/day), in addition to folic acid and other drugs, and both discontinued hydroxyurea when pregnancy was confirmed at approximately 5 and 4 weeks, respectively. One woman delivered a 2750-g male infant at 37 weeks’ gestation with Apgar scores of 8 and 9 at 1 and 5 minutes, respectively. The infant was developing normally at age 17 months. The second woman delivered a premature, 1365-g, male baby at 32.5 weeks’ gestation with Apgar scores of 8 and 9 at 1 and 5 minutes, respectively. Because of his prematurity, the infant required treatment for respiratory distress syndrome, hyperbilirubinemia, patent ductus arteriosus, and sepsis during the first 6 weeks, but was developing normally at age 21 months (24).

In a 2009 report from the Multicenter Study of Hydroxyurea in Sickle Cell Anemia, attempts were made to prevent pregnancies during the randomized double-blind placebo-controlled trial (25). Among the 299 study participants, 153 were females and, of these, 77 (50.3%) were in the hydroxyurea group. During the trial, there were six pregnancies in female participants taking the drug. When pregnancy was diagnosed, all were taken off of the drug. The outcomes of the six pregnancies were two live births, three EABs, and one spontaneous abortion (25).

A 2010 case report described the pregnancy outcome of a 25-year-old patient with sickle- β thalassemia who had been treated with hydroxyurea during the first 9 weeks of gestation (26). At that time, hydroxyurea was stopped and other therapy initiated. Although the remainder of her pregnancy was complicated, she eventually gave birth at 38 weeks' to a healthy 2.68-kg female infant who was growing normally at 1 year of age (26).

The outcomes of pregnancies exposed to chemotherapy for gestational trophoblastic disease before conception were evaluated in two reports (27,28). In 436 long-term survivors treated with chemotherapy between 1958 and 1978, 69 (16%) received hydroxyurea as part of their treatment regimens (27). Of the 69 women, 14 (20%) had at least one live birth (numbers in parentheses refer to mean/maximum hydroxyurea dose in grams) (3.6/8.0), 3 (4%) had no live births (6.3/16.0), 3 (4%) failed to conceive (3.0/6.0), and 49 (71%) did not try to conceive (9.4/47.0). Additional details, including congenital anomalies observed, are described in the monograph for methotrexate (see Methotrexate) (27). In the other report, 336 women, who had tried to conceive, had previously received various combinations of chemotherapeutic agents, some of which included hydroxyurea (28). In comparison with a group receiving single-agent therapy (N = 392; methotrexate), no differences in pregnancy outcome were observed in the number of live births, unsuccessful pregnancies, and an inability to become pregnant. Only 18 major or minor congenital abnormalities (affecting 1.7% of the births) were reported. However, the stillbirth rate in all women treated for gestational trophoblastic disease was significantly higher than that of the general population (odds ratio 2.87; 95% confidence interval 2.44–3.03; $p < 0.001$) (28).

A woman treated for acute lymphoid leukemia with a combination of nine antineoplastic agents, one of which was hydroxyurea, conceived two pregnancies, 2 and 4 years after chemotherapy was stopped (29). Apparently normal term infants, a 3850-g male and a 3550-g female, resulted and both were doing well at 7 and 4.5 years, respectively.

Hydroxyurea was used to treat polycythemia vera for 18 months before a 34-year-old woman became pregnant (30). Her pregnancy was diagnosed at 9 weeks' and hydroxyurea was stopped. Her erythrocytosis was controlled with phlebotomy. At 37 weeks' she gave birth to normal 2550-g male infant. The infant's development up to 12 months of age was normal (30).

Occupational exposure of the mother to antineoplastic agents during pregnancy may present a risk to the fetus. A position statement from the National Study Commission on Cytotoxic Exposure and a research article involving some antineoplastic agents are presented in the monograph for cyclophosphamide (see Cyclophosphamide).

BREASTFEEDING SUMMARY

Hydroxyurea is excreted into human milk. A 29-year-old breastfeeding woman with recently diagnosed chronic myelogenous leukemia was treated with hydroxyurea, 500 mg orally 3 times daily (31). Breastfeeding was halted before initiation of the chemotherapy. Milk samples were collected 2 hours after the last dose for 7 days. Because of technical difficulties with the analysis, milk concentrations of hydroxyurea could be determined only on days 1, 3, and 4. The mean level of hydroxyurea was 6.1 mg/L (range 3.8–8.4 mg/L). Based on a milk intake of 600 mL/day, the authors estimated that a nursing infant would have received 3–4 mg/day of the drug. Serum concentrations were not measured (31).

Because the mother's weight was not provided, a comparison to the maternal weight-adjusted dose could not be calculated. Although the concentrations are low, the potential for adverse effects in the infant suggests that nursing should be considered contraindicated during hydroxyurea therapy.

HYDROXYZINE

Antihistamine

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

In animal studies, high doses of hydroxyzine were associated with developmental toxicity (structural anomalies and death), but the human data suggest low risk. Although a surveillance study found an increased risk of oral clefts, this defect has not been observed in other studies. Withdrawal or seizures have been reported in two newborns exposed near term.

FETAL RISK SUMMARY

Hydroxyzine belongs to the same class of compounds as buclizine, cyclizine, and meclizine. The drug is teratogenic in mice and rats, but not in rabbits, at high doses (1–5). One report suggested that hydroxyzine teratogenicity was mediated by a metabolite (norchlorcyclizine) that was common to four antihistamines (hydroxyzine, buclizine, meclizine, and chlorcyclizine) (3). High-dose hydroxyzine (6–12 mg/kg/day) resulted in abortions in rhesus monkeys (6). The manufacturer considers hydroxyzine to be contraindicated in early pregnancy because of the lack of clinical data (1,2).

It is not known if hydroxyzine crosses the human placenta. The molecular weight of the free base (about 376) suggests that the drug will cross to the embryo and fetus.

In 100 patients treated in the 1st trimester with oral hydroxyzine (50 mg daily) for nausea and vomiting, no significant difference from nontreated controls was found in fetal wastage or anomalies (7). A woman treated with 60 mg/day of hydroxyzine during the 3rd trimester gave birth to a normal infant (8).

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 50 of whom had 1st trimester exposure to hydroxyzine (9, pp. 335–337, 341). For use anytime during pregnancy, 187 exposures were recorded (9, p. 438). Based on five malformed children, a possible relationship was found between

1st trimester use and congenital defects.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 828 newborns had been exposed to hydroxyzine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 48 (5.8%) major birth defects were observed (42 expected). Specific data were available for six defect categories, including (observed/expected) 9/8 cardiovascular defects, 1/0.4 spina bifida, 0/2 polydactyly, 2/1 limb reduction defects, 0/2 hypospadias, and 3/1 oral clefts. Only with the latter defect is there a suggestion of a possible association, but other factors, including the mother's disease, concurrent drug use, and chance, may be involved.

Withdrawal in a newborn exposed to hydroxyzine 600 mg/day throughout gestation has been reported (10). The mother, who was being treated for severe eczema and asthma, was also treated with phenobarbital, 240 mg/day for 4 days and then 60 mg/day, for mild preeclampsia during the 3-week period before delivery. Symptoms in the newborn, some beginning 15 minutes after birth, consisted of a shrill cry, jitteriness with clonic movements of the upper extremities, irritability, and poor feeding. The presumed drug-induced withdrawal persisted for approximately 4 weeks and finally resolved completely after 2 weeks of therapy with phenobarbital and methscopolamine. The infant was apparently doing well at 9 months of age. Although phenobarbital withdrawal could not be excluded, and neonatal withdrawal is a well-known complication of phenobarbital pregnancy use, the author concluded the symptoms in the infant were primarily caused by hydroxyzine (10).

A 1996 report described the use of hydroxyzine, droperidol, diphenhydramine, and metoclopramide in 80 women with hyperemesis gravidarum (11). The mean gestational age at the start of treatment was 10.9 weeks. All women received approximately 200 mg/day of hydroxyzine in divided dosage for up to a week after discharge from the hospital, and 12 (15%) required a second course of therapy for recurrence of their symptoms. Three of the mothers (all treated in the 2nd trimester) delivered offspring with congenital defects: Poland's syndrome, fetal alcohol syndrome, and hydrocephalus and hypoplasia of the right cerebral hemisphere. Only the latter anomaly is a potential drug effect, but the most likely cause was thought to be the result of an in utero fetal vascular accident or infection (11).

A 2001 study, using a treatment method similar to the above study, described the use of droperidol and diphenhydramine in 28 women hospitalized for hyperemesis gravidarum (12). Pregnancy outcomes in the study group were

compared with a historical control of 54 women who had received conventional antiemetic therapy. Oral metoclopramide and hydroxyzine were used after discharge from the hospital. Therapy was started in the study and control groups at mean gestational ages of 9.9 and 11.1 weeks, respectively. The study group appeared to have more severe disease than controls as suggested by a greater mean loss from the prepregnancy weight, 2.07 kg vs. 0.81 kg (ns), and a slightly lower serum potassium level, 3.4 vs. 3.5 mmol/L (ns). Compared with controls, the droperidol group had a shorter duration of hospitalization (3.53 vs. 2.82 days, $p = 0.023$), fewer readmissions (38.9% vs. 14.3%, $p = 0.025$), and lower average daily nausea and vomiting scores (both $p < 0.001$). There were no statistical differences in outcomes (study vs. controls) in terms of spontaneous abortions ($N = 0$ vs. $N = 2$ [3.7%]), elective abortions ($N = 3$ [10.7%] vs. $N = 3$ [5.6%]), Apgar scores at 1, 5, and 10 minutes, age at birth (37.3 vs. 37.9 weeks), and birth weight (3114 vs. 3347 g) (12). In controls, there was one major malformation of unknown cause, an acardiac fetus in a set of triplets, and one newborn with a genetic defect (Turner syndrome). There was also one unexplained major birth defect in the droperidol group (bilateral hydronephrosis), and there were two genetic defects (translocation of chromosomes 3 and 7; tyrosinemia) (12).

A prospective controlled study published in 1997 evaluated the teratogenic risk of hydroxyzine and cetirizine (see also Cetirizine) in human pregnancy (13). A total of 120 pregnancies (two sets of twins) exposed to either hydroxyzine ($N = 81$) or cetirizine ($N = 39$) during pregnancy were identified and compared with 110 controls. The control group was matched for maternal age, smoking, and alcohol use. The drugs were taken during the 1st trimester in 53 (65%) of the hydroxyzine cases and in 37 (95%) of the cetirizine exposures for various indications (e.g., rhinitis, urticaria, pruritic urticarial papules and plaques of pregnancy, sedation, and other nonspecified reasons). Fourteen spontaneous abortions (hydroxyzine 3, cetirizine 6, controls 5) and 11 induced abortions (hydroxyzine 6, controls 5) occurred in the three groups. Among the live births, there were no statistical differences between the groups in birth weight, gestational age at delivery, rate of cesarean section, or neonatal distress. In the hydroxyzine group, two of the live births had major malformations: one with a ventricular septal defect and one with a complex congenital heart defect (also exposed to carbamazepine). A third infant, exposed after organogenesis, also had a ventricular septal defect. Minor abnormalities were observed in four hydroxyzine-exposed infants: one case each of hydrocele, inguinal hernia, hypothyroidism (mother also taking propylthiouracil), and strabismus. Two

minor anomalies were observed in liveborn infants exposed to cetirizine during organogenesis: one with an ectopic kidney and one with undescended testes. No major abnormalities were seen in this group. In the control group, no major malformations were observed, but five infants had minor defects (dislocated hip, growth hormone deficiency, short lingual frenulum, and two unspecified defects). Statistically, there were no differences between the groups in outcome (13).

A 1997 article compared the published pregnancy outcomes, in terms of congenital malformations, of various first and second generation antihistamines (14). Based on 995 hydroxyzine-exposed liveborn infants, the relative risk for any congenital malformation ranged from 1.2 (95% confidence interval [CI] 0.4–0.9) to 3.4 (95% CI 1.6–17.9). Based on analysis of published reports, the authors concluded that in pregnancy, chlorpheniramine is the oral antihistamine of choice and that diphenhydramine should be used if a parenteral antihistamine is required (14).

A 2005 case report described seizures in a newborn exposed to hydroxyzine in late pregnancy (15). The 36-year-old mother began taking hydroxyzine 150 mg/day for anxiety at 35 weeks' gestation. Four weeks later, a scheduled cesarean section delivered a 4.120-kg male infant with Apgar scores of 9 and 10 at 1 and 5 minutes, respectively. Four hours after birth, the infant developed clonic movements of the upper extremities that spread to the entire body followed by a tonic-clonic seizure lasting 4 minutes. No further seizures were observed and an extensive workup revealed no cause for the seizures. A hydroxyzine plasma concentration in the mother, 6 hours after birth, was 7.3 ng/mL (therapeutic concentrations 50–90 ng/mL), whereas in the infant, levels at 6 and 24 hours of age were 7.4 and 2.3 ng/mL, respectively. At 6 months of age, the infant was well with normal neurodevelopmental testing (15).

During labor, hydroxyzine has been shown to be safe and effective for the relief of anxiety (16,17). No effect on the progress of labor or on neonatal Apgar scores was observed. In a study published in 1978, however, a 75-mg IM dose administered during labor caused a statistically significant decrease in fetal heart rate (FHR) variability in 10 of 16 cases (18). Maximal effects on the FHR were observed within 25 minutes after which they returned to normal values. Administration of hydroxyzine close to delivery reduces newborn platelet aggregation, but the clinical significance of this is unknown (19).

BREASTFEEDING SUMMARY

No reports describing the use of hydroxyzine during lactation have been

located. The molecular weight (about 448) is low enough that excretion into breast milk should be expected. The effects, if any, on the nursing infant are unknown.

I-HYOSCYAMINE

Parasympatholytic (Anticholinergic)

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

I-Hyoscyamine is an anticholinergic agent. No published reports of its use in pregnancy have been located (see also Belladonna or Atropine).

FETAL RISK SUMMARY

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 281 newborns had been exposed to I-hyoscyamine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 12 (4.3%) major birth defects were observed (11 expected). Specific data were available for six defect categories, including (observed/expected) 1/3 cardiovascular defects, 0/0.5 oral clefts, 0/0 spina bifida, 0/1 hypospadias, 2/1 polydactyly, and 2/0.5 limb reduction defects. Only with the latter two defects is there a suggestion of a possible association, but other factors, including the mother's disease, concurrent drug use, and chance, may be involved.

BREASTFEEDING SUMMARY

No reports describing the use of I-hyoscyamine during human lactation have been located (see also Atropine).

HYPERALIMENTATION, PARENTERAL

Nutrient

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The use of total parenteral hyperalimentation (TPN) does not pose a significant risk to the fetus or newborn provided that normal procedures, as with nonpregnant patients, are followed to prevent maternal complications.

FETAL RISK SUMMARY

TPN is the administration of an IV solution designed to provide complete nutritional support for a patient unable to maintain adequate nutritional intake. The solution is normally composed of dextrose (5%–35%), amino acids (3.5%–5%), vitamins, electrolytes, and trace elements. Lipids (IV fat emulsions) are often given with TPN to supply essential fatty acids and calories (see Lipids). A number of studies describing the use of TPN in pregnant women have been published (1–26). A report of four additional cases with a review of the literature appeared in 1986 (27), followed by another review in 1990 (28). This latter review also included an in-depth discussion of indications, fluid, caloric (including lipids), electrolyte, and vitamin requirements for gestation and lactation, and monitoring techniques (28).

Maternal indications for TPN have been varied, with duration of therapy ranging from a few days to the entire pregnancy. Eleven patients were treated during the 1st trimester (1–5). No fetal complications attributable to TPN, including newborn hypoglycemia, have been identified in any of the reports. Intrauterine growth restriction occurred in five infants, and one of them died, but the restricted growth and neonatal death were most likely caused by the underlying maternal disease (2–4,6–9,22). In a group of eight women treated with TPN for severe hyperemesis gravidarum who delivered live babies, the ratio of birth weight to standard mean weight for gestational age was >1.0 in each case (5).

Obstetric complications included the worsening of one mother's renal hypertension after TPN was initiated, but the relationship between the effect and the therapy is not known (8). In a second case, resistance to oxytocin-induced labor was observed, but again, the relationship to TPN is not clear (9).

Maternal and fetal death secondary to cardiac tamponade during central hyperalimentation has been reported (29). A 22-year-old woman in the 3rd trimester of pregnancy was treated with TPN for severe hyperemesis gravidarum. Seven days after commencing central TPN therapy, the patient experienced acute sharp retrosternal pain and dyspnea (29). Cardiac tamponade was subsequently diagnosed, but the mother and the fetus expired before the condition could be corrected. Percutaneous pericardiocentesis yielded 70 mL of fluid that was a mixture of the TPN and lipid solutions that the patient had been receiving.

A stillborn male fetus was delivered at 22 weeks' gestation from a 31-year-old woman with hyperemesis gravidarum following 8 weeks of parenteral hyperalimentation with lipid emulsion (fat composed 24% of total calories) (30). The tan-yellow placenta showed vacuolated syncytial cells and Hofbauer cells that stained for fat (30).

BREASTFEEDING SUMMARY

No problems should be expected in nursing infants whose mothers are receiving TPN.

IBANDRONATE

Bisphosphonate

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of ibandronate in human pregnancy have been located. In one animal species, the drug caused growth restriction at doses ≤ 10 times the human dose, but maternal deaths at these doses also were observed. The lack of human pregnancy experience with ibandronate and the very limited human data for the bisphosphonate class prevent further assessment of the risk. The amount of drug retained in bone and eventually released back into the systemic circulation is directly related to the dose and duration of treatment. Because ibandronate probably crosses the placenta, treatment of the mother before conception could result in continuous exposure of the embryo and fetus to an unknown amount of drug. Moreover, animal data suggest that fetal bone has a greater uptake of bisphosphonates than maternal bone. Therefore, the use of ibandronate is not recommended in women who may become pregnant or during pregnancy. There is a theoretical risk of fetal harm (e.g., skeletal and other abnormalities) (1), but the magnitude of this risk cannot be estimated. Infants exposed in utero to ibandronate should be monitored for hypocalcemia during the first few days after birth.

FETAL RISK SUMMARY

Ibandronate is a bisphosphonate in the same class as alendronate, etidronate, pamidronate, risedronate, tiludronate, and zoledronic acid. It is available as IV

and oral formulations. Ibandronate is indicated for the treatment and prevention of osteoporosis in postmenopausal women. The drug is apparently not metabolized in humans. After IV or oral administration, ibandronate elimination is multiphasic, with plasma concentrations declining to 10% of the peak concentrations within 3 or 8 hours, respectively. The initial decrease in the plasma concentration results from renal clearance and distribution into bone. The apparent terminal half-life after a 150-mg oral dose is 37–157 hours (1).

Reproduction studies have been conducted in rats and rabbits. During organogenesis, giving pregnant rats an IV dose that was ≥ 47 times the human exposure at the recommended IV dose of 3 mg every 3 months based on AUC (HERD-IV) resulted in an increased incidence of renal pelvis ureter syndrome. Oral doses ≥ 30 times the human exposure at the recommended daily dose of 2.5 mg (HERD-DD) or ≥ 9 times the human exposure at the recommended once-monthly dose of 150 mg (HERD-MD), both based on AUC, also resulted in an increased incidence of renal pelvis ureter.

In other studies, an IV dose during gestation that was ≥ 5 times the HERD-IV was associated with decreased fetal weight and pup growth. Impaired pup neuromuscular development was noted when female rats were given, from 14 days before mating through lactation, oral doses that were 45 times the HERD-DD or 13 times the HERD-MD. However, maternal deaths were observed with doses that were ≥ 2 times the HERD-IV, ≥ 3 times the HERD-DD, or ≥ 1 times the HERD-MD (1).

In rabbits, an IV dose during organogenesis that was 19 times the recommended IV dose of 3 mg every 3 months based on BSA was associated with maternal deaths, reduced maternal body weight gain, increased resorption rates, and decreased fetal weights. Oral doses during gestation that were ≥ 8 times the recommended daily dose of 2.5 mg or ≥ 4 times the recommended once-monthly dose of 150 mg, both based on BSA, caused maternal death (1).

Ibandronate was not carcinogenic in long-term (104-week) studies in male and female rats, or in male and female mice studied up to 78 weeks. In a 90-week study, however, dose-related increases in adrenal subcapsular adenoma/carcinoma were observed in female mice. The drug was not mutagenic or clastogenic in a number of assays. Fertility was impaired in both male and female rats given high IV doses, ≥ 40 and 117 times the HERD-IV, respectively, for 2–4 weeks before mating. Fertility also was impaired in female rats given oral doses that were 45 times the HERD-DD or 13 times the HERD-MD (1).

It is not known if ibandronate crosses the human placenta. The molecular

weight (about 318 for the free acid), prolonged elimination half-life, and lack of metabolism suggest that the active drug will cross to the embryo and fetus.

A 2008 review described 51 cases of exposure to bisphosphonates before or during pregnancy: alendronate (N = 32) pamidronate (N = 11), etidronate (N = 5), risedronate (N = 2), and zoledronic acid (N = 1) (2). The authors concluded that although these drugs may affect bone modeling and development in the fetus, no such toxicity has yet been reported.

BREASTFEEDING SUMMARY

No reports describing the use of ibandronate during lactation have been located. The molecular weight (about 318 for the free acid), prolonged elimination half-life (up to 157 hours), and lack of metabolism suggest that active drug will be excreted into breast milk. Although the oral bioavailability in infants differs from that of adults, the very low adult oral bioavailability (<1% if fasting, much less with food) and the binding of ibandronate by the calcium in milk suggest that the amount absorbed by the infant will be clinically insignificant. Thus, breastfeeding is probably compatible with ibandronate treatment.

IBRITUMOMAB TIUXETAN

Antineoplastic

PREGNANCY RECOMMENDATION: No Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of ibritumomab tiuxetan in human pregnancy have been located. Rituximab has limited human pregnancy experience and immunosuppression has been the only documented developmental toxicity. However, the ibritumomab tiuxetan therapeutic regimen includes radioactive components. Because of this, ibritumomab tiuxetan should not be used in pregnancy. If inadvertent pregnancy does occur, the woman should be informed of the potential for embryo–fetal harm.

FETAL RISK SUMMARY

Ibritumomab tiuxetan is an immunoconjugate consisting of ibritumomab and the linker-chelator tiuxetan. Ibritumomab, a murine immunoglobulin G₁ (IgG₁) κ monoclonal antibody, is directed against the CD20 antigen found on the surface of normal and malignant B lymphocytes. Tiuxetan provides a high-affinity chelation site for indium-111 and yttrium-90. The therapeutic regimen includes indium-111 ibritumomab tiuxetan and yttrium-90 ibritumomab tiuxetan, prepared immediately before administration, and preceding rituximab (see also Rituximab). Ibritumomab tiuxetan, as part of the therapeutic regimen, is indicated for the treatment of patients with relapsed or refractory low-grade, follicular, or transformed B-cell non-Hodgkin's lymphoma, including patients with rituximab refractory follicular non-Hodgkin's lymphoma. In patients receiving the therapeutic regimen, the mean effective half-life for yttrium-90 activity in blood was 39 hours (1).

The ibritumomab tiuxetan therapeutic regimen may cause severe, infusion-related toxicity, including hypotension and other adverse effects. Premedication with acetaminophen and an antihistamine (e.g., diphenhydramine) is recommended before each infusion of rituximab (1). Hypotension in a pregnant

woman could have deleterious effects on placental perfusion resulting in embryo and fetal harm.

Animal reproduction studies have not been conducted with ibritumomab tiuxetan. Neither have studies been conducted for carcinogenicity, mutagenicity, or effects on fertility. However, radiation is a potential carcinogen and mutagen. Moreover, the ibritumomab tiuxetan therapeutic regimen results in a significant radiation dose to the testes. The radiation dose to the ovaries has not been determined. Although it has not been studied, the therapeutic regimen does have the potential to cause toxic effects on the male and female gonads (1).

It is not known if ibritumomab tiuxetan or the components of the therapeutic regimen cross the human placenta. The high molecular weight (about 148,000) of ibritumomab tiuxetan suggests that it will not cross. However, human IG does cross and, therefore, ibritumomab tiuxetan, with the tightly bound radioactive components, may also cross. Rituximab, a component of the therapeutic regimen, does cross the placenta, at least at term (see Rituximab).

BREASTFEEDING SUMMARY

No reports describing the use of ibritumomab tiuxetan or its therapeutic regimen during human lactation have been located. The high molecular weight (about 148,000) of ibritumomab tiuxetan suggests that it will not be excreted into breast milk. It also is not known if rituximab, a component of the therapeutic regimen, is excreted into milk (see Rituximab). However, human IG is excreted into milk and, therefore, both rituximab and ibritumomab tiuxetan, with the tightly bound radioactive components, may also be excreted. The effects of this potential exposure on a nursing infant are unknown, but immunosuppression and other severe adverse effects, including those from radiation, are potential complications.

IBUPROFEN

Nonsteroidal Anti-inflammatory

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 1st and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Constriction of the ductus arteriosus in utero is a pharmacologic consequence arising from the use of prostaglandin synthesis inhibitors during pregnancy (see also Indomethacin) (1). Persistent pulmonary hypertension of the newborn may occur if these agents are used in the 3rd trimester close to delivery (1–3). These drugs also have been shown to inhibit labor and prolong pregnancy, both in humans (4) and in animals (5). Women attempting to conceive should not use any prostaglandin synthesis inhibitor, including ibuprofen, because of the findings in a variety of animal models that indicate these agents block blastocyst implantation (6,7). Moreover, as noted below, nonsteroidal anti-inflammatory drugs (NSAIDs) also have been associated with spontaneous abortion (SAB) and with cardiac defects, oral clefts, and gastroschisis. The risk for these defects, however, appears to be small.

FETAL RISK SUMMARY

Ibuprofen is an NSAID that is indicated for the reduction of fever and mild-to-moderate pain. It is the same subclass (propionic acids) as five other NSAIDs (fenoprofen, flurbiprofen, ketoprofen, naproxen, and oxaprozin). No evidence of developmental abnormalities was observed in reproduction studies in rats and rabbits at doses slightly less than the maximum human clinical dose (8).

The manufacturer has received information by a voluntary reporting system on the use of ibuprofen in 50 pregnancies (9). Seven of these cases were reported retrospectively and 43 prospectively. The results of the retrospective cases included one fetal death (cause of death unknown, no abnormalities observed) after 3rd trimester exposure, and one SAB without abnormality. Five infants with defects were observed, including an anencephalic infant exposed

during the 1st trimester to ibuprofen and Bendectin (doxylamine succinate and pyridoxine hydrochloride), petit mal seizures progressing to grand mal convulsions, cerebral palsy (the fetus had also been exposed to other drugs), a hearsay report of microphthalmia with nasal cleft and mildly rotated palate, and tooth staining (M. M. Westland, personal communication, The Upjohn Company, 1981) (9). A cause and effect relationship between the drug and these defects is doubtful.

Prospectively, 23 of the exposed pregnancies ended in normal outcomes, 1 infant was stillborn, and 1 ended in SAB, both without apparent abnormality (9). Seven of the pregnancies were electively terminated, 3 had unknown outcomes, and 8 of the pregnancies were progressing at the time of the report.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 3178 newborns had been exposed to ibuprofen during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 143 (4.5%) major birth defects were observed (129 expected). Specific data were available for six defect categories, including (observed/expected) 33/30 cardiovascular defects, 7/5 oral clefts, 3/2 spina bifida, 11/9 polydactyly, 5/5 limb reduction defects, and 4/8 hypospadias.

A combined 2001 population-based observational cohort study and a case-control study estimated the risk of adverse pregnancy outcome from the use of NSAIDs (10). The studies were based on data from the Danish Birth Registry and the North Jutland County's hospital discharge registry collected between 1991 and 1998. Only those women who had received a prescription for a NSAID at doses equivalent to 400 or 600 mg of ibuprofen were classified as exposed (NSAID doses equivalent to 200 mg of ibuprofen are over-the-counter drugs in Denmark). The cohort involved 1462 pregnant women who had received an NSAID prescription in the interval from 30 days before conception to birth and a reference group of 17,259 pregnant women who had not been prescribed any drugs during pregnancy. In both groups, only pregnancies lasting >28 weeks were included. There were 1106 women (76%) who had received an NSAID prescription between 30 days before conception and the end of the 1st trimester. The prevalences of congenital malformations in infants of these women and the reference group were N = 46, 4.2%, 95% confidence interval [CI] 3.0–5.3% vs. N = 564, 3.3%, 95% CI 3.0–3.5%), respectively; adjusted odds ratio (aOR) 1.27 (95% CI 0.93–1.75). A total of 997 women received an NSAID prescription in the 2nd and/or 3rd trimesters. In this group, the OR for preterm delivery was 1.05 (95% CI 0.80–1.39) and that for low birth

weight (excluding preterm infants) was 0.79 (95% CI 0.45–1.38). Adjusting the data for the use of indomethacin (the tocolytic of choice in Denmark) did not affect the results. There was no evidence of a specific grouping of defects or of a dose–response relationship for adverse birth outcome. Based on the analysis, the authors concluded that NSAIDs were not associated with adverse birth outcome (10).

In the case–control portion of the above study, cases were defined as first recorded SAB in women who had received a prescription for NSAIDs in the 12 weeks before the date of discharge from the hospital after the SAB (63 of 4268 women who had SAB) (10). The controls were 29,750 primiparous women who had live births, 318 of whom had received a prescription for NSAIDs in the 1st trimester. The data were analyzed for the time from receiving an NSAID prescription in the weeks before the SAB (or missed abortion), adjusted for maternal age. The aOR (95% CI) for 1 week, 2–3 weeks, 4–6 weeks, 7–9 weeks, and 10–12 weeks before the SAB were 6.99 (2.75–17.74), 3.00 (1.21–7.44), 4.38 (2.66–7.20), 2.69 (1.81–4.00), and 1.26 (0.85–1.87), respectively. The results indicated that NSAIDs were associated with SAB because the OR decreased as the interval from assumed NSAID exposure to SAB increased (10).

A 2003 population-based cohort study involving 1055 pregnant women investigated the prenatal use of aspirin, NSAIDs, and acetaminophen (11). Fifty-three women (5%) reported use of NSAIDs around the time of conception or during pregnancy, 13 of whom had an SAB. After adjustment, an 80% increased risk of SAB was found for NSAIDs (adjusted hazard ratio 1.8, 95% CI 1.0–3.2). Moreover, the association was stronger if the initial use of drugs was around conception or if they were used for >1 week. A similar association was found with aspirin, but it was weaker because there were only 22 exposures (5 SABs). No association was observed with acetaminophen (11).

A prospective study of drug use in the 1st trimester examined the relationship between NSAIDs (N = 2557 infants born to exposed women) and congenital malformations (12). After adjustment, the aOR for any birth defect was 1.04 (95% CI 0.84–1.29). However, the aOR for cardiac defects (N = 36) and orofacial clefts (N = 6) were 1.86 (95% CI 1.32–2.62) and 2.61 (95% CI 1.01–6.78), respectively. There was no drug specificity for cardiac malformations, but five of the six cases of orofacial clefts had been exposed to naproxen (12).

A 2003 case–control study was conducted to identify drug use in early pregnancy that was associated with cardiac defects (13). Cases (cardiovascular defects without known chromosome anomalies) were drawn

from three Swedish health registers (N = 5015) and controls consisting of all infants born in Sweden (1995–2001) (N = 577,730). Among the NSAIDs, only naproxen had a positive association with the defects (see Naproxen). For ibuprofen, there were 4124 pregnant women exposed and 37 cases of cardiac defects (OR 1.08, 95% CI 0.78–1.50) (13).

A 1996 case–control study of gastroschisis found a significantly elevated risk for ibuprofen (N = 6; OR 4.0, 95% CI 1.0–16.0) and other medications and exposures (14). A significant association was also found for aspirin (N = 7; OR 4.67, 95% CI 1.21–18.05). The data supported a vascular hypothesis for the pathogenesis of gastroschisis (14).

A 2006 case–control study found a significant association between congenital anomalies, specifically cardiac septal defects, and the use of NSAIDs in the 1st trimester (15). A population-based pregnancy registry (N = 36,387) was developed by linking three databases in Quebec (see Naprosyn for other study details). Case infants were those with any congenital anomaly diagnosed in the first year of life and were compared with matched controls. There were 93 infants (8.8%) with congenital defects from 1056 mothers who had filled prescriptions for NSAIDs in the 1st trimester. In controls, there were 2478 infants (7%) with anomalies from 35,331 mothers who had not filled such a prescription. The aOR was 2.21 (95% CI 1.72–2.85). The aOR for cardiac septal closure was 3.34 (95% CI 1.87–5.98). There also was a significant association for anomalies of the respiratory system 9.55 (95% CI 3.08–29.63), but this association disappeared when cases coded as “unspecified anomaly of the respiratory system” were excluded. For the cases involving septal closure, 61% were atrial septal defects and 31% were ventricular septal defects (VSDs). There were no significant associations for oral clefts or defects involving other major organ systems. The five most common NSAIDs were naproxen (35%), ibuprofen (26%), rofecoxib (15%), diclofenac (9%), and celecoxib (9%). Among these agents, the only significant association was for ibuprofen prescriptions in the 1st trimester and congenital defects ($p < 0.01$) (15).

In contrast to the above study, a 2004 case–control study involved 168 infants with a nonsyndromic muscular VSD who were compared with 692 infants without birth defects (16). No significant associations were found between the occurrence of the VSD and maternal use of NSAIDs or acetaminophen after adjusting for maternal fever nor were they detected between maternal fever and the defect.

The use of ibuprofen as a tocolytic agent has been associated with reduced

amniotic fluid volume (17–19). Fourteen (82.3%) of 17 women treated with an NSAID had decreased amniotic fluid volume (17). Of the 17 women, ibuprofen, 1200–2400 mg/day, was used alone in three pregnancies and was combined with ritodrine in one. The other 13 women were treated with indomethacin (see also Indomethacin). One woman who was treated with ibuprofen for 44 days returned to a normal amniotic fluid volume after the drug was stopped (time for reversal not specified) (17).

Ibuprofen, 600 mg every 6 hours, was used as a tocolytic in a woman with a triplet pregnancy at approximately 26 weeks' gestation (18). Terbutaline and magnesium sulfate were combined with ibuprofen at various times for tocolysis. Oligohydramnios in each sac (pockets <1 cm) was documented by ultrasonogram on the 20th day of therapy and ibuprofen therapy was stopped. Therapy was restarted 5 days later when normal fluid volume for the three fetuses was observed, but oligohydramnios was again evident after 4 days and ibuprofen was discontinued. Tocolysis was then maintained with terbutaline and normal fluid volumes were observed 5 days after the second course of ibuprofen. The triplets were eventually delivered by elective cesarean section at 35 weeks' gestation, but no details on the infants were given (18).

A brief 1992 abstract described the results of using ibuprofen, 1200–2400 mg/day, as a tocolytic agent in 52 pregnancies (61 fetuses) up to 32 weeks' gestation (19). Amniotic fluid volumes were evaluated every 1–2 weeks. No cases of true oligohydramnios were observed, although 3 cases of low-normal fluid occurred that resolved after discontinuation of ibuprofen. Periodic Doppler echocardiography during therapy revealed a non-dose-related mild constriction of the ductus arteriosus in 4 (6.6%) of the fetuses. Ductal constriction was observed in three of the fetuses within 1 week of starting ibuprofen. Normal echocardiograms were obtained in all four cases within 1 week of discontinuing therapy (19).

Ibuprofen is commonly used by pregnant women, according to a 2003 study that identified the medications taken by a rural population (20). Among 578 participants, 86 (15%) took ibuprofen during pregnancy, including 20 during the 3rd trimester. Ibuprofen was the fourth most commonly used over-the-counter medication (after acetaminophen, calcium carbonate, and cough drops) (20).

A 2012 report from the National Birth Defects Prevention Study found associations between exposures to NSAIDs (aspirin, ibuprofen, and naproxen) and several birth defects (21). The data for this case–control study came from approximately 20,470 women with expected due dates in 1997–2004. Among this group, 3173 women (15.5%) were exposed to NSAIDs in the 1st trimester.

Although the results suggested that NSAIDs are not a major cause of birth defects, the study did find several small-to-moderate but statistically significant increases in nine defects. The drug, aOR, and 95% CI for each defect were as follows: anencephaly/craniorachischisis—[aspirin](#) (2.1; 1.1–4.3); spina bifida—[ibuprofen](#) (1.6; 1.2–2.1); encephalocele—[naproxen](#) (3.5; 1.2–10); anophthalmia/microphthalmia—[aspirin](#) (3.0; 1.3–7.3), [ibuprofen](#) (1.9; 1.1–3.3), and [naproxen](#) (2.8; 1.1–7.3); cleft lip ± cleft palate—[ibuprofen](#) (1.3; 1.1–1.6) and [naproxen](#) (1.7; 1.1–2.5); cleft palate—[aspirin](#) (1.8; 1.1–2.9); transverse limb deficiency—[naproxen](#) (2.0; 1.0–3.8); amniotic bands/limb body wall—[aspirin](#) (2.5; 1.1–5.6) and [ibuprofen](#) (2.2; 1.4–3.5); and a heart defect (isolated pulmonary valve stenosis)—[naproxen](#) (2.4; 1.3–4.5). The analysis of the latter defect was limited to term births only. The authors acknowledged that further studies were needed because most of these associations had not been reported from other databases ([21](#)).

A 2013 study evaluated the effect of prolonged use of [ibuprofen](#) and [acetaminophen](#) during pregnancy on the neurodevelopment of 3-year-old same-sex sibling pairs ([22](#)). The cases came from the prospective Norwegian Mother and Child Cohort Study (see [Acetaminophen](#) for study details and results with [acetaminophen](#)). Prenatal [acetaminophen](#) was associated with significantly poorer outcomes than nonexposed siblings. In contrast, [ibuprofen](#) prenatal exposure was not associated with adverse neurodevelopment outcomes ([22](#)).

BREASTFEEDING SUMMARY

[Ibuprofen](#) is excreted into human milk. Two studies were unable to detect the drug ([23–25](#)), but a third using a more sensitive assay (lower limit 2.5 ng/mL) was able to quantify [ibuprofen](#) in milk ([26](#)). In 12 patients taking 400 mg every 6 hours for 24 hours, an assay capable of detecting 1 mcg/mL failed to demonstrate [ibuprofen](#) in the milk ([23,24](#)). In a second report, a woman was treated with 400 mg twice daily for 3 weeks ([25](#)). Milk levels shortly before and up to 8 hours after drug administration were all <0.5 mcg/mL.

The third study involved a lactating woman who underwent maxillary surgery ([26](#)). After surgery, she took [ibuprofen](#) 400 mg six times over a 42.5-hour interval for postoperative pain. Ten breast milk samples were collected during this same period. [Ibuprofen](#) was detected (13 ng/mL) 30 minutes after the first dose. The maximum milk concentration, 181 ng/mL, was found 20.5 hours after the first dose (about 5 hours after the third dose). Although the infant was not nursing, the infant's weight-adjusted dose would have been an estimated 0.0008% of the mother's dose ([26](#)).

The American Academy of Pediatrics classifies ibuprofen as compatible with breastfeeding (27).

IBUTILIDE

Antiarrhythmic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Animal data in the one species tested suggest a moderate risk to the human embryo–fetus. Three women in the second half of pregnancy with atrial flutter or fibrillation were successfully converted to sinus rhythm and, although there was no information on the newborns, apparently gave birth to normal infants at term. The limited human pregnancy experience, however, prevents a complete assessment of the embryo–fetal risk, but the benefits of therapy appear to outweigh the unknown risk. This conclusion is based on two considerations. First, the indication for ibutilide (i.e., rapid conversion of atrial fibrillation or atrial flutter of recent onset to sinus rhythm) is indicative of severe maternal disease that would be, in itself, harmful to the fetus if not treated. Second, treatment with ibutilide would be short term and occur in a hospital with the fetus under surveillance.

FETAL RISK SUMMARY

Ibutilide is a cardiac antiarrhythmic agent with predominantly class III (cardiac action potential prolongation) properties (1). Other available class III antiarrhythmic agents are amiodarone, sotalol, and bretylium (2). Ibutilide is administered by IV injection only. It undergoes rapid and extensive hepatic metabolism to eight metabolites, only one of which is active. Ibutilide has an average elimination half-life of about 6 hours (range 2–12 hours) (1).

Dose-related teratogenic, embryocidal effects, and fetal toxicity were observed in rats given ibutilide orally on days 6–15 of gestation (1,3,4). The no-observed-adverse-effect level (NOAEL), corrected for the 3% oral bioavailability, was 5 mg/kg/day, approximately the same as the maximum

recommended human dose based on BSA (MRHD). Scoliosis was observed at a dose double the MRHD, but the incidence was not significantly different from controls (4). At four and eight times the MRHD, a significant dose–response effect was observed for adactyly, interventricular septal defects, scoliosis, and pharynx and palate malformations. A significant increase in embryo resorptions and fetal toxicity occurred at eight times the MRHD (4).

It is not known if ibutilide crosses the human placenta. The molecular weight (about 443 for the fumarate salt) and long elimination half-life suggest that the drug, and possibly its active metabolite, will cross to the embryo–fetus.

Two 2007 reports have described the use of ibutilide during three pregnancies (5,6). In the first case, a 20-year-old woman at 24 weeks' gestation presented with atrial flutter (5). Propranolol, esmolol, and sotalol were ineffective and could not be continued due to hypotension. IV ibutilide 1 mg successfully converted the patient to a sinus rhythm. She was discharged home on flecainide 50 mg twice daily and metoprolol 25 mg/day. She carried her pregnancy to term without further complication (5). No information was provided on the status of the newborn.

In the second case, a 27-year-old woman at 30 weeks' gestation had atrial fibrillation attributable to Wolff–Parkinson–White syndrome that was converted to a sinus rhythm with two doses of IV doses of ibutilide (0.87 mg) given at 30-minute intervals (6). She was maintained on flecainide 100 mg twice daily and atenolol 50 mg/day and delivered a healthy baby at term. The third case involved a 34-year-old woman at 23 weeks' who presented with atrial fibrillation. IV ibutilide 0.25 mg converted her to a sinus rhythm. She was discharged home on atenolol 50 mg/day and delivered a healthy baby at term. Both women remained asymptomatic throughout the remainder of their pregnancies (6). No additional information was given for either of the newborns.

BREASTFEEDING SUMMARY

No reports describing the use of ibutilide during lactation have been located. Because of the indication for this drug, it is doubtful if such reports will occur. In addition, its low oral bioavailability suggests that a nursing infant would absorb minimal amounts.

ICATIBANT

Hematologic (Bradykinin Inhibitor)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of icatibant in human pregnancy have been located. Although the drug was not teratogenic in rats and rabbits, it did cause other forms of developmental toxicity. However, the absence of human pregnancy experience prevents a more complete assessment of embryo–fetal risk. Because of the lack of information, if a pregnant woman has an attack of hereditary angioedema, treatments other than icatibant should be considered. A 2013 review recommended plasma-derived C1-INH as the drug of choice for hereditary angioedema in pregnancy and, if not available, then fresh frozen plasma (1).

FETAL RISK SUMMARY

Icatibant, a bradykinin (a vasodilator) B₂ receptor inhibitor that is given SC, is a synthetic decapeptide with five proteinogenic amino acids. It is indicated for the treatment of acute attacks of hereditary angioedema in adults 18 years of age and older. Icatibant is extensively metabolized to inactive metabolites. The mean elimination half-life is 1.4 hours. The manufacturer did not mention if the drug binds to plasma proteins (2).

Reproduction studies have been conducted in rats and rabbits. In rats, delayed parturition and fetal death occurred at exposures that were 0.5 and 2 times, respectively, the maximum recommended human dose (MRHD) based on AUC (MRHD-AUC) and increased preimplantation loss occurred at 7 times the MRHD-AUC. Impairment of pup air-righting reflex and decreased pup hair growth also occurred at 7 times the MRHD-AUC. In rabbits, a dose <1/40th the MRHD based on BSA resulted in an increase in premature birth and abortion rates. Also, in rabbits, exposures that were 13 times the MRHD-AUC resulted

in preimplantation loss and increased fetal deaths (2).

Long-term studies for carcinogenic effects have not been conducted. The drug was not mutagenic in three assays. Daily SC doses in rats and dogs caused ovarian, uterine, and testicular atrophy/degeneration, as well as adverse effects on the mammary and prostate glands. These toxicities were not observed in dogs with less frequent dosing. Daily dosing in male and female mice had no effects on fertility or reproductive performance (2).

It is not known if icatibant crosses the human placenta. The molecular weight (about 1305) should limit the amount crossing, but the mean elimination half-life and, possibly, the lack of plasma protein binding might allow exposure, especially in the 3rd trimester.

BREASTFEEDING SUMMARY

No reports describing the use of icatibant during human lactation have been located. The molecular weight (about 1305) should limit excretion into mature breast milk, but mean elimination half-life (1.4 hours) and, possibly, the lack of plasma protein binding might allow some excretion. The effect of this exposure on a nursing infant is unknown, but the drug is a peptide and might be digested in the infant's gut. Nevertheless, if a mother is taking this drug and breastfeeding, her nursing infant must be monitored for the most common (>1%) adverse reactions: pyrexia, transaminase increase, dizziness, and rash (2).

IDARUBICIN

Antineoplastic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Limited pregnancy experience, all in the 2nd trimester, suggests that idarubicin may cause significant fetal toxicity. Exposure during organogenesis has not been reported.

FETAL RISK SUMMARY

Idarubicin, an anthracycline antineoplastic antibiotic agent, is a DNA-intercalating analog of daunorubicin. It is used in the treatment of acute myeloid leukemia. It is in the same antineoplastic subclass of anthracyclines as daunorubicin, doxorubicin, epirubicin, and valrubicin.

In pregnant rats, a dose 10% of the human dose (HD) produced embryotoxicity and teratogenicity without causing maternal toxicity. Embryotoxicity, but not teratogenicity, occurred in rabbits treated with doses up to about 20% of the HD. However, this dose caused maternal toxicity (1).

Shepard (2) reviewed three reproductive studies in which IV doses up to 0.2 mg/kg were given to rats. When treatment occurred early in pregnancy, fetal loss, intrauterine growth restriction (IUGR), decreased ossification, and skeletal defects such as fused ribs were observed at the highest dose. These effects were not seen when treatment occurred perinatally. Infertility may have occurred in the second generation.

A 26-year-old woman at 20 weeks' gestation who presented with acute myeloblastic leukemia, was treated with an induction course of cytarabine and daunorubicin that failed to halt the disease progression (3). At approximately 23 weeks' gestation, a second induction course was started with mitoxantrone and cytarabine. Complete remission was achieved 60 days from the start of therapy. Weekly ultrasound examinations documented normal fetal growth. Because of the long interval required for remission, treatment was changed to

idarubicin (10 mg/m², days 1 and 2) and cytarabine. She tolerated this therapy and was discharged home, but returned 2 days later complaining of abdominal pain and the loss of fetal movements. A stillborn, 2200-g fetus (gestational age not specified) without evidence of congenital malformations was delivered after induction. Permission for an autopsy was denied. Although the authors did not specify a mechanism, they concluded that the cause of the fetal death was due to idarubicin.

A 1998 case report described a woman with acute myeloid leukemia who was treated with idarubicin and cytarabine during the 2nd trimester (4). Treatment was begun at 21 weeks' gestation with IV idarubicin 10 mg/m² on days 1, 3, and 5 and IV cytarabine 100 mg/m² on days 1–10. A 6-day consolidation course of IV cytarabine, 1000 mg/m² every 12 hours, was given 6 weeks later. Complete remission was documented after recovery from this course. IUGR and decreased fetal movements were diagnosed at 32 weeks' gestation and a week and half later, a 1408-g female infant was delivered by cesarean section. Apgar scores were 4, 7, and 10 at 1, 5, and 10 minutes, respectively. Except for hyperbilirubinemia, the infant was healthy and was doing well on discharge. An echocardiographic examination revealed no evidence of cardiac anomalies or signs of cardiomyopathy (4).

A 22-year-old woman at 22 weeks' gestation with acute lymphoblastic leukemia type T was treated with idarubicin (9 mg/m² on days 1, 2, 3, and 8), cyclophosphamide (750 mg/m² on days 1 and 8), vincristine (2 mg/day on days 1, 8, 15, and 22), and prednisone (60 mg/m² on days 1–7 and 15–21) (5). The patient tolerated the therapy except for agranulocytosis with fever, which was treated with antibiotics. A complete remission was documented by 27 weeks' gestation. Before consolidation chemotherapy, a 1024-g male infant was delivered by cesarean section 1 week later. Apgar scores were 6, 8, and 8 at 1, 5, and 10 minutes, respectively. Neonatal complications, related to prematurity, were respiratory distress syndrome, necrotizing enterocolitis, and grade II ventricular hemorrhage (5). In addition, acute heart failure occurred during the first 3 days after birth (5). Diffuse cardiomyopathy involving both ventricles and the interventricular septum without anomalies was revealed by echocardiography. The condition was thought to be related to the chemotherapy, especially, idarubicin. With supportive care, the cardiac function returned to normal within 3 days. Except for slight delay in the acquisition of language, the infant was progressing normally at 18 months of age (5).

In a 2009 case report, a woman with relapse of acute myeloid leukemia at 22 weeks' gestation was treated with idarubicin, fludarabine, cytarabine,

mitoxantrone, and gemtuzumab ozogamicin (6). The fetus developed signs of idarubicin-induced cardiomyopathy, transient cerebral ventriculomegaly, anemia, and intrauterine growth restriction. The newborn, delivered at 33 weeks' by cesarean section, showed no congenital malformations.

Occupational exposure of the mother to antineoplastic agents during pregnancy may present a risk to the fetus. A position statement from the National Study Commission on Cytotoxic Exposure and a research article involving some antineoplastic agents are presented in the monograph for cyclophosphamide (see Cyclophosphamide).

BREASTFEEDING SUMMARY

No reports describing the use of idarubicin during lactation have been located. The molecular weight (about 498 for the free base) is low enough that excretion into breast milk should be expected. Because of the potential toxicity, a woman treated with this drug should not breastfeed until idarubicin and its cytotoxic and presumed active metabolite, idarubicinol, have been eliminated from her system. Idarubicin has a mean terminal half-life of 20–22 hours (range 4–46 hours), but the estimated mean terminal half-life of idarubicinol exceeds 45 hours (1). Thus, elimination of the two agents may require 10 days or longer. The American Academy of Pediatrics classifies similar antineoplastic agents (e.g., doxorubicin) as contraindicated during breastfeeding because of the potential for immune suppression and an unknown effect on growth or association with carcinogenesis (7).

IDOXURIDINE

Antiviral

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of idoxuridine in human pregnancy have been located. The drug is teratogenic in some species of animals after injection and ophthalmic use (1–3).

FETAL RISK SUMMARY

Idoxuridine is a topical ophthalmic preparation that is indicated for the treatment of keratitis caused by the virus of herpes simplex (1). Systemic exposure after topical use was not reported by the manufacturer.

Reproduction studies have been conducted in rabbits, rats, and mice. In pregnant rabbits given the drug topically to the eyes in doses similar to those used in humans, idoxuridine crossed the placenta and caused fetal malformations. Fetal malformations also occurred in rats and mice given intraperitoneal, oral, or SC injections of the drug (1).

Adequate studies for carcinogenicity have not been conducted but is considered potentially carcinogenic. Idoxuridine has caused chromosome aberrations in mice and is mutagenic in mammalian cells in culture.

BREASTFEEDING SUMMARY

No reports describing the use idoxuridine during human lactation have been located. Systemic concentrations after topical use have apparently not been determined. The manufacturer states that the drug should not be used during breastfeeding because the drug and metabolites may be excreted into breast milk (1).

IFOSFAMIDE

Antineoplastic

PREGNANCY RECOMMENDATION: Contraindicated—1st Trimester

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

There is limited human pregnancy experience with ifosfamide. The drug is carcinogenic and mutagenic in experimental studies. In addition, it is teratogenic and embryotoxic in three animal species at doses far less than the recommended human dose. Because of the close relationship of ifosfamide to cyclophosphamide, a known human teratogen, ifosfamide should be considered an agent with a high potential for human teratogenicity and embryo–fetal toxicity.

FETAL RISK SUMMARY

Ifosfamide is chemically related to the nitrogen mustards and is a synthetic analog of cyclophosphamide (see also Cyclophosphamide). Ifosfamide is a prodrug that requires metabolic activation by microsomal liver enzymes to produce biologically active metabolites. It is indicated for the treatment of germ cell testicular cancer. Combination with a prophylactic agent such as mesna is recommended to prevent hemorrhagic cystitis (1).

Ifosfamide was carcinogenic in rats (including a significant incidence of leiomyosarcomas and mammary fibroadenomas in female rats) and mutagenic in several assays (1). Reproduction studies have been conducted in pregnant mice, rats, and rabbits. In mice, a single dose of 30 mg/m² (1/40 the daily recommended human dose of 1200 mg/m²) administered on gestational day 11 caused an increase in the incidence of resorptions and anomalies (not specified). Evidence of embryoletality was observed in rats given 54-mg/m² doses on gestational days 6–15. Embryotoxic effects (not specified) were observed when a smaller dose (18 mg/m²) was administered over the same period. Embryotoxicity and teratogenicity were observed in rabbits given 88 mg/m²/day on gestational days 6–18 (1). Maternal toxicity was not mentioned in any of the above studies.

A 1973 study described the teratogenic and embryotoxic effects of various single intraperitoneal doses (5, 10, and 20 mg/kg) of ifosfamide given to mice on gestational day 11 (2). Only the 20-mg/kg dose was embryolethal (significantly increased resorption rates), but significant fetal toxicity (decreased body weight and/or crown–rump length) was observed with the 10- and 20-mg/kg doses. A number of anomalies were observed in the highest dose group: open eyes, internal and external hydrocephalus, microphakia, micromelia, adactyly, syndactyly, microcaudate, kinky tails, kidney ectopia, and hydronephrosis. Both 10- and 20-mg/kg doses increased the number of skeletal defects and the 5-mg/kg dose was associated with a significant increase in supernumerary ribs. Finally, a single SC dose of 45 mg/kg administered to 1-day-old mice resulted in reduced body weight and altered development (2).

In sexually mature male rabbits, single IV doses of ifosfamide (0, 60, 90, 120, or 240 mg/kg) caused transient and dose-dependent depression of spermatocytogenesis, spermiogenesis, and sperm maturation in comparison to controls (3). In the second part of this study, using the same methods, the investigators combined ifosfamide with mesna (an uroprotectant agent) (4). Three groups of male rabbits were given different doses of the combination (ifosfamide 30, 45, or 60 mg/kg plus mesna 6, 9, or 12 mg/kg, followed by a second equal dose of mesna 4 hours later). Each group received 10 weekly treatments. Controls were given either mesna alone (three groups) or saline (one group). Dose-related ifosfamide–mesna suppression of spermatogenesis and epididymal sperm maturation was observed. In addition, the investigators noted incomplete recovery of the germinal epithelium (4).

A 1997 review stated that ifosfamide is less toxic for stem cell spermatogonia (type A spermatogonia) than is cyclophosphamide (5). In 15 of 16 patients who received 15–30 g/m² of ifosfamide, the median follicle-stimulating hormone levels returned to normal. In addition, there was no evidence of an increased risk of malformations or malignancies in offspring fathered by patients with germ cell cancer after chemotherapy (5). However, a 2003 study confirmed that ifosfamide exposure is a potential cause of male infertility (6). A significant ($p = 0.005$) dose-dependent relationship was observed between increasing doses of ifosfamide and infertility in patients treated for osteosarcoma.

It is not known if ifosfamide or its active metabolites cross the placenta to the fetus. The low molecular weight of the parent prodrug (about 261) suggests that it reaches the fetal circulation.

A 20-year-old woman at 23 weeks' gestation was treated with ifosfamide (5 g/day on days 1 and 2), vincristine (2 mg/day on days 1 and 14), and dactinomycin (1 mg/day on days 1 and 2) for advanced rhabdomyosarcoma of the face (7). In addition to the antineoplastics, the patient also received mesna and urate oxidase (used for the treatment of hyperuricemia). A second course of therapy was given 4 weeks later. At initiation of the chemotherapy, the fetal weight was estimated to be at the 20th percentile with normal amniotic fluid volume and active movements. At the time of the second course of chemotherapy, ultrasound revealed a complete absence of amniotic fluid, an empty fetal bladder, cessation of fetal growth, and absence of fetal movements. An emergency cesarean section was performed 2 weeks later after evidence of continued anhydramnios, intrauterine growth arrest, and acute fetal hypoxia. A 720-g female was delivered with Apgar scores of 3, 7, and 7 at 1, 5, and 10 minutes, respectively. An ultrasound of the neonate revealed bilateral intraventricular hemorrhage and left occipital meningeal hematomas. Anuria persisted, and the girl died at age 7 days. Autopsy noted extensive cerebral lesions associated with prematurity but no renal lesions or chromosome abnormalities. The placenta had large areas of ischemic necrosis without evidence of chorioamnionitis. No cancer cells were found in the fetus or placenta. The authors speculated that the lack of renal lesions suggested that causes in addition to ifosfamide-induced toxicity should be considered to explain the anuria in the fetus and newborn (7).

In contrast to the above study, a 21-year-old woman was treated with three courses of ifosfamide/mesna (each 5 g/m² three times weekly) and doxorubicin (50 mg/m² three times weekly) for Ewing's sarcoma of the pelvis (8). The three courses were given in the 27th, 30th, and 33rd week of pregnancy. Mild intrauterine growth restriction was detected by ultrasound. A cesarean section at the beginning of the 36th gestational week delivered a 42-cm-long, 1300-g female infant. No adverse effects were noted in the infant, who was doing well at 2 years of age (8).

In a 2004 case report, a 17-year-old woman at 22 weeks' gestation was diagnosed with an extraskeletal Ewing's sarcoma (9). She was treated with doxorubicin 50 mg/m² by 48-hour continuous infusion and ifosfamide 2 g/m² as a single injection, both given at 25, 28 and 30 weeks'. Mild fetal growth restriction was noted from the 29th week of gestation. An elective cesarean section delivered a 1.245-kg male infant with Apgar scores of 7 and 9 at 1 and 5 minutes, respectively. Based on weight and length (38 cm), the infant was small for gestational age. The infant had no congenital anomalies and no

respiratory distress syndrome, but did have mild hyperbilirubinemia. He was growing well at 8 months of age (9).

A 2006 case report described the pregnancy outcome of a 21-year-old woman with Burkitt's lymphoma who was treated with intensive chemotherapy (10). Beginning at 26 weeks, she was treated with two cycles of chemotherapy that included ifosfamide, cyclophosphamide, vincristine, doxorubicin, cytarabine, etoposide, cytarabine, and mesna. At 32 weeks, a cesarean section delivered a 1.731-kg male infant with Apgar scores of 8 and 9 at 1 and 5 minutes, respectively. His weight, length, and head circumference were within normal limits for gestational age. No anomalies were noted but respiratory distress was evident. At 9 months of age, his weight was 6.36 kg. He had mild delayed motor skills that were thought to result from his premature birth. Otherwise he was healthy (10).

BREASTFEEDING SUMMARY

No reports describing the use of ifosfamide during lactation have been located. Ifosfamide is excreted into breast milk (1). This is consistent with its low molecular weight (about 261). Although the amount of ifosfamide in milk was not stated, severe toxicity in a nursing infant is a potential concern (e.g., bone marrow depression, urinary system, and CNS toxicity). Therefore, women receiving ifosfamide should not breastfeed.

ILOPERIDONE

Antipsychotic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of iloperidone in human pregnancy have been located. Animal reproduction studies observed two types of developmental toxicity (death and decreased weight) in one animal species. There is no evidence with other agents in this subclass of embryo or fetal harm. However, because of the very limited human pregnancy experience with atypical antipsychotics, the American College of Obstetricians and Gynecologists does not recommend the routine use of these agents in pregnancy, but a risk–benefit assessment may indicate that such use is appropriate (1). Because iloperidone is indicated for severe debilitating mental disease, the benefits to the mother appear to outweigh the unknown risk. A 1996 review on the management of psychiatric illness concluded that patients with histories of chronic psychosis represent a high-risk group (for both the mother and the fetus) and should be maintained on pharmacologic therapy before and during pregnancy (2). Folic acid 4 mg/day has been recommended for women taking atypical antipsychotics because they may have a higher risk of neural tube defects due to inadequate folate intake and obesity (3).

FETAL RISK SUMMARY

The atypical antipsychotic iloperidone is a benzisoxazole derivative in the same subclass of antipsychotic agents as paliperidone, risperidone, and ziprasidone. Iloperidone is indicated for the acute treatment of schizophrenia in adults. It is extensively metabolized to two predominate metabolites, P88 and P95, one (P88) of which is active. The parent drug and the two metabolites are highly bound (about 95%) to serum proteins. The mean elimination half-lives of

iloperidone and the two metabolites (P88 and P95) in extensive metabolizers were 18, 26, and 23 hours, respectively, whereas in poor metabolizers the half-lives were 33, 37, and 31 hours, respectively (4).

Reproduction studies have been conducted in rats and rabbits. During organogenesis, rats were given doses 1.6–26 times the maximum recommended human dose of 24 mg/day based on BSA (MRHD). The highest dose caused increased early intrauterine deaths, decreased fetal weight and length, decreased skeletal ossification, and an increased incidence of minor fetal skeletal anomalies and variations and also was maternal toxic (decreased food consumption and weight gain). In separate studies, rats were given doses 1.6–26 times the MRHD either before conception or from gestational day 17 through weaning. Adverse effects included prolonged pregnancy and parturition, increased stillbirth rates, increased incidence of fetal visceral variations, decreased fetal and pup weights, and decreased postpartum pup survival. Maternal toxicity occurred at the higher doses. An increase in stillbirths occurred at all doses. The no-effect dose for the other effects ranged from 1.6 to about 5 times the MRHD. No drug effects on neurobehavioral or reproductive development were noted in the surviving pups. In rabbits during organogenesis, the highest dose tested (20 times the MRHD) was not teratogenic but did cause increased early intrauterine deaths, decreased fetal viability at term, and maternal toxicity (4).

Because P95 is not present in significant amounts in rats, a separate study was conducted in this species with the metabolite. During organogenesis, doses resulting in plasma levels up to twice those in humans receiving the MRHD did not cause teratogenicity, but delayed skeletal ossification occurred at all doses. No significant maternal toxicity was noted (4).

Long-term studies for carcinogenicity have been conducted in mice and rats. An increased incidence of malignant mammary gland tumors occurred in female mice that were considered to be prolactin mediated. No drug-related carcinogenicity was observed in rats. Long-term exposure to the P95 metabolite in rats resulted in proliferative responses in several organs. Neither iloperidone nor P95 was mutagenic in various assays, but the parent drug did cause chromosomal aberrations in one in vitro assay that also resulted in cytotoxicity. Decreased fertility in male and females was observed at doses ≈ 5 times the MRHD. The no-effect dose for impaired fertility was 1.6 times the MRHD (4).

It is not known if iloperidone or the two metabolites cross the human placenta. The molecular weight of the parent drug (about 426) and the long

elimination half-lives suggest that the parent drug and possibly the metabolites will cross to the embryo–fetus. The high serum protein binding of iloperidone might limit some of this exposure.

BREASTFEEDING SUMMARY

No reports describing the use of iloperidone during human lactation have been located. The molecular weight (about 426) and the long elimination half-lives (ranging from 18–36 hours) suggest that the drug will be excreted into breast milk. However, there are two major metabolites, one of which is active, and these may also be excreted into milk. The amount of iloperidone and metabolites in milk might be limited by their high (about 95%) serum protein binding. The effect of this exposure on a nursing infant is unknown.

The manufacturer recommends women receiving iloperidone should not breastfeed (4). Moreover, the American Academy of Pediatrics classifies other atypical antipsychotics (e.g., see Ziprasidone) as drugs whose effect on the nursing infant is unknown but may be of concern (5).

Because of the very limited human experience with atypical antipsychotics, the American College of Obstetricians and Gynecologists does not recommend the routine use of these agents during lactation, but a risk–benefit assessment may indicate that such use is appropriate (1).

ILOPROST

Vasodilator

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Not Relevant

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Pregnancy is not advised in women with pulmonary arterial hypertension (PAH) because of the high risk of morbidity and death. However, pregnancy exposures to iloprost have occurred apparently without embryo–fetal harm. The animal reproduction data are not relevant because the oral and IV doses were not compared with the human dose. Nevertheless, PAH is a high-risk condition and, if indicated, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Iloprost is a synthetic analog of prostacyclin PGI_2 given by inhalation or IV (outside of the U.S.). Iloprost is indicated for the treatment of PAH. The agent dilates systemic and pulmonary arterial vascular beds. There are no other agents in its subclass of prostacyclin analogs. The absolute bioavailability of inhaled iloprost has not been determined, but it was generally not detectable in plasma 30–60 minutes after a dose. When given IV, the half-life is 20–30 minutes and the plasma protein binding was about 60%, mainly to albumin. The main metabolite was inactive in animals (1).

Reproduction studies have been conducted in rats, rabbits, and monkeys. In Han-Wistar rats, a continuous IV dose (serum levels not specified) caused shortened digits of the thoracic extremity in fetuses–pups. In comparable studies giving oral or IV iloprost to Sprague-Dawley rats, rabbits, and monkeys, these anomalies were not observed. However, a maternal toxic oral dose in Sprague-Dawley rats significantly increased the number of nonviable fetuses and an IV dose that was 10 times the teratogenic dose in Han-Wistar rats was embryolethal (1). None of the studies compared the exposures with the human

exposure from inhalation or IV use.

Iloprost was not carcinogenic, mutagenic, or clastogenic in multiple studies and assays, and did not cause chromosomal aberrations. The fertility of male and female rats was not impaired with embryo-lethal IV doses (1).

It is not known if iloprost crosses the human placenta. The molecular weight (about 360) is low enough, but the very short plasma half-life suggests that exposure of the embryo–fetus will be limited.

A 2005 report described three women with PAH who were treated with inhaled iloprost (2). Treatment was initiated at 8, 19, and 17 weeks' with doses titrated to the patient's condition and administered 7 times daily. The first woman had been treated with bosentan and warfarin until the therapy was changed at 8 weeks'. This woman suffered a cardiorespiratory arrest at about 25 weeks but was successfully resuscitated after about 1 minute and was converted to IV iloprost for 5 days. At that time, a cesarean section delivered a 0.65-kg male infant with Apgar scores of 8 and 9. The child was progressing well at 16 months of age. Because of premature labor, the second woman underwent a cesarean section at 36 weeks' to deliver a 2.8-kg male infant with Apgar scores of 9 and 9. At 18 months, the mother and her son were doing well. Placenta previa was diagnosed in the third woman and a cesarean section at 35 weeks delivered a 2.16-kg female infant with Apgar scores of 9, 9, and 10. At 12 weeks, the mother and her daughter were doing well. No congenital anomalies were noted in the three infants (2).

A 21-year-old with idiopathic PAH was treated with inhaled iloprost from 24 to 34 weeks' gestation, at which time she underwent a cesarean section because of oligohydramnios (3). The mother and infant were clinically well and were discharged home 8 days after delivery. No other details about the infant were provided.

Bosentan (250/day), sildenafil (150 mg/day), hydroxychloroquine (200 mg/day), azathioprine (100 mg/day), and phenprocoumon were used up to 5 weeks' gestation in a 29-year-old woman with systemic lupus erythematosus-associated PAH (4). At that time, bosentan and phenprocoumon were discontinued and the other three agents were continued with low-molecular-weight heparin. At 35 weeks', inhaled iloprost was added. At 37 weeks, a planned cesarean section delivered a healthy 2.760-kg female infant with Apgar scores of 8, 9, and 10. Breastfeeding was declined. At the time of the report, the child was doing well (4).

A 2013 case report described a 30-year-old pregnant woman who was diagnosed with PAH at 24 weeks' (5). She was treated with inhaled iloprost,

oral sildenafil, oxygen, and low-molecular-weight heparin. Five days before delivery, inhaled iloprost was replaced with IV iloprost. At about 32 weeks', a cesarean section gave birth to 1.7-kg male infant with Apgar scores of 8 and 9 at 1 and 5 minutes, respectively. Weight, length, and head circumference were within normal limits for gestational age. No congenital anomalies were noted, but the infant had sinus tachycardia and mild respiratory distress syndrome. He was apparently doing well at 18 days of age (5).

BREASTFEEDING SUMMARY

No reports describing the use of iloprost during human lactation have been located. The molecular weight (about 360) is low enough, but the very short plasma half-life suggests that excretion of the drug into breast milk will be limited. The effect of exposure on a nursing infant is unknown.

IMATINIB

Antineoplastic (Tyrosine Kinase Inhibitor)

PREGNANCY RECOMMENDATION: Human and Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

After use of imatinib in pregnancy, both normal and abnormal outcomes have been reported.

Because agents in this subclass inhibit angiogenesis, a critical component of embryonic and fetal development, avoiding the drug in pregnancy, especially during organogenesis, is the safest course. However, leukemia is a serious disease that presents a risk to the mother and the eventual outcome of her pregnancy. Consequently, if indicated, treatment with imatinib should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Imatinib (formerly ST1571) is an oral tyrosine kinase inhibitor that inhibits tumor growth, pathologic angiogenesis, and metastatic progression of cancer. There are several other agents in this subclass (see Appendix). Imatinib is indicated for the treatment of newly diagnosed adult patients with Philadelphia chromosome-positive chronic myeloid leukemia in chronic phase. Imatinib is extensively metabolized in the liver. One metabolite has activity that is equipotent to imatinib. The plasma AUC for the active metabolite is about 15% of the AUC for imatinib. The plasma elimination half-lives of imatinib and the active metabolite are about 18 and 40 hours, respectively. Elimination is primarily in the feces. Plasma protein binding is about 95%, mostly to albumin and α -1 glycoprotein (1).

Reproduction studies have been conducted in rats. During organogenesis, oral doses about equal to or greater than the maximum human clinical dose of 800 mg/day based on BSA (MHCD) caused teratogenic effects that included exencephaly or encephalocele, and absent/reduced frontal and absent parietal bones. Doses about half the MHCD during pregnancy were associated with

significant postimplantation loss as evidenced by early fetal resorption or stillbirths, nonviable pups, and pup mortality within 4 days of birth. When a dose greater than the MHCD was given, total fetal loss occurred in all animals. Fetal death was not observed at doses one-third the MHCD (1).

Male and female rats were exposed in utero to daily maternal doses of imatinib that were about half the MHCD from day 6 of gestation and through milk during the lactation period. Body weights were reduced from birth. No drug exposure occurred over the next 2 months. Although fertility was not affected, fetal loss was observed when these animals were mated (1).

Imatinib was carcinogenic in 2-year studies in rats, causing renal adenomas/carcinomas, urinary bladder papillomas, and papillomas/carcinomas of the preputial and clitoral gland. Genotoxic and clastogenic effects were seen in some tests. Male rats given daily doses about three-fourths the MHCD for 70 days had decreased testicular and epididymal weights and percent motile sperm. These effects were not seen at one-fourth the MHCD. In female rats, no effects on mating or the number of pregnant females were observed at doses one-fourth the MHCD (1).

It is not known if imatinib or its active metabolite crosses the human placenta. The molecular weight (about 494 for the free base) for the parent compound and the long elimination half-lives for imatinib and its metabolite suggest that the drug will cross to the embryo and fetus.

A 2003 report from the manufacturer described the effects of imatinib on male fertility (2). Although spermatogenesis was impaired in rats, dogs, and monkeys, clinical experience had not confirmed this in humans. The authors cited 18 pregnancies in the partners of men under treatment with imatinib, 13 during clinical trials and 5 from voluntary reports. In the clinical trial group, eight were treated with 400 mg/day for chronic-phase chronic myelogenous (i.e., myeloid) leukemia (CML), four with 800 mg/day for accelerated-phase CML, and one with 800 mg/day for gastrointestinal stromal tumors (GISTs). The outcomes of the pregnancies that occurred during clinical trials were four normal infants, one SAB, two EAs (normal abortuses), one death in utero at 13 weeks' gestation, three with no information, and two with ongoing pregnancies. There was limited information on the five pregnancies in the voluntary reports, four of which were ongoing (2).

The manufacturer also had reports of 26 pregnancies exposed to imatinib, 15 in clinical trials and 11 from voluntary reports (2). In the first group, pregnancy was detected between 5 and 22 weeks' gestation and imatinib therapy was stopped. However, in one woman who was taking 600 mg/day for blast-crisis

CML and whose therapy was stopped at 22 weeks, imatinib was restarted when the leukemia relapsed. The woman ultimately delivered a normal infant at term. The remaining 14 women in the clinical trial were treated with 400 mg/day for chronic-phase CML. The pregnancy outcomes of these patients were one SAB, nine EAs (no information on abortuses), two pregnancies ongoing, one term normal infant, and one infant with hypospadias (timing of exposure not specified). In the voluntary reports group, pregnancy was detected at 5–23 weeks. Five of the women were being treated for chronic-phase CML (400 mg/day), three for accelerated-phase CML (600 mg/day), one for GIST (200 mg/day), and two unknown. The outcomes of these pregnancies were four SABs, two EAs (one because of hydrocephalus, congenital heart defect, and a two-vessel cord), two ongoing pregnancies, and three with no information (2).

In a 2004 case report, a woman with Philadelphia-positive chronic-phase CML was treated with imatinib 400 mg/day from before conception through the first 7 weeks of gestation (3). Imatinib was stopped immediately when the pregnancy was diagnosed and no further treatment was given until hydroxyurea was started at 29 weeks because of very high white blood cell count. A 2820-g female infant was delivered at 38 weeks' gestation. The infant was morphologically normal but developed pyloric stenosis at 8 weeks of age. She underwent successful surgical correction and is healthy and developing normally at 25 months of age (3).

In a 2005 case similar to the one above, the woman also had Philadelphia-positive chronic-phase CML (4). She had been treated with imatinib for 5 months when a pregnancy was detected at 8 weeks' gestation. Imatinib was stopped and the woman eventually delivered a healthy, 3200-g female in the 38th week. The infant was growing normally (4). Another 2005 report described two women, with the same diagnosis as above, who were treated with imatinib before and throughout three pregnancies (5). One patient taking 400 mg/day delivered a healthy but small (1870-g) infant that was doing well. This patient's second pregnancy ended in an SAB at about 2 months. The second woman took imatinib 200 mg/day and delivered not only a healthy but also small 2540-g infant (5).

A 2005 case report described two women with CML who were treated throughout pregnancy with imatinib 400 mg/day (6). Both women delivered healthy, term infants. The authors noted that long-term follow-up of the infants was required to look for late developing toxicity (6). In contrast, a fatal fetal outcome was reported in 2006 (7). The woman was treated for chronic-phase CML before and during the first 6 weeks of gestation until her pregnancy was

diagnosed. Therapy was stopped until the completion of the 1st trimester, at which time hydroxyurea was started. At 30 weeks', a fetal ultrasound revealed a meningocele and 4 weeks later the woman delivered a dead fetus (7).

A 36-year-old woman with accelerated-phase CML was treated with imatinib 600 mg/day until pregnancy was diagnosed in the 12th week (8). Imatinib was discontinued and she was treated with interferon- α for the remainder of the pregnancy. A healthy baby girl weighing 3280-g was delivered at 38 weeks' gestation. The infant was growing and developing normally at 44 months (8).

A 2006 retrospective study reported 19 pregnancies involving 18 patients (10 females and 8 males) with CML who were treated with imatinib (9). In the female patients, receiving 300–800 mg/day, pregnancy was diagnosed between 4 and 9 weeks' gestation and imatinib therapy was discontinued. The pregnancy outcomes (other therapy during remainder of pregnancy) were two SABs (none), one EA (none), seven (1 set of twins) normal infants (hydroxyurea three, interferon one, leukapheresis one, none two), and one infant with hypospadias (hydroxyurea and anagrelide started at 5 weeks'). The male patients, receiving 400–1000 mg/day, fathered eight infants (one fathered two) and an SAB occurred in the 9th pregnancy. One of the infants, a female delivered at 40 weeks' with a birth weight of about 3.4 kg, had a mild rotation of the small intestine that was corrected surgically shortly after birth (9).

In a 2009 report, pregnancy was diagnosed at 21 weeks' in a patient with CML who had been on imatinib throughout (10). Her therapy was changed to interferon- α and she delivered a healthy, full-term male infant who was developing normally (10). A brief 2009 case report described the outcome of a 34-year-old woman with CML who was treated during the first 4 months of an unplanned pregnancy with imatinib (400 mg/day) (11). When pregnancy was diagnosed, imatinib was stopped and hydroxyurea was started. At 37 weeks', she delivered a healthy 3.12-kg infant with Apgar scores of 9 and 10. The child was doing well at 26 months of age. Nine months later, she became pregnant again while on 800 mg/day of imatinib. The therapy was continued throughout pregnancy. She gave birth to a healthy 2.98-kg baby at 37 weeks' with Apgar scores of 10 and 10. The infant was doing well at 9 months of age (11). In a 2011 case report, the therapy of a 24-year-old patient with CML was changed at 10 weeks' from imatinib to hydroxyurea and maintained on the agent for the remainder of her pregnancy (12). A healthy 2.5-kg female baby was born at 37 weeks. At 1-year follow-up, her growth and development were normal (12).

A 27-year-old pregnant woman was diagnosed with Philadelphia chromosome-positive chronic-phase CML (13). Imatinib 400 mg/day was given

during 21–39 weeks' gestation, resulting in complete hematological and cytogenetic remission. Fetal growth was normal and a healthy male infant, without defects, was born at 39 weeks. Imatinib concentrations in cord blood and the infant's peripheral blood, 16 hours after the mother's last dose, were 338 ng/mL and 478 ng/mL, respectively (13).

BREASTFEEDING SUMMARY

Consistent with the molecular weight (about 494 for the free base) of the parent compound and the long elimination half-lives of imatinib (18 hours) and its active metabolite (40 hours), both are excreted into breast milk. In a brief 2007 report, a woman taking imatinib 400 mg/day was nursing her 1-month-old infant (14). Steady-state concentrations of the parent drug and metabolite were 1.1–1.4 mcg/mL and 0.8 mcg/mL, respectively. The milk:plasma ratios were 0.5 and 0.9, respectively. Based on the infant's weight, the estimated infant dose from milk was about 10% of the therapeutic dose. No adverse effects in the nursing infant were mentioned (14).

In a case described in the Fetal Risk Summary, a mother with Philadelphia chromosome-positive chronic-phase CML was receiving imatinib 400 mg/day (13). Breast milk concentrations were measured on postpartum days 7, 14, 15, and 16. The concentrations ng/mL (hours after a maternal dose) were 2385 (12 hours), 1430 (14 hours), 2623 (10 hours), 1921 (16 hours), and 2378 (12 hours). The baby had normal growth and development at 10 months of age (13).

A 34-year-old woman taking imatinib 400 mg/day for CML became pregnant and the drug was stopped (15). She delivered a healthy baby at term. Imatinib was immediately restarted and breastfeeding was not recommended. Plasma and milk concentrations of the parent drug and active metabolite were measured at 3, 27, 51, and 171 hours after the start of therapy. Plasma concentrations of imatinib and metabolite were 1301–2003 ng/mL and 177–301 ng/mL, respectively, whereas the milk concentrations were 751–1153 ng/mL and 409–1052 ng/mL, respectively (15).

IMIGLUCERASE

Endocrine/Metabolic Agent (Gaucher's Disease)

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

No imiglucerase-related adverse effects in embryos and fetuses have been reported in the limited data on pregnancies complicated by type I Gaucher's disease. Pregnancy may exacerbate existing disease or result in new disease manifestations, but the data suggest that treatment may reduce the risk of spontaneous abortion and bleeding complications. However, systematic human or animal studies have not been conducted. Nevertheless, a brief 2009 review cited a recommendation from the European Medicines Agency that in women receiving imiglucerase, treatment continuation throughout pregnancy should be considered (1).

FETAL RISK SUMMARY

Imiglucerase, an enzyme given by IV infusion, is used in the treatment of patients with type I Gaucher's disease. It is in the same pharmacologic subclass as alglucerase, taliglucerase alfa, and velaglucerase alfa. Imiglucerase replaces the endogenous enzyme β -glucocerebrosidase. Imiglucerase is produced by recombinant DNA technology and differs from the endogenous enzyme by one amino acid substitution. After infusion, the terminal elimination half-life is 3.6–10.4 minutes (2).

Reproduction studies with imiglucerase have apparently not been conducted. Moreover, the carcinogenic and mutagenic potential of imiglucerase has not been studied.

It is not known if imiglucerase crosses the human placenta. The relatively high molecular weight (about 55,600) and the short terminal half-life suggest that placental transfer will be limited.

A 2007 case report described the pregnancy outcome of a 23-year-old

woman with Gaucher's disease who was treated throughout gestation with imiglucerase 30 U/kg every 2 weeks (3). She gave birth to a healthy female infant at term (additional details not provided).

Outcomes of exposed pregnancies treated with either imiglucerase or the similar enzyme, alglucerase, have been summarized from surveys gathered from international treatment centers, from reports in the literature, as well as from the manufacturer's pharmacovigilance database. The total number of exposed patients is unclear as there could be overlap between the various sources of reports. However, as reviewed in a 2010 publication, among 43 to 78 treated pregnancies compared with 71 to 388 untreated pregnancies with the same disease, the risk of spontaneous abortion, disease-related bleeding complications at delivery, and disease-related complications postpartum were reduced. No evidence of teratogenic risk was noted (4,5). An additional four case reports (which may or may not have been included in the larger review) described successful pregnancy outcome in patients treated with imiglucerase, including three healthy liveborn singletons and one set of healthy liveborn twins (6–8).

BREASTFEEDING SUMMARY

Although the relatively high molecular weight (about 55,600) and the short terminal elimination half-life (3.6–10.4 minutes) suggest that excretion of the enzyme in milk will be limited, one case report did detect imiglucerase. Samples were collected from maternal serum and breast milk before and up to 24 hours after an imiglucerase IV infusion (8). Slightly increased enzymatic activity was observed in the first breast milk sample after the infusion, but levels were undetectable thereafter.

In a 2007 case report discussed earlier, a 23-year-old woman took imiglucerase 30 U/kg every 2 weeks throughout pregnancy and during the first 3 months of breastfeeding (3). Because of Gaucher's disease progression, her dose was increased to 60 U/kg every 2 weeks. She continued this dose until breastfeeding was discontinued at 1 year. Apparently, no toxicity was noted in the infant, but the infant's condition was not mentioned (3).

The effect, if any, on a nursing infant is unknown. However, the enzyme is probably digested in the infant's gut and is unlikely to reach the systemic circulation (1).
