IMIPENEM-CILASTATIN SODIUM

Antibiotic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest LowRisk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of this antibiotic–enzyme inhibitor combination in the 1st trimester of nonterminated human pregnancies have been located. Four sources consider imipenem–cilastatin to be a safe and effective agent during the perinatal period (1–4).

FETAL RISK SUMMARY

Imipenem, a semisynthetic carbapenem related to the β -lactam antibiotics, is only available in the United States in a 1:1 combination with the enzyme inhibitor cilastatin sodium. The latter agent is a specific, reversible inhibitor of dehydropeptidase I, an enzyme that is present in the proximal renal tubular cells and inactivates imipenem. By inhibiting this enzyme, cilastatin results in higher urinary concentrations of imipenem (5).

Reproductive studies in pregnant rabbits and rats with imipenem at doses up to 2 and 30 times, respectively, and with cilastatin sodium at 10 and 33 times, respectively, the maximum recommended human dose showed no evidence of adverse fetal effects. Similar negative findings were found with imipenem–cilastatin sodium in pregnant mice and rats treated with doses up to 11 times the maximum human dose (5).

Adverse effects observed in pregnant monkeys given either 40 mg/kg/day (IV) or 160 mg/kg/day (SC) included loss of appetite, weight loss, emesis, diarrhea, abortion, and death in some animals. No significant toxicity was observed in nonpregnant monkeys given 180 mg/kg/day SC. An IV infusion of 100 mg/kg/day (approximately three times the maximum daily recommended human IM dose) in pregnant monkeys did not produce significant maternal toxicity or teratogenic effects, but it did result in an increase in embryonic loss

(5).

Imipenem–cilastatin crosses the placenta to the fetus (1,6). Seven women at a mean gestational age of 8.6 weeks' gestation (immediately before pregnancy termination) and seven at a mean gestational age of 38.7 weeks were given a single 20-minute IV infusion of 500 mg of imipenem–cilastatin (6). A third, nonpregnant group was also studied. Maternal plasma and amniotic fluid samples were collected at frequent intervals for 8 hours. In comparison with nonpregnant women, imipenem concentrations in maternal plasma were significantly lower in both early and late pregnancy. The mean concentrations in the amniotic fluid in early and late pregnancy were 0.07 and 0.72 mcg/mL, respectively. At delivery, the mean cord venous and arterial blood concentrations were 1.72 and 1.64 mcg/mL, respectively, representing a fetal:maternal mean ratio of 0.33 (venous) and 0.31 (arterial). Transfer of both imipenem and cilastatin across the placenta at term was observed in two Japanese studies (1,2). Peak concentrations of both agents were about 30% of those measured in the maternal blood (2). Both drugs were also transferred to the amniotic fluid, with the highest concentrations occurring, after a single dose, at about 5–6 hours. Peak amniotic fluid:maternal blood ratios for imipenem and cilastatin were approximately 0.30 and 0.45, respectively (2).

In a 2005 study from Japan, the pregnancy outcomes of 100 women who had preterm premature rupture of membranes (PPROM) at 24–31 weeks' and who received imipenem/cilastatin sodium (plus betamethasone) were compared with a control group of 40 women with PPRM who were treated with other antibiotics, such as penicillins or cephalosporins, but not betamethasone (4). The mean time from PPRM to delivery in the study and control groups were 11 and 6 days, respectively. No infants died within 1 year of birth in the study group compared with five infants in controls (4).

BREASTFEEDING SUMMARY

Small amounts of imipenem–cilastatin are excreted into breast milk. These amounts are comparable to other β -lactam antibiotics (1). The effects, if any, on a nursing infant are unknown.

IMIPRAMINE

Antidepressant

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although structural anomalies have been reported following 1st trimester exposure to imipramine, no pattern of defects is evident when all reports are examined. Neonatal withdrawal is a potential complication when the drug is used near birth.

FETAL RISK SUMMARY

Shepard reviewed six animal reproductive studies involving imipramine in 1989 (1). Some defects were observed in one investigation using rabbits, but other studies with mice, rats, rabbits, and monkeys revealed no evidence of drug-induced teratogenicity.

Bilateral amelia was reported in one child whose mother had ingested imipramine during pregnancy (2). An analysis of 546,505 births, 161 with 1st trimester exposure to imipramine, however, failed to find an association with limb reduction defects (3–15). Reported malformations other than limb reduction included: defective abdominal muscles (1 case); diaphragmatic hernia (2 cases); exencephaly, cleft palate, adrenal hypoplasia (1 case); cleft palate (2 cases); and renal cystic degeneration (1 case) (4–6). These reports indicate that imipramine is not a major cause of congenital limb deformities.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 75 newborns had been exposed to imipramine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Six (8.0%) major birth defects were observed (three expected), including (observed/expected) 3/0.8 cardiovascular defects, 1/0.2 spina bifida, and 1/0.2 hypospadias. No anomalies were observed in three other defect categories (oral clefts, polydactyly, and limb reduction defects) for which specific data were available. Only with cardiovascular

defects is there a suggestion of an association, but other factors, including the mother's disease, concurrent drug use, and chance, may be involved.

In a 1996 descriptive case series, the European Network of the Teratology Information Services (ENTIS) prospectively examined the outcomes of 689 pregnancies exposed to antidepressants (16). Multiple drug therapy occurred in about two-thirds of the mothers. Imipramine exposure occurred in 30 pregnancies (1 set of twins). The outcomes of these pregnancies were 1 elective abortion, 3 spontaneous abortions, 25 normal newborns, and 2 infants with congenital defects. The defects (all exposed in the 1st trimester or longer) were six fingers on right hand, and an omphalocele (16).

Neonatal withdrawal symptoms have been reported with the use of imipramine during pregnancy (17–19). Symptoms observed in the infants during the 1st month after birth were colic, cyanosis, rapid breathing, and irritability. Urinary retention in the neonate has been associated with maternal use of nortriptyline (chemically related to imipramine) (20).

A 2002 prospective study compared two groups of mother–child pairs exposed to antidepressants throughout gestation (46 exposed to tricyclics—12 to imipramine; 40 to fluoxetine) with 36 nonexposed, not depressed controls (21). Offspring between the ages 15 and 71 months were studied for effects of antidepressant exposure in terms of IQ, language, behavior, and temperament. Exposure to antidepressants did not adversely affect the measured parameters, but IQ was significantly and negatively associated with the duration of depression, and language was negatively associated with the number of depression episodes after delivery (21).

BREASTFEEDING SUMMARY

Imipramine and its metabolite, desipramine, enter breast milk in low concentrations (22–24). A milk:plasma ratio of 1 has been suggested (22). Assuming a therapeutic serum level of 200 ng/mL, an infant consuming 1000 mL of breast milk would ingest a daily dose of about 0.2 mg. Ten nursing infants of mothers taking antidepressants (four with imipramine 75–150 mg/day) were compared with 15 bottle-fed infants of mothers with depression who did not breastfeed (24). Concentrations of imipramine in fore- and hindmilk ranged from 34 to 408 ng/mL and from 48 to 622 ng/mL, respectively. The milk:maternal plasma ratios were 0.7–1.7 and 1.2–2.3, respectively. In two infants, plasma levels were 0.6 ng/mL (mother's dose 75 mg/day) and 3.3–7.4 ng/mL (mother's dose 75–100 mg/day). No toxic effects or delays in development were observed in the infants. The estimated daily dose consumed

by the infants was about 1% of the mother's weight-adjusted dose (24).

The clinical significance of these amounts is unknown. The American Academy of Pediatrics classifies imipramine as an agent whose effect on the nursing infant is unknown but may be of concern (25).

IMIQUIMOD

Immunomodulator

PREGNANCY RECOMMENDATION: Limited Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The animal reproduction data suggest that the risk of embryo–fetal harm is low. Moreover, an in vitro study with cultured human placental trophoblasts found that the systemic imiquimod concentrations obtained clinically should not alter normal placental function. The human pregnancy experience, however, is limited. Although the combined data suggest that the potential for human developmental toxicity is low, the data are too limited for a more complete assessment. Until such data are available, the safest course is to avoid imiquimod in pregnancy, but if exposure does occur, the risk to the embryo and/or fetus appears to be low.

FETAL RISK SUMMARY

The topical immune response modifier imiquimod is indicated for the treatment of: clinically typical, nonhyperkeratotic, nonhypertrophic actinic keratoses on the face and scalp of immunocompetent adults; biopsy-confirmed primary superficial basal cell carcinoma in immunocompetent adults; and external genital and perianal warts/condyloma acuminata in individuals 12 years of age or older. Small amounts of imiquimod are absorbed systemically and are eliminated slowly with a half-life of about 20 hours. An average dose of 4.6 mg, applied to the affected skin of patients with genital/perianal warts, produced a mean peak serum drug concentration of 0.4 ng/mL. In patients with actinic keratoses treated for 16 weeks, peak serum drug concentrations were 0.1–3.5 ng/mL. The amount absorbed systemically appears to be more related to the surface area treated than to the dose (1).

In vitro studies conducted with imiquimod have shown that it stimulates the production of the cytokines interferon- α , interleukin-1 α , interleukin-1 β ,

interleukin-6, and interleukin-8 (2). Because placental trophoblasts also express many of these same cytokines, an in vitro study was conducted to determine if imiquimod exposure during pregnancy could alter normal placental function. In 1st trimester trophoblasts cultured with imiquimod concentrations up to 5.0 mcg/mL, no increase in any of the above interleukins was detected. The results suggested that imiquimod would not induce the expression of inflammatory cytokines in placenta trophoblasts (2).

Reproduction studies have been conducted with oral and IV doses in rats and rabbits. In rats during organogenesis, oral doses 577 times the maximum recommended human dose (MRHD) based on AUC (MRHD-AUC) caused maternal and fetal toxicity. The fetal effects included increased resorptions, decreased body weight, delays in skeletal ossification, and bent limb bones. Two fetuses, among 1567, had exencephaly, protruding tongues, and low-set ears. The no-observed-effect-level for embryo–fetal developmental toxicity was 98 times the MRHD-AUC. In rabbits during organogenesis, no embryo or fetal developmental toxicity was observed with IV doses up to 1.5 times the MRHD based on BSA or with a dose that was 407 times the MRHD-AUC (1).

When imiquimod was given to male and female rats before and during mating, no effects on fertility or mating were noted with oral doses up to 87 times the MRHD-AUC. When these doses were continued throughout pregnancy, parturition, and lactation, no effects were observed on growth or postnatal development. However, bent limb bones in the fetuses were noted, as they were with exposure during organogenesis, in the absence of maternal toxicity. No treatment-related effects were noted at 41 times the MRHD-AUC. Multiple tests with imiquimod revealed no evidence of mutagenic or clastogenic potential (1).

It is not known if imiquimod crosses the human placenta. The low molecular weight (about 240) and long elimination half-life after systemic absorption (about 20 hours) suggest that the drug will reach the embryo and/or fetus. However, because the systemic concentrations are very low, the actual exposure appears to be clinically insignificant.

A 2004 case report described the use of topical imiquimod for the treatment of condylomata acuminata in a woman at 16 weeks' gestation (3). The initial treatment was 3 nights a week for 4 weeks. Because there was very good clinical response, she was prescribed additional treatment, but the woman was lost to follow-up until she delivered vaginally at 41 weeks. The 3.74-kg normal female infant had Apgar scores of 6 and 10 at 1 and 10 minutes, respectively. Subsequent development was apparently normal (3).

A 2006 report described the outcomes of seven pregnancies exposed to topical imiquimod, all ending in live births with a mean birth weight of 3528 g (4). No major malformations or other adverse effects were noted in the infants. The drug had been used for genital warts in four cases and for warts of the hand, face, or foot in three. Doses of the 5% cream ranged from once daily to four times per week with durations ranging from 1 to 10 weeks (average 5 weeks). Two women used the drug in the 1st trimester, one in the 2nd trimester, two in the 2nd and 3rd trimesters, and two in the 3rd trimester only (4).

Two studies reported the use of imiquimod for the treatment of anogenital warts in a total of 21 pregnant women (5,6). No adverse pregnancy outcomes or fetal anomalies were observed.

BREASTFEEDING SUMMARY

No reports describing the use of imiquimod during lactation have been located. The relatively low molecular weight (about 240) and long elimination half-life (about 20 hours) suggest that the drug will be excreted into breast milk. However, the amount absorbed systemically and available for excretion into milk is very low and probably is clinically insignificant. Therefore, although the risk to a nursing infant is unknown, use of imiquimod by the mother appears to be compatible with breastfeeding.

IMMUNE GLOBULIN, HEPATITIS B

Serum

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The American College of Obstetricians and Gynecologists recommends use of hepatitis B immune globulin in pregnancy for postexposure prophylaxis (1).

FETAL RISK SUMMARY

Hepatitis B immune globulin is used to provide passive immunity following exposure to hepatitis B. When hepatitis B occurs during pregnancy, an increased rate of abortion and prematurity may be observed (1). No risk to the fetus from the immune globulin has been reported (1–3).

BREASTFEEDING SUMMARY

No reports describing the use of hepatitis B immune globulin during human lactation have been located.

IMMUNE GLOBULIN INTRAMUSCULAR

Serum

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The American College of Obstetricians and Gynecologists recommends the use of immune globulin intramuscular (IGIM) for postexposure prophylaxis of hepatitis A and measles (rubeola) (1). No risk to the fetus from this therapy has been reported (2).

FETAL RISK SUMMARY

A solution of immunoglobulin, primarily immunoglobulin G, IGIM is prepared from pooled plasma that takes 2–5 days to obtain adequate serum levels (3). It is indicated for postexposure prophylaxis of hepatitis A and measles (rubeola) and in the prevention of serious infections in patients with immunoglobulin deficiencies. In cases of rubella exposure of the pregnant woman, IGIM administered as soon as possible after exposure may prevent or modify maternal infection, but there is no evidence that it will prevent fetal infection (4). However, its use in such cases may be of benefit in women who will not consider therapeutic abortion.

BREASTFEEDING SUMMARY

No reports describing the use of IGIM during human lactation have been located.

IMMUNE GLOBULIN INTRAVENOUS

Serum

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No embryo–fetal risk attributable to immune globulin IV has been identified.

FETAL RISK SUMMARY

Immune globulin IV (IGIV) is a solution of immunoglobulin, primarily immunoglobulin G (IgG), prepared from pooled plasma that, in contrast to the IM preparation, provides immediate serum concentrations of antibodies (1).

IgG administered IV was shown to cross the human placenta in significant amounts only if the gestational age was >32 weeks (2). Placental transfer was also a function of dose, as well as gestational age. Four subclasses of IgG and two different antibodies in the preparation also crossed to the fetus in a similar manner (2). Others have found that the placental transfer of exogenous IgG depends on the dose and duration of treatment and, possibly, on the method of IgG preparation (3).

A 1988 review of IGIV summarized the clinical indications for the product in pregnancy (4). The indications included hypogammaglobulinemia such as common variable immunodeficiency, autoimmune diseases such as chronic immune thrombocytopenic purpura, and alloimmune disorders such as severe Rh-immunization disease and alloimmune thrombocytopenia. Recent reports have described the use of IGIV for the prevention of intracranial hemorrhage in fetal alloimmune thrombocytopenia (5,6), recurrent abortions caused by antiphospholipid antibodies (7,8), neonatal congenital heart block caused by maternal antibodies to Ro (SS-A) and La (SS-B) autoantigens (9), and severe isoimmunization with either Rh or Kell antibodies (10). No adverse effects were observed in the fetus or newborns in any of the above reports, but caution has been advised in its use to prevent spontaneous abortion (11).

BREASTFEEDING SUMMARY

No reports describing the use of immune globulin IV during human lactation have been located.

IMMUNE GLOBULIN, RABIES

Serum

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Rabies immune globulin is used to provide passive immunity following exposure to rabies combined with active immunization with rabies vaccine (1). Because rabies is nearly 100% fatal if contracted, both the immune globulin and the vaccine should be given for postexposure prophylaxis (1). No risk to the fetus from the immune globulin has been reported (see also Vaccine, Rabies [Human]) (1–3). The American College of Obstetricians and Gynecologists recommends use of rabies immune globulin in pregnancy for postexposure prophylaxis (1).

BREASTFEEDING SUMMARY

No reports describing the use of rabies immune globulin during human lactation have been located.

IMMUNE GLOBULIN, TETANUS

Serum

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Tetanus immune globulin is used to provide passive immunity following exposure to tetanus combined with active immunization with tetanus toxoid (1). Tetanus produces severe morbidity and mortality in both the mother and the newborn. No risk to the fetus from the immune globulin has been reported (1–3). The American College of Obstetricians and Gynecologists recommends the use of tetanus immune globulin in pregnancy for postexposure prophylaxis (1).

BREASTFEEDING SUMMARY

No reports describing the use of tetanus immune globulin during human lactation have been located.

IMMUNE GLOBULIN, VARICELLA-ZOSTER (HUMAN)

Serum

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The American College of Obstetricians and Gynecologists recommends that one IM dose of the immune globulin should be given to healthy pregnant women within 96 hours of exposure to varicella to protect against maternal, but not congenital, infection (1). There is no known fetal risk from exposure to immune globulin (2).

FETAL RISK SUMMARY

Varicella-zoster (human) immune globulin (VZIG) is obtained from the plasma of normal volunteer blood donors. In most of the United States, it is available from the American Red Cross Blood Services.

Varicella-zoster immune globulin is indicated for susceptible (seronegative) pregnant women exposed to chickenpox because of the increased severity of maternal chickenpox, including death, in adults compared with children (1,3–14). One reference cited the increased risk of complications in adults as 9- to 25-fold greater than in children (6). It is not known whether administration of VZIG to the mother will protect the fetus from infection or the low risk of defects associated with the congenital varicella syndrome (3,11,13,14). Moreover, VZIG may modify the mother's infection such that she has a subclinical, asymptomatic infection, but not prevent fetal infection or disease (3,11,12,14).

Congenital malformations following intrauterine varicella in pregnancy are relatively uncommon, but case reports have periodically appeared since 1947 (7–9,11,12,15–19). In addition to cicatricial skin lesions, defects associated with this syndrome involve the brain, eyes, skeleton, and gastrointestinal and genitourinary tracts, with the highest risk occurring if the mother has varicella

between the 8th and 21st weeks of gestation (7,9,11,19), although one case occurred when the mother had varicella at 25.5 weeks' gestation (20). One review (11) found that the incidence of congenital malformations after 1st trimester chickenpox infection was 2.3% (3/131; 95% confidence intervals 0.5–6.5%), but a second review (9) found a lower rate of 1.3% (4/308) if all cases of intrauterine varicella infection were included.

There is no known fetal risk from passive immunization of pregnant women with varicella-zoster immune globulin (1–3). Administration of VZIG to newborns of mothers who develop varicella within a 5-day interval before or 48 hours after delivery is recommended (1,3,7,13,14).

BREASTFEEDING SUMMARY

No reports describing the use of varicella-zoster immune globulin during human lactation have been located.

INDACATEROL

Respiratory Drug (Bronchodilator)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of indacaterol in human pregnancy have been located. The animal reproduction data suggest low risk, but the absence of human pregnancy experience prevents a more complete assessment of embryo–fetal risk. Nevertheless, only small amounts reach the systemic circulation, so if the drug is indicated, it should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Indacaterol is a long-acting β_2 -adrenergic agonist that is available as an inhalation powder. It is indicated for long-term, once-daily maintenance bronchodilator treatment of airflow obstruction in patients with chronic obstructive pulmonary disease (COPD), including chronic bronchitis and/or emphysema. The absolute bioavailability after an inhaled dose was, on average, 43–45%.

Indacaterol is extensively metabolized to apparently inactive metabolites. The human serum and plasma protein binding is about 95% and 96%, respectively. The average terminal half-life ranges from 45.5 to 126 hours (1).

Reproduction studies have been conducted with SC doses in rats and rabbits. In these species, indacaterol doses that were about 130 and 260 times, respectively, the human 75 mcg dose based on BSA were not teratogenic (1).

In carcinogenic studies, the drug showed no statistically significant increase in tumor formation in mice or rats. However, similar to other β_2 -adrenergic agonists, lifetime treatment in female rats resulted in an increased incidence of benign ovarian leiomyomas. Multiple assays for mutagenic or clastogenic

effects were negative. The drug did not impair fertility of rats in reproduction studies (1).

It is not known if indacaterol crosses the human placenta. The molecular weight (about 509) and long terminal half-life suggest that exposure of the embryo–fetus will occur. However, the high serum and plasma protein binding might limit the exposure. Moreover, a relatively small amount of the drug will reach the systemic circulation.

BREASTFEEDING SUMMARY

No reports describing the use of indacaterol during human lactation have been located. The molecular weight (about 509) and long terminal half-life (45.5–126 hours) suggest that the drug will be excreted into breast milk. However, the high serum and plasma protein binding (about 95% and 96%) might limit the exposure. Moreover, a relatively small amount of the drug will reach the systemic circulation. Taken in sum, the drug is probably compatible with breastfeeding.

INDAPAMIDE

Diuretic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Although not thought to be teratogenic, diuretics are not recommended for the treatment of gestational hypertension and preeclampsia because of the maternal hypovolemia characteristic of these conditions.

FETAL RISK SUMMARY

Indapamide is an oral active antihypertensive–diuretic of the indoline class that is closely related to the thiazide diuretics (see also Chlorothiazide for a discussion of this class of diuretics). No evidence of impaired fertility, fetal harm, or effect on postnatal development was observed in mice, rats, or rabbits given doses up to 6250 times the therapeutic human dose during pregnancy (1). However, fetal growth restriction has been reported in rats dosed at 1000 mg/kg/day (2).

In an FDA surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 46 newborns had been exposed to indapamide during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Three (6.5%) major birth defects were observed (two expected). Details on the malformations were not available, but no anomalies were observed in six defect categories (cardiovascular defects, oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available.

BREASTFEEDING SUMMARY

No reports describing the use of indapamide during lactation have been located. The closely related thiazide diuretics have been used to suppress lactation (see Chlorothiazide).

INDIGO CARMINE

Dye (Diagnostic)

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Indigo carmine is used as a diagnostic dye. No reports linking its use with congenital defects have been located. Intra-amniotic injection has been conducted without apparent effect on the fetus (1–4). Because of its known toxicities after IV administration, however, the dye should not be considered totally safe (5).

FETAL RISK SUMMARY

A report of jejunal atresia, possibly secondary to the use of methylene blue (see Methylene Blue) during genetic amniocentesis in pregnancies with twins was published in 1992 (6). A portion of this report described 67 newborns treated for the defect, 20 of whom were one of a set of twins. Of these latter cases, 2nd trimester amniocentesis had been performed with indigo carmine in 1 case and with methylene blue in 18 cases. An accompanying commentary noted that indigo carmine, like methylene blue, is a vasoconstrictor and may also induce small bowel atresia (7).

A brief 1993 report described the use of indigo carmine in women with twins who underwent amniocentesis between 1977 and 1991 in the United States (8). A total of 195 women were included, 78 (40%) of whom were administered indigo carmine during the procedure. Of the 156 fetuses (total data included live births, stillbirths, intrauterine deaths, and fetuses that were electively terminated; specific data for indigo carmine were not given), 7 (4.5%) had a major birth defect. Included in this number were two infants from the same set of twins who had syndactyly, one clubfoot, one hydrocephaly, one urethral obstruction sequence, and two multiple congenital defects (8). None of the exposed infants had small intestinal atresia.

BREASTFEEDING SUMMARY

No reports describing the use of indigo carmine during human lactation have been located.

INDINAVIR

Antiviral

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

The limited human data do not suggest a major embryo–fetal risk, but the animal data involving birth defects are a concern. The finding of anophthalmia in rat pups at a systemic exposure approximately equivalent to human exposure needs further investigation. The authors of that study also observed anophthalmia in a rat experiment with ritonavir (1 of 113 offspring, unpublished data), another protease inhibitor (1). An editorial, accompanying this study, reviewed how the changes in the treatment of HIV disease (e.g., multiple combinations of drugs and use of agents throughout gestation) were altering the risk:benefit ratio of antiretroviral therapy during pregnancy (2). However, if indicated, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

The antiretroviral agent, indinavir, is an inhibitor of the HIV protease, an enzyme that is required for the cleavage of viral polyprotein precursors into active functional proteins found in infectious HIV.

Indinavir was not teratogenic in rats and rabbits at doses comparable to or slightly higher than those used in humans (3). In rats, however, an increase in the incidence of supernumerary ribs (at exposures at or less than those in humans) and cervical ribs (at exposures at or slightly greater than those in humans) were observed. These changes were not observed in rabbits and no effects were noted on embryonic and/or fetal survival or on fetal weight in either rats or rabbits. A study in dogs (because fetal exposure was about 2% of maternal levels in rabbits) observed no indinavir-related effects on embryo or fetal survival, fetal weight, or teratogenicity. At the highest dose tested in dogs, 80 mg/kg/day, fetal drug levels were about 50% of the maternal levels (3).

A study of the developmental toxicity of indinavir in rats was reported in 2000 (1). Pregnant rats were given an oral dose of 500 mg/kg once daily during day 6 to 15 of gestation or twice daily from day 9 to 11 of gestation (a dose of 640 mg/kg/day produces systemic exposure in the rat that is comparable to or slightly greater than human exposure). In both groups, an increased incidence of supernumerary ribs and variations of the vertebral ossification centers occurred, but no effects on litter sizes, fetal weight, or viability were observed. Unilateral anophthalmia was observed in 7 pups (3%) from 2 of the 19 litters. On examination, the ocular bulbs were noted to be absent and the bulbar cavity was filled with an enlarged lacrimal gland. No such cases were noted in controls. Other postnatal abnormalities included delayed fur development, eye opening, and slightly earlier descent of the testis. In addition, some liver changes were noted in dams (hepatocellular inclusions of lipids and myelin figure-like structures) and in offspring (infiltration with granulocytes) (1).

It is not known if indinavir crosses the human placenta. The molecular weight (about 712 for the sulfate salt) is low enough that transfer to the fetus should be expected. The drug has been found in fetal plasma of rats, rabbits, dogs, and monkeys (3). In monkeys, fetal plasma drug levels were 1%–2% of maternal plasma levels about 1 hour after a dose given in the 3rd trimester (3).

The pharmacokinetics of indinavir during pregnancy has been reported in two women (800 mg every 8 hours) (4). A marked decrease in maternal drug concentrations occurred around 33–34 weeks' gestation, suggesting that women may be exposed to subtherapeutic levels late in pregnancy.

The Antiretroviral Pregnancy Registry reported, for the period January 1989 through July 2009, prospective data (reported before the outcomes were known) involving 4702 live births that had been exposed during the 1st trimester to one or more antiretroviral agents (5). Congenital defects were noted in 134, a prevalence of 2.8% (95% confidence interval [CI] 2.4–3.4). In the 6100 live births with earliest exposure in the 2nd/3rd trimester, there were 153 infants with defects (2.5%, 95% CI 2.1–2.9). The prevalence rates for the two periods did not differ significantly. There were 288 infants with birth defects among 10,803 live births with exposure anytime during pregnancy (2.7%, 95% CI 2.4–3.0). The prevalence rate did not differ significantly from the rate expected in a nonexposed population. There were 436 outcomes exposed to indinavir (276 in the 1st trimester and 160 in the 2nd/3rd trimester) in combination with other antiretroviral agents. There were nine birth defects (six in the 1st trimester and three in the 2nd/3rd trimester). In reviewing the birth defects of prospective and retrospective (pregnancies reported after the outcomes were known)

registered cases, the Registry concluded that, except for isolated cases of neural tube defects with efavirenz exposure in retrospective reports, there was no other pattern of anomalies (isolated or syndromic) (5) (see Lamivudine for required statement).

In an unusual case, a woman was exposed to HIV through self-insemination with fresh semen obtained from a man with a high HIV ribonucleic acid viral load (>750,000 copies/mL plasma) (6). Ten days later, she was started on a prophylactic regimen of indinavir (2400 mg/day), zidovudine (600 mg/day), and lamivudine (300 mg/day). Pregnancy was confirmed 14 days after insemination. Four weeks after the start of therapy, the indinavir dose was reduced to 1800 mg/day because of the development of renal calculi. The antiretroviral therapy was stopped after 9 weeks because of negative tests for HIV. She gave birth at 40 weeks' gestation to a healthy 3490-g male infant, without evidence of HIV disease, who was developing normally at 2 years of age (6).

The experience of one perinatal center with the treatment of HIV-infected pregnant women was summarized in a 1999 abstract (7). Of 55 women receiving ≥ 3 antiviral drugs, 39 were treated with a protease inhibitor (5 with indinavir). The outcomes included 2 spontaneous abortions, 5 elective abortions, 27 newborns, and 5 ongoing pregnancies. One woman was taken off indinavir because of ureteral obstruction and another woman (drug therapy not specified) developed gestational diabetes. None of the newborns tested positive for HIV or had major congenital anomalies or complications (7).

A study published in 1999 evaluated the safety, efficacy, and perinatal transmission rates of HIV in 30 pregnant women receiving various combinations of antiretroviral agents (8). Many of the women were substance abusers. Protease inhibitors (indinavir N = 6, nelfinavir N = 7, and saquinavir N = 1 in combination with nelfinavir) were used in 13 of the women. Antiretroviral therapy was initiated at a median of 14 weeks' gestation (range preconception to 32 weeks). In spite of previous histories of extensive antiretroviral experience and of vertical transmission of HIV, combination therapy was effective in treating maternal disease and in preventing transmission to the current newborns. The outcomes of the pregnancies treated with protease inhibitors appeared to be similar to the 17 cases in which these were not used, except that the birth weights were lower (8).

Indinavir has frequently produced hyperbilirubinemia in adults, but it is not known whether treatment of the mother prior to delivery will exacerbate physiologic hyperbilirubinemia in the neonate (3). No such effects have been observed in monkey neonates exposed in utero to indinavir during the 3rd

trimester.

A public health advisory was issued by the FDA on the association between protease inhibitors and diabetes mellitus (9). Because pregnancy is a risk factor for hyperglycemia, there was concern that these antiviral agents would exacerbate this risk. An abstract published in 2000 described the results of a study involving 34 pregnant women treated with protease inhibitors (4 with indinavir) compared with 41 controls that evaluated the association with diabetes (10). No relationship between protease inhibitors and an increased incidence of gestational diabetes was found.

A multicenter, retrospective survey of pregnancies exposed to protease inhibitors was published in 2000 (11). There were 92 liveborn infants delivered from 89 women (3 sets of twins) at six health care centers. One nonviable infant, born at 22 weeks' gestation, died. The surviving 91 infants were evaluated in terms of adverse effects, prematurity rate, and frequency of HIV-1 transmission. Most of the infants were exposed in utero to a single protease inhibitor, but a few were exposed to more than one because of sequential or double-combined therapy. The number of newborns exposed to each protease inhibitor was indinavir (N = 23), nelfinavir (N = 39), zidovudine (N = 5), and saquinavir (N = 34). Protease inhibitors were started before conception in 18, during the 1st, 2nd, or 3rd trimester in 12, 44, and 14, respectively, and not reported in one. Other antiretrovirals used with the protease inhibitors included four nucleoside reverse transcriptase inhibitors (NRTIs) (didanosine, lamivudine, stavudine, and zidovudine). The most common NRTI regimen was a combination of zidovudine and lamivudine (65% of women). In addition, seven women were enrolled in the AIDS Clinical Trials Group Protocol 316 and, at the start of labor, received either a single dose of the nonnucleoside reverse transcriptase inhibitor, nevirapine, or placebo. Maternal conditions, thought possibly or likely to be related to therapy, were mild anemia in eight, severe anemia in one (probably secondary to zidovudine), and thrombocytopenia in one. Gestational diabetes mellitus was observed in three women (3.3%), a rate similar to the expected prevalence of 2.6% in a nonexposed population. One mother developed postpartum cardiomyopathy and died 2 months after birth of twins, but the cause of death was not known. For the surviving newborns, there was no increase in adverse effects over that observed in previous clinical trials of HIV-positive women, including the prevalence of anemia (12%), hyperbilirubinemia (6%; none exposed to indinavir), and low birth weight (20.6%). Premature delivery occurred in 19.1% of the pregnancies (close to the expected rate). The percentage of infants infected with HIV was 0 (95% CI

0–3%) (11).

Two reviews, one in 1996 and the other in 1997, concluded that all women receiving antiretroviral therapy should continue to receive therapy during pregnancy and that treatment of the mother with monotherapy should be considered inadequate therapy (12,13). The same conclusion was reached in a 2003 review with the added admonishment that therapy must be continuous to prevent emergence of resistant viral strains (14). In 2009, the updated U.S. Department of Health and Human Services guidelines for the use of antiretroviral agents in HIV-1-infected patients continued the recommendation that therapy, with the exception of efavirenz, should be continued during pregnancy (15). If indicated, therefore, protease inhibitors, including indinavir, should not be withheld in pregnancy because the expected benefit to the HIV-positive mother outweighs the unknown risk to the fetus. Pregnant women taking protease inhibitors should be monitored for hyperglycemia. Updated guidelines for the use of antiretroviral drugs to reduce perinatal HIV-1 transmission also were released in 2010 (16). Women receiving antiretroviral therapy during pregnancy should continue the therapy but, regardless of the regimen, zidovudine administration is recommended during the intrapartum period to prevent vertical transmission of HIV to the newborn (16).

BREASTFEEDING SUMMARY

No reports describing the use of indinavir during lactation have been located. The molecular weight (about 712 for the sulfate salt) is low enough that excretion into breast milk should be expected.

Reports on the use of indinavir during lactation are unlikely because of the potential toxicity in the nursing infant, especially hyperbilirubinemia, and because the drug is indicated in the treatment of patients with HIV. HIV-1 is transmitted in milk, and in developed countries, breastfeeding is not recommended (12,13,15,17–19). In developing countries, breastfeeding is undertaken, despite the risk, because there are no affordable milk substitutes available. Until 1999, no studies have been published that examined the effect of any antiretroviral therapy on HIV-1 transmission in milk. In that year, a study involving zidovudine was published that measured a 38% reduction in vertical transmission of HIV-1 infection despite breastfeeding when compared with controls (see Zidovudine).

INDOMETHACIN

Nonsteroidal Anti-inflammatory

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 1st and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Indomethacin use during the latter part of pregnancy may cause severe fetal toxicity. Short-term use, such as 24–48 hours, lessens the risk. Based on animal data, prostaglandin synthesis inhibitors, including indomethacin, might block blastocyst implantation. Nonsteroidal anti-inflammatory agents (NSAIDs) also have been associated with spontaneous abortions (SABs) and congenital malformations, but the absolute risk appears to be low.

FETAL RISK SUMMARY

Indomethacin is an NSAID. It is indicated for the relief of the signs and symptoms of moderate-to-severe rheumatoid arthritis, osteoarthritis, gouty arthritis, ankylosing spondylitis, and acute painful shoulder (bursitis and/or tendonitis). Indomethacin is in the same subclass (acetic acids) as three other NSAIDs (diclofenac, sulindac, and tolmetin).

Shepard (1) reviewed four reproduction studies on the use of indomethacin in mice and rats. Fused ribs, vertebral abnormalities, and other skeletal defects were seen in mouse fetuses, but no malformations were observed in rats except for premature closure of the ductus arteriosus in some fetuses. A 1990 report described an investigation on the effects of several nonsteroidal anti-inflammatory agents on mouse palatal fusion both in vivo and in vitro (2). All of the compounds were found to induce some degree of cleft palate, although indomethacin was associated with the lowest frequency of cleft palate of the five agents tested (diclofenac, indomethacin, mefenamic acid, naproxen, and sulindac).

Indomethacin crosses the placenta to the fetus with concentrations in the fetus equal to those in the mother (3). Twenty-six women, between 23 and 37

weeks' gestation, who were undergoing cordocentesis for varying indications, were given a single 50-mg oral dose approximately 6 hours before the procedure. Mean maternal and fetal indomethacin levels were 218 and 219 ng/mL, respectively, producing a mean ratio of 0.97. The mean amniotic fluid level, 21 ng/mL, collected during cordocentesis, was significantly lower than the maternal and fetal concentrations. Neither fetal nor amniotic fluid concentrations varied with gestational age.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 114 newborns had been exposed to indomethacin during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Seven (6.1%) major birth defects were observed (five expected), two of which were cardiovascular defects (one expected). No anomalies were observed in five other defect categories (oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available.

A combined 2001 population-based, observational cohort study and a case–control study estimated the risk of adverse pregnancy outcome from the use of NSAIDs (4). The use of NSAIDs during pregnancy was not associated with congenital malformations, preterm delivery, or low birth weight, but a positive association was discovered with SABs. A similar study, also published in 2001, failed to find a relationship, in general, between NSAIDs and congenital malformations, but did find a significant association with cardiac defects and orofacial clefts (5). In addition, a 2003 study found a significant association between exposure to NSAIDs in early pregnancy and SABs (6) (see Ibuprofen for details on these three studies).

A brief 2003 editorial on the potential for NSAID-induced developmental toxicity concluded that NSAIDs, and specifically those with greater COX-2 affinity, had a lower risk of this toxicity in humans than aspirin (7).

Indomethacin is occasionally used in the treatment of premature labor (8–40). The drug acts as a prostaglandin synthesis inhibitor and is an effective tocolytic agent, including in those cases resistant to β -mimetics. Niebyl (33) reviewed this topic in 1981. Daily doses ranged from 100 to 200 mg usually by the oral route, but rectal administration was used as well. In most cases, indomethacin, either alone or in combination with other tocolytics, was successful in postponing delivery until fetal lung maturation had occurred. More recent reviews on the use of indomethacin as a tocolytic agent appeared in 1992 (37) and 1993 (38). The latter review concluded that the prostaglandin synthesis inhibitors, such as indomethacin, might be the only effective tocolytic

drugs (38).

In a 1986 report, 46 infants exposed in utero to indomethacin for maternal tocolysis were compared with two control groups: (a) 43 infants exposed to other tocolytics and (b) 46 infants whose mothers were not treated with tocolytics (34). Indomethacin-treated women received one or two courses of 150 mg orally over 24 hours, all before 34 weeks' gestation. No significant differences were observed between the groups in Apgar scores, birth weight, or gestational age at birth. Similarly, no differences were found in the number of neonatal complications such as hypocalcemia, hypoglycemia, respiratory distress syndrome, need for continuous positive airway pressure, pneumothorax, patent ductus arteriosus, sepsis, exchange transfusion for hyperbilirubinemia, congenital anomalies, or mortality (34).

A 1989 study compared indomethacin, 100-mg rectal suppository followed by 25 mg orally every 4 hours for 48 hours, with IV ritodrine in 106 women in preterm labor with intact membranes who were at a gestational age of ≤ 32 weeks (39). Fifty-two women received indomethacin and 54 received ritodrine. Thirteen (24%) of the ritodrine group developed adverse drug reactions severe enough to require discontinuance of the drug and a change to magnesium sulfate: cardiac arrhythmia (N = 1), chest pain (N = 2), tachycardia (N = 3), and hypotension (N = 7). None of the indomethacin-treated women developed drug intolerance ($p < 0.01$). The outcomes of the pregnancies were similar, regardless of whether delivery occurred close to the time of therapy or not. Of those delivered within 48 hours of initiation of therapy, the mean glucose level in the ritodrine-exposed newborns (N = 9) was significantly higher than the level in those exposed to indomethacin (N = 8), 198 vs. 80 mg/dL ($p < 0.05$), respectively. No cases of premature closure of the ductus arteriosus or pulmonary hypertension were observed. A reduction in amniotic fluid volume was noted in 3 (5.6%) of the ritodrine group and in 6 (11.5%) of those treated with indomethacin. With regard to cost, tocolysis with indomethacin was 17 times less costly than tocolysis with ritodrine (39).

The tocolytic effects of indomethacin and magnesium sulfate (MgSO_4) were compared in a study of women in labor at less than 32 weeks' gestation (40). A total of 49 women were treated with indomethacin, 100 mg per rectum followed by 25 mg orally every 4 hours for 48 hours, whereas 52 women were administered IV MgSO_4 . Women who had responded to the initial treatment were then changed to oral terbutaline. All women received betamethasone and vitamin K and some received IV phenobarbital as prophylaxis against hyaline membrane disease and neonatal intracranial hemorrhage. Both indomethacin

and MgSO_4 were effective in delaying delivery more than 48 hours, 90% vs. 85%, respectively, and combined with terbutaline, in extending the gestation, 22.9 vs. 22.7 days, respectively (40). Renal function of the newborns delivering at ≤ 48 hours (indomethacin, $N = 5$; MgSO_4 , $N = 8$) as measured by blood urea nitrogen, creatinine, and urine output during the first 2 days after birth were statistically similar between the groups. Other neonatal outcomes, including the incidence of respiratory distress syndrome, intraventricular hemorrhage (all grades), and intraventricular hemorrhage (grades 3 and 4), were also similar. Tocolytic therapy was discontinued in eight (15%) of the women treated with MgSO_4 because of maternal adverse reactions compared with none in the indomethacin group ($p < 0.05$) (40).

Complications associated with the use of indomethacin during pregnancy may include premature closure of the ductus arteriosus, which may result in primary pulmonary hypertension of the newborn and, in severe cases, neonatal death (8–12,37,38,41–48). Ductal constriction is dependent on the gestational age of the fetus, starting as early as 27 weeks (49,50), and increasing markedly at 27–32 weeks (50,51), and occur with similar frequencies in singleton and multiple gestations (51). Further, constriction is independent of fetal serum indomethacin levels (49,50). Primary pulmonary hypertension of the newborn is caused by the shunting of the right ventricular outflow into the pulmonary vessels when the fetal ductus arteriosus narrows. This results in pulmonary arterial hypertrophy (48). Persistent fetal circulation occurs after birth secondary to pulmonary hypertension shunting blood through the foramen ovale, bypassing the lungs and still patent ductus arteriosus, with resultant difficulty in adequate oxygenation of the neonate (48).

Using fetal echocardiography, researchers described the above effects in a study of 13 women (14 fetuses, 1 set of twins) between the gestational ages of 26.5 and 31.0 weeks (48). The patients were treated with 100–150 mg of indomethacin orally per day. Fetal ductal constriction occurred in 7 of 14 fetuses 9.5–25.5 hours after the first dose and was not correlated with either gestational age or maternal indomethacin serum levels. In two other cases not included in the present series, ductal constriction did not occur until several weeks after the start of therapy. Tricuspid regurgitation was observed in three of the fetuses with ductal constriction. This defect was caused by the constriction-induced elevated pressure in the right ventricular outflow tract producing mild endocardial ischemia with papillary muscle dysfunction (48). All cases of constriction, including two of the three with tricuspid regurgitation, resolved within 24 hours after indomethacin was discontinued. The third

tricuspid case returned to normal 40 hours after resolution of the ductal constriction. No cases of persistent fetal circulation were observed in the 11 newborns studied. Some have questioned the methods used in the aforementioned study and whether the results actually reflected fetal ductal constriction (52). In response, the authors of the original paper defended their techniques based on both animal and human experimental findings (53).

A 1987 report described a patient with premature labor who was treated for 29 days between 27 and 32 weeks' gestation with a total indomethacin dose of 6.2 g (54). The woman delivered a female infant who had patent ductus arteriosus that persisted for 4 weeks. A macerated twin fetus, delivered at the same time as the surviving infant, was thought to have died before the initiation of treatment.

Administration of indomethacin to the mother results in reduced fetal urine output. Severe oligohydramnios, meconium staining, constriction of the ductus arteriosus, and death were reported in the offspring of three women treated for preterm labor at 32–33 weeks' gestation (55). Indomethacin doses were 100 mg (1 case) and 400 mg (2 cases) during the first 24 hours, followed by 100 mg/day for 2–5 days. Two of the fetuses were stillborn, and the third died within 3 hours of birth. A second report described a woman with preterm labor at 24 weeks' gestation, who was treated with IV ritodrine and indomethacin, 300 mg/day, for 8 weeks (56). A reduction in the amount of amniotic fluid was noted at 28 weeks' gestation (after 4 weeks of therapy), and severe oligohydramnios was present 4 weeks later. Filling of the fetal bladder could not be visualized at this time. The infant, who died 47 hours after birth, had the characteristic facies of Potter's syndrome (i.e., oligohydramnios sequence), but autopsy revealed a normal urinary tract with normal kidneys. Both cardiac ventricles were hypertrophic and the lungs showed no evidence of pulmonary hypertension (56).

In a 1987 study involving eight patients with polyhydramnios and premature uterine contractions, indomethacin, administered by oral tablets or vaginal suppositories in a dose of 2.2–3.0 mg/kg/day, resolved the condition in each case (57). Four of the patients had diabetes mellitus. The gestational age of the patients at the start of treatment ranged between 21.5 and 34 weeks. The duration of therapy, which was stopped between 34.5 and 38 weeks' gestation, ranged from 2 to 11 weeks. The average gestational age at birth was 38.6 weeks and none was premature. All infants were normal at birth and at follow-up for 2–6 months. In addition to the reduced urine output, indomethacin was thought to have minimized the amount of fluid produced by the amnion and

chorion (57).

A case report described a 33-year-old woman with a low serum α -fetoprotein level at 16 weeks' gestation and symptomatic polyhydramnios and preterm labor at 26 weeks' gestation who was treated with indomethacin, 25 mg orally every 4 hours, after therapeutic decompression had removed 3000 mL of amniotic fluid (58). During the 9 weeks of therapy, periodic fetal echocardiography was conducted to ensure that the fetal ductus arteriosus remained patent. Fetal urine output declined significantly (<50%) as determined by ultrasound examinations during therapy. Therapy was stopped at 35 weeks' gestation, and a 2280-g female infant was delivered vaginally a week later. Chromosomal analysis of the amniotic fluid at 26 weeks and of the infant after birth revealed 46 chromosomes with an additional marker or ring chromosome. No structural defects were noted in the infant, who was developing normally at 3 months of age (58).

In two women treated for premature labor, indomethacin-induced oligohydramnios was observed at 1 and 3.5 weeks, respectively, after starting therapy (59). Treatment was continued for 3 weeks in one patient and for 8 weeks in the other, with therapy discontinued at 31 and 32 weeks' gestation, respectively. Within a week of stopping indomethacin, amniotic fluid volume had returned to normal in both patients. Ultrasonography revealed that both fetuses had regular filling of their bladders. The newborns, delivered 3–4 weeks after indomethacin treatment was halted, had normal urine output. Neither premature closure of the ductus arteriosus nor pulmonary hypertension was observed (59). Another case of reversible indomethacin-induced oligohydramnios was reported in 1989 (60). The woman was treated from 20 to 28 weeks' gestation with indomethacin, 100–200 mg/day, plus various other tocolytic agents for premature labor. Ten days after indomethacin therapy was stopped, the volume of amniotic fluid was normal. She was eventually delivered of a 2905-g female infant at 36 weeks' gestation. Development was normal at 1 year of age (60).

The effects of tocolytic therapy on amniotic fluid volume were the subject of a 1989 study (61). Of 27 women meeting the criteria for the study, 13 were treated either with indomethacin alone (N = 9) or indomethacin combined with ritodrine (N = 2), terbutaline (N = 1), or magnesium sulfate (N = 1). Indomethacin dosage varied from 100 to 200 mg/day with a mean duration of treatment of 15.3 days (range 5–44 days). Four other patients were treated with ibuprofen, another nonsteroidal anti-inflammatory agent. Fourteen of the seventeen patients (82.3%) either had a decrease in amniotic fluid volume to

low-normal levels or had oligohydramnios compared with none of the 10 women treated only with terbutaline, ritodrine, or magnesium sulfate ($p < 0.001$). The mean time required to reaccumulate amniotic fluid in 7 women after stopping nonsteroidal anti-inflammatory therapy was 4.4 days. In one other woman who had an ultrasound examination after therapy was discontinued, amniotic fluid volume remained in the low-normal range (61).

A study published in 1988 described the treatment with indomethacin, 100–150 mg/day, for premature labor in eight women at 27–32 weeks' gestation (62). Fetal urine output fell from a mean pretreatment value of 11.2 to 2.2 mL/hour at 5 hours, then stabilized at 1.8 mL/hour at 12 and 24 hours. Mean output 24 hours after stopping indomethacin was 13.5 mL/hour. No correlation was found between maternal indomethacin serum levels and hourly fetal urine output. Three of the four fetuses treated with indomethacin every 4 hours had ductal constriction at 24 hours that apparently resolved after therapy was halted. All newborns had normal renal function in the neonatal period.

Fetal adverse effects described during treatment of premature labor with indomethacin in recent studies include primary pulmonary hypertension (four cases) (35,63), ductal constriction with or without tricuspid regurgitation (36,64–67), and, in infants less than 30 weeks' gestation, a significantly increased incidence compared with controls of intracranial hemorrhage, necrotizing enterocolitis, and patent ductus arteriosus requiring ligation (68,69). A possible interaction between cocaine abuse and indomethacin resulting in fetal anuria, generalized massive edema, and neonatal gastrointestinal hemorrhage has been reported (70).

A number of reports have described the use of indomethacin for the treatment of symptomatic polyhydramnios in singleton and multiple pregnancies (71–82), including a 1991 review of this indication (83). Indomethacin-induced constriction of the ductus arteriosus and tricuspid regurgitation were observed in some of the studies (70,72,74,80). In one report, indomethacin was used to treat polyhydramnios because of feto-fetal transfusion syndrome in two sets of twins (80). One twin survived from each pregnancy, but one was oliguric (urine output 0.5 mL/kg/hour) and the other was anuric requiring peritoneal dialysis. The authors speculated that the renal failure in both infants was secondary to indomethacin. A unilateral pleural effusion developed in one twin fetus after 28 days of indomethacin therapy for polyhydramnios, possibly because of ductus arteriosus constriction (82). The condition resolved completely within 48 hours of stopping the drug.

A probable drug interaction between indomethacin and β -blockers resulting in

severe maternal hypertension was reported in two women in 1989 (84). One woman, with a history of labile hypertension of 6 years' duration, was admitted at 30 weeks' gestation for control of her blood pressure. She was treated with propranolol 80 mg/day with good response. Indomethacin was started because of premature uterine contractions occurring at 32 weeks' gestation. An initial 200-mg rectal dose was followed by 25 mg orally/day. On the 4th day of therapy, the patient suffered a marked change in blood pressure, which rose from 135/85 mmHg to 240/140 mmHg, with cardiocographic signs of fetal distress. A cesarean section was performed, but the severely growth-restricted newborn died 72 hours later. The second patient developed signs and symptoms of preeclampsia at 31 weeks' gestation. She was treated with pindolol 15 mg/day with good blood pressure response. Two weeks later, indomethacin was started, as in the first case, for preterm labor. On the 5th day of therapy, blood pressure rose to 230/130 mmHg. Signs of fetal distress were evident and a cesarean section was performed. The low-weight infant survived (84). In a brief letter referring to the above study, one author proposed that the mechanism of nonsteroidal anti-inflammatory-induced hypertension may be related to the inhibition of prostaglandin synthesis in the renal vasculature (85). On the basis of this theory, the author recommended that all similar agents should be avoided in women with preeclampsia. Although the mechanism is unknown, one source has reviewed several cases of the interaction and observed that indomethacin may inhibit the effects of β -blockers, as well as antihypertensives in general (86).

Severe complications after in utero exposure to indomethacin were reported in three preterm infants (87). The three mothers had been treated with indomethacin, 200–300 mg/day, for 4 weeks, 3 days, and 2 days, respectively, immediately before delivery. Complications in the newborns included edema or hydrops, oliguric renal failure (<0.5 mL/kg/hour) lasting for 1–2 days, gastrointestinal bleeding occurring on the 4th and 6th days (2 infants), subcutaneous bruising, intraventricular hemorrhage (1 infant), absent platelet aggregation (2 infants; not determined in the third infant), and perforation of the terminal ileum. The authors attributed the problems to maternal indomethacin therapy because of (a) the absence of predisposing factors, and the lack of diagnostic evidence, for necrotizing enterocolitis, and (b) the close similarity and sequential pattern of the signs and symptoms in the three newborns (87).

A single case of phocomelia with agenesis of the penis has been described, but the relationship between indomethacin and this defect is unknown (88). Inhibition of platelet aggregation may have contributed to postpartum

hemorrhage in 3 of 16 women given a 100-mg indomethacin suppository during term labor (19).

The use of indomethacin as a tocolytic agent during the latter half of pregnancy may cause constriction of the fetal ductus arteriosus, with or without tricuspid regurgitation. These effects are usually transient and reversible if therapy is stopped at an adequate time before delivery. Premature closure of the ductus arteriosus can result in primary pulmonary hypertension of the newborn that, in severe cases, may be fatal (89). Reduced fetal urine output should be expected when indomethacin is administered to the mother. This may be therapeutic in cases of symptomatic polyhydramnios, but the complications of this therapy may be severe. Oliguric renal failure, hemorrhage, and intestinal perforation have been reported in premature infants exposed immediately before delivery. Use of indomethacin with antihypertensive agents, particularly the β -blockers, has been associated with severe maternal hypertension and resulting fetal distress. Short courses of indomethacin, such as 24–48 hours with allowance of at least 24 hours or more between the last dose and delivery, should prevent complications of this therapy in the newborn. Use of the smallest effective dose is essential, although maternal serum levels of indomethacin that are effective for tocolysis have not yet been defined (48) and, at least one complication, ductal constriction, is independent of fetal drug serum levels (49,50). Restriction of indomethacin tocolysis to gestational ages between 24 and 32 completed weeks, when therapy for premature labor is most appropriate, will also lessen the incidence of complications (38), although a higher rate of newborn complications has been observed when delivery occurred before 30 weeks' gestation (68,69). Other uses of indomethacin, such as for analgesia or inflammation, have not been studied in pregnancy but should be approached with caution because of the effects described above. Moreover, women attempting to conceive should not use any prostaglandin synthesis inhibitor, including indomethacin, because of the findings in a variety of animal models that indicate these agents block blastocyst implantation (90,91).

BREASTFEEDING SUMMARY

Indomethacin is excreted in breast milk. Although an earlier reference speculated that milk levels were similar to maternal plasma levels (92), a study published in 1991 reported a median milk:plasma ratio of 0.37 in 7 of 16 women taking 75–300 mg/day (93). The other nine women did not have measurable drug levels in both milk and plasma. The investigators calculated that the total infant dose ingested (assuming 100% absorption) ranged from

0.07% to 0.98% (median 0.18%) of the weight-adjusted maternal dose (93).

A case report of possible indomethacin-induced seizures in a breastfed infant has been published (92), although the causal link between the two events has been questioned (94). The mother was taking 200 mg/day (3 mg/kg/day). The American Academy of Pediatrics noted the above possible adverse reaction but classified indomethacin as compatible with breastfeeding (95).

INFLIXIMAB

Antirheumatic Agent/Gastrointestinal Agent

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk (Contraindicated If Combined with Methotrexate)

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

The maternal benefits of therapy with infliximab appear to far outweigh embryo–fetal risks (1,2). In 2011, the World Congress of Gastroenterology stated “Infliximab in pregnancy is considered to be low risk and compatible with use during conception in men and women and during pregnancy in at least the first two trimesters” (3). Animal reproduction studies have not been conducted with infliximab because the mechanism of action is different from that in humans. However, the agent should be avoided if it is combined with methotrexate, a potential teratogen, for the treatment of rheumatoid arthritis. Because of the long elimination half-life, use before conception may result in inadvertent exposure of an unplanned pregnancy. An indirect risk during any stage of gestation may exist because of the potential for severe maternal toxicity in some patient populations. This includes increased incidence of mortality in patients with moderate-to-severe congestive heart failure and an increased risk of severe infections.

FETAL RISK SUMMARY

Infliximab, a chimeric (mouse/human) immune globulin G (IgG1) monoclonal antibody, is indicated for the treatment of rheumatoid arthritis (in combination with methotrexate) and for severe Crohn’s disease, including fistulizing Crohn’s disease. Infliximab binds specifically to human tumor necrosis factor alpha (TNF α) to inhibit its activity. TNF α is a pro-inflammatory cytokine with a central role in inflammatory processes. Infliximab is in the same subclass of immunomodulators (blockers of TNF α activity) as adalimumab, certolizumab pegol, and golimumab. The agent has an elimination half-life of 8.0–9.5 days (4).

Animal reproduction studies have not been conducted with infliximab because

it does not cross-react with TNF α in species other than humans and chimpanzees (4). However, when a reproduction study was conducted in mice with an analogous antibody that binds specifically to mouse TNF α , no evidence of maternal toxicity, embryo toxicity, or teratogenicity was observed (4,5).

Although the molecular weight is very high (about 149,100), infliximab crosses the human placenta to the fetus in late gestation (6). As an IgG1 antibody, the drug would be transported actively across the placenta, especially in the 3rd trimester, but with minimal transfer in the 1st trimester. In 11 cases at a mean gestational age 40 weeks (range 38–41 weeks), the median and range of infliximab concentrations in cord blood as a percentage of maternal concentration were 160% (87%–400%). Moreover, infliximab was detected in the infants for 2–7 months. No birth defects nor neonatal intensive care unit stays occurred in any infant (6).

A 2001 case report described the pregnancy outcome of a 26-year-old woman with Crohn's disease who had received infliximab early in gestation (7). The woman had a 6-year history of Crohn's disease and was symptomatic with a rectovaginal fistula while receiving azathioprine, metronidazole, and mesalamine. She was given two infusions of infliximab (dose not specified); the first occurred at about 1–2 weeks' gestation and the second at about 2–3 weeks. A planned third infusion was canceled when her pregnancy was diagnosed. She eventually delivered a premature 681-g infant at 24 weeks of conception who died 3 days later (7).

The author of the above report also cited data received from the manufacturer on 27 women who had been treated with infliximab immediately before or during the 1st trimester (7). Of the 27 women, 3 aborted spontaneously (SAB), 1 had an elective abortion (EAB) (for personal reasons), and 6 delivered term infants. (No information was given on the condition of the infants.) Another woman had received infliximab during the 1st trimester and delivered an infant with tetralogy of Fallot. No data were provided on the remaining 16 pregnancies. The author noted the close relationship between infliximab's mechanism of action and that of thalidomide, a known human teratogen that decreases the production of TNF α (7). This relationship has been noted by others (8).

In an extension of the above report (some of the same data are reported), a 2001 abstract evaluated data from 59 women who had received infliximab before or during pregnancy for the treatment of Crohn's disease (N = 45), rheumatoid arthritis (N = 5; not specified if these cases also received methotrexate), or unknown disease (N = 9) (9). The cases were retrieved from

the infliximab postmarketing safety database. Treating physicians were contacted to document pregnancy outcomes. The timing of exposures were 27 before pregnancy, 11 before pregnancy and during the 1st trimester, 5 during the 1st trimester, and 16 unknown. Pregnancy outcomes were known for 36 cases (time of exposure not specified): 26 live births, 5 SABs, and 5 EABs. Among the live births, two had complications: 681-g infant delivered at 23 weeks' and died at age 3 weeks; and an infant with tetralogy of Fallot (corrected surgically) that is otherwise currently healthy. The investigators concluded the outcomes were consistent with those expected in healthy women (9).

In a 2003 case report, a 29-year-old woman with chronic, severe Crohn's disease received three infusions of infliximab (600 mg/dose) over a 6-week period (10). Three months later, she received a fourth infusion of 500 mg. This dose was given approximately 3 days after conception. She eventually delivered a healthy infant at 36 weeks' gestation (birth weight and other details not specified). The child has normal growth and development at 20 months of age (10).

A survey of 600 members of the American College of Rheumatology, partially conducted to determine the outcomes of pregnancies exposed to disease-modifying antirheumatic drugs (DMARD) (etanercept, infliximab, leflunomide, and methotrexate), was published in 2003 (11). From the 175 responders, the outcomes of two pregnancies exposed to infliximab were one full-term, healthy infant and one unknown outcome (11).

The similarity between the mechanism of action of infliximab and thalidomide is of interest. However, decreased production of TNF α may not be a primary cause of the teratogenicity of thalidomide (see Thalidomide). Theoretically, TNF α antagonists could interfere with implantation and ovulation, but this has not been shown clinically (12).

The preliminary results of an ongoing prospective collaborative study of rheumatoid arthritis medicines in pregnancy conducted by the Organization of Teratology Information Specialists (OTIS) have been reported (13,14). The study covered the period 1999–2004. There were 33 women exposed in the 1st trimester to either etanercept (N = 29) or infliximab (N = 4). The outcomes of these pregnancies were compared with 77 prospectively ascertained disease-matched controls (did not use anti-TNF α agents) and 50 prospectively ascertained healthy controls. Three controls were lost to follow-up. There was no difference between the groups in the number of SABs and EABs. One malformation (1/33; 3.0%) was reported in the subject group (a chromosomal

anomaly, trisomy 18; spontaneously aborted by a woman exposed to etanercept). Major malformations in the other groups were 4.0% (3/75) in disease-matched controls and 4.1% (2/49) in healthy controls. However, women exposed to etanercept or infliximab and disease-matched controls were significantly more likely to give birth to infants <37 weeks' gestation and to have lower-birth-weight full-term infants than healthy controls. These results suggested that the disease itself was the causal factor (13,14).

A 2004 study reported data from the manufacturer's database of pregnancies exposed to infliximab (15). Among 146 pregnancies, 131 were direct exposures (drug given to women) and 15 were indirect (drug given to male partners). Among the direct exposures, there were outcome data for 96 (73%); 82 involving mothers with Crohn's disease and 14 with rheumatoid arthritis. The timing of the direct exposures were 53 exposed within 3 months of conception with 28 of these also exposed during the 1st trimester; 30 exposed during the 1st trimester; 7 exposed more than 3 months before conception; and 6 exposed at an unknown time. The outcomes for the 96 direct exposures were 64 (67%) pregnancies with live births (68 infants—4 sets of twins), 14 (15%) SABs, and 18 (19%) EABs. For the 82 women with Crohn's disease, the outcomes were 55 (67%) pregnancies with live births (58 infants—3 sets of twins), 11 (13%) SABs, and 18 (22%) EABs. There were five fetal complications, including two structural anomalies, among the 96 live births: (a) birth at 24 weeks of a 681-g infant, died shortly thereafter of intracerebral and intrapulmonary hemorrhage; (b) neonate with respiratory distress, jaundice, and a seizure, reported to be doing well at 9 months of age; (c) twin with delayed development and hypothyroidism; (d) infant with tetralogy of Fallot, defect corrected surgically and infant doing well at 1 year of age, mother was treated with infliximab about 1 year before conception and during the 1st trimester; and (e) infant with intestinal malrotation, mother received infliximab and leflunomide before conception and in pregnancy. Taken in sum, the outcomes did not differ significantly from pregnancy outcomes in the U.S. population or from pregnant women with Crohn's disease not exposed to infliximab (15).

A 2006 communication from England described the pregnancy outcomes of 23 women directly exposed to TNF α agents at the time of conception (17 etanercept, 3 adalimumab, and 3 infliximab) (16). Additional therapy included methotrexate in nine women and leflunomide in two. There also were nine patients (4 etanercept, 5 infliximab) that discontinued therapy before conception. The outcomes for the 32 pregnancies were 7 SABs, 3 EABs, and 22 live births. No major anomalies were observed in the live births, including

one infant exposed to adalimumab and methotrexate early in gestation (16).

A 32-year-old woman with Crohn's disease was treated throughout pregnancy with five infusions of infliximab 10 mg/kg (17). The last dose was given 2 weeks for the birth at term of a healthy 3.29-kg female infant. Apgar scores were 9 and 9. At 6 months of age, the infant's immune development was normal, including an appropriate immune response to routine childhood immunizations (17).

A 2008 case report described a 22-year-old woman with Crohn's disease who was treated with infliximab (10 mg/kg every 4 weeks) and daily mesalamine before and during pregnancy and during breastfeeding (18). She received six doses of infliximab in pregnancy with the last dose given about 2 weeks before birth of a term, healthy 3.35-kg male infant. At 27 months of age, no developmental abnormalities were noted in the child (18).

A report using data from the FDA database described 61 congenital anomalies in 41 children born to mothers taking a TNF antagonist (22 etanercept and 19 infliximab) (19). The authors concluded that 24 of the children had one or more of the congenital anomalies that are part of VACTERL association (vertebral anomalies, anal atresia, cardiac defects, tracheoesophageal, renal, and limb abnormalities) and the rate was higher than historical controls (19). An accompanying editorial, however, concluded that the evidence for teratogenicity or with the VACTERL association was insufficient (20). Many of the anomalies reported occur commonly, such as ventricular septal defects. In addition, such databases have selection bias (only cases with adverse outcomes are reported and emphasis placed on exposures to new drugs) (20).

A 2009 study from France reported the outcomes of 15 women who took anti-TNF drugs during pregnancy (10 etanercept, 3 infliximab, and 2 adalimumab) (21). The drugs were given in the 1st, 2nd, and 3rd trimesters in 12, 3, and 2 cases, respectively. The outcomes were 2 SABs, 1 EAB, and 12 healthy babies without malformation or neonatal illness. They also reviewed the literature regarding the use of anti-TNF agents in pregnancy and found more than 300 cases. They concluded that, although only 29 were treated throughout gestation, the malformation rate was similar to the general population (21).

Three women with Crohn's disease were treated with infliximab 5 mg/kg before and during pregnancy (22). Two patients received infliximab every 8 weeks (4 doses) through gestational week 31 and 32, respectively, whereas the third patient received the drug at gestational weeks 19, 21, and 25. The first two patients gave birth at 38 and 39 weeks' gestation to

healthy infants with birth weights of about 2.84 and 2.70 kg, respectively. The third patient gave birth at 36 weeks' to a healthy infant with birth weight of about 2.78 kg. All Apgar scores were in the normal range. At follow-up, all of the children were developing normally and had not developed atypical infections or more typical infections than expected for their age group. Moreover, all had sero-converted after childhood immunizations, suggesting normal immune responses (22).

BREASTFEEDING SUMMARY

In a case discussed above, a mother with Crohn's disease breastfed her infant while receiving infliximab (17). The mother's last dose during pregnancy was 2 weeks before birth of her female infant and her postpartum 10 mg/kg doses were at 2 and 10 weeks. Maternal serum infliximab concentrations at 6, 10, and 13 weeks were 40, 9.3, and 84 mcg/mL, respectively. In contrast, breast milk concentrations were not detectable. A serum sample obtained from the infant at 6 weeks had a concentration of 39.5 mcg/mL, identical to the mother's level. Although the drug was not detected in milk, breastfeeding was halted for 3 weeks and resumed when the mother received her second postpartum dose at 10 weeks. Infant serum infliximab levels continued to decline in spite of the mother's second dose, leading the investigators to conclude that breast milk was not the source (17).

In a second case, a mother with Crohn's disease was treated during pregnancy with infliximab (10 mg/kg every 4 weeks) (18). She decided to continue treatment while breastfeeding her infant. Breast milk samples were collected immediately before her first postpartum dose and daily postdose for 30 days. Infliximab was not detected in any of the samples (18).

Three mothers breastfed their infants while resuming treatment with infliximab on postpartum days 3, 10, and 14, respectively (22). Maternal serum samples were collected 6–43 days postdose and breast milk samples 7–43 days postdose. Infant serum samples were collected at 5 and 43 days postdose in two infants. Serum was not available in the third infant. The maternal serum concentrations ranged from about 60 to 74 mcg/mL, but all milk and infant serum concentrations were below the level of detection (0.10 mcg/mL) (22).

In the above reports, infliximab was not detected in any milk samples. It also was not detected in the serum of two nursing infants, but was in the serum of a third infant. The reason for this difference is unknown. Moreover, no adverse effects were observed on the immune function of four infants (17,22). Although the data are limited, these results suggest that the risk of toxicity for a nursing

infant is low, if it exists at all. In 2011, the World Congress of Gastroenterology stated that infliximab was compatible with breastfeeding (3).

INGENOL MEBUTATE

Dermatological Agent

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of ingenol mebutate in human pregnancy have been located. Animal reproduction studies have been conducted with IV formulations and are not relevant. Moreover, systemic exposure to the drug and two metabolites was not detected in subjects with actinic keratosis. Consequently, the drug appears to be compatible for use in pregnancy.

FETAL RISK SUMMARY

Ingenol mebutate, an inducer of cell death, is a clear colorless gel (0.015% or 0.05%) for topical administration. It is indicated for the topical treatment of actinic keratosis. Blood levels of ingenol mebutate and two of its metabolites were below the lower limit of quantification (0.1 ng/mL) in 16 subjects with actinic keratosis when 1 g of the 0.05% gel was applied to an area of 100 cm² on the dorsal forearm once daily for 2 consecutive days (1).

Reproduction studies have been conducted in rats and rabbits given IV doses. During organogenesis in rats, no treatment-related effects on embryo–fetal toxicity or teratogenicity were observed. In rabbits during organogenesis, increases in embryo–fetal mortality were noted at the highest dose. When two lower doses were given, all 3 doses caused an increase in the incidence of fetal visceral and skeletal variations. However, the clinical relevance of these results is questionable since, as noted earlier, systemic exposure was not observed in human subjects (1).

Long-term animal studies for carcinogenic potential have not been conducted. Three assays for mutagenicity were negative but one assay was positive. Effects on fertility in animals have not been evaluated (1).

It is not known if ingenol mebutate or its metabolites cross the human placenta. The molecular weight (about 431) is low enough, but the absence of quantifiable levels suggest that clinically significant amounts of the drug and metabolites will not cross the embryo or fetus.

BREASTFEEDING SUMMARY

No reports describing the use of ingenol mebutate during human lactation have been located. The molecular weight (about 431) is low enough, but the absence of quantifiable levels of the parent drug and two metabolites suggest that clinically significant amounts will not be excreted into breast milk.

INSULIN

Antidiabetic Agent

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Insulin, a naturally occurring polypeptide hormone, is the drug of choice for the control of diabetes mellitus in pregnancy.

FETAL RISK SUMMARY

Because it is a very large molecule, it has been believed that insulin does not cross the human placenta. Research published in 1990, however, found that animal (bovine or porcine) insulin does cross the human placenta as an insulin-antibody complex, and that the amount of transfer directly correlated with the amount of anti-insulin antibody in the mother (1). Moreover, high concentrations of animal insulin in cord blood were significantly associated with the development of fetal macrosomia, suggesting that the transferred insulin had biologic activity and that the fetal condition was determined by factors other than the mother's glycemic control (1). This latter conclusion has been challenged (2,3) and defended (4) and it requires additional study. The results of the study do underscore the argument that immunogenic insulin should not be used in women who may become pregnant (1,2).

Human insulin does not cross the placenta in clinically significant amounts, probably because of its high molecular weight (5808) (5). However, there may be endogenous carrier proteins that allow passage of insulin to the embryo early in gestation. After that period, the fetus produces its own insulin as insulin-secreting cells in the fetal pancreas become differentiated near the end of the 1st trimester (6).

Infants of diabetic mothers are at risk for an increased incidence of congenital anomalies, 3 to 5 times that of normal controls (7-14). The rate of malformations appears to be related to maternal glycemic control in the 1st trimester of pregnancy, but the exact mechanisms causing structural defects are unknown. A 1996 review examined this issue and concluded that

uncontrolled diabetes, occurring very early in gestation (i.e., <8 weeks of gestation), causes an abnormal metabolic fuel state and that this condition leads to a number of processes, operating via a common pathway, that results in cell injury (13).

Congenital malformations are now the most common cause of perinatal death in infants of diabetic mothers (7,8). Not only is the frequency of major defects increased, but so is the frequency of multiple malformations (affecting more than one organ system) (7). Malformations observed in infants of diabetic mothers include the following (11,12,14–16):

Caudal regression syndrome (includes anomalies of the lower neural tube resulting in sacral agenesis and defects of lumbar vertebrae; defects of lower extremities, and gastrointestinal and genitourinary tracts [17])

Femoral hypoplasia and unusual facies syndrome

Spina bifida, hydrocephalus, and other CNS defects

Anencephalus

Cardiovascular: transposition of great vessels; ventricular septal defect; atrial septal defect

Anal and rectal atresia

Renal: agenesis, multicystic dysplasia, ureter duplex

Gastrointestinal: situs inversus, tracheoesophageal fistula, bowel atresias, imperforate anus, small left colon

Infants of diabetic mothers may have significant perinatal morbidity, even when the mothers have been under close diabetic control (14). Perinatal morbidity in one series affected 65% (169/260) of the infants and included hypoglycemia, hyperbilirubinemia, hypocalcemia, and polycythemia (18).

In contrast to the data relating to the adverse fetal effects of poor maternal hyperglycemia control, animal studies have documented that short periods of hypoglycemia during early organogenesis are associated with malformations of the skeleton and heart (19–21), and reduced growth, including some major organs (22). Although hypoglycemia in humans has not been shown to be teratogenic (23,24), at least one author has concluded that this has not been adequately studied (25).

BREASTFEEDING SUMMARY

Insulin is a naturally occurring constituent of the blood and is excreted into breast milk. In a 2012 study, milk samples were obtained from breastfeeding mothers, five without diabetes, four with type 1 diabetes, and five with type 2

diabetes (26). Samples were analyzed for total and endogenous insulin and for c-peptide. The type 1 diabetics were treated with artificial insulin (aspart plus glargine), whereas the type 2 diabetics received a diabetic diet either with (N = 3) or without (N = 2) metformin. Insulin was present in all of the samples, but only artificial insulin was detected in the milk of type 1 diabetics. The results showed that insulin, both endogenous and exogenous, is actively transported from the blood into milk and is protected from degradation and, presumably, has a functional or developmental role in the infant. If so, the authors suggested, it might be beneficial for formula-fed infants if insulin was added to formula milk (26).

INSULIN ASPART

Antidiabetic Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

There are no reasons to believe that insulin aspart would pose a risk to the embryo or fetus different from that of other insulins. Older forms of insulin, whether of human or of porcine origin, are considered compatible with pregnancy. Insulin aspart can be classified similarly. As with all insulins, the primary concern is severe maternal hypoglycemia.

FETAL RISK SUMMARY

Insulin aspart is a rapid-acting human insulin analog that differs from regular human insulin by a single substitution of the amino acid proline by aspartic acid at position B28. It is produced by recombinant DNA technology. Insulin aspart is indicated for the treatment of patients with diabetes mellitus, for the control of hyperglycemia. It may be given by SC injection, as an SC infusion by an external insulin pump, or IV. The mechanism of action of insulin aspart is similar to human insulin in that it binds to receptors in muscle and fat cells to facilitate the cellular uptake of glucose and, at the same time, inhibits glucose release from the liver. Because the substitution at position B28 reduces the tendency to form hexamers, as observed with regular human insulin, insulin aspart is absorbed more rapidly after SC injection and has a shorter duration of action. Similar to regular insulin, plasma protein binding of insulin aspart is low (0%–9%) (1).

The median times to maximum serum concentrations for insulin aspart and regular insulin after SC administration are 40–50 minutes and 80–120 minutes, respectively. The elimination half-life of insulin aspart also is shorter than regular insulin, 81 vs. 141 minutes, respectively (1).

Reproduction studies of SC insulin aspart have been conducted in rats and rabbits. In female rats, insulin aspart was given before and during mating, and

throughout gestation. The embryo–fetal effects observed with insulin aspart did not differ from human insulin. These effects were pre- and postimplantation losses and visceral/skeletal malformations at a daily dose about 32 times the human dose based on BSA (HD). Similar results were obtained in rabbits given daily doses that were about three times the HD during organogenesis. The effects in both species probably were due to maternal hypoglycemia. No significant effects were observed in rats and rabbits at doses that were about eight times and equal to the HD, respectively (1).

In rats, insulin aspart given over a 52-week period resulted in an increased incidence of mammary gland tumors in females at the highest SC dose tested (about 32 times the HD). Similar effects have been observed with human regular insulin. Insulin aspart was not genotoxic in multiple tests, nor did it have any effect on fertility or reproductive performance in male and female rats, at SC doses up to 32 times the HD (1).

It is not known if insulin aspart crosses the human placenta. Human insulin does not cross the placenta in clinically significant amounts (2). Because of the very close similarity between insulin aspart and human insulin, and its high molecular weight (about 5826), insulin aspart probably does not cross either. However, there may be endogenous carrier proteins that allow passage of insulin, including insulin aspart, to the embryo early in gestation. After that period, the fetus produces its own insulin as insulin-secreting cells in the fetal pancreas become differentiated near the end of the 1st trimester (3).

A 2003 report compared the effects of single doses of insulin aspart and human regular insulin on alternate days in 15 women with gestational diabetes (4). Pregnancy outcomes were not discussed.

In 2007, the FDA approved a change in the risk factor for insulin aspart from C to B (Novo Nordisk, press release, January 30, 2007). Insulin aspart was compared with human regular insulin in a randomized controlled trial at 63 sites in 18 countries involving 322 pregnant women with type 1 diabetes. The rates of maternal hypoglycemia and changes in hemoglobin A_{1c} (HbA_{1c}) were comparable between the two groups. However, insulin aspart showed improved, though not statistically significant outcomes in terms of fewer preterm deliveries ($p < 0.053$), reduced risk of neonatal hypoglycemia requiring treatment, and consistently low rates of major hypoglycemia. The study was too small to evaluate the risk of congenital malformations (Novo Nordisk, data on file, January 30, 2007).

A 2008 study compared insulin aspart with human insulin, both combined with NPH insulin, in a randomized study involving 322 pregnant women (5). There

was no difference between the groups with respect to fetal loss, perinatal mortality, congenital anomalies, and neonatal short-term complications,

One review concluded that rapid-acting insulin analogs (aspart and lispro) could be considered the insulin of choice in pregnancy (6).

BREASTFEEDING SUMMARY

Insulin is a naturally occurring constituent of the blood and is excreted into breast milk. In a 2012 study, milk samples were obtained from breastfeeding mothers, five without diabetes, four with type 1 diabetes, and five with type 2 diabetes (7). Samples were analyzed for total and endogenous insulin and for c-peptide. The type 1 diabetics were treated with artificial insulin (aspart plus lantis), whereas the type 2 diabetics received a diabetic diet either with (N = 3) or without (N = 2) metformin. Insulin was present in all of the samples at comparable concentration to serum, but only artificial insulin was detected in the milk of type 1 diabetics. The results showed that insulin, both endogenous and exogenous, is actively transported from the blood into milk and is protected from degradation and, presumably, has a functional or developmental role in the infant. If so, the authors suggested, it might be beneficial for formula-fed infants if insulin was added to formula milk (7).

INSULIN DETEMIR

Antidiabetic Agent

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

The human data presented by the manufacturer and other sources indicate that the effects of insulin detemir on the embryo and/or the fetus are similar to human insulin. The animal data suggest risk, but the embryotoxicity and teratogenicity was thought to be secondary to maternal hypoglycemia. Moreover, there was no difference in developmental toxicity between insulin detemir and human insulin (1). Older forms of insulin, whether of human or of porcine origin, are considered compatible with pregnancy. As with all insulins, the primary concern is severe maternal hypoglycemia.

FETAL RISK SUMMARY

Insulin detemir is a long-acting basal insulin analog that differs from regular human insulin by the omission of the amino acid threonine in position B30 and the attachment of a C14 fatty-acid chain to amino acid B29. It is produced by recombinant DNA technology. Insulin detemir is indicated for once- or twice-daily SC administration for the treatment of adult and pediatric patients with type 1 diabetes mellitus or adult patients with type 2 diabetes mellitus who require basal (long-acting) insulin for the control of hyperglycemia.

The mechanism of action of insulin detemir is similar to human insulin in that it binds to receptors in muscle and fat cells to facilitate the cellular uptake of glucose and, at the same time, inhibits glucose release from the liver. The duration of action ranges from 5.7 hours at the lowest dose to 23.2 hours at the highest dose. The long duration results from the slow systemic absorption of insulin detemir from the injection site caused by the strong self-association of the insulin molecules and the high binding to albumin in the blood. In contrast to human insulin, more than 98% of insulin detemir in the blood is bound to albumin (1).

Reproduction studies have been conducted in rats and rabbits. When female

rats were given daily doses about 1.5 and 3 times the recommended human dose based on AUC (RHD) before and during mating and throughout pregnancy, an increased number of fetuses with visceral anomalies were observed at both doses. No effect on fertility was observed. In pregnant rabbits, a dose that was 135 times the RHD was associated with gall bladder abnormalities described as small, bilobed, bifurcated, and missing. When human insulin was used in control groups, the effects of insulin detemir and human insulin were similar in terms of embryotoxicity and teratogenicity. Carcinogenicity studies have not been conducted with insulin detemir, but no mutagenic or clastogenic effects were observed in tests (1).

It is not known if insulin detemir crosses the human placenta. Human insulin does not cross the placenta in clinically significant amounts (2). Because of the close similarity between insulin detemir and human insulin, and its high molecular weight (about 5917), insulin detemir probably does not cross either. However, there may be endogenous carrier proteins that allow passage of insulin, including insulin detemir, to the embryo early in gestation. After that period, the fetus produces its own insulin as insulin-secreting cells in the fetal pancreas become differentiated near the end of the 1st trimester (3).

The manufacturer reported an open-label, clinical study in 310 pregnant women with type 1 diabetes (1). The women, between 8 and 12 weeks' gestation, were divided into two groups, insulin detemir N = 152 and NPH N = 158. The pregnancy outcomes in the two groups were similar (1).

Several reports have described the use of insulin detemir in human pregnancy (4–8). These reports concluded that the insulin analog had maternal efficacy and safety similar to other insulins. No embryo–fetal adverse effects related to the drug were observed (4–8).

BREASTFEEDING SUMMARY

No reports describing the use of insulin detemir during human lactation have been located. Insulin is a natural component of the blood and is excreted into breast milk. Insulin detemir probably also is present in milk.

INSULIN GLARGINE

Antidiabetic Agent

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

The human pregnancy experience with insulin glargine demonstrates that the risk of embryo or fetal harm is low, if it exists at all. The use of insulin glargine during organogenesis at a dose close to that used in humans was associated with developmental toxicity in one animal species but not in another. Although it was not stated, the observed toxicity in rabbits may have been related to maternal hypoglycemia. Older forms of insulin, whether of human or of porcine origin, are considered compatible with pregnancy and, most likely, insulin glargine can be classified similarly. As with all insulins, the primary concern is severe maternal hypoglycemia.

FETAL RISK SUMMARY

Insulin glargine is a long-acting basal insulin analog that differs from regular human insulin by the replacement of the amino acid asparagine at A21 with glycine and two arginines are added to the C-terminus of the B-chain. It is produced by recombinant DNA technology. Insulin glargine is indicated for once-daily SC administration for the treatment of adult and pediatric patients with type 1 diabetes mellitus or adult patients with type 2 diabetes mellitus who require basal (long-acting) insulin for the control of hyperglycemia. The mechanism of action of insulin glargine is similar to human insulin in that it binds to receptors in muscle and fat cells to facilitate the cellular uptake of glucose and, at the same time, inhibits glucose release from the liver. Insulin glargine is an acidic solution (pH of about 4) that is neutralized in SC tissues, leading to the formation of micro-precipitates. The precipitates are slowly and continuously released over a 24-hour period with no pronounced peak (1).

Reproduction studies have been conducted in rats and rabbits. Female rats were given daily doses about seven times the recommended human SC starting dose based on BSA (RHD) before and during mating, and throughout

pregnancy. Pregnant rabbits were given daily doses during organogenesis that were about twice the RHD. In both species, the effects of insulin glargine did not generally differ from those resulting from human insulin. However, in rabbits, five fetuses from two litters had dilation of the cerebral ventricles. In female rats and rabbits, no effects on fertility were observed (1).

In mice and rats, 2-year carcinogenicity studies were conducted with doses up to 5 and 10 times the RHD, respectively. Excessive mortality in female mice prevented conclusive evaluation in that group. Histiocytomas were found at the injection sites in male rats (statistically significant) and male mice (not significant) receiving insulin glargine. The tumors were not found in groups receiving saline or comparative human insulin in a non-acid-containing vehicle. Insulin glargine was not mutagenic or clastogenic in tests (1).

It is not known if insulin glargine crosses the human placenta. Human insulin does not cross the placenta in clinically significant amounts (2). Because of the close similarity between insulin glargine and human insulin, and its high molecular weight (6063), insulin glargine probably does not cross either. However, there may be endogenous carrier proteins that allow passage of insulin, including insulin glargine, to the embryo early in gestation. After that period, the fetus produces its own insulin as insulin-secreting cells in the fetal pancreas become differentiated near the end of the 1st trimester (3).

Several reports have described the use of insulin glargine in human pregnancy (4–14). These reports concluded that the insulin analog had maternal efficacy and safety similar to other insulins. No embryo–fetal adverse effects related to the drug were observed (4–14).

BREASTFEEDING SUMMARY

Insulin is a naturally occurring constituent of the blood and is excreted into breast milk. In a 2012 study, milk samples were obtained from breastfeeding mothers, five without diabetes, four with type 1 diabetes, and five with type 2 diabetes (15). Samples were analyzed for total and endogenous insulin and for c-peptide. The type 1 diabetics were treated with artificial insulin (aspart plus glargine), whereas the type 2 diabetics received a diabetic diet either with (N = 3) or without (N = 2) metformin. Insulin was present in all of the samples at comparable concentration to serum, but only artificial insulin was detected in the milk of type 1 diabetics. The results showed that insulin, both endogenous and exogenous, is actively transported from the blood into milk and is protected from degradation and, presumably, has a functional or developmental role in the infant. If so, the authors suggested, it might be beneficial for formula-fed

infants if insulin was added to formula milk (15).

INSULIN GLULISINE

Antidiabetic Agent

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No reports describing the use of insulin glulisine in human pregnancy have been located. The animal data suggest that the risk to the embryo or fetus is low. Although there are no human data, there are no reasons to believe that insulin glulisine would pose a risk to the embryo or fetus different from that of other insulins. Older forms of insulin, whether of human or of porcine origin, are considered compatible with pregnancy. Insulin glulisine probably can be classified similarly. As with all insulins, the primary concern is severe maternal hypoglycemia.

FETAL RISK SUMMARY

Insulin glulisine is a rapid-acting human insulin analog that differs from regular human insulin by a single substitution of the amino acid asparagine by lysine at position B3. It is produced by recombinant DNA technology. Insulin glulisine is indicated for the treatment of adult patients with diabetes mellitus for the control of hyperglycemia. It may be given by SC injection or as an SC infusion by an external insulin pump. The mechanism of action of insulin glulisine is similar to human insulin, in that it binds to receptors in muscle and fat cells to facilitate the cellular uptake of glucose and, at the same time, inhibits glucose release from the liver. The apparent elimination half-life of insulin glulisine is 42 minutes, compared with 86 minutes for human regular insulin (1).

Reproduction studies have been conducted in rats and rabbits using regular human insulin as a comparator. In pregnant rats given daily SC doses up to twice the average human dose based on BSA (HD) throughout gestation, no embryo or fetal toxicity different from that observed with human insulin was noted. In pregnant rabbits, daily SC doses up to 0.5 times the HD were associated with developmental toxicity, but only at doses that induced maternal

toxicity (hypoglycemia). At the highest dose, increased postimplantation losses and skeletal defects were observed, as was maternal mortality. The no-effect SC dose in rabbits was 0.1 times the HD. The embryo–fetal toxicity in rabbits did not differ from that observed with human insulin at the same dose (1).

In a 12-month carcinogenicity study, rats were given daily SC doses of 1–20 times the HD. A non-dose-dependent increased incidence of mammary gland tumors was observed in female rats compared with untreated controls. However, the incidence of mammary gland tumors was similar to that noted in female rats given human regular insulin. Insulin glulisine was not mutagenic or clastogenic in tests. In male and female rats given daily SC doses up to twice the HD, no clear evidence of impaired fertility or reproductive performance was observed (1).

It is not known if insulin glulisine crosses the human placenta. Human insulin does not cross the placenta in clinically significant amounts (2). Because of the close similarity between insulin glulisine and human insulin, and its high molecular weight (5823), insulin glulisine probably does not cross either. However, there may be endogenous carrier proteins that allow passage of insulin, including insulin glargine, to the embryo early in gestation. After that period, the fetus produces its own insulin as insulin-secreting cells in the fetal pancreas become differentiated near the end of the 1st trimester (3).

BREASTFEEDING SUMMARY

No reports describing the use of insulin glulisine during human lactation have been located. Insulin is a natural component of the blood and is excreted into breast milk (1). Insulin glulisine probably also is present in milk.

INSULIN LISPRO

Antidiabetic Agent

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

The animal and human data suggest that the use of insulin lispro during pregnancy can be considered low risk for the embryo–fetus. Insulin lispro is very closely related to human insulin, differing only in the reversal of two amino acids in the B chain. There is no reason to believe that insulin lispro would pose a risk to the embryo or fetus different from that of other insulins. Older forms of insulin, whether of human or of porcine origin, are considered compatible with pregnancy and insulin lispro can be classified similarly. As with all insulins, the primary concern is severe maternal hypoglycemia.

FETAL RISK SUMMARY

Insulin lispro is a rapid-acting human insulin analog that differs from regular human insulin by the reversal of the amino acids at positions B28 and B29. It is produced by recombinant DNA technology. Insulin lispro is indicated for the treatment of adult patients with diabetes mellitus for the control of hyperglycemia. It may be given by SC injection or as an SC infusion by an external insulin pump. The mechanism of action of insulin lispro is similar to human insulin, in that it binds to receptors in muscle and fat cells to facilitate the cellular uptake of glucose and, at the same time, inhibits glucose release from the liver. The elimination half-life of SC insulin lispro is 1 hour, compared with 1.5 hours for human regular insulin (1).

Reproduction studies have been conducted in pregnant rats and rabbits. In these species, SC doses up to 4 and 0.3 times the average human dose (40 U/day) based on BSA revealed no evidence of impaired fertility or fetal harm due to insulin lispro. Long-term studies of carcinogenicity have not been conducted. The drug was not mutagenic or clastogenic in tests (1).

A 2001 study briefly described the use of normal, term human placentas to

determine if insulin lispro crossed to the fetal circulation (2). Two concentrations, 0.1 and 0.5 U/mL, were studied in the dual-perfused isolated cotyledon system. Time-dependent transfer of insulin lispro to the fetal side was observed, but the concentrations used were >50 times the normal human therapeutic doses (2).

A 2003 study used a similar system to determine the amount of insulin lispro crossing the placenta (3). Placental transfer was not observed during perfusions with 100 and 200 micro-U/mL, but did occur at concentrations ≥ 580 micro-U/mL. To determine clinically relevant levels, serum concentrations were measured in 11 women at 31–40 years of age (9 pregnant; 1 in 1st trimester, 8 in 2nd or 3rd trimester) receiving insulin lispro. Concentrations ranged from 2 to 576 micro-U/mL. There was an apparent linear relationship between dose and serum levels. Ten women had levels <200 micro-U/mL (single doses less than 50 U), whereas one woman, who received a 52-U dose, had a serum level of 576 micro-U/mL (3). Using a human-perfused placental cotyledon, a 2004 study found no detectable insulin lispro on the fetal side with the highest maternal steady-state concentration of 48 micro-U in the maternal artery (4). However, very high concentrations of insulin lispro (1836 micro-U without specifying a denominator) were found in placental tissue.

Based on the above studies, insulin lispro, depending on the dose, could cross to the embryo–fetus. Moreover, there may be endogenous carrier proteins that allow passage of insulin, including insulin lispro (molecular weight 5808; identical to human insulin), to the embryo early in gestation. After that period, the fetus produces its own insulin as insulin-secreting cells in the fetal pancreas become differentiated near the end of the 1st trimester (5).

A 1997 case report described the pregnancy outcomes of two women with type 1 diabetes who were treated with insulin lispro and NPH insulin during pregnancy (6). In the first case, insulin lispro was started before conception. The pregnancy was terminated at 20 weeks' gestation because of intrauterine growth restriction and severe fetal embryopathy but a normal karyotype. The female fetus had left-sided pulmonary and atrial isomerism, a right-sided aortic arch, a single atrium with one atrioventricular valve, a large ventricular septal defect, a double-outlet right ventricle, polysplenia, and abdominal situs inversus. In the second mother, insulin lispro was started in the third week of gestation. An elective cesarean section at 37 weeks delivered a 2.82-kg male infant with normal Apgar scores. No neonatal complications were noted, but the infant died suddenly at 3 weeks of age. At autopsy, a congenital diaphragmatic hernia with herniation of the stomach and intestine into the chest and bilateral undescended

testes were found. The cause of the defects in the two cases was unknown, but the authors did not believe they were due to suboptimal glycemic control. They also mentioned four other cases involving insulin lispro during pregnancy. Three of the women were still in the 1st trimester. The fourth woman was started at 26 weeks and she gave birth to a normal infant at 38 weeks (6).

In reply to the above cases, representatives of the manufacturer noted that the risk of congenital defects was known to be increased in infants of women with diabetes, especially cardiac defects (7). During clinical trials with insulin lispro, pregnancy was an exclusion, but 19 women gave birth to live infants. Only one infant had a birth defect (a right dysplastic kidney). The representatives cautioned that although case reports were important to raise hypotheses, they could not be used to infer a causal relationship (7).

Eight studies that included fetal outcomes have described the use of insulin lispro during 836 pregnancies (8–16). Diabetic types included 735 pregestational (types 1 and 2) and 101 gestational (type 3). No embryo, fetal, or neonatal complications attributable to insulin lispro were reported in 303 of the pregnancies (8–15).

The remaining pregnancies came from a multinational, multicenter study (16). The medical charts of 533 pregnancies (496 women) complicated by pregestational diabetes were examined and anomalies were assessed by two independent dysmorphologists. There were 542 outcomes involving 500 live births, 31 spontaneous abortions, 7 elective abortions, and 4 stillbirths. The mothers had a mean age of 29.9 years, 85.6% were white, and 97.2% had type 1 diabetes. All of the women had used insulin lispro for at least 1 month before conception and during at least the 1st trimester. More than 96% continued insulin lispro during the 2nd and 3rd trimesters. Twenty-seven (5.4%) of the offspring, including two that were electively aborted, had major congenital defects and two (0.4%) had minor anomalies. The anomaly rate among pregnancies that resulted in a live or stillbirth was 5.2%. Comparing these rates with the current published rates of 2.1%–10.9% for major defects in infants of diabetic mothers treated with insulin, the investigators concluded that their results suggested no difference in the anomaly rates between insulin lispro and regular insulin (16).

The cases of congenital defects in infants of two women using insulin lispro cited above were most likely due to diabetes or unknown causes. Four reviews concluded that the use of insulin lispro in pregnancy was appropriate and often gave better glycemic control than regular human insulin (17–20). However, a fifth review, published in 2006, cautioned that more comparative data were

needed before insulin lispro could be recommended in pregnancy or alternatively avoided (21).

A 2003 study compared the progression of retinopathy in pregnant women with type 1 diabetes who were treated with insulin lispro (N = 36) or human insulin (N = 33) (22). Patients treated with insulin lispro had improved glycemic control with no adverse impact on progression of diabetic retinopathy.

BREASTFEEDING SUMMARY

No reports describing the use of insulin lispro during human lactation have been located. Insulin is a natural component of the blood and is excreted into breast milk (1). Insulin lispro probably also is present in milk.

INTERFERON, ALFA

Antineoplastic/Immunologic Agent (Immunomodulator)

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Based on a limited number of human cases, the maternal administration of interferon alfa does not appear to pose a significant risk to the developing embryo and fetus. There does not seem to be a difference in risk among the subtypes but, in many cases, the actual product used was not specified. Although very high doses are abortifacient in rhesus monkeys, doses used clinically apparently do not have this effect. No teratogenic or other reproductive toxicity, other than that noted above, has been observed in animals, and no toxicity of any type attributable to interferon alfa has been observed in humans. However, because of the antiproliferative activity of these agents, they should be used cautiously during gestation until more data are available to assess their risk.

FETAL RISK SUMMARY

Interferon alfa is a family of at least 23 structurally similar subtypes of human proteins and glycoproteins that have antiviral, antineoplastic, and immunomodulating properties (1). Five preparations are available in the United States: interferon alfa-n3, interferon alfa-N1 (orphan drug status), interferon alfa-2a, interferon alfa-2b, and peginterferon alfa-2B. Interferon alfa-2c has been used in pregnancy, but this product is not available in the United States. No reports describing the placental transfer of interferon alfa have been located.

Shepard reviewed four studies in which human interferon alfa (subtype not specified) was administered by various parenteral routes to rats and rabbits during pregnancy (2–5). No teratogenicity or adverse developmental changes were observed in the offspring.

Interferon alfa-2a produced a statistically significant increase in abortions in rhesus monkeys given 20–500 times the human dose (HD) (6). No teratogenic effects, however, were observed in this species when doses of 1–25 million IU/kg/day were administered during the early to mid-fetal period (days 22–70 of gestation) (6). Interferon alfa-2b also had abortifacient effects in rhesus monkeys treated with doses that were 90–360 times the human dose (7). Reproduction studies have not been conducted with interferon alfa-n3 (8).

Administration of interferon alfa to female sheep before conception resulted in an increased number of pregnant ewes and embryonic survival (9). This effect may have been the result of enhanced biochemical communication between the mother and conceptus (9). A study published in 1986 demonstrated that human fetal blood and organs, placenta, membranes, amniotic fluid, and decidua contain significant concentrations of interferon alfa (10). In contrast, maternal blood and blood and tissues from nonpregnant adults contained little or none of these proteins. The investigators concluded that one of the effects of interferon alfa may involve the preservation of the fetus as a homograft (10). Other effects and actions of endogenous interferons (alfa, beta, and gamma) in relation to animal and human pregnancies and the presence of these proteins in various maternal and fetal tissues have been summarized in two reviews (11,12).

A number of reports have described the use of interferon alfa in all phases of pregnancy for the treatment of leukemia (13–20). The first reported case involved a woman with chronic myelogenous leukemia (CML) who was treated before conception and throughout a normal pregnancy with 4 million U/m² (6.4 million U) of interferon alfa-2a every other day (13). She delivered a term, healthy, 3487-g female infant whose growth and development continued to be normal at 15 months of age. The newborn had an elevated white blood cell count (40,000/mm³) that normalized at 48 hours of age with no signs or symptoms of infection. Since this report, 10 other pregnancies have been described in which interferon alfa was used for CML or hairy cell leukemia (14–20).

In one case, a woman was treated with interferon alfa-2c (not available in the United States) (16). In two of the pregnancies, the concentrations of interferon alfa in the newborns were <0.6 and <1 U/mL, respectively, while those in the mothers were 20.8 and 58 U/mL, respectively (18). Normal pregnancy outcomes were observed in all of the above cases and there were no fetal or newborn toxic effects attributable to interferon alfa (13–20). In addition, four infants have been followed for periods ranging from 6 to 44 months and all had

normal growth and development (14).

A 1995 reference reported the use of interferon alfa-2a for the treatment of multiple myeloma before and during approximately the first 6 weeks of pregnancy (21). The woman delivered a normal male infant at 38 weeks' gestation.

As noted above, interferon alfa does not appear to cross the placenta to the fetus. A study published in 1995 specifically evaluated this in two HIV-seropositive women who were undergoing abortions at 19 and 24 weeks (22). Both women were given a single IM injection of 5 million U interferon alfa-2a. Peak blood concentrations of the drug were reached at 3 hours in both women, 100 U and 400 U, respectively. Fetal blood and amniotic fluid samples were drawn at 1 hour from one fetus and at 4 hours from the other. Concentrations in the four samples were all below the detection limit of the assay (<2 U).

A number of pregnant women have been treated with interferon alfa (usually interferon alfa-2a) for essential thrombocythemia (23–34), although not without controversy (35–37). In some of these cases, the women were receiving interferon therapy at the time of conception (23,24,26,28,29) and, in most, the treatment was continued throughout pregnancy (26,28,29). No adverse effects in the fetuses or in the newborns attributable to the drug therapy were reported.

An HIV-infected pregnant woman was treated with IM interferon alfa, 2 million units twice weekly, and oral and IV glycyrrhizin during the 3rd trimester (38). Two weeks after interferon alfa was started, an elective cesarean section was performed at 37 weeks' gestation. The healthy, 2320-g female was alive and well at 4 years of age without evidence of HIV infection.

Two reports have described the use of interferon alfa for the treatment of chronic hepatitis C (39,40). In both cases, treatment was started before conception and continued into the 2nd trimester. Interferon alfa treatment throughout the 1st trimester also occurred in a woman with advanced Hodgkin's disease (41). Normal newborns resulted in all three of these pregnancies.

BREASTFEEDING SUMMARY

Interferon alfa is excreted into breast milk. A study published in 1996 measured interferon alfa milk concentrations in two women who had been treated with the drug throughout the 2nd and 3rd trimesters for CML (18). Both women were receiving 8 million units SC 3 times a week at the time of delivery. Immediately postpartum, milk concentrations in the two patients were 1.4 and 6 U/mL (time of the last dose in relationship to milk sampling not specified), while the serum

levels in the mothers were 20.8 and 58 U/mL, respectively. The authors did not specify if the infants were allowed to breastfeed.

Breastfeeding was allowed in a second reference (25). The woman was being treated with interferon alfa-2a, 3 million units SC 3 times weekly, for essential thrombocythemia. Nursing was halted 2 weeks postpartum because of the onset of bilateral mastitis. In a 2000 case report, a woman with malignant melanoma received 30 million IU IV over 30 minutes (42). Breast milk samples were collected before (to measure endogenous interferon alfa) and after the infusion. Only small amounts of interferon alfa were transferred into milk (peak level 1551 IU/mL vs. 1249 IU/mL before infusion). The infant did not breastfeed during the therapy.

The American Academy of Pediatrics classifies interferon alfa as compatible with breastfeeding (43).

INTERFERON BETA-1B

Immunologic Agent (Immunomodulator)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Although no published reports of its use in human pregnancy have been located, the manufacturer states that spontaneous abortions occurred in four patients who were participating in the Betaseron Multiple Sclerosis clinical trial (1). The relationship between interferon beta-1b and the abortions cannot be determined, at least partially because of the lack of details involving this clinical trial, such as the timing of abortion to drug administration, the dose used, the clinical condition of the women, and the number of pregnant women in the trial. Also unknown is the effect of multiple sclerosis on early pregnancy, although it appears that the physiologic immunomodulation that occurs in pregnancy offers some protection from relapses of the disease during gestation (2,3).

FETAL RISK SUMMARY

Interferon beta-1b, prepared by recombinant DNA technology, is used for the symptomatic treatment of multiple sclerosis and investigational in the therapy of AIDS, some neoplasms, and acute non-A/non-B hepatitis. No teratogenic effects were observed in rhesus monkeys given doses up to 40 times the recommended human dose based on BSA (RHD) on gestation days 20–70 (1). However, dose-related abortifacient activity occurred in these monkeys with doses that were 2.8–40 times the RHD.

BREASTFEEDING SUMMARY

No reports describing the use of interferon beta-1b during human lactation have been reported.

INTERFERON GAMMA-1B

Immunologic Agent (Immunomodulator)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of interferon gamma-1b in human pregnancy have been located. Interferon gamma-1b, produced by recombinant DNA technology, is used to reduce the frequency and severity of serious infections in patients who have chronic granulomatous disease (1). Because of this indication, the opportunities for its use in human pregnancy should be rare.

FETAL RISK SUMMARY

Interferon gamma-1b has abortifacient activity in nonhuman primates treated with a dose approximately 100 times the human dose (HD) (1). Similar activity was observed in mice treated with maternally toxic doses. Other effects noted in mice were an increased incidence of uterine bleeding and decreased neonatal viability (1). However, no evidence of teratogenicity was found in primates with doses of 2–100 times the HD (1).

Treatment of pregnant mice with 5000 U/day for 6 days produced maternal and fetal hematologic toxicity (2). In addition to an increase in aborted fetuses and decreased fetal weight, severe anomalies, consisting of inhibition or retardation of eye formation and brain hematomas, were observed in surviving fetuses (2).

Two reviews have summarized the effects and actions of endogenous interferons (alfa, beta, and gamma) in animal and human pregnancies and the presence of these proteins in various maternal and fetal tissues (3,4).

BREASTFEEDING SUMMARY

No reports describing the use of interferon gamma-1b during human lactation

have been located.

See Diatrizoate.

IODAMID

[Withdrawn from the market. See 9th edition.]

IODINATED GLYCEROL

Respiratory Drug (Expectorant)

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Iodinated glycerol is a stable complex containing 50% organically bound iodine (see Potassium Iodide).

FETAL RISK SUMMARY

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 1453 newborns had been exposed to iodinated glycerol during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 65 (4.5%) major birth defects were observed (61 expected). Specific data were available for six defect categories, including (observed/expected) 11/15 cardiovascular defects, 0/2 oral clefts, 1/1 spina bifida, 8/4 polydactyly, 1/2 limb reduction defects, and 1/3 hypospadias. An additional 1338 newborns were exposed to the general class of expectorants during the 1st trimester with 63 (4.7%) major birth defects observed (57 expected). Specific malformations were (observed/expected) 9/13 cardiovascular defects, 0/2 oral clefts, 1/1 spina bifida, 7/4 polydactyly, 1/2 limb reduction defects, and 3/3 hypospadias. These data do not support an association between 1st trimester use of either iodinated glycerol or the general class of expectorants and congenital defects.

IDOQUINOL

Amebicide

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Iodoquinol (di-iodohydroxyquinoline; diiodohydroxyquin) is used in the treatment of intestinal amebiasis. It has been used in pregnancy apparently without causing fetal harm.

FETAL RISK SUMMARY

Two case reports described the use of iodoquinol in pregnancy for the treatment of a rare skin disease. The first case involved a woman with chronic acrodermatitis enteropathica, who was treated with the amebicide in the 2nd and 3rd trimesters of her first pregnancy (1). She delivered a typical achondroplastic dwarf who died in 30 minutes. The second case also involved a woman with the same disorder who took iodoquinol throughout gestation (2). Dose during the 1st trimester, 1.3 g/day, was systematically increased during pregnancy in an attempt to control the cutaneous lesions, eventually reaching 6.5 g/day during the last 4 weeks. A normal male infant was delivered at term. Physical examinations of the infant, including ophthalmic examinations, were normal at birth and at 6 weeks follow-up.

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 169 of whom had 1st trimester exposure to iodoquinol (3, pp. 299, 302). Ten of the infants were born with a congenital malformation, corresponding to a hospital standardized relative risk (SRR) of 0.88. Based on three infants, an SRR of 6.6 for congenital dislocation of the hip was calculated, but this association is uninterpretable without confirming evidence (3, pp. 467, 473). For use anytime during pregnancy, 172 exposures were recorded (3, pp. 434, 435). With the same caution as noted earlier, an SRR of 1.68 (95% confidence interval 0.62–3.58) was estimated based on malformations in 6 infants. The SRR for

congenital dislocation of the hip after use anytime during pregnancy was 6.5 (3, p. 486).

BREASTFEEDING SUMMARY

No reports describing the use of iodoquinol during lactation have been located. Although the oral bioavailability is low, the molecular weight (397) should allow transfer of some drug from the plasma into the milk. In addition, protein-bound serum iodine levels may be increased with the administration of iodoquinol and may persist for as long as 6 months after discontinuation of therapy (4). The effects on a nursing infant from this exposure are unknown, but because iodide is concentrated in breast milk, serum and urinary iodide levels in the infant may be elevated (see Potassium Iodide).

IOFLUPANE IODINE¹²³

Diagnostic

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of ioflupane iodine¹²³ in human pregnancy have been located. Reproduction studies in animals have not been performed. In 2012, the Society of Nuclear Medicine stated that the drug was contraindicated in pregnancy (1).

FETAL RISK SUMMARY

Ioflupane iodine¹²³ is a radiopharmaceutical for IV injection. It is indicated for striatal dopamine transporter visualization using single photon emission computed tomography brain imaging to assist in the evaluation of adult patients with suspected parkinsonian syndromes. The recommended dose is 111–185 MBq (3–5 mCi). Only about 5% of the administered radioactivity remained in whole blood 5 minutes after injection. By 48 hours, about 60% of the radioactivity had been excreted in the urine and about 14% in the feces. The physical half-life of iodine¹²³ is 13.2 hours (2).

Reproduction studies in animals have not been conducted. Studies for carcinogenic potential and reproductive toxicity of ioflupane have not been conducted, but there was no evidence of mutagenesis in multiple assays (2).

In humans, a dose of 185 MBq results in an absorbed radiation dose to the uterus of 0.3 rad. Radiation doses >15 rad have been associated with congenital anomalies but doses <5 rad generally have not. However, radioactive iodine products cross the placenta and, depending on the stage of fetal development, can permanently impair fetal thyroid function (2).

BREASTFEEDING SUMMARY

Although no specific reports describing the use of ioflupane iodine¹²³ during lactation have been located, it is known that iodine¹²³ is excreted into breast

milk. The manufacturer recommends that breastfeeding should not be started before the radiopharmaceutical is administered, or if breastfeeding is already underway, it should be interrupted. Based on the physical half-life of iodine¹²³ (13.2 hours), nursing women should pump and discard breast milk for 6 days to minimize risks to a nursing infant (2). The breasts should be emptied regularly and completely. Milk that has been pumped during this period should either be discarded or stored in a refrigerator. The stored milk can be given to infant after 10 physical half-lives, or about 5.5 days have elapsed since pumping (3).

IOHEXOL

Diagnostic

PREGNANCY RECOMMENDATION: Compatible (Intravenous Use)

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

The various preparations of iohexol contain a high concentration of organically bound iodine. In the two reports below, the authors concluded that IV iodinated contrast material did not harm the thyroid function of newborns.

FETAL RISK SUMMARY

Iohexol, a nonionic radiopaque agent, contains a high concentration of organically bound iodine (140–350 mg iodine/mL). Iohexol was not detected in the fetuses or amniotic fluid of mid-term rabbits (1).

A study published in 2010 described the thyroxine (T4) and/or thyroid stimulating hormone (TSH) concentrations in newborns whose mothers received IV iohexol during pregnancy (2). The data for the study came from 344 maternal and 343 newborn records. The mothers had undergone multidetector pulmonary computed tomographic angiography because of suspected pulmonary embolism between 2004 and 2008. The mean gestational age of the test was 27.8 weeks and the mean dose of total iodine administered was 45,000 mg/L. All newborns had a normal T4 concentration at birth. One newborn had a transiently abnormal TSH, which normalized at day 6 of life (2).

A 2012 study evaluated the thyroid function of 64 neonates who been exposed in utero when 61 mothers had received IV iodinated contrast material (not further identified) for computed tomographic scans (3). One neonate had a low T4 concentration but a normal TSH level. That infant was born at 25 weeks' and developed respiratory distress syndrome and sepsis (3).

BREASTFEEDING SUMMARY

Iohexol is excreted into breast milk (3). Four lactating women received the IV

contrast media (1 mL/kg) (1 mL contained 350 mg iodine) in the postpartum period (1 week to 14 months) (4). Breastfeeding was stopped for 48 hours. The amount excreted over a 24-hour period was 0.5% of the maternal weight-adjusted dose. This amount did not appear to be clinically significant (4). The American Academy of Pediatrics classifies iohexol as compatible with breastfeeding (5).

IOPAMIDOL

Diagnostic Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

There is limited information on the use of iopamidol during human pregnancy. The animal data suggest low risk but the results were based on body weight and may not be interpretable. The iodine in this agent is organically bound, but the formulations may contain some free iodine either from contamination or from deiodination. Even though iopamidol crosses the placenta, at least in the 3rd trimester, none of the four newborns exposed in utero had hypothyroidism or goiter. The guidelines of the Contrast Media Safety Committee of the European Society of Urogenital Radiology recommend that iodinated contrast media may be used in pregnancy if such use is essential (1). This is consistent with a 2008 reference that concluded that intravascular use of nonionic iodinated contrast media was probably safe in pregnancy (2). However, there was a potential for neonatal hypothyroidism if ionic iodinated contrast media was instilled into the amniotic cavity during amniocentesis (2). Therefore, with any use of iodinated contrast media, the thyroid function of the newborn should be monitored in the 1st week (1).

FETAL RISK SUMMARY

Iopamidol is an aqueous, nonionic, radiopaque diagnostic agent that, depending on the formulation used, contains about 200–370 mg of organically bound iodine per mL. It is indicated for angiography throughout the cardiovascular system, including cerebral and peripheral arteriography, coronary arteriography and ventriculography, pediatric angiocardiology, selective visceral arteriography and aortography, peripheral venography (phlebography), and adult and pediatric intravenous excretory urography and intravenous adult and

pediatric contrast enhancement of computed tomographic (CT) head and body imaging. There appears to be no significant deposition of iopamidol in tissues. The agent undergoes no significant metabolism or deiodination and the elimination serum or plasma half-life is about 2 hours (3).

Reproduction studies have been conducted in rats and rabbits. In these species, doses up to 2.7 and 1.4 times the maximum recommended human dose based on body weight, respectively, revealed no evidence of impaired fertility or harm to the fetus (3).

Long-term studies for carcinogenic effects have not been conducted. No evidence of genetic toxicity was obtained with in vitro assays (3).

Consistent with its molecular weight (about 777) and elimination half-life, iopamidol crosses the human placenta. A 2011 case report described the use of the agent in a woman in the 3rd trimester (specific date not given) for evaluation of chest pain (4). The woman received two doses of the 370-mg/mL formulation because the first dose was given through an infiltrated IV catheter. The second dose was given 24 hours later. The chest CT resulted in the diagnosis of pericardial effusion. Premature dizygotic twin males, 1490 g and 1150 g, were delivered at 29 weeks' gestation by cesarean section because of the mother's severe preeclampsia. Apgar scores of twin A were 7 and 8 at 1 and 5 minutes, respectively, whereas in twin B, the scores were 1, 3, and 7 at 1, 5, and 10 minutes, respectively. Both infants had abdominal radiopaque densities that made exclusion of necrotizing enterocolitis difficult. Serial images showed the opacities progressing through multiple loops of intestine and made the bowel wall appear thickened. When twin A passed meconium, the presence of intraluminal radiopaque material was confirmed. Thyroid function tests in both infants during this period were normal (4).

In a 2008 retrospective report, two pregnant women received iopamidol (5). The first woman, at 33 weeks' gestation, received the formulation with 370 mg/mL of organically bound iodine for imaging of her chest and abdomen, whereas the second woman, at 23 weeks, received the formulation with 300 mg/mL for imaging of the chest. Both infants, born at 38 and 24 weeks', respectively, had normal TSH levels. Thirty-three months after birth, neither mother reported known thyroid illness in the children (5).

A 2009 retrospective study compared pulmonary CT angiography (CTA) using iopamidol (370 mg/mL) with lung scintigraphy using low-dose (90 MBq) technetium Tc-99m to diagnose pulmonary embolism in pregnancy (6). There were 25 pregnant patients in each group. The authors concluded that lung scintigraphy was more reliable than pulmonary CTA in pregnant patients. The

mean gestational ages in the two groups were not statistically different (30.6 ± 6.4 weeks vs. 26.5 ± 8.9 weeks). No information was provided on newborn outcomes (6).

A 22-year-old woman at 33 2/7 weeks' gestation with a history of asthma and migraine headaches and documented allergies to penicillin and codeine was admitted for chest pain, shortness of breath, and tachycardia (7). She was evaluated for pulmonary embolism with a CT angiogram conducted with an infusion of iopamidol (300 mg/mL formulation). During the infusion, she developed facial flushing, throat tightness, and worsening dyspnea. The infusion was stopped and she was treated for an allergic reaction with complete resolution of her symptoms. The imaging was negative for pulmonary embolism and she was discharged home. Several hours later, she returned with bleeding from the IV site and numerous ecchymoses and petechiae. Her platelet count, which had been 172,000/microliter the night before, was now 4000. She was transferred to another hospital and treated with dexamethasone 40 mg IV for 4 days. Her platelet count rose to 33,000 24 hours after transfer and was 99,000 when discharged on day 5. Ten days later, her thrombocytopenia had resolved with count of 220,000. She had an uncomplicated repeat cesarean section at 39 weeks' (no information on the newborn was given) (7).

BREASTFEEDING SUMMARY

No reports describing the use of iopamidol during human lactation have been located. The molecular weight (about 777) and elimination half-life (about 2 hours) suggest that limited amounts of the agent will be excreted into breast milk. Although the iodine in the agent is organically bound and significant deiodination does not occur, ingestion of the agent by the infant might release iodine that would be absorbed systemically. However, it is doubtful if clinically significant amounts of either iopamidol or iodine would be absorbed by a nursing infant. A 2005 review concluded that breastfeeding may be continued normally when iodinated agents are given to the mother (1).

IOPANOIC ACID

Diagnostic

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Iopanoic acid contains a high concentration of organically bound iodine. See Diatrizoate.

BREASTFEEDING SUMMARY

Iopanoic acid is excreted into breast milk. Cholecystography was performed in 11 lactating patients with iopanoic acid (1). The mean amount of iodine administered to five patients was 2.77 g (range 1.98–3.96 g) and the mean amount excreted in breast milk during the next 19–29 hours was 20.8 mg (0.08%) (range 6.72–29.9 mg). The nursing infants showed no reaction to the contrast media. The American Academy of Pediatrics classifies iopanoic acid as compatible with breastfeeding (2). See Diatrizoate.

IOTHALAMATE

Diagnostic

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Iothalamate contains a high concentration organically bound iodine. See Diatrizoate for possible effects on the fetus and newborn.

FETAL RISK SUMMARY

Iothalamate has been used for diagnostic procedures during pregnancy. Amniography was performed in one patient to diagnose monoamniotic twinning shortly before an elective cesarean section (1). No effect on the two newborns was mentioned. In a second study, 17 women were given either iothalamate or metrizoate for ascending phlebography during various stages of pregnancy (2). Two patients, one exposed in the 1st trimester and the other in the 2nd trimester, were diagnosed as having deep vein thrombosis and were treated with heparin. The baby from the 2nd trimester patient was normal, but the other newborn had hyperbilirubinemia and undescended testis (2). The relationship between the diagnostic agents (or other drugs) and the defects is not known.

BREASTFEEDING SUMMARY

See Diatrizoate.

IPILIMUMAB

Antineoplastic

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of ipilimumab in human pregnancy have been located. Although the absence of human pregnancy experience prevents a better assessment of the risk, severe fetal toxicity was observed in pregnant monkeys. The drug should be considered contraindicated in pregnancy. However, melanoma is a potentially fatal disease. If a pregnant woman requires ipilimumab, she should be informed of the possible risk to her embryo and/or fetus.

FETAL RISK SUMMARY

Ipilimumab, an IgG1 kappa immunoglobulin, is a recombinant, human monoclonal antibody that binds to the cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4). It is produced in mammalian (Chinese hamster ovary) cell culture. Ipilimumab is indicated for the treatment of unresectable or metastatic melanoma. Neither the metabolism nor plasma protein binding was reported by the manufacturer, but the terminal half-life was 14.7 days (1).

Cynomolgus monkeys were given IV ipilimumab every 21 days from the onset of organogenesis through parturition at doses that were 2.6 and 7.2 times the recommended human dose based on AUC. Severe toxicities including increased incidences of 3rd trimester abortion, stillbirth, premature delivery, low birth weight, and infant death were observed. In mice in which the gene for CTLA-4 had been deleted, offspring lacking CTLA-4 were born healthy, but died within 3–4 weeks due to multiorgan infiltration and damage by lymphocytes (1).

Studies evaluating carcinogenesis, mutagenesis, and impairment of fertility have not been conducted (1).

It is not known if ipilimumab crosses the human placenta. The molecular weight (about 148,000) suggests that it will not cross, at least early in

pregnancy. However, human IgG1 is known to cross, and ipilimumab is an IgG1 (1). Moreover, the prolonged terminal half-life (14.5 days) will increase the opportunity for transfer. Thus, fetal exposure should be expected, especially in the latter part of pregnancy.

BREASTFEEDING SUMMARY

No reports describing the use of ipilimumab during human lactation have been located. The molecular weight (about 148,000) suggests that it will not be excreted into mature breast milk, However, human IgG1 is known to be excreted into colostrum, and ipilimumab is an IgG1 (1). Moreover, the prolonged terminal half-life (14.5 days) will increase the opportunity for excretion. The effect of this exposure on a nursing infant is unknown, but the best course is to not breastfeed if the mother requires ipilimumab.

IPRATROPIUM

Respiratory Drug (Bronchodilator)

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

A number of sources recommend the use of inhaled ipratropium for severe asthma, especially in patients not responding adequately to other therapy (1–4). The consensus appears to be that although human data are rare, there is no evidence that the drug is hazardous to the fetus. Moreover, it produces fewer systemic effects than atropine (1), and may have an additive bronchodilatory effect to β_2 agonists (2).

FETAL RISK SUMMARY

Ipratropium, an anticholinergic compound chemically related to atropine, is a quaternary ammonium bromide used as a bronchodilator for the treatment of bronchospasm. Its use during pregnancy is primarily confined to patients with severe asthma (1).

Ipratropium was not teratogenic in mice, rats, and rabbits when administered either orally or by inhalation (5). Oral doses used in the reproductive toxicity studies were 2000, 200,000, and 26,000 times the maximum recommended human daily dose (MRHDD), respectively. Doses used by inhalation in rats and rabbits were, respectively, 312 and 375 times the MRHDD. Schardein cited a German study that found no evidence of teratogenicity in mice, rats, and rabbits (6). A Japanese study involving rats and rabbits that found no adverse fetal effects except a slight weight reduction was described by Shepard (7).

Data from a surveillance study of Medicaid patients between 1982 and 1994 indicated that 37 women took this drug during the 1st trimester (F. Rosa, personal communication, FDA, 1996). One malformation, a renal obstruction, was observed. Preliminary analysis found no brain defects among 80 recipients following exposure anytime during pregnancy.

A brief 1991 report described the use of nebulized ipratropium, among other

drugs, in the treatment of life-threatening status asthmaticus in a pregnant patient at 12.5 weeks' gestation (8). She eventually delivered a term 3440-g male infant (information on the condition of the newborn was not provided).

BREASTFEEDING SUMMARY

No reports describing the excretion of ipratropium into human milk have been located. A chemically related drug, atropine, is considered compatible with breastfeeding by the American Academy of Pediatrics (9), although definitive data on the appearance of atropine in milk have not been published. Ipratropium is lipid-insoluble and, similar to other quaternary ammonium bases, may appear in milk. The amounts, although unknown, are probably clinically insignificant, however, especially after inhalation.

IRBESARTAN

Antihypertensive

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The human pregnancy experience with irbesartan is limited. However, the antihypertensive mechanisms of action of irbesartan and angiotensin-converting enzyme (ACE) inhibitors are very close. That is, the former selectively blocks the binding of angiotensin II to AT₁ receptors, whereas the latter prevents the formation of angiotensin II itself. Therefore, use of this drug during the 2nd and 3rd trimesters may cause teratogenicity and severe fetal and neonatal toxicity that is identical to that seen with ACE inhibitors (e.g., see Captopril or Enalapril). Fetal toxic effects may include anuria, oligohydramnios, fetal hypocalvaria, intrauterine growth restriction, premature birth, and patent ductus arteriosus. Anuria-associated oligohydramnios may produce fetal limb contractures, craniofacial deformation, and pulmonary hypoplasia. Severe anuria and hypotension, that is resistant to both pressor agents and volume expansion, may occur in the newborn following in utero exposure to irbesartan. Newborn renal function and blood pressure should be closely monitored.

FETAL RISK SUMMARY

Irbesartan is a selective angiotensin II receptor blocker (ARB) that is used either alone, or in combination with other antihypertensive agents, for the treatment of hypertension. Irbesartan blocks the vasoconstrictor and aldosterone-secreting effects of angiotensin II by preventing angiotensin II from binding to AT₁ receptors.

Reproduction studies have been conducted in pregnant rats and rabbits (1). In the pregnant rat, doses approximately equal to or higher than the maximum recommended human dose of 300 mg/day based on BSA (MRHD) were

associated with increased incidences of renal pelvic cavitation, hydroureter, and/or absence of renal papilla. At four times the MRHD, subcutaneous edema was observed in the fetuses. The anomalies appeared to be related to late, rather than early, gestational exposure (1). Doses approximately 1.5 times the MRHD in pregnant rabbits produced maternal mortality and abortion. Surviving rabbits had a slight increase in early resorptions (1). No adverse effects on fertility or reproductive performance were seen in male and female rats at an oral dose about 5 times the MRHD (1).

It is not known if irbesartan crosses the human placenta to the fetus. The molecular weight (about 429) is low enough that transfer to the fetus should be expected. The drug does cross the placentas of rats and rabbits in late gestation (1).

A 24-year-old woman with type 1 diabetes, hypothyroidism, and hypertension was being treated with irbesartan 300 mg/day, hydrochlorothiazide 12.5 mg/day, insulin (glargine and regular), levothyroxine 0.125 mg/day, and epoetin alfa (2). An unplanned pregnancy occurred that was diagnosed at 8 weeks and irbesartan and hydrochlorothiazide were replaced with methyldopa. The patient's HbA1c was 7%. Ultrasonography at 13 weeks' detected an exencephaly and the pregnancy was terminated. Autopsy revealed a partial exencephaly and unilateral renal agenesis. The cause of the defects could not be determined, but the authors suspected irbesartan (2). However, unilateral renal agenesis is possibly autosomal dominant inheritance with variable expressivity and penetrance (3).

A 35-year-old woman with hypertension was exposed to irbesartan, atorvastatin, and sibutramine from 6 weeks to 8 days before conception (4). She had a 1st trimester miscarriage. Examination of the embryo revealed delayed development of the upper extremities. The karyotype was 45,XO (Turner syndrome), a chromosomal abnormality.

A 2009 report described three cases of irbesartan exposure before and during pregnancy (5). In each case, the drug was used to treat hypertension and was stopped at 5, 9, and 18 weeks' gestation, respectively. The three pregnancy (gestational age at birth) outcomes were small-for-gestational-age (39 weeks), polydactyly (40 weeks), and complications of prematurity (29 weeks), respectively. In the latter case, oligohydramnios was observed at 18 weeks. Other than the polydactyly, no structural malformations were reported (5).

A 2012 review of the use of ACE inhibitors and ARBs in the 1st trimester concluded that there may be an elevated teratogenic risk, but the risk appeared

to be related to other factors (6). The factors, which typically coexist with hypertension in pregnancy, included diabetes, advanced maternal age, and obesity.

BREASTFEEDING SUMMARY

No reports describing the use irbesartan during human lactation have been located. Because of the relatively low molecular weight (about 429), excretion into human breast milk should be expected. The effect of this exposure on a nursing infant is unknown. The American Academy of Pediatrics, however, classifies ACE inhibitors, a closely related group of antihypertensive agents, as compatible with breastfeeding (see Captopril or Enalapril).

IRINOTECAN

Antineoplastic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

One report described the use of irinotecan, combined with 5-fluorouracil and folinic acid, in the 2nd and 3rd trimesters that ended with a healthy infant. The animal reproduction data suggest risk, but the near absence of human pregnancy experience prevents a more complete assessment of embryo–fetal risk. Because of the potential for embryo and fetal harm, women of childbearing potential should employ adequate contraceptive methods to prevent pregnancy. Moreover, the recommended regimen for irinotecan sometimes includes the antineoplastic fluorouracil; the combined therapy might increase the embryo–fetal risk, especially in the 1st trimester. However, the indications for irinotecan involve potentially fatal cancers, so if informed consent is obtained, treatment should not be withheld because of pregnancy. If an inadvertent pregnancy occurs during therapy, the woman should be advised of the unknown, but potentially severe risk for her embryo–fetus.

FETAL RISK SUMMARY

The DNA topoisomerase I-inhibitor, irinotecan, is a semisynthetic derivative of camptothecin, an alkaloid extract from plants such as *Camptotheca acuminata*. It is given as an IV infusion. Irinotecan is in the same antineoplastic subclass as topotecan. It is indicated, either as a single agent or in combination with 5-fluorouracil and leucovorin, for the treatment of metastatic carcinoma of the colon or rectum. The cytotoxicity of irinotecan and its active metabolite, SN-38, is thought to involve the inhibition of the enzyme responsible for the repair of normally occurring single-strand breaks in DNA. However, the plasma AUC values for the active metabolite are only 2%–8% of irinotecan, so the precise contribution of SN-38 to the cytotoxicity activity of irinotecan is unknown.

Irinotecan is metabolized primarily in the liver. Binding of irinotecan and SN-38 to plasma proteins is about 50% and 95%, respectively. The mean terminal elimination half-lives are 6–12 hours and 10–20 hours, respectively (1).

Reproduction studies have been conducted in rats and rabbits. In pregnant rats, an IV dose during organogenesis that produced an AUC that was about 0.2 times the AUC obtained with a human dose of 125 mg/m² (HD) caused increased postimplantation loss and decreased numbers of live fetuses. Doses producing AUC values that were greater than about 0.025 times the HD caused structural defects, including a variety of external, visceral, and skeletal abnormalities. In pregnant rabbits, an IV dose during organogenesis that was about 0.5 times the weekly starting dose based on BSA (WSD) caused similar embryoletality and structural defects. In rats, when a dose producing an AUC that was about 0.2 times the HD was given after organogenesis through weaning, decreased learning ability and decreased female body weights in offspring were observed (1).

Standard tests for carcinogenicity have not been conducted with irinotecan. When rats were given an IV dose that produced an AUC that was about 1.3 times the HD or a lower dose that was 8% (based on body weight) of the higher dose once weekly for 13 weeks and then allowed to recover for 91 weeks, there was a significant linear trend with dose for the incidence of combined uterine horn endometrial stromal polyps and endometrial stromal sarcomas. Neither irinotecan nor SN-38 was mutagenic, but irinotecan was clastogenic. Irinotecan did not cause significant adverse effects on fertility or reproductive performance in rats and rabbits given IV doses up to 0.2 times the HD or 0.5 times the WSD, respectively. However, multiple daily doses in rodents and dogs that produced an AUC that was about 1 and 0.07 times the HD, respectively, were associated with atrophy of male reproductive organs (1).

It is not known if irinotecan crosses the human placenta. The molecular weight (about 587 for the nonhydrated free base), moderate plasma protein binding, and long elimination half-life suggest that the drug will cross to the embryo–fetus.

A 2009 case report described a 34-year-old woman who was diagnosed with an ovarian adenocarcinoma tumor metastatic from a colon cancer that had been previously treated with surgery (2). After left salpingoophorectomy, treatment was begun at 18 weeks' gestation with irinotecan, 5-fluorouracil, and folinic acid every 2 weeks until the 36th week of pregnancy (total 10 courses). At 37 5/7 weeks, 13 days after the final chemotherapy course, her membranes

ruptured and she gave birth to 5 lb 14 oz (about 2667 g) female infant with Apgar scores of 9 and 9 at 1 and 5 minutes, respectively. The infant was developing normally at 4 months of age with no teratogenic effects (2).

BREASTFEEDING SUMMARY

No reports describing the use of irinotecan during human lactation have been located. The molecular weight (about 587 for the nonhydrated free base), moderate plasma protein binding, and long elimination half-life suggest that the drug will be excreted into breast milk. The potential effect of this exposure on a nursing infant is unknown, but may be severe. It is best that a woman receiving this agent does not breastfeed. However, if she chooses to do so, the infant should be closely monitored for the most common or serious adverse effects observed in adults treated with the drug, such as gastrointestinal tract effects (nausea, vomiting, diarrhea, anorexia), bone marrow suppression (leukopenia, neutropenia, anemia), headache, abdominal pain, alopecia, and hepatic toxicity.

ISOCARBOXAZID

Antidepressant

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Isocarboxazid is a monoamine oxidase inhibitor. Other agents in this subclass are iproniazid, nialamide, phenelzine, and tranylcypromine. The human pregnancy experience is limited. There are no animal reproduction data (see also Tranylcypromine).

FETAL RISK SUMMARY

The Collaborative Perinatal Project monitored 21 mother–child pairs exposed to these drugs during the 1st trimester, 1 of which was exposed to isocarboxazid (1). Three of the 21 infants had malformations (relative risk 2.26). Details of the single case with exposure to isocarboxazid were not given.

It is not known if isocarboxazid crosses the human placenta. The molecular weight (about 231) is low enough that exposure of the embryo–fetus should be expected.

BREASTFEEDING SUMMARY

No reports describing the use of isocarboxazid during human lactation have been located. The molecular weight (about 231) is low enough that excretion into breast milk should be expected.

ISOETHARINE

[Withdrawn from the market. See 9th edition.]

ISOFLURANE

General Anesthetic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Isoflurane was not teratogenic in three animal species at doses that did not cause maternal toxicity. No reports of its use early in human gestation have been located. The absence of human experience during organogenesis prevents a complete assessment of the risk for structural anomalies. In addition, general anesthesia usually involves the use of multiple pharmacological agents. Although no teratogenicity has been observed with two other halogenated general anesthetic agents (halothane and methoxyflurane), only halothane has 1st trimester human exposure data. Isoflurane has been used immediately prior to delivery for analgesia and anesthesia. This use does not appear to affect the newborn any differently from other general anesthetic agents. The uterine effects of isoflurane (relaxation and increased blood loss) also appear to be similar to other agents in this class. All anesthetic agents can cause depression in the newborn that may last for 24 hours or more. The potential reproductive toxicity (spontaneous abortion [SAB] and infertility) of occupational exposure to isoflurane has not been studied but is a concern based on the exposure concentration found in one study. Further, occupational exposure to nitrous oxide was also measured in that study, and indicated that the nurses were exposed to both nitrous oxide and volatile anesthetic agents at the same time.

FETAL RISK SUMMARY

The nonflammable general anesthetic isoflurane is in the same class of volatile liquid halogenated agents such as desflurane, enflurane, halothane, methoxyflurane, and sevoflurane. It is closely related to desflurane and

enflurane. The only difference between isoflurane and desflurane is the presence of a chlorine atom in isoflurane instead of a fluorine atom. This small difference, however, produces marked pharmacokinetic and clinical effects. The potency of isoflurane is five times that of desflurane, the blood–gas partition coefficient is increased (i.e., increased solubility in blood) (1.46 vs. 0.42), tissue solubility is increased (brain–blood partition coefficient 1.6 vs. 1.3), and recovery from anesthesia is slower (1).

In an animal reproductive study, mean anesthetic concentrations (about 1.6%) of isoflurane were administered to male and female rats for 5-day intervals up to 15 days before pairing (2). No adverse effects on mating and fertility indices were observed. Studies for structural anomalies were conducted in pregnant rats and rabbits in the same way. Three groups of rats received mean anesthetic doses of 1.6%–1.7% for 5-day intervals between day 1 and day 15 of gestation, whereas three groups of rabbits received mean doses of 2.3% for 4- or 5-day intervals between day 6 and 18 of gestation. No congenital malformations related to the exposures were found in either animal species (2). In the third segment of this study, pregnant rats were exposed to isoflurane 1.74% for 1 hour/day on gestation days 15–20. Maternal weight gain was significantly less in the exposed group, and fetal survival was also decreased (2).

Three dose-levels of isoflurane were administered in a reproduction study with pregnant mice: trace (0.006%), subanesthetic (0.06%), and light anesthetic (0.6%) (3). No adverse maternal or fetal effects were observed when the two smaller concentrations were administered for 4 hours daily on days 6–15 of pregnancy. When given the same way, the light anesthetic dose, however, resulted in significantly lower maternal weight gain. Fetal toxicity included a significant decrease in fetal weight, decreased skeletal ossification, minor hydronephrosis, and increased pelvic cavitation (3). In addition, an increased incidence of cleft palate was observed (12.1% vs. 0.75% for controls). The incidence of cleft palate also was higher than that observed in previous experiments with halothane (1.2%) or enflurane (1.9%) (3).

In a second study by the authors of the above report, the effects of four general anesthetic agents were compared in pregnant rats (4). The doses and agents used were nitrous oxide (75%; 0.55 minimum alveolar anesthetic concentration [MAC]), enflurane (1.65%; 0.75 MAC), halothane (0.8%; 0.75 MAC), and isoflurane (1.05%; 0.75 MAC). (Note: The MAC is the concentration that causes immobility in 50% of patients exposed to a noxious stimulus such as a surgical incision; it represents the ED₅₀ [5]). Each agent was

administered for 6 hours on each of three consecutive days in one of three gestational periods: pregnancy days 8–10, 11–13, or 14–16. Compared with controls, significantly decreased maternal weight gain was observed in three of the groups (nitrous oxide, isoflurane, and enflurane) after exposure on days 14–16. Exposure on those days resulted in significantly decreased fetal weight in all four groups and, when exposure occurred on days 8–10, in three groups (all except nitrous oxide). Nitrous oxide exposure during days 14–16 resulted in significant increases (three-fold) in total fetal wastage and resorptions. However, no major or minor teratogenic effects were observed in any of the groups (4).

The teratogenic potential of isoflurane, enflurane, and sevoflurane was studied by evaluating the effect of each agent on the proliferation and differentiation of cells exiting from the G1-phase of the cell cycle (6). The theory behind the study was that normal development during embryogenesis, organogenesis, and histogenesis depended on the proliferation and differentiative processes of cell migration (6). For example, valproate, a known human teratogen, is a potent G1-phase inhibitor of the in vitro proliferation rate at concentrations <2 times the therapeutic plasma concentration. At anesthetic concentrations <2 times the MAC, the antiproliferative potency of the three agents was isoflurane=enflurane>>sevoflurane. However, in the growth-arrested cell population, there was no specific accumulation of any cell-cycle phase and no specific effect on the G1 phase. The investigators concluded that the three agents lacked the specific in vitro characteristics of valproate (6).

Three anesthetic agents, isoflurane, halothane, and methoxyflurane, were administered to pregnant (near term) and nonpregnant ewes in a study designed to determine the requirement for inhaled anesthetic agents (7). The MAC was decreased in the pregnant animals in each case, 40%, 25%, and 32% less, respectively. In a 1994 study, women at 8–12 weeks' gestation (all undergoing termination of pregnancy) were matched with women undergoing gynecologic surgery (8). The MAC was reduced by 28% in comparison with the nonpregnant controls (median end-tidal concentration 0.775% vs. 1.075%, respectively).

Two reviews concluded that, in general, inhalational anesthetics are freely transferred to fetal tissues (9,10) and, in most cases, the maternal and fetal concentrations are equivalent (10). The low molecular weight (about 185) and the presence of isoflurane in the maternal brain support this assertion. In agreement, research has demonstrated the rapid uptake of isoflurane by the fetus (11).

A 1991 case report described two liver transplant procedures, 3 days apart, in a pregnant woman at approximately 21 weeks' gestation (12). Isoflurane was the only inhaled anesthetic agent used, although a number of other drugs were administered during the combined 24.4 hours of anesthesia. The woman eventually delivered a healthy infant by cesarean section (12).

Subanesthetic doses of isoflurane have been used for labor analgesia (13–15). A study published in 1985 compared the self-administration of isoflurane (0.75% in oxygen) or 50% nitrous oxide in oxygen given in a random sequence in 32 women (13). Isoflurane use resulted in better analgesia but increased drowsiness. The condition of the newborns was not mentioned. A 1989 study used isoflurane (0.2%–0.7%) or 30%–60% nitrous oxide (30 in each group) for labor analgesia (14). Seven percent of the newborns in both groups were depressed (1-minute Apgar scores 5–7), but all had Apgar scores of 8–10 at 5 minutes. There was also no difference in neonatal neurobehavior as measured by the Neurologic and Adaptive Capacity Scores (NACS) at 15 minutes, 2 hours, and 24 hours of age. Although specific percentages were not given, it was stated that there was no significant difference between the groups in the percentage of infants who scored 35–40 on the NACS. Mothers in the isoflurane group had higher concentrations of fluoride in their urine at 12–24 hours postpartum than those who had received nitrous oxide (36.5 vs. 23.6 $\mu\text{mol/L}$), but the fluoride blood levels were similar ($<5.6 \mu\text{mol/L}$). The fluoride urine levels in the newborns (first void) also were similar ($<5.6 \mu\text{mol/L}$) (14). In a 1993 report, 17 laboring women received alternating doses of 0.2% isoflurane plus 50% nitrous oxide/oxygen or nitrous oxide/oxygen alone, each over 1-hour intervals, for a total of 3 hours (15). Analgesia was significantly better when the women were receiving isoflurane. Progressive drowsiness was noted over the 3-hour period, but it was not considered clinically significant. The newborns were delivered vaginally and all had 1- and 5-minute Apgar scores of 8 to 10. Neurobehavior assessment was not conducted (15).

Isoflurane has been used for anesthesia during cesarean section (11, 16–19). As with vaginal delivery, some degree of neonatal depression may occur as indicated by Apgar scores <7 at 1 minute (11, 16–18) or an NACS <35 at 2 and 24 hours of age (16). A small 1983 study compared the neonatal outcomes in four groups (10 patients each) of women receiving general anesthesia for cesarean section: 50% nitrous oxide and 50% oxygen either alone, or combined with 0.5% halothane, 1.0% enflurane, or 0.75% isoflurane (19). One newborn had an Apgar score <7 at 1 minute (enflurane group), but all newborns in all groups had scores of ≥ 7 at 5 minutes. There were no significant

differences between the groups in neonatal neurobehavior assessment 2–4 hours after delivery or in maternal or umbilical blood gas analysis at delivery.

In a 1977 *in vitro* study, isoflurane was shown to have a statistically significant depressive effect on myometrial strips from nonpregnant and pregnant uteri (20). Three anesthetic agents, isoflurane, enflurane, and halothane, were studied at three concentrations (0.5, 1.0, and 1.5 MAC). The amount of depression was dose-related for each agent and was similar with all agents (20). Another study also demonstrated a dose-related relaxing effect of isoflurane (0.5%, 1.0%, and 1.5%) on isolated pregnant human uterine muscle (21). All doses caused a significant decrease in uterine activity, but oxytocin, in a dose similar to that used clinically, reversed the effects of the anesthetic (21). In another study, the subjective assessment of maternal blood loss and uterine relaxation was less for isoflurane than for halothane (16).

A study published in 1998 evaluated the exposure of nine nurses in a postanesthesia care unit (PACU) to exhaled isoflurane and desflurane and compared these exposures with the National Institute of Occupational Safety and Health (NIOSH)-recommended exposure limits (22). The NIOSH recommendation for volatile anesthetics (without concomitant nitrous oxide exposure) is a maximum of 2 parts per million, but has not been adopted by the Occupational Safety and Health Administration. Moreover, the recommended limit is controversial and is thought by some to be inappropriately low (22). However, a potential for reproductive risk (SAB and infertility) is thought to exist for some anesthetic agents. The study involved exposure in the PACU to exhaled anesthetic gases from 50 adult patients (isoflurane N = 19, desflurane N = 31) over an approximately 1-hour recovery time. About one-half of the patients were extubated in the PACU. Exposure was continuously measured from the shoulders (i.e., breathing-zone) of the nurses. Breathing-zone anesthetic concentrations of isoflurane and desflurane exceeded the NIOSH limits in 37% and 87% of the cases, respectively. These exposures were above the limit 12% of the time for isoflurane and 49% of the time for desflurane. The investigators listed several limitations to their study and concluded that the results might represent a “worst-case analysis” (22).

A 2004 study found a significant association between maternal occupational exposure to waste anesthetic gases during pregnancy and developmental deficits in their children, including gross and fine motor ability, inattention/hyperactivity, and IQ performance (see Nitrous Oxide).

BREASTFEEDING SUMMARY

Although isoflurane has been administered during labor and delivery, the effects of this exposure on the infant that begins nursing immediately after birth have not been described. Isoflurane is probably excreted into colostrum and milk as suggested by its presence in the maternal blood and its low molecular weight (about 185), but the toxic potential of this exposure for the infant is unknown. However, the risk to a nursing infant from exposure to isoflurane via milk is probably very low (24,25). Another halogenated inhalation anesthetic, halothane, is classified as compatible with breastfeeding by the American Academy of Pediatrics (see Halothane).

ISOFLUROPHATE

[Withdrawn from the market. See 9th edition.]

ISOMETHEPTENE

Sympathomimetic (Adrenergic)

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports of human developmental toxicity or animal reproductive studies have been located.

FETAL RISK SUMMARY

The sympathomimetic drug, isometheptene, is commercially available in combination with dichloralphenazone and acetaminophen (e.g., Isocom, Isopap, Midchlor, Midrin, and Migratine) for the treatment of tension and vascular (migraine) headaches (see also Dichloralphenazone and Acetaminophen).

The Collaborative Perinatal Project, conducted between 1958 and 1965, recorded eight 1st trimester exposures to isometheptene among 96 mothers who had consumed a miscellaneous group of sympathomimetics (1). From these 96 mothers, 7 children had congenital malformations giving a standardized relative risk (SRR) of 0.96. When only malformations showing uniform rates by hospital were analyzed, the number of children with defects decreased to 4 (SRR 0.81). The authors of this study concluded there was no association between these agents and congenital anomalies.

A 1984 source briefly reviewed isometheptene (2). Although citing no primary references, the authors concluded that the agent was not contraindicated in pregnancy because of the lack of reports of harmful effects on the fetus, the mother, and the pregnancy (2).

BREASTFEEDING SUMMARY

No reports describing the use of isometheptene during human lactation have been located.

ISONIAZID

Antituberculosis Agent

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >> Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Isoniazid does not appear to be a human teratogen. The American Thoracic Society recommends use of the drug for tuberculosis occurring during pregnancy because, “Untreated tuberculosis represents a far greater hazard to a pregnant woman and her fetus than does treatment of the disease” (1).

FETAL RISK SUMMARY

Isoniazid is used in the prevention and treatment of pulmonary tuberculosis. Reproduction studies in mice, rats, and rabbits have not revealed teratogenic effects, but embryocidal effects were observed in rats and rabbits (2).

An official statement of the American Thoracic Society published in 1986 recommends isoniazid as part of the treatment regimen for women who have tuberculosis during pregnancy (1). Other reviewers also consider isoniazid as part of the treatment of choice for tuberculosis occurring during pregnancy (3).

Isoniazid crosses the placenta to the fetus (4–6). In a 1955 study, 19 women in labor were given a single 100-mg dose of isoniazid 0.25–4.25 hours before delivery (4). The mean maternal serum concentration at birth was 0.32 mcg/mL compared with a cord blood level of 0.22 mcg/mL. The mean cord:maternal ratio was 0.73, but in seven of the patients, cord blood concentrations exceeded those in the maternal plasma. Another study examined the placental transfer of isoniazid in two women who had been treated with 300 mg/day during the 3rd trimester (5). One hour before delivery, the women were given a single 300-mg IM dose. Mean cord blood and maternal serum concentrations were 4 and 6.5 mcg/mL, respectively, a ratio of 0.62. These studies and the elimination kinetics of intrauterine-acquired isoniazid in the newborn were

reviewed in 1987 (6).

Reports discussing fetal effects of isoniazid during pregnancy reflect multiple drug therapies. Early reports identified slow psychomotor activity, psychic retardation, convulsions, myoclonia, myelomeningocele with spina bifida and talipes, and hypospadias as possible effects related to isoniazid therapy during pregnancy (7,8). The Collaborative Perinatal Project monitored 85 patients who received isoniazid during the 1st trimester (9, pp. 299, 313). They observed 10 malformations, an incidence almost twice the expected rate, but they cautioned that their findings required independent confirmation. For use anytime during pregnancy, 146 mother–child pairs were exposed to isoniazid, with malformations that may have been produced after the 1st trimester observed in 4 infants (9, p. 435). This was close to the expected frequency. Adverse outcomes in the fetus and newborn after intrauterine exposure to isoniazid have not been confirmed by other studies (10–15). Retrospective analysis of >4900 pregnancies in which isoniazid was administered demonstrated rates of malformations similar to those in control populations (0.7%–2.3%). A 1980 review also found no association between isoniazid and fetal anomalies (16).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 11 newborns had been exposed to isoniazid during the 1st trimester (F. Rosa, personal communication, FDA, 1993). One (9.1%) major birth defect was observed (0.5 expected), a case of polydactyly.

A case report of a malignant mesothelioma in a 9-year-old child who was exposed to isoniazid in utero was published in 1980 (17). The authors suggested a possible carcinogenic effect of isoniazid because of the rarity of malignant mesotheliomas during the first decade and supportive animal data. However, an earlier study examined 660 children up to 16 years of age and found no association with carcinogenic effects (18).

An association between isoniazid and hemorrhagic disease of the newborn has been suspected in two infants (19). The mothers were also treated with rifampin and ethambutol, and in a third case, only with these latter two drugs. Although other reports of this potentially serious reaction have not been found, prophylactic vitamin K₁ is recommended at birth (see Phytonadione).

BREASTFEEDING SUMMARY

No reports of isoniazid-induced effects in the nursing infant have been located, but the potential for interference with nucleic acid function and for hepatotoxicity may exist (20,21). Both isoniazid and its metabolite, acetylisoniazid, are

excreted in breast milk (21–23). A woman was given a single oral dose of 300 mg after complete weaning of her infant (21). Both isoniazid and the metabolite were present in her milk within 1 hour, with peak levels of isoniazid (16.6 mcg/mL) occurring at 3 hours and those of the metabolite (3.76 mcg/mL) at 5 hours. At 5 and 12 hours after the dose, isoniazid levels in the milk were twice the levels in simultaneously obtained plasma. Levels of acetylisoniazid were similar in plasma and milk at 5 and 12 hours. The elimination half-life for milk isoniazid was calculated to be 5.9 hours, whereas that of the metabolite was 13.5 hours. Both were detectable in milk 24 hours after the dose. The 24-hour excretion of isoniazid was estimated to be 7 mg. Two other studies also reported substantial excretion of isoniazid into human milk (22,23). A milk:plasma ratio of 1.0 was reported in one of these studies (22). In another, milk levels 3 hours after a maternal dose of 5 mg/kg were 6 mcg/mL (23). Doubling the maternal dose doubled the milk concentration.

Based on the above information, at least one review concluded that women can safely breastfeed their infants while taking isoniazid if, among other precautions, the infant is periodically examined for signs and symptoms of peripheral neuritis or hepatitis (20). Moreover, the American Academy of Pediatrics classifies isoniazid as compatible with breastfeeding (24).

ISOPROPAMIDE

[Withdrawn from the market. See 9th edition.]

ISOPROTERENOL

Sympathomimetic/Bronchodilator

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports linking the human use of isoproterenol with congenital defects have been located. Isoproterenol was not teratogenic in rats and rabbits, but was in hamsters (1,2). Sympathomimetics are often administered in combination with other drugs to alleviate the symptoms of upper respiratory infections. Thus, the fetal effects of sympathomimetics, other drugs, and viruses cannot be totally separated.

FETAL RISK SUMMARY

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 31 of whom had 1st trimester exposure to isoproterenol (3, pp. 346–347). No evidence was found to suggest a relationship between large categories of major or minor malformations or to individual defects. However, an association in the 1st trimester was found between the sympathomimetic class of drugs as a whole and minor malformations (not life-threatening or major cosmetic defects), inguinal hernia, and clubfoot (3, pp. 345–356).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 16 newborns had been exposed to isoproterenol during the 1st trimester (F. Rosa, personal communication, FDA, 1993). One (6.3%) major birth defect was observed (0.7 expected), an oral cleft.

Isoproterenol has been used during pregnancy to accelerate heart rhythm when high-grade atrioventricular block is present and to treat ventricular arrhythmias associated with prolonged QT intervals (4). Because of its β -adrenergic effect, the agent will inhibit contractions of the pregnant uterus (4). Of incidental interest, five-term, nonlaboring pregnant women were discovered

to have an increased resistance to the chronotropic effect of isoproterenol in comparison to nonpregnant women (5). One fetus had an isolated 5-beats/minute late deceleration 2 minutes after the mother received 0.25 mcg of the drug (5).

BREASTFEEDING SUMMARY

No reports describing the use of isoproterenol during human lactation have been located.

ISOSORBIDE

Diuretic

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Isosorbide is an osmotic diuretic used for the short-term reduction of intraocular pressure in acute glaucoma before and after intraocular surgery. No published reports describing the use of isosorbide in pregnancy have been located.

FETAL RISK SUMMARY

In an FDA surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 13 newborns had been exposed to isosorbide during the 1st trimester (F. Rosa, personal communication, FDA, 1993). No major birth defects were observed (0.6 expected).

BREASTFEEDING SUMMARY

No reports describing the use of isosorbide during human lactation have been located.

ISOSORBIDE DINITRATE

Vasodilator

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Isosorbide is a nitric oxide donor, similar to nitroglycerin that is used in the management of angina pectoris and of heart failure. No reports have described pregnancy outcomes following therapeutic use of this agent.

FETAL RISK SUMMARY

Isosorbide is administered sublingually, as chewable tablets, and as oral tablets. An oral spray is also available outside of the United States. The molecular weight (about 236) is low enough that passage to the fetus should be expected.

The drug produces dose-related embryotoxicity in rabbits at doses 35 and 150 times the maximum recommended human dose (1) (see also Nitroglycerin and Amyl Nitrite).

Two full reports and one abstract have described the use of isosorbide dinitrate during human pregnancy (2–4). However, all of the pregnancies in these reports had prescheduled elective terminations for nonmedical reasons shortly after the drug exposure. In a 1996 study (first published as an abstract in 1995), 18 women in the 2nd trimester received a single 5-mg sublingual dose of isosorbide dinitrate (2,3). Statistically significant decreases in the maternal systolic and diastolic blood pressures were observed 6 minutes after the dose. The blood pressures gradually returned to control levels over the ensuing 30 minutes. The mean maternal heart rate significantly increased from about 85 beats/minute to 96 beats/minute at 6 minutes, but declined to near control levels at 8 minutes. The mean systolic–diastolic flow velocity ratios in the umbilical and uterine arteries declined significantly, reaching nadirs at 6 and 10 minutes, respectively, before gradually returning to predose levels. These

findings suggested that isosorbide dinitrate may be beneficial in reversing the effects of endothelial cell dysfunction–induced generalized vasoconstriction and increased vascular resistance to flow in the uteroplacental circulation, such as that occurs in preeclampsia (2,3).

In a similar investigation by these same researchers, 11 women at a mean gestational age of 10.0 weeks (range 8.2–11.6 weeks) were given a single 5-mg sublingual dose of the drug (4). The results of this study were comparable to the researchers previous work and led them to a similar conclusion that isosorbide dinitrate may be effective in reversing the effects of the endothelial cell dysfunction that is observed in preeclampsia (4).

BREASTFEEDING SUMMARY

No reports describing the use of isosorbide dinitrate during lactation have been located. The molecular weight (about 236) is low enough that excretion into breast milk should be expected. The effect of this exposure on a nursing infant is unknown.

ISOSORBIDE MONONITRATE

Vasodilator

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The vasodilator isosorbide mononitrate is the major active metabolite of isosorbide dinitrate. The drug has been used for cervical ripening.

FETAL RISK SUMMARY

In rats and rabbits administered doses up to 250 mg/kg/day, no adverse effects on reproduction and development were observed, but doses of 500 mg/kg/day in rats caused significant increases in prolonged gestation, prolonged parturition, stillbirth, and neonatal death (1).

A number of reports have described the use of vaginal isosorbide mononitrate for cervical ripening at term (2–11). No adverse fetal effects were observed.

BREASTFEEDING SUMMARY

No reports describing the use of isosorbide mononitrate during human lactation have been located.

ISOTRETINOIN

Vitamin

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Isotretinoin is a potent human teratogen. Critically important is the fact that a high percentage of the recipients of this drug are women with childbearing potential. Estimates have indicated that 38% of isotretinoin users are women aged 13–19 years (1). Pregnancy must be excluded and prevented in these and other female patients before isotretinoin is prescribed.

FETAL RISK SUMMARY

Isotretinoin (Accutane) is a vitamin A isomer used for the treatment of severe, recalcitrant cystic acne. The animal teratogenicity of this drug was well documented before its approval for human use in 1982 (2,3). The mechanism of isotretinoin teratogenicity in animals may involve cytotoxic peroxy free radical generation by metabolism with prostaglandin synthase (4). Newborn mice exposed in utero to isotretinoin at a critical point in gestation had characteristic craniofacial and limb malformations, but concurrent treatment with aspirin, a prostaglandin synthase inhibitor, resulted in a dose-dependent decrease in the overall incidence of abnormalities, the number of anomalies per fetus, and the incidence of specific craniofacial and limb defects (4).

Shortly after its approval, several publications appeared warning of the human teratogenic potential if isotretinoin was administered to women who were pregnant or who may become pregnant (5–10). In the 22 months following its introduction (September 1982 through July 5, 1984), the manufacturer, the FDA, and the CDC received reports on 154 isotretinoin-exposed pregnancies (11). Some of these cases had been described in earlier reports (1,12–20). Of the 154 pregnancies, 95 were electively aborted, 12 aborted spontaneously, 26 infants were born without major defects (some may

not have been exposed during the critical gestational period), and 21 had major malformations (11). Three of the 21 infants were stillborn and 9 died after birth. A characteristic pattern of defects was observed in the 21 infants that closely resembled that seen in animal experiments (11). The syndrome of defects observed in these infants and in other reported cases (21–34) consists of all or part of the following:

Central nervous system

- Hydrocephalus
- Facial (VII nerve) palsy
- Posterior fossa structure defects
- Cortical and cerebellar defects
- Cortical blindness
- Optic nerve hypoplasia
- Retinal defects
- Microphthalmia

Craniofacial

- Microtia or anotia
- Low-set ears
- Agenesis or marked stenosis of external ear canals
- Micrognathia
- Small mouth
- Microcephaly
- Triangular skull
- Facial dysmorphism
- Depressed nasal bridge
- Cleft palate
- Hypertelorism

Cardiovascular

- Conotruncal malformations
- Transposition of great vessels
- Tetralogy of Fallot
- Double-outlet right ventricle
- Truncus arteriosus communis
- Ventricular septal defect
- Atrial septal defect
- Branchial-arch mesenchymal-tissue defects
- Interrupted or hypoplastic aortic arch
- Retrosophageal right subclavian artery

Thymic defects

- Ectopia, hypoplasia, or aplasia

Miscellaneous defects (sporadic occurrence)

- Spina bifida

- Nystagmus

- Hepatic abnormality

- Hydroureter

- Decreased muscle tone

- Large scrotal sac

- Simian crease

- Limb reduction

Other defects have been reported with isotretinoin, but in these cases exposure had either been terminated before conception or was outside the critical period for the defect (33). These defects are thought to be nonteratogenic or have occurred by chance (33). Similarly, three reports of anomalies in children in which only the father was exposed (biliary atresia and ventricular septal defect; four-limb ectromelia and hydrocephalus; anencephaly) also probably occurred by chance (33).

A 1985 case report proposed that reduction deformities observed in all four limbs of a male infant were induced by isotretinoin (35,36). Other evidence suggested that these defects may have been secondary to amniotic bands (37). However, a 1991 reference described an infant and a fetus with limb reduction deformities after 1st trimester exposure to isotretinoin (38). A 17-year-old mother took 50 mg/day of isotretinoin for 10 days during the 2nd month of gestation. Abnormalities present in the infant were absence of the right clavicle and nearly absent right scapula, a short humerus, and a short, broad, completely synostotic right radius and ulna (38). Other defects present were asymmetrical ventriculomegaly, minor dysmorphic facial features, a short sternum with a sterno-umbilical raphe, and developmental delay (38). The second case involved an 18-year-old woman who took 60 mg/day of isotretinoin during the first 62 days of gestation (38). The pregnancy was terminated at 22 weeks' gestation because of fetal hydrocephalus and cystic kidney. Multiple defects were noted in the fetus, including an absent left thumb but with normal proximal bony structures, a single umbilical artery, anal and vaginal atresia, urethral agenesis with dysplastic, multicystic kidneys, and other malformations consistent with isotretinoin exposure (38).

Because isotretinoin causes CNS abnormalities, concern has been raised over the potential for adverse behavioral effects in infants who seemingly are

normal at birth (39). Long-term studies are in progress to evaluate behavioral toxicities, such as mental retardation and learning disabilities, but have not been concluded because the exposed children are still too young for tests to produce meaningful results (40).

The teratogenic mechanism of isotretinoin and its main metabolite, 4-oxo-isotretinoin, is thought to result from an adverse effect on the initial differentiation and migration of cephalic neural crest cells (11,41). Daily doses in the range of 0.5–1.5 mg/kg were usually ingested in cases with adverse outcome (11), but doses as low as 0.2 mg/kg or lower may also have caused teratogenicity (34,42). The critical period of exposure is believed to be 2–5 weeks after conception, but clinically it is difficult to establish the exact dating in many cases (33). Because of the high proportion of spontaneous abortions in prospectively identified exposed women, the CDC commented that fetotoxicity may be a more common adverse outcome than liveborn infants with abnormalities (12).

The lack of reports of isotretinoin-induced abnormalities from areas other than the United States and Canada caused speculation that this was caused by the use of lower doses, more restricted use in women, or later marketing of the drug (43). Several groups of investigators have responded to this, and although under diagnosis and underreporting may contribute, the reasons are still unclear (44–47).

An autosomal or X-linked recessive syndrome with features of isotretinoin-induced defects has been described in three male siblings (48). Although the mother had no history of isotretinoin or vitamin A use, the authors did not rule out a defect in vitamin A metabolism.

In a follow-up to a previous report involving 36 pregnancies, investigators noted the outcome of an additional 21 pregnancies exposed in the 1st trimester to isotretinoin (49). The outcomes of the 57 pregnancies were 9 spontaneous abortions, 1 malformed stillborn, 10 malformed live births, and 37 normal live births. In this population, the absolute risk for a major defect in pregnancies extending to 20 weeks' gestation or longer was 23% (11 of 48) (49).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 6 newborns had been exposed to isotretinoin during the 1st trimester (F. Rosa, personal communication, FDA, 1993). One (16.7%) major birth defect was observed (0.3 expected). Specific data were not available for the anomaly, but it was not one of six defect categories (cardiovascular defects, oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data

were available.

The outcome of pregnancies occurring after the discontinuation of isotretinoin was described in a 1989 article (50). Of 88 prospectively ascertained pregnancies, conception occurred in 77 within 60 days of the last dose of the drug. In 10 cases, the date of conception (defined as 14 days after the last menstrual period) occurred within 2–5 days after the last dose of isotretinoin. These 10 pregnancies ended in 2 spontaneous abortions and 8 normal infants. Three women who had taken their last dose within 2 days of the estimated date of conception delivered normal infants. The outcomes of all 88 pregnancies were as follows: 8 (9.1%) spontaneous abortions, 1 abnormal birth (details not provided), 75 (85.3%) normal infants, and 4 (4.5%) infants with congenital malformations. The defects observed were small anterior fontanelle (1 case), congenital cataract with premature hypertrophic vitreous membrane (1 case), congenital cataract (1 case), and hypospadias (1 case). The mothers had taken their last dose of isotretinoin 33, 22, 17, and 55 days before conception, respectively. These anomalies are not characteristic of those reported with in utero exposure to isotretinoin. In an additional 13 cases obtained retrospectively, 5 ended in spontaneous abortions, 4 normal infants were delivered, and 4 infants had congenital defects: syndactyly (1 case), Down's syndrome (1 case), hypoplasia of left side of heart (1 case), and unknown defects (1 case). In the cases of known defects, the mothers had stopped isotretinoin at least 9 months before conception. As with the prospective cases, the defects described in the three infants were not those typical of isotretinoin-induced anomalies. Moreover, retrospective reports are probably more likely to report abnormal outcomes and to underreport normal infants (50).

In one study the drug did not interfere with the action of oral contraceptive steroids (51). Initially, recommendations included stopping therapy at least 1 month before conception (1), but others indicated that shorter intervals between the last dose of isotretinoin and conception were apparently safe (50). Labeling by the manufacturer states that a negative serum pregnancy 2 weeks before beginning therapy is required (52,53). A recent statement by the Teratology Society supplemented the manufacturer's recommendations, for treatment of women of childbearing potential with isotretinoin, with additional recommendations and reviewed the animal and human teratogenicity of this agent (53).

BREASTFEEDING SUMMARY

It is not known whether isotretinoin or its metabolite, 4-oxo-isotretinoin, is excreted into human milk. The closely related retinoid, vitamin A, is excreted (see Vitamin A), and the presence of isotretinoin in breast milk should be expected.

ISOXSUPRINE

Sympathomimetic (Vasodilator)

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports linking the use of isoxsuprine with congenital defects have been located.

FETAL RISK SUMMARY

Isoxsuprine, a β -sympathomimetic, is indicated for vasodilation, but it has been used to prevent premature labor (1–6). Uterine inhibitory effects usually require high IV doses, which increase the risk for serious adverse effects (7,8). Maternal heart rate increases and blood pressure decreases are usually mild at lower doses (2,4,6). A decrease in the incidence of neonatal respiratory distress syndrome has been observed (9). However, in one study, neonatal respiratory depression was increased if cord serum levels exceeded 10 ng/mL (10). The depression was always associated with hypotension, so the mechanism of the defect may have been related to pulmonary hypoperfusion.

Neonatal toxicity is generally rare if cord levels of isoxsuprine are <2 ng/mL (corresponding to a drug-free interval of >5 hours), but levels >10 ng/mL (drug-free interval of 2 hours or less) were associated with severe neonatal problems (10). These problems include hypocalcemia, hypoglycemia, ileus, hypotension, and death (10–12). Hypotension and neonatal death occurred primarily in infants of 26–31 weeks' gestation, especially if cord levels exceeded 10 ng/mL, and in infants whose mothers developed hypotension or tachycardia during isoxsuprine infusion (10,11). Neonatal ileus, up to 33% in some series, was not related to cord isoxsuprine concentrations, but hypotension and hypocalcemia were directly related, reaching 89% and 100%, respectively, when cord levels exceeded 10 ng/mL (10,12). Fetal tachycardia is a common side effect. As compared with controls, no increase in late or variable decelerations was seen

(10). In contrast to the above, infusion of isoxsuprine 30 minutes before cesarean section under general anesthesia was not observed to produce adverse effects in the mother, fetus, or newborn (13). Cord concentrations were not measured.

Long-term evaluation of infants exposed to β -mimetics in utero has been reported but not specifically for isoxsuprine (14). No harmful effects in the infants resulting from this exposure were observed.

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 54 of whom were exposed to isoxsuprine during the 1st trimester (15, pp. 346–347). For use anytime during pregnancy, 858 exposures were recorded (15, p. 439). In neither case was evidence found for an association with malformations.

BREASTFEEDING SUMMARY

No reports describing the use of isoxsuprine during human lactation have been located.

ISRADIPINE

Calcium Channel Blocker

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Several studies have described the use of isradipine in pregnant women (1–8). No adverse fetal effects attributable to the drug were observed. Isradipine crosses the placenta to the fetus at term (3).

FETAL RISK SUMMARY

Isradipine is a calcium channel-blocking agent used in the treatment of hypertension. The drug is not teratogenic in rats or rabbits at doses 150 and 25 times the maximum recommended human dose, respectively. Embryotoxicity was not observed in either species at doses that were not maternally toxic (9).

In a study to determine the effects of isradipine on maternal and fetal hemodynamics, 27 women with pregnancy-induced hypertension in the 3rd trimester were treated with the drug, 2.5 mg twice daily for 4 days and then 5 mg twice daily (1). Hemodynamic measurements, conducted before and after 1 week of therapy, demonstrated a significant reduction in mean arterial pressure without a significant change in uteroplacental or fetal blood flows. The lack of change in uteroplacental blood flow suggested that there was uterine vasodilation with decreased uterine vascular resistance. No fetal adverse effects were observed (1).

A 1992 study examined the effect of isradipine on three standardized physical stress tests in 14 women under treatment for hypertension (3 with essential hypertension, 11 with preeclampsia) (2). Treatment with isradipine, 5 mg once daily for 4 days and then 5 mg twice daily, was begun at a mean 33 weeks' gestation with delivery occurring at a mean of 38 weeks. The pregnancy outcomes were normal except for one newborn whose birth weight was below the 10th percentile and transient hyperbilirubinemia in two neonates

(2).

A study reported in 1999 compared antihypertensive effect of isradipine (N = 20) with hydralazine and methyldopa (N = 19) in women with severe preeclampsia (8). There were no differences in the outcomes in terms of gestational age at birth, Apgar scores, and birth weight.

BREASTFEEDING SUMMARY

No reports describing the use of isradipine during human lactation have been located. The relatively low molecular weight (about 371), however, suggests that the drug is excreted into breast milk. The potential effects of this exposure on a nursing infant are unknown.

ITRACONAZOLE

Antifungal

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

The human pregnancy experience suggests that the risk of itraconazole-induced structural anomalies is low. However, another triazole antifungal agent, fluconazole, has demonstrated a possible dose-related relationship with major malformations (see Fluconazole). For itraconazole, the animal data cannot be adequately interpreted because maternal toxicity was evident and comparisons with the human dose appeared to be based on body weight. Therefore, the safest course is to avoid itraconazole, if possible, during organogenesis. If inadvertent exposure does occur during the 1st trimester, or if itraconazole must be used during early pregnancy, the woman can be reassured that the risk to her embryo or fetus is low, if it exists at all.

FETAL RISK SUMMARY

Itraconazole is a triazole antifungal agent that is structurally related to a number of other antifungal agents, including the imidazole derivatives butoconazole, clotrimazole, and ketoconazole, and to the triazoles, fluconazole and terconazole (1). Other triazole antifungals are posaconazole and voriconazole.

A dose-related increase in toxicity and teratogenicity was found in both rats and mice (2). In pregnant rats treated with a dose 5–20 times the maximum recommended human dose (MRHD), maternal and embryo toxicity was observed, as were major skeletal malformations. In mice given 10 times the MRHD, maternal toxicity, embryo toxicity, and malformations consisting of encephaloceles or macroglossia occurred.

It is not known if itraconazole crosses the human placenta. The molecular weight (about 706) is low enough that passage to the fetus should be expected.

Cohort data presented at a 1996 meeting on single-dose fluconazole or itraconazole exposures during organogenesis did not demonstrate adverse outcomes in approximately 70 exposed pregnancies (3). However, the FDA has received 14 case reports of malformations following use of itraconazole, 4 of which involved limb defects (includes 1 case of agenesis of the fingers and toes (3)).

A 1998 noninterventional observational cohort study described the outcomes of pregnancies in women who had been prescribed one or more of 34 newly marketed drugs by general practitioners in England (4). Data were obtained by questionnaires sent to the prescribing physicians one month after the expected or possible date of delivery. In 831 (78%) of the pregnancies, a newly marketed drug was thought to have been taken during the 1st trimester, with birth defects noted in 14 (2.5%) singleton births of the 557 newborns (10 sets of twins). In addition, two birth defects were observed in aborted fetuses. However, few of the aborted fetuses were examined. Itraconazole was taken during the 1st trimester in 41 pregnancies. The outcomes of these pregnancies included 1 ectopic pregnancy, 2 spontaneous abortions (SABs), 6 elective abortions (EABs), 2 cases lost to follow-up, and 30 normal newborns (1 premature) (4). One of the normal, full-term newborns, however, had a minor congenital anomaly consisting of a thin, prominent, protruding left ear. Although no major congenital malformations were observed, the study lacked the sensitivity to identify minor anomalies because of the absence of standardized examinations. Late-appearing major defects may also have been missed due to the timing of the questionnaires.

A prospective cohort study published in 2000 evaluated the pregnancy outcomes of 198 women exposed to itraconazole in the 1st trimester (5). The pregnancy exposures had been reported to the manufacturer, before the outcomes were known, between April 1989 and June 1998. The median itraconazole dose was 200 mg (range 50–800 mg) with mean therapy duration of 8.5 days (range 1–90 days). A matched control group (N = 198) was formed from pregnant women who had contacted the Motherisk Program, a teratogen information service in Toronto, Canada. The control group had not been exposed to any known teratogens (acceptable exposures were acetaminophen, penicillins, prenatal vitamins, dental radiography, or no exposures). There were no statistical differences between the groups in gravidity, parity, alcohol use, or cigarette smoking, but the maternal age in the study group was significantly less than controls (30.1 vs. 31.0 years, $p = 0.02$). Among pregnancy outcomes, there were no statistical differences between the groups in delivery method,

rates of term, preterm, and postterm deliveries, 1- and 5-minute Apgar scores, sex ratios, and rates of neonatal complications. Significantly more pregnancy losses occurred in the exposed group than in controls (relative risk 1.75, 95% confidence interval 1.47–2.09), including SABs (12.6% vs. 4.0%), EABs (7.5% vs 0.5%), and fetal deaths (1.5% vs. 1.0%). The authors attributed these differences to group differences, rather than to effects of itraconazole exposure (5). In addition, the birth weight of exposed newborns was significantly lower than controls (3.33 vs. 3.46 kg. $p = 0.048$), but this finding was probably not clinically significant (5). There was no statistical difference between the groups in major congenital malformations. Among the 156 live births in the study group, there were five infants (3.2%) with major anomalies (microphthalmia, dysplasia of the right hand, pyloric stenosis, hip joint dysplasia, and congenital heart disease [type not specified]). There were nine newborns (4.8%) with major defects among the 187 controls with live births (congenital heart disease [three cases—two with ventricular septal defect and one not specified], hypospadias requiring surgery [two cases], and one each of oversized tongue, congenital hip dislocation, cleft palate, and Down's syndrome with atrioventricular canal). The study had 80% power to detect a threefold increased risk of major defects (5), but no evaluation was conducted for minor defects.

The authors of the above study, in a letter correspondence that predated that study, demonstrated that retrospective reports to the manufacturer, at least for itraconazole, involved reporting bias (6). The rates for retrospective vs. prospective outcomes, all of which were significant, were live births (64% vs. 79%), EABs (15% vs. 8%), SABs (18% vs. 13%), major anomalies (13% vs. 3%), and major anomalies including EABs (15% vs. 3%). The authors concluded that women with poor outcomes were more likely to report the event than those with good outcomes (6).

A prospective cohort study involving itraconazole pregnancy exposure was published in 2009 (7). The data were collected by two teratology information services in Italy. During the period 2002–2006, 206 women called the services because of 1st trimester exposure to the drug and their pregnancy outcomes were compared with 207 controls. The rates of major congenital anomalies in the two groups were not significant (1.8% vs. 2.1%, respectively). The three anomalies in the exposed group and the maternal daily dose were cerebral calcification and hepatomegaly (200 mg), unilateral hydronephrosis (100 mg), and interatrial defect (100 mg). There were no significant differences in the rates of vaginal delivery, premature births, low birth weight, and high birth

weight. However, significant differences were found for live births (79.1% vs. 91.8%), SABs (11.2% vs. 4.8%), and EABs (9.2% vs. 3.4%). The lower live birth rate was obviously due to the higher rates of abortion (7).

BREASTFEEDING SUMMARY

Itraconazole is excreted into breast milk. Two healthy lactating women each took two oral doses of 200 mg 12 hours apart (total dose 400 mg) (personal communication, EK Cazzaniga and A Chanlam, Janssen Pharmaceuticals, 1996). Neither infant was allowed to nurse during the study. At 4, 24, and 48 hours after the second dose, the average milk concentrations of itraconazole were 70, 28, and 16 ng/mL, respectively. At 72 hours, the milk level was 20 ng/mL in one woman and not detectable (<5 ng/mL) in the other. The average milk:plasma ratios at 4, 24, and 48 hours were 0.51, 1.61, and 1.77, respectively. Based on the 4-hour concentration (the approximate time of the peak plasma level), and assuming that the infants consumed 500 mL of milk/day, the maximum 24-hour average dose the infants would have received was 35 mcg.

Although the above amount seems small, peak plasma concentrations in healthy male volunteers taking itraconazole 200 mg twice daily were not reached until about 15 days (2). The mean peak concentration of the parent compound in these volunteers was 2282 ng/mL, or about 15 times the average peak concentration measured in the two women above. Moreover, the mean plasma concentration of one of the metabolites (hydroxyitraconazole) exceeded that of the parent compound. Continuous daily dosing, even with lower doses, should result in milk levels of the drug much higher than those found above and could result in widespread tissue accumulation in nursing infants. Because the potential effects of this exposure have not been studied, women taking itraconazole should probably not breastfeed.

IVACAFTOR

Endocrine/Metabolic Agent (Miscellaneous)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of ivacaftor in human pregnancy have been located. The animal data suggest low risk, but the absence of human pregnancy experience prevents a more complete assessment of embryo–fetal risk. However, cystic fibrosis can be a debilitating chronic disease. If the drug is indicated it should not be withheld because of pregnancy, but the woman should be informed of the lack of human data.

FETAL RISK SUMMARY

Ivacaftor is an orally administered potentiator of the cystic fibrosis transmembrane conductance regulator (CFTR) protein. It is indicated for the treatment of cystic fibrosis in patients 6 years and older who have a G551D mutation in the CFTR gene. Ivacaftor is extensively metabolized to a partially active metabolite (1/6th the potency of the parent drug) and to inactive metabolites. Plasma protein binding (about 99%) is primarily to α -1-acid glycoprotein and albumin. The apparent terminal half-life is about 12 hours (1).

Reproduction studies have been conducted in rats and rabbits. In these species, ivacaftor was not teratogenic at exposures that were about 6 and 12 times, respectively, the maximum recommended human dose based on summed AUCs (MRHD) for ivacaftor and its metabolites. Placental transfer of ivacaftor was observed in rats and rabbits (1).

Two-year studies in mice and rats for carcinogenicity were negative, as were multiple assays for genotoxicity. Ivacaftor impaired fertility and reproductive performance indices in male and female rats at exposures that were about 5 and 6 times, respectively, the MRHD. In rats dosed before and during pregnancy, increases in prolonged diestrus and the number with all nonviable

embryos were observed. Decreased corpora lutea, implantations, and viable embryos were also noted. The effects on the male and female indices were attributed to severe toxicity. No effects were observed on the indices at exposures that were about 3 times the MRHD (1).

It is not known if ivacaftor or its metabolites crosses the human placenta. The molecular weight of the parent drug (about 392) and the long terminal half-life suggest that the parent drug will cross to the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use of ivacaftor during human lactation have been located. The molecular weight of the parent drug (about 392) and the long terminal half-life (about 12 hours) suggest that the parent drug will be excreted into breast milk. The effect of this exposure on a nursing infant is not known. The most common ($\geq 8\%$) adverse effects in patients were headache, oropharyngeal pain, upper respiratory tract infection, nasal congestion, abdominal pain, nasopharyngitis, diarrhea, rash, nausea, and dizziness (1). If a woman taking this drug and breastfeeding, her infant should be monitored for these effects.

IVERMECTIN

Anthelmintic

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Ivermectin was teratogenic in three animal species, but only at doses at or near those producing maternal toxicity. No teratogenicity or toxicity attributable to ivermectin has been observed in limited human pregnancy experience. A 1997 review, citing a World Health Organization reference, stated that because of the high risk of blindness from onchocerciasis, and the lack of reported adverse outcomes, the use of ivermectin after the 1st trimester was probably acceptable (1).

FETAL RISK SUMMARY

Ivermectin is a semisynthetic anthelmintic. It is a mixture of two components derived from the avermectins, a class of antiparasitic agents isolated from the fermentation of *Streptomyces avermitilis*. Ivermectin is indicated for the treatment of intestinal strongyloidiasis infections due to the nematode *Strongyloides stercoralis* and onchocerciasis due to the nematode *Onchocerca volvulus* (2).

In reproduction studies with mice, rats, and rabbits, ivermectin was teratogenic when given in repeated doses of 0.2, 8.1, and 4.5 times, respectively, the maximum recommended human dose based on BSA. The malformations observed, cleft palate (in all three species) and clubbed forepaws in rabbits, however, were only observed at or near doses producing maternal toxicity. The results were thought to indicate that ivermectin was not selectively toxic to the developing fetus (2).

It is not known if ivermectin crosses the human placenta. The molecular weights of the two components in the product, approximately 875 and 861, are low enough that some exposure of the embryo or fetus probably occurs.

A well-conducted study published in 1990 described the pregnancy outcomes

of women who were inadvertently exposed to ivermectin during community-based ivermectin distribution programs (1987–1989) for onchocerciasis on a Liberian rubber plantation (14,000 people) (3). The average oral ivermectin dose was 150 mcg/kg as a single dose. Because the women did not recall the date of their last menstrual period before delivery, pregnancy exposure was defined as a delivery occurring within 40 weeks of treatment. During the distribution programs, 2884 women received treatment, including 200 (7%) that were inadvertently treated during pregnancy. Of those treated during pregnancy, 85% were treated in the first 12 weeks of pregnancy and 36% occurred within the first 4 weeks. The outcomes of all pregnancies were followed up by a field census team, systematic examination of all babies born at the hospital, and a year-round plantation-wide surveillance system of all births and deaths. All children under 12 months of age were examined by a physician and children aged 12–24 months were examined by a pediatrician. Among the 203 pregnancy outcomes from exposed pregnancies, there were 10 (4.9%) abnormal events—5 stillbirths and 5 congenital malformations (single-dose exposure in weeks before delivery shown in parentheses): anal atresia (34 weeks); cleft palate and lip (33 weeks); Pierre–Robin syndrome, micrognathia, glossoptosis, low-slung ears, and shortening of limbs in a stillborn infant (32 weeks); Turner’s syndrome (24 weeks); and deafness plus probable ventricular septal defect (VSD) (33 weeks). Among the 1767 pregnancy outcomes not exposed to ivermectin, there were 76 (4.3%) abnormal events: 55 stillbirths or miscarriages and 21 congenital anomalies. The congenital anomalies were: polydactyly (N = 6), convergent strabismus (N = 3), talipes equinovarus (N = 2), unspecified (N = 2), and 1 each deafness, facial malformations, hypopigmented skin, hypospadias, microcephaly, Down’s syndrome, syndactyly, and VSD. There were no significant differences between the treated and untreated groups in the rates of congenital malformations, stillbirths, or all abnormalities (congenital malformations, stillbirths, and miscarriages). Also, no statistical differences were found in terms of health status and malformations between infants (aged 2–7 months) and children (aged 12–24 months) whose mothers had been treated in comparison with untreated controls, matched for age, sex, and distance from the hospital (3).

A brief 1993 communication from Cameroon described the outcomes of pregnancies in 110 women who had inadvertently received ivermectin treatment during a mass treatment campaign for onchocerciasis (4). During the 2-year campaign, 401 of 2710 women were excluded from treatment because of pregnancy. Of the remaining 2309 women who were treated, 110 were

discovered to be pregnant during regularly scheduled follow-up. Treatment was considered to have been given during pregnancy if delivery occurred within 40 weeks of ivermectin distribution. A comparison of the 110 women treated during gestation with the 401 pregnant women who did not receive treatment revealed no statistical differences in early abortion (<4 months) (3.6% vs. 2.2%), late abnormal events (abortion, miscarriage, stillbirth) (15.5% vs. 11%), children lost to follow-up (7.3% vs. 11.2%), infants with malformations (0 vs 0.5%), or normal infants (74.5% vs. 75.8%). The prevalence of all abnormal obstetric events of treated women was similar to that of those not treated ($p > 0.37$). Only two newborns with congenital malformations were observed, both in the untreated group. In a second analysis, pregnancy outcomes of 97 women treated in the 1st trimester were compared with the outcomes of 142 untreated women. As before, no statistical differences were observed. The authors concluded that ivermectin did not present a major risk to the fetus (4).

BREASTFEEDING SUMMARY

Ivermectin is excreted into breast milk, but its use during breastfeeding has not been reported. Four healthy women, who had lost their babies at birth, were given a single 150 mcg/kg oral ivermectin dose after an overnight fast (5). Ivermectin was detected in the plasma and breast milk within 1 hour. The mean peak concentration in plasma was 37.9 ng/mL and in milk was 14.1 ng/mL. The mean milk:plasma ratio was 0.51 (range 0.39–0.57). The steady-state ivermectin concentration in milk over a 24-hour period was approximately 10 ng/mL. The investigators estimated that the dose a 1-month-old African infant would receive from breast milk was 2.75 mcg/kg. This dose is much lower than an estimated dose of 21.8 mcg/kg they calculated for a 1-month-old infant (5). (Note: In the United States, because the safety and effectiveness have not been established, ivermectin is not recommended for children weighing <15 kg [1]). In Nigeria, where the study was conducted, lactating women within the first week of breastfeeding were excluded from community-wide ivermectin distribution because of the concerns for infant safety (5). The investigators concluded, however, that the benefits of treatment for the lactating woman, combined with the impracticality of withholding nursing for a week, the low drug levels in milk, and the lack of reported adverse effects in nursing infants in their population, suggested that the drug should be given to the mother regardless of her lactation status (5). The American Academy of Pediatrics classifies ivermectin as compatible with breastfeeding (6).

IXABEPILONE

Antineoplastic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of ixabepilone in human pregnancy have been located. Teratogenicity was not observed in two animal species. However, embryo death (in the absence of maternal toxicity) was noted in one species. Because of maternal toxicity, the highest doses that could be given were about 10% of the human exposure or dose. The absence of human pregnancy experience prevents a complete assessment of the embryo–fetal risk, but the drug should be avoided in pregnancy. If it must be administered for the mother’s benefit, avoiding the 1st trimester should be considered.

FETAL RISK SUMMARY

Ixabepilone is a semisynthetic analog of epothilone B, a polypeptide macrolide isolated from the myxobacterium *Sorangium cellulosum*. There are no other agents in this antineoplastic subclass. Ixabepilone is a microtubule inhibitor that is given as an IV infusion every 3 weeks. It is indicated in combination with capecitabine (see Capecitabine) for the treatment of metastatic or locally advanced breast cancer resistant to an anthracycline and a taxane, or in patients whose cancer is taxane resistant and for whom further anthracycline therapy is contraindicated. It also is indicated as monotherapy for the treatment of metastatic or locally advanced breast cancer resistant to anthracyclines, taxanes, and capecitabine. The drug is extensively metabolized in the liver to inactive compounds. Binding to human serum proteins ranges between 67% and 77%, and the terminal elimination half-life is about 52 hours (1).

Reproductive studies have been conducted in rats and rabbits. No teratogenic effects were observed in rats with doses producing exposures up to about 0.1 times the human clinical exposure based on AUC (HCE). The

highest dose was maternal toxic and resulted in fetal death and decreased fetal weight. In rabbits, no teratogenicity was observed at doses up to about 0.1 times the human clinical dose based on BSA, but maternal and fetal toxicity (death in both) was noted at the highest dose (1).

Carcinogenicity studies with ixabepilone have not been conducted. The drug was not mutagenic in one assay but was clastogenic in one of two tests. No effect on the fertility of male and female rats was observed with doses producing exposures that were about 0.07 times the HCE. However, when female rats were given an IV infusion at this dose during breeding and through the first 7 days of gestation, a significant increase in resorptions and pre- and postimplantation loss, and a decrease in the number of corpora lutea were observed. Testicular atrophy or degeneration was observed in male rats when IV doses that were 2.1 times the HCE were given every 21 days for 6 months. Similar toxicity was observed in male dogs when IV doses that were ≥ 0.2 times the HCE were given every 21 days for 9 months (1).

It is not known if ixabepilone crosses the human placenta. The molecular weight (about 507), the moderate serum protein binding, and the very long elimination half-life suggest that the drug will cross to the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use of ixabepilone during human lactation have been located. The molecular weight (about 507), the moderate serum protein binding (67%–77%), and the very long elimination half-life (about 52 hours) suggest that the drug will be excreted into breast milk. The effects of this exposure on a nursing infant are unknown, but there is potential for severe toxicity. The most common adverse reactions in adults were peripheral sensory neuropathy, fatigue/asthenia, myalgia/arthralgia, alopecia, nausea, vomiting, stomatitis/mucositis, diarrhea, and musculoskeletal pain (1). Because of the risk, women receiving ixabepilone should not breastfeed.

K

KANAMYCIN

Antibiotic (Aminoglycoside)

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Except for ototoxicity, no reports of congenital defects due to kanamycin have been located. Embryos were examined from five patients who aborted during the 11th and 12th weeks of pregnancy and who had been treated with kanamycin during the 6th and 8th weeks (1). No abnormalities in the embryos were found.

FETAL RISK SUMMARY

Kanamycin is an aminoglycoside antibiotic. At term, the drug was detectable in cord serum 15 minutes after a 500-mg IM maternal dose (2). Mean cord serum levels at 3–6 hours were 6 mcg/mL. Amniotic fluid levels were undetectable during the first hour, and then rose during the next 6 hours to a mean value of 5.5 mcg/mL. No effects on the infants were mentioned.

Eighth cranial nerve damage has been reported following in utero exposure to kanamycin (1,3). In a retrospective survey of 391 mothers who received kanamycin, 50 mg/kg, for prolonged periods during pregnancy, 9 (2.3%) children were found to have hearing loss (1). Complete hearing loss in a mother and her infant was reported after the mother had been treated during pregnancy with IM kanamycin, 1 g/day for 4.5 days (3). Ethacrynic acid, an ototoxic diuretic, was also given to the mother during pregnancy.

BREASTFEEDING SUMMARY

Kanamycin is excreted into breast milk. Milk:plasma ratios of 0.05–0.40 have been reported (4). A 1-g IM dose produced peak milk levels of 18.4 mcg/mL (5). No effects were reported in the nursing infants. Because oral absorption of kanamycin is poor, ototoxicity would not be expected. However, three potential problems exist for the nursing infant: modification of bowel flora, direct effects on the infant, and interference with the interpretation of culture results if a fever workup is required. The American Academy of Pediatrics classifies kanamycin as compatible with breastfeeding (6).

KAOLIN/PECTIN

Antidiarrheal

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports have related the use of the kaolin/pectin mixture in pregnancy with adverse fetal outcome. There have been reports of iron-deficiency anemia and hypokalemia secondary to the eating of clays (i.e., geophagia) containing kaolin (1–3).

FETAL RISK SUMMARY

Kaolin is hydrated aluminum silicate clay used for its adsorbent properties in diarrhea, and pectin is a polysaccharide obtained from plant tissues that is used as a solidifying agent. Neither agent is absorbed into the systemic circulation.

The mechanism for iron deficiency anemia is thought to be either a reduction in the intake of foods containing absorbable iron or an interference with the absorption of iron. In humans, iron-deficiency anemia may significantly enhance the chance for a low-birth-weight infant and preterm delivery (4,5).

Rats fed a diet containing 20% kaolin became anemic and delivered pups with a significant decrease in birth weight (6). When an iron supplement was added to the kaolin-fortified diet, no anemia or reduced birth weight was observed.

BREASTFEEDING SUMMARY

Other than producing anemia in the mother after prolonged, chronic use, the kaolin/pectin mixture should have no effect on lactation or the nursing infant.

KETAMINE

General Anesthetic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Although ketamine anesthesia close to delivery may induce dose-related, transient toxicity in the newborn, these effects are usually avoided with the use of lower maternal doses. No reports of malformations in humans (1) or in animals attributable to ketamine have been located, although experience with the anesthetic agent during human organogenesis apparently has not been published.

FETAL RISK SUMMARY

Ketamine is a rapid-acting IV general anesthetic agent related in structure and action to phencyclidine. No teratogenic or other adverse fetal effects have been observed in reproduction studies during organogenesis and near delivery with rats, mice, rabbits, and dogs (2–6). In one study with pregnant rats, a dose of 120 mg/kg/day for 5 days during organogenesis resulted in no malformations or effect on fetal weight (5).

Ketamine rapidly crosses the placenta to the fetus in animals and humans (7,8). Pregnant ewes were given 0.7 mg/kg IV, and 1 minute later the maternal and fetal concentrations of ketamine were 1230 ng/mL and 470 ng/mL (ratio 0.38), respectively (7). Maternal effects were slight, transitory increases in mean arterial pressure and cardiac output; respiratory acidosis; and an increase in uterine tone without changes in uterine blood flow. In humans, the placental transfer of ketamine was documented in a study in which a dose of 250 mg IM was administered when the fetal head reached the perineum (8). The ketamine concentration in cord venous plasma at the 0- to 10-minute dose-to-delivery interval was 0.61 mcg/mL, compared with 1.03 mcg/mL at the 10- to 30-minute interval, reflecting absorption following the IM route.

Pregnant monkeys were administered ketamine in IV doses of 2 mg/kg (N = 3) or 1 mg/kg (N = 2) in an investigation of the anesthetic's effects on the fetus and newborn (9). No fetal effects were observed from either dose. The newborns from the mothers given 2 mg/kg, but not those exposed to lower doses, had profound respiratory depression.

The use of ketamine (C-581) for obstetric anesthesia was first described in 1966 (10). Since then, a large number of references have documented its use for this purpose (11–39). Among the maternal and newborn complications reported with ketamine are oxytocic properties, an increase in maternal blood pressure, newborn depression, and an increased tone of newborn skeletal musculature. These adverse effects were usually related to higher IV doses (1.5–2.2 mg/kg) administered during early studies rather than to the lower IV doses (0.2–0.5 mg/kg) now commonly used.

Ketamine usually demonstrates a dose-related oxytocic effect with an increase in uterine tone, and in frequency and intensity of uterine contractions (10–13,23,38), but one investigator reported weakened uterine contractions following a 250-mg IM dose administered when the fetal head reached the perineum (8). Uterine tetany was observed in one case (13). Low IV doses (0.275–1.1 mg/kg) of ketamine increased only uterine contractions, whereas a higher IV dose (2.2 mg/kg) resulted in a marked increase in uterine tone (23). Maximum effects were observed within 2–4 minutes of the dose. In one study, however, the effect on uterine contractions from an IV dose of 1 mg/kg, followed by succinylcholine 1 mg/kg, was no different from thiopental (15). No effect on intrauterine pressure was measured in 12 term patients treated with IV ketamine 2 mg/kg, in contrast to a marked uterine pressure increase in patients in early pregnancy undergoing termination (40). Similarly, in 12 women given IV ketamine 2.2 mg/kg for termination of pregnancy at 8–19 weeks, uterine pressure and the intensity and frequency of contractions were increased (41).

Several investigators noted a marked increase in maternal blood pressure, up to 30%–40% in systolic and diastolic in some series, during ketamine induction (8,11,13,14,16,24,25). An increased maternal heart rate was usually observed. These effects are dose-related, with the greatest increases occurring when 2–2.2 mg/kg IV was administered, but smaller elevations of pressure and pulse were noted with lower IV doses.

Maternal ketamine anesthesia may cause depression of the newborn (8,13,16–19,22,24,27,33). As with the other complications, the use of higher IV doses (1.5–2.2 mg/kg) resulted in the highest incidence of low neonatal Apgar

scores and requirements for newborn resuscitation. The induction-to-delivery (ID) interval is an important determinant for neonatal depression (8,22,33,35). In two studies, neonatal depression was markedly lower or absent if the ID interval was <10 minutes (8,33). In a third study, significant depression occurred with an ID interval of 9.2 minutes, but an IV dose of 2.1 mg/kg had been used (22).

The use of ketamine in low doses apparently has little effect on fetal cardiovascular status or acid–base balance as evidenced by neonatal blood gases (8,25,27,30,32–34). In one study, a ketamine dose of 25 mg IV administered with nitrous oxide and oxygen within 4 minutes of delivery did not adversely affect neonatal blood pressure (39).

Ketamine doses of 2 mg/kg IV have been associated with excessive neonatal muscle tone, sometimes with apnea (11,12,18). In some cases, the increased muscle tone made endotracheal intubation difficult. In contrast, lower doses (e.g., 0.25–1 mg/kg) have not been associated with this complication (25).

Neonatal neurobehavior, as measured by the Scanlon Group of Early Neonatal Neurobehavioral Tests during the first 2 days, is depressed following maternal ketamine (1 mg/kg IV) anesthesia but less than the effect measured after thiopental anesthesia (4 mg/kg IV) (42,43). In these studies, spinal anesthesia with 6–8 mg of tetracaine was associated with the best performance, general anesthesia with ketamine was intermediate, and that with thiopental was the poorest in performance.

BREASTFEEDING SUMMARY

Because ketamine is a general anesthetic agent, breastfeeding would not be possible during use of the drug, and no reports have been located that measured the amount of the agent in milk. The elimination half-life of ketamine has been reported to be 2.17 hours in unpremedicated patients (32). Thus, the drug should be undetectable in the mother's plasma approximately 11 hours after a dose. Nursing after this time should not expose the infant to pharmacologically significant amounts of ketamine.

KETOCONAZOLE

Antifungal

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk (Oral) No Human Data—Probably Compatible (Topical)

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Ketoconazole is a synthetic, broad-spectrum antifungal agent. It has been used, apparently without fetal harm, for the treatment of vaginal candidiasis occurring during pregnancy (1).

FETAL RISK SUMMARY

Ketoconazole is in the same antifungal class of imidazole derivatives as butoconazole, clotrimazole, econazole, miconazole, oxiconazole, sertaconazole, sulconazole, and tioconazole.

Ketoconazole is embryotoxic and teratogenic in rats, producing syndactyly and oligodactyly at a dose 10 times the maximum recommended human dose (weight basis) (2,3). However, the dose caused maternal toxicity.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 20 newborns had been exposed to oral ketoconazole during the 1st trimester (F. Rosa, personal communication, FDA, 1993). No major birth defects were observed (one expected). Since this study, the FDA has received six reports of limb defects (F. Rosa, personal communication, FDA, 1996).

Limb malformations were reported in a 1985 abstract (4). A Turkish woman had used ketoconazole, 200 mg daily, during the first 7 weeks of gestation. Hydrops fetalis was diagnosed at 29 weeks' gestation and she delivered a female infant at 30.5 weeks'. The infant, with a normal karyotype (46,XX), had multiple anomalies of the limbs (further details not specified).

Women infected with HIV frequently have vaginal candidiasis. Maternal symptoms, such as pruritus, may require treatment; in these cases, therapeutic and prophylactic ketoconazole regimens are recommended, even though the

fungal infection has little perinatal significance (5).

Ketoconazole inhibits steroidogenesis in fungal cells. In humans, high doses, such as those >400 mg/day, impair testosterone and cortisol synthesis (6–9). Because of this effect, ketoconazole has been used in the treatment of hypercortisolism (10). A review summarizing the treatment of 67 cases of Cushing's syndrome occurring during pregnancy did not find any cases treated with ketoconazole (10). A 1990 report, however, described a ketoconazole-treated 36-year-old pregnant woman with Cushing's syndrome (11). The pregnancy, in addition to Cushing's syndrome, was complicated by hypertension, diabetes mellitus diagnosed at 9 weeks' gestation, and intrauterine growth restriction. Ketoconazole, 200 mg every 8 hours, was started at 32 weeks' gestation and continued for 5 weeks because of maternal clinical deterioration resulting from the sustained hypercortisolism. Rapid clinical improvement was noted in the mother after therapy was begun. A growth-restricted, 2080-g, but otherwise normal, female infant was delivered by elective cesarean section at 37 weeks. The Apgar scores were 9 and 9 at 1 and 5 minutes, respectively. No clinical or biochemical evidence of adrenal insufficiency was found in the newborn. The infant's basal cortisol and adrenocorticotrophic hormone levels, 306 nmol/L and 8.1 pmol/L, respectively, were normal. The child was growing normally at 18 months of age.

BREASTFEEDING SUMMARY

Ketoconazole is excreted into breast milk (12). A 41-year-old, 82-kg woman took 200 mg/day for 10 days while nursing her 1-month-old infant. Five manually expressed milk samples were collected over a 24-hour interval (1.75–24 hours postdose) on day 10. The maximum milk concentration (0.22 mcg/mL) was measured at 3.25 hours postdose. Ketoconazole was undetectable (detection limit 0.005 mcg/mL) at 24 hours postdose. The mean milk concentration, based on AUC for 0–24 hours, was 0.068 mcg/mL. The level corresponded to an estimated infant dose (based on 150 mL/kg/day) of 0.01 mg/kg/day (maximum estimated dose 0.033 mg/kg/day). The dose was about 0.4% of the mother's weight-adjusted dose. No adverse effects were observed in the infant (12).

The effects on the nursing infant from exposure to drug in the milk are unknown, but the exposure in the above case does not appear to be clinically significant. The American Academy of Pediatrics classifies ketoconazole as compatible with breastfeeding (13).

KETOPROFEN

Nonsteroidal Anti-inflammatory

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 1st and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Constriction of the ductus arteriosus in utero is a pharmacologic consequence arising from the use of prostaglandin synthesis inhibitors during pregnancy (see also Indomethacin) (1). Persistent pulmonary hypertension of the newborn may occur if these agents are used in the 3rd trimester close to delivery (1,2). These drugs also have been shown to inhibit labor and prolong pregnancy, in both humans (3) (see also Indomethacin) and animals (4). Women attempting to conceive should not use any prostaglandin synthesis inhibitor, including ketoprofen, because of the findings in a variety of animal models indicating that these agents block blastocyst implantation (5,6). As noted below, nonsteroidal anti-inflammatory drugs (NSAIDs) have been associated with spontaneous abortions (SABs) and congenital malformations (see also Ibuprofen), but the risk for these defects appears to be low.

FETAL RISK SUMMARY

Ketoprofen is an NSAID that is indicated for the management of the signs and symptoms of rheumatoid arthritis and osteoarthritis. It is in the same subclass (propionic acids) as five other NSAIDs (fenoprofen, flurbiprofen, ibuprofen, naproxen, and oxaprozin). The drug undergoes metabolism to an inactive metabolite but can be converted back to the parent compound. Plasma protein binding, mainly to albumin, is high (>99%) and the elimination half-life is about 2 hours (7).

Reproductive studies in mice and rats at about 0.2 times the maximum recommended human dose based on BSA revealed no teratogenic or embryotoxic effects (7). In rabbits, maternally toxic doses were embryotoxic

but not teratogenic (7). Shepard (8) reviewed four animal studies that used mice, rats, and monkeys and found no adverse fetal effects or congenital malformations.

Consistent with the low molecular weight (about 254), ketoprofen crosses the human placenta. A 1998 study, using a human isolated perfused placenta, demonstrated transfer of the drug (9). The investigators had previously shown that the drug crosses to the fetus and is detectable in the newborn (10).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 112 newborns had been exposed to ketoprofen during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Three (2.7%) major birth defects were observed (five expected), including (expected/observed) 1/1 cardiovascular defect and 1/0.3 polydactyly. No anomalies were observed in four other categories of defects (oral clefts, spina bifida, limb reduction defects, and hypospadias) for which specific data were available.

A combined 2001 population-based, observational cohort study and a case–control study estimated the risk of adverse pregnancy outcome from the use of NSAIDs (11). The use of NSAIDs during pregnancy was not associated with congenital malformations, preterm delivery, or low birth weight, but a positive association was discovered with SABs. A similar study with NSAIDs found a significant association with cardiac defects and orofacial clefts (12). In addition, a 2003 study found a significant association between exposure to NSAIDs in early pregnancy and SABs (13). (See Ibuprofen for details on these three studies.)

A brief 2003 editorial on the potential for NSAID-induced developmental toxicity concluded that NSAIDs, and specifically those with greater cyclooxygenase 2 (COX-2) affinity, had a lower risk of this toxicity in humans than aspirin (14).

In a 2007 study, atosiban (an oxytocin inhibitor not available in the United States) was compared with ritodrine for the prevention of preterm labor (15). Ketoprofen was added to 51.1% of the atosiban group and 47.7% of the ritodrine group because the response to the single drug was unsatisfactory. The ketoprofen dose was 100 mg IV followed by 100–150 mg IV every 12 hours for a total duration up to 48 hours. Neonatal mortality and morbidity were unrelated to ketoprofen exposure (15).

BREASTFEEDING SUMMARY

No reports describing the use of ketoprofen during breastfeeding have been

located. However, in a 2007 report, 18 non-breastfeeding women immediately after delivery were given IV ketoprofen (100 mg every 12 hours) and nalbuphine (0.2 mg/kg every 4 hours) for postpartum pain (16). The mean and maximum ketoprofen milk concentrations were 57 and 91 ng/mL, respectively. Assuming a milk volume of 150 mL/kg/day, the estimated mean and maximum infant doses were 8.5 and 13.6 mcg/kg/day, respectively. The relative infant dose as a percentage of the weight-adjusted maternal dose was 0.31% (16). (See Nalbuphine for additional data.)

The above data are consistent with the low molecular weight (about 254) of ketoprofen as well as the relatively short elimination half-life (about 2 hours) and the high plasma protein binding (>99%). Although the amounts measured in the above are low, an abstract from France reported that ketoprofen use during breastfeeding was associated with adverse renal and gastrointestinal effects (17). Based on this information, maternal use of other agents should be considered, such as ibuprofen, which is classified as compatible with breastfeeding by the American Academy of Pediatrics (see Ibuprofen).

KETOROLAC

Nonsteroidal Anti-inflammatory

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 1st and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Because ketorolac is a prostaglandin synthesis inhibitor, constriction of the ductus arteriosus in utero and fetal renal impairment are potential complications when multiple doses of the drug are administered during the latter half of pregnancy (1) (see also Indomethacin). Premature closure of the ductus can result in primary pulmonary hypertension of the newborn that, in severe cases, may be fatal (1,2). Other complications that have been associated with nonsteroidal anti-inflammatory drugs (NSAIDs) are inhibition of labor and prolongation of pregnancy. Women attempting to conceive should not use any prostaglandin synthesis inhibitor, including ketorolac, because of the findings in a variety of animal models indicating that these agents block blastocyst implantation (3,4). Moreover, as noted above, NSAIDs have been associated with spontaneous abortions (SABs) and congenital malformations (see also Ibuprofen). The risk for these defects, however, appears to be low.

In a “black box” warning, the FDA stated that ketorolac was contraindicated in labor and delivery because its prostaglandin synthesis inhibitory effect may adversely affect fetal circulation and inhibit uterine contractions.

FETAL RISK SUMMARY

Ketorolac is an NSAID indicated for the short-term (≤ 5 days) treatment of pain. The drug is also available as a solution for ocular pain. Ketorolac is in an NSAID subclass (pyrrolizine carboxylic acid) with no other members.

Ketorolac was not teratogenic in rats (1.0 times the human AUC) and rabbits (0.37 times the human AUC) treated with daily oral doses of the drug during organogenesis. Oral dosing in rats at 0.14 times the human AUC after day 17

of gestation caused dystocia and decreased pup survivability (5).

In a study using chronically catheterized pregnant sheep, an infusion of ketorolac completely blocked the ritodrine-induced increase of prostaglandin $F_{2\alpha}$, a potent uterine stimulant, in the uterine venous plasma (6,7). The researchers speculated that ritodrine stimulation of prostaglandin synthesis in pregnant uterine tissue might contribute to the tachyphylaxis sometimes observed with the tocolytic agent.

It is not known if ketorolac crosses the human placenta. The molecular weight (about 376) is low enough that passage to the embryo and fetus should be expected.

A combined 2001 population-based, observational cohort study and a case–control study estimated the risk of adverse pregnancy outcome from the use of NSAIDs (8). The use of NSAIDs during pregnancy was not associated with congenital malformations, preterm delivery, or low birth weight, but a positive association was discovered with SABs. A similar study, also published in 2001, failed to find a relationship, in general, between NSAIDs and congenital malformations, but did find a significant association with cardiac defects and orofacial clefts (9). In addition, a 2003 study found a significant association between exposure to NSAIDs in early pregnancy and SABs (10). (See Ibuprofen for details on these three studies.)

A brief 2003 editorial on the potential for NSAID-induced developmental toxicity concluded that NSAIDs, and specifically those with greater cyclooxygenase 2 (COX-2) affinity, had a lower risk of this toxicity in humans than aspirin (11).

A randomized, double-blind study published in 1992 compared single IM doses of ketorolac 10 mg, meperidine 50 mg, and meperidine 100 mg in multiparous women in labor (12). All patients also received a single dose of prochlorperazine (for nausea and vomiting) and ranitidine for acid reflux. Ineffective pain relief was observed in all three treatment groups, but both doses of meperidine were superior to ketorolac. Duration of labor was similar among the three groups, as was the occurrence of adverse effects, including maternal blood loss. One-minute Apgar scores were significantly greater in the ketorolac group compared with the meperidine groups, most likely because of the lack of respiratory depressant effects of ketorolac, but this difference was not observed at 5 minutes (12).

A 1997 abstract and later full report described the use of ketorolac for acute tocolysis in preterm labor (13,14). Women, at ≤ 32 weeks' gestation, were randomized to receive either ketorolac (N = 45), 60 mg IM and then 30 mg IM

every 4–6 hours, or magnesium sulfate (N = 43), 6 g IV and then 3–6 g/hour IV. Therapy was stopped if 48 hours lapsed, labor progressed (>4 cm), severe side effects occurred, or uterine quiescence was achieved. Ketorolac was significantly better than magnesium sulfate in the time required to stop uterine contractions (2.7 vs. 6.2 hours), but no difference was found between the two regimens for the other parameters (failed tocolysis, birth weight, gestational age at delivery, and neonatal morbidity). There was no difference in the incidence of maternal and neonatal adverse effects between the groups (13,14).

BREASTFEEDING SUMMARY

Ketorolac is excreted into breast milk (15). Ten women, 2–6 days postpartum, were given oral ketorolac, 10 mg four times daily for 2 days. Their infants were not allowed to breastfeed during the study. Four of the women had milk concentrations of the drug below the detection limit of the assay (<5 ng/mL) and were excluded from analysis. In the remaining six women, the mean milk:plasma ratios 2 hours after doses 1, 3, 5, and 7 ranged from 0.016 to 0.027, corresponding to mean milk concentrations ranging from 5.2 to 7.9 ng/mL. Based on a milk production of 400–1000 mL/day, the investigators estimated that the maximum amount of drug available to a nursing infant would range from 3.16 to 7.9 mcg/day (Note: The cited reference indicated 3.16–7.9 mg/day, but this appears to be an error), equivalent to 0.16%–0.40% of the mother's dose on a weight-adjusted basis. These amounts were considered clinically insignificant (15).

The FDA has placed a “Black Box” warning on ketorolac, stating that drug is contraindicated during breastfeeding because of the potential adverse effects of prostaglandin-inhibiting drugs on neonates.

KUDZU

Herb

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No studies describing the use of kudzu during animal or human pregnancy have been located. Because the herb has been used as a medicine for more than 2500 years, it is doubtful that it causes developmental toxicity. Moreover, many chemical constituents of kudzu can also be found in foods. Nevertheless, the safest course is to avoid high, frequent doses of the herb or its individual constituents during pregnancy.

FETAL RISK SUMMARY

Kudzu, a fast-growing vine native to Japan, China, and Fiji, was introduced to the United States in the late 1800s to control soil erosion. It is well established in moist southern regions and is now considered an invasive pest. In China, kudzu has been used as a medicine since the 6th century BC as therapy for alcoholism, muscular pain, and treatment of measles. Treatment of alcohol hangover, drunkenness, and alcoholism is its primary indications. It also has been used for numerous other indications, none of which have been adequately studied. Kudzu also has been investigated for its antiproliferative activity in some cancers (breast, ovarian, and cervical), its cardiovascular activity for arrhythmia, ischemia, and angina pectoris, and for hepatic protection, hyperlipidemia, and osteogenic activity. Some constituents of kudzu are phytoestrogens and antioxidants (1,2).

The chemical constituents identified from the root, flowers, and leaves include flavonoids, isoflavonoids, and isoflavones. Specific constituents that have been identified include kudzu saponins, robinin, tectoridin, kakkalide, formononetin, biochanin A, plant sterols, and the isoflavones daidzein, daidzin, genistein, genistin, and puerarin. Many of these agents are found in food, such

as daidzein and genistein from soybeans (1,2).

A long-term study in mice evaluated the fertility and reproductive toxicity of kudzu (3). Toxicity with high daily doses (100 mg/kg) included prolonged estrous cycles, hyperplasia of the uterine endothelium, and a decrease in the number of growing ovarian follicles. This dose also resulted in a decrease in mating efficiency. The effects were attributed to decreases in the serum concentrations of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). In contrast, a 10-mg/kg/day dose induced no changes in the hypothalamic–pituitary–ovarian–uterine axis (3).

BREASTFEEDING SUMMARY

No reports describing the use of kudzu during lactation have been located. Because the herb has been used as a medicine for more than 2500 years, it is doubtful that it causes harm during breastfeeding. Moreover, many chemical constituents of kudzu can also be found in foods. Nevertheless, nursing women should avoid high, frequent doses of the herb or its individual constituents.

KUNECATECHINS

Dermatologic Agent

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of kunecatechins ointment in human pregnancy have been located. The animal reproductive data suggest low risk, but the absence of human pregnancy experience prevents a complete assessment of the embryo–fetal risk. Kunecatechins is a water extract of green tea leaves. Moderate consumption of green tea during pregnancy is thought to be safe (1). If the recommended dose and directions are followed, the risk for an embryo or fetus appears to be low, if it exists at all.

FETAL RISK SUMMARY

Kunecatechins is a partially purified fraction of the water extract of green tea leaves [*Camellia sinensis* (L.) O Kuntze]. It is a mixture of eight catechins (85%–95% of the total weight) and other green tea components (about 2.5% of the total weight) including gallic acid, caffeine, and theobromine. It is available as a 15% ointment that is applied three times daily for a maximum of 16 weeks. The systemic absorption of repeated topical administration of kunecatechins has not been adequately studied but is thought to be less than that obtained after a single oral intake of 400 mL of green tea. Kunecatechins is indicated for the topical treatment of external genital and perianal warts (*Condylomata acuminata*) in immunocompetent patients 18 years and older. Treatment of urethral, intravaginal, cervical, rectal or intra-anal human papilloma viral disease has not been evaluated and the ointment should not be used for these conditions (2).

Reproductive studies have been conducted in rats and rabbits. Comparisons, based on body weight, were made based on the maximum recommended

human dose of the ointment (250 mg three times daily; 750 mg of the ointment or 125.5 mg kunecatechins per day) (MRHD). During organogenesis, daily oral doses in rats and rabbits of ≤ 86 and ≤ 173 times, respectively, the MRHD revealed no effects on embryo or fetal development or teratogenicity. In rabbits during organogenesis, daily SC doses that were about 2.1 and 6.3 times the MRHD caused maternal toxicity (marked local irritation at the injection site and decreased body weight and food consumption) and fetal toxicity (reduced body weights and delayed skeletal ossification). The no-effect dose for fetal toxicity was 0.7 times the MRHD. In a combined fertility/embryo–fetal development test, female rats were given daily vaginal doses of the ointment that were ≤ 8 times the MRHD from day 4 before mating through day 17 of gestation. No adverse effects on mating performance or fertility or on the embryo–fetus were observed (2).

Carcinogenicity studies were conducted in mice with daily doses ≤ 22 times the MRHD for 26 weeks. There was an increased incidence of either neoplastic or non-neoplastic lesions in the organs and tissues examined. In mutagenicity tests, four assays were negative and one was positive (2).

It is not known if the major components (i.e., catechins) of kunecatechins cross the human placenta. The molecular weights of the eight catechins are varied but are < 500 and would be expected to cross the placenta. However, systemic concentration of kunecatechins is thought to be low.

BREASTFEEDING SUMMARY

No reports describing the use of kunecatechins ointment during lactation have been located. It is not known if the major components (i.e., catechins) of kunecatechins are excreted into breast milk. The molecular weights of the eight catechins are varied but are < 500 and would be expected to pass into milk. However, systemic concentrations of kunecatechins are thought to be low. Moreover, kunecatechins is a water extract of green tea leaves. Moderate consumption of green tea during breastfeeding is thought to be safe (1). If the recommended dose and directions are followed, the risk for a nursing infant appears to be low, if it exists at all.

L

LABETALOL

Sympatholytic (Antihypertensive)

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

The use of labetalol for the treatment of maternal hypertension does not appear to pose a risk to the fetus, except possibly in the 1st trimester, and may offer advantages over the use of agents with only β -blocker activity. Most studies have found no effect on fetal growth, but one did find fetal growth restriction when used for the treatment of mild preeclampsia. Some β -blockers may cause intrauterine growth restriction (IUGR) and reduced placental weight, especially those lacking intrinsic sympathomimetic activity (ISA) (i.e., partial agonist). Labetalol does not possess ISA. IUGR and reduced placental weight may potential occur with all agents within this class and can be a consequence of maternal hypertension. Although IUGR is a serious concern, the benefits of maternal therapy with labetalol outweigh the risks to the fetus. If used near delivery, the newborn infant should be closely observed for 24–48 hours for signs and symptoms of β -blockade. Long-term effects of in utero exposure to labetalol have not been studied but warrant evaluation.

FETAL RISK SUMMARY

Labetalol, a combined α/β -adrenergic blocking agent, has been used for the treatment of hypertension occurring during pregnancy (1–29). No teratogenicity was observed in rats and rabbits at oral doses 6 and 4 times the maximum recommended human dose (MRHD), respectively (30). However, increased fetal resorptions occurred in both species at doses approximately equivalent to

the MRHD. In rabbits, IV doses ≤ 1.7 times the MRHD revealed no drug-related fetal harm (30).

Labetalol crosses the human placenta to produce cord serum concentrations averaging 40%–80% of peak maternal levels (1–5). Maternal serum and amniotic fluid concentrations are approximately equivalent 1–3 hours after a single IV dose (4). After oral dosing (1–42 days) in eight women, amniotic fluid concentrations of labetalol were in the same range as, but lower than, the plasma concentrations in six of the women (6). The pharmacokinetics of labetalol in pregnant patients has been reported (7,8).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 29 newborns had been exposed to labetalol during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Four (13.8%) major birth defects were observed (one expected). Details on the malformations were not available, but no anomalies were observed in six defect categories (cardiovascular defects, oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available. Although the number of exposures is small, the incidence of malformations is suggestive of an association, but other factors, including the mother's disease, concurrent drug use, and chance, may be involved.

No published reports of fetal malformations attributable to labetalol have been located, but experience during the 1st trimester, except for the surveillance study described above, is lacking. Most reports have found no adverse effects on birth weight, head circumference, Apgar scores, or blood glucose control after in utero exposure to labetalol (9–13). One case of neonatal hypoglycemia has been mentioned, but the mother was also taking a thiazide diuretic (2). Offspring of mothers treated with labetalol had a significantly higher birth weight than infants of atenolol-treated mothers, 3280 vs. 2750 g, respectively (14). However, in a study comparing labetalol plus hospitalization with hospitalization alone for the treatment of mild preeclampsia presenting at 26–35 weeks' gestation, labetalol treatment did not improve perinatal outcome, and a significantly higher number of labetalol-exposed infants were growth restricted, 19.1% (18 of 94) vs. 9.3% (9 of 97), respectively (15).

Fetal heart rate is apparently unaffected by labetalol treatment of hypertensive pregnant women. However, two studies have observed newborn bradycardia in five infants (16,17). In one of these infants, bradycardia was marked (<100 beats/minute) and persistent (17). All five infants survived.

Hypotension was noted in another infant delivered by cesarean section at 28 weeks' gestation (1). In a study examining the effects of labetalol exposure on term (≥ 37 weeks) newborns, mild transient hypotension, which resolved within 24 hours, was observed in 11 infants compared with 11 matched controls (18). Maternal dosage varied from 100 to 300 mg 3 times daily with the last dose given within 12 hours of birth. The mean systolic blood pressures at 2 hours of age in exposed and nonexposed infants were 58.8 and 63.3 mmHg ($p < 0.05$), respectively. Other measures of β -blockade, such as heart and respiratory rates, palmar sweating, blood glucose control, and metabolic and vasomotor responses to cold stress, did not differ between the groups. The investigators concluded that labetalol did not cause clinically significant β -blockade in mature newborn infants (18).

Several investigations have shown a lack of effect of labetalol treatment on uterine contractions (1–3,16,19–21). One study did report a higher incidence of spontaneous labor in labetalol-treated mothers (6 of 10) than in a similar group treated with methyldopa (2 of 9) (22). In another report, 3 of 31 patients treated with labetalol experienced spontaneous labor, one of whom delivered prematurely (23). The authors attributed the uterine activity to the drug because no other causes were found. However, because most trials with labetalol in hypertensive women have not shown this effect, it is questionable whether the drug has any direct effect on uterine contractility.

Labetalol does not change uteroplacental blood flow despite a drop in blood pressure (2,4,5,24,25). The lack of effect on blood flow was probably caused by reduced peripheral resistance.

Labetalol apparently reduces the incidence of hyaline membrane disease in premature infants by increasing the production of pulmonary surfactant (1,2,4,16,26). The mechanism for this effect may be mediated through β_2 -adrenoceptor agonist activity that the drug partially possesses (1,2,4,16,26).

Follow-up studies have been completed at 6 months of age on 10 infants exposed in utero to labetalol (27). All infants demonstrated normal growth and development. In addition, no ocular toxicity was observed in newborns, even though labetalol has an affinity for ocular melanin (1,2,26).

The experience with labetalol in pregnancy was briefly reviewed in a 1988 article (31). A 2000 meta-analysis concluded that IV labetalol for late-onset hypertension in pregnancy was safer than IV hydralazine or diazoxide in terms of drug-induced maternal hypotension and fewer cesarean sections (32).

BREASTFEEDING SUMMARY

Labetalol is excreted into breast milk (1,6). In 24 lactating women at 3 days postpartum, administration of 330–800 mg/day produced a mean milk level of 33 ng/mL. No adverse effects were observed in the nursing infants. One patient, consuming 1200 mg/day, had a mean milk concentration of 600 ng/mL, but this woman did not breastfeed. Three women at 6–9 days postpartum consumed daily doses of labetalol of 600, 600, and 1200 mg and produced peak milk concentrations of the drug of 129, 223, and 662 ng/mL, respectively (6). Peak concentrations of labetalol in the milk occurred between 2 and 3 hours after a dose. Measurable plasma concentrations of labetalol were found in only one infant: 18 ng/mL at 4 hours and 21 ng/mL at 8 hours. Although no adverse effects have been reported, nursing infants should be closely observed for bradycardia, hypotension, and other symptoms of α/β -blockade. Long-term effects of exposure to labetalol from milk have not been studied but warrant evaluation. The American Academy of Pediatrics classifies labetalol as compatible with breastfeeding (33).

LACOSAMIDE

Anticonvulsant

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports of human pregnancy experience have been located. Lacosamide was not teratogenic in two animal species but, in one, was associated with developmental neurobehavioral toxicity at plasma exposures close to those obtained in humans. Moreover, in vitro studies have shown that lacosamide interferes with the activity of collapsin response mediator protein-2 (CRMP-2), which is involved in neuronal differentiation and control of axonal outgrowth (1). Thus, lacosamide could cause adverse effects on CNS development if used in pregnancy. Until human data are available, the safest course is to avoid this drug in pregnancy.

FETAL RISK SUMMARY

Chemically, lacosamide is a functionalized amino acid that was approved by the FDA in 2008 as an anticonvulsant. It is available in both oral and IV formulations. The oral tablets are indicated as adjunctive therapy in the treatment of partial-onset seizures in patients with epilepsy aged ≥ 17 years. IV injection is indicated in the same population when oral administration is temporarily not feasible. It is partially metabolized before elimination into an inactive metabolite. Plasma protein binding is minimal (about 15%), but the elimination half-life (about 13 hours) is prolonged (1).

Reproduction studies have been conducted in rats and rabbits. In rats, oral doses given during organogenesis that resulted in plasma exposures that were about twice the human exposure (AUC) from the maximum recommended dose of 400 mg/day (MRHD) caused maternal toxicity and embryo–fetal death. No teratogenic effects were observed. This dose, when given throughout

gestation, parturition, and lactation, increased perinatal mortality and decreased body weights in the offspring. The no-effect dose for prenatal and postnatal developmental toxicity produced plasma concentrations approximately equal to the MRHD. In rabbits, oral doses that produced plasma exposures about equal to the MRHD caused maternal toxicity but no teratogenicity (1).

Oral lacosamide also was given to rats during the neonatal and juvenile periods because the early postnatal period is thought to correspond to the 3rd trimester in humans in terms of brain development (1). This exposure resulted in decreased brain weights and long-term neurobehavioral changes (altered open field performance and deficits in learning and memory). The no-effect dose for developmental neurotoxicity was plasma concentrations about 0.5 times the MRHD (1).

Lacosamide was not carcinogenic in 2-year studies in mice and rats at doses producing plasma exposures up to about one and three times, respectively, the MRHD. Two of three mutagenicity studies were negative. In fertility studies, no adverse effects were observed on fertility or reproduction in male or female rats (1).

It is not known if lacosamide crosses the human placenta. The molecular weight (about 250), low plasma protein binding, and long elimination half-life suggest that it will cross to the embryo–fetus.

The manufacturer has established the UCB AED Pregnancy Registry in which either the healthcare provider or the patient can initiate enrollment by calling 1-888-537-7734. The manufacturer also recommends that patients enroll in the North American Antiepileptic Drug Pregnancy Registry by calling 1-888-233-2334. (This must be done by the patients themselves.) (1).

BREASTFEEDING SUMMARY

No reports describing the use of lacosamide during human lactation have been located. The molecular weight (about 250), low plasma protein binding (about 15%), and long elimination half-life (about 13 hours) suggest that the drug will be excreted into breast milk. The effects of this exposure on a nursing infant are unknown. However, consideration should be given to the neurobehavioral toxicity observed in neonatal rats at clinically relevant plasma exposures. Until human data are available, the safest course is for women taking this drug to not breastfeed.

LACTULOSE

Laxative

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Lactulose is a synthetic disaccharide that is biodegraded only by bacteria in the colon to the low-molecular-weight acids, lactic acid, formic acid, and acetic acid. Small amounts of lactulose, about 3% of a dose, are absorbed following oral administration (1).

FETAL RISK SUMMARY

No impairment of fertility or fetal harm has been observed in pregnant mice, rats, and rabbits at doses up to three or six times the usual human oral dose (2). No reports on the use of this product in human pregnancy or lactation have been located, but the risk to the fetus and the newborn appears to be negligible.

BREASTFEEDING SUMMARY

No reports describing the use of lactulose during human lactation have been located.

LAMIVUDINE

Antiviral

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo/Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

The animal and human data suggest that lamivudine is a low risk to the developing fetus for structural malformations. Theoretically, exposure to agents in this class at the time of implantation could result in impaired fertility as a result of embryonic cytotoxicity, but this has not been studied in humans. The risk of mitochondrial dysfunction with nucleoside analog reverse transcriptase inhibitors (NRTIs) needs confirmation. However, even if an association is proven, the risk of mortality and morbidity from HIV infection outweighs the risk (1). If indicated, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Lamivudine (2',3'-dideoxy-3'-thiacytidine, 3TC), an antiviral agent structurally similar to zalcitabine, inhibits viral reverse transcription via viral DNA chain termination. It is classified as an NRTI that is used for the treatment of HIV infection. Lamivudine is believed to be converted by intracellular enzymes to the active metabolite, lamivudine-5'-triphosphate (3TC-TP) (2).

No teratogenic effects were observed in rats and rabbits administered lamivudine up to approximately 130 and 60 times, respectively, the usual human adult dose. Early embryo lethality was observed in rabbits at doses close to those used in humans and above. This effect was not observed in rats given ≥ 130 times the usual human dose. Lamivudine crossed the placenta to the fetus in both animal types (2).

Adverse effects on neurobehavior development in mice offspring resulting from a combination of lamivudine and zidovudine were described in a 2001 study (3). Pregnant mice received both drugs from day 10 of gestation to delivery. The effects on somatic and sensorimotor development were minor but

more marked in exposed offspring than when either drug was given alone (2). Both developmental endpoints were delayed with respect to control animals. Further, alterations of social behavior were observed in both sexes of exposed offspring (3).

The low molecular weight (about 229) of lamivudine suggests that it will cross the placenta. A study published in 1997 described the human placental transfer of lamivudine using an ex vivo single cotyledon perfusion system (4). Lamivudine crossed the placenta to the fetal side by simple diffusion. Transfer did not appear to be affected by the presence of zidovudine. Confirming this, a 1998 study found that combination therapy with zidovudine did not affect the pharmacokinetics of lamivudine (5). Lamivudine freely crossed the placenta when given near term with nearly equivalent drug levels in the mother, cord blood, and newborn.

The Antiretroviral Pregnancy Registry reported, for the period January 1989 through July 2009, prospective data (reported before the outcomes were known) involving 4702 live births that had been exposed during the 1st trimester to one or more antiretroviral agents (6). Congenital defects were noted in 134, a prevalence of 2.8% (95% confidence interval [CI] 2.4–3.4). In the 6100 live births with earliest exposure in the 2nd/3rd trimesters, there were 153 infants with defects (2.5%, 95% CI 2.1–2.9). The prevalence rates for the two periods did not differ significantly. There were 288 infants with birth defects among 10,803 live births with exposure anytime during pregnancy (2.7%, 95% CI 2.4–3.0). The prevalence rate did not differ significantly from the rate expected in a nonexposed population. There were 8331 outcomes exposed to lamivudine (3314 in the 1st trimester and 5017 in the 2nd/3rd trimesters) in combination with other antiretroviral agents. There were 222 birth defects (96 in the 1st trimester and 126 in the 2nd/3rd trimesters). In reviewing the birth defects of prospective and retrospective (pregnancies reported after the outcomes were known) registered cases, the Registry concluded that, except for isolated cases of neural tube defects with efavirenz exposure in retrospective reports, there was no other pattern of anomalies (isolated or syndromic) (6). (See required statement below.)

A study published in 1999 evaluated the safety, efficacy, and perinatal transmission rates of HIV in 30 pregnant women receiving various combinations of antiretroviral agents (7). Many of the women were substance abusers. Lamivudine was taken by 29 women in various combinations that included zidovudine, nelfinavir, indinavir, stavudine, nevirapine, and saquinavir. Antiretroviral therapy was initiated at a median of 14 weeks' gestation (range

preconception to 32 weeks). In spite of previous histories of extensive antiretroviral experience and of vertical transmission of HIV, combination therapy was effective in treating maternal disease and in preventing transmission to the current newborns. The outcomes of the pregnancies included one stillbirth, one case of microcephaly, and five infants with birth weights <2500 g, two of whom were premature (7).

In an unusual case, a woman was exposed to HIV through self-insemination with fresh semen obtained from a man with a high HIV ribonucleic acid viral load (>750,000 copies/mL plasma) (8). Ten days later, she was started on a prophylactic regimen of lamivudine (300 mg/day), zidovudine (600 mg/day), and indinavir (2400 mg/day). Pregnancy was confirmed 14 days after insemination. The indinavir dose was reduced to 1800 mg/day, 4 weeks after the start of therapy because of the development of renal calculi. All antiretroviral therapy was stopped after 9 weeks because of negative tests for HIV. She gave birth at 40 weeks' gestation to a healthy 3490-g male infant, without evidence of HIV disease, who was developing normally at 2 years of age (8).

Several reports have described the apparent safe use of lamivudine, usually in combination with other agents, during human pregnancy (9–12). Occasional mild adverse effects were observed in the newborns (e.g., anemia), but no birth defects attributable to drug therapy. In one report, lamivudine concentrations in the newborn were similar to those in the mother (11).

A 1999 report from France described the possible association of zidovudine and lamivudine (NRTIs) use in pregnancy with mitochondrial dysfunction in the offspring (13). Mitochondrial disease is relatively rare in France (estimated prevalence 1 in 5000–20,000 children). From an ongoing epidemiological survey of 1754 mother–child pairs exposed to zidovudine and other agents during pregnancy, however, 8 children with possible mitochondrial dysfunction were identified. None of the eight infants was infected with HIV, but all received prophylaxis for up to 6 weeks after birth with the same antiretroviral regimen as given during pregnancy. Four of the cases were exposed to zidovudine alone and four to a combination of zidovudine and lamivudine. Two from the combination group died at about 1 year of age. All eight cases had abnormally low respiratory-chain enzyme activities. The authors concluded that their results supported the hypothesis of a causative association between mitochondrial respiratory-chain dysfunction and NRTIs. Moreover, the toxicity may have been potentiated by combination of these agents (13).

In a paper following the above study, investigators noted that NRTIs inhibit DNA polymerase γ , the enzyme responsible for mitochondrial DNA replication

(14). They then hypothesized that this inhibition would induce depletion of mitochondrial DNA and mitochondrial DNA-encoded mitochondrial enzymes, thus resulting in mitochondrial dysfunction. Moreover, they stated that support for their hypothesis was suggested by the closeness of the clinical manifestations of inherited mitochondrial diseases with the adverse effects attributed to NRTIs. These adverse effects included polyneuropathy, myopathy, cardiomyopathy, pancreatitis, bone marrow suppression, and lactic acidosis. They also postulated this mechanism was involved in the development of a lipodystrophy syndrome of peripheral fat wasting and central adiposity, a condition that has been thought to be related to protease inhibitors (14).

A commentary on the above two studies concluded that the evidence for NRTI-induced mitochondrial dysfunction was equivocal (1). First, the clinical presentations in the infants were varied and not suggestive of a single cause; indeed, three of infants were symptom-free and one had Leigh's syndrome, a classic mitochondrial disease. Second, the clinical features, in some cases, were not suggestive of mitochondrial dysfunction. Although three had neurological symptoms, none had raised levels of lactate in the cerebrospinal fluid. Moreover, histological or histochemical features of mitochondrial disease were found in only two cases. Finally, low mitochondrial DNA, which would have been direct evidence of NRTI toxicity, was not found in the three cases in which it was measured (1).

A case of combined transient mitochondrial and peroxisomal β -oxidation dysfunction after exposure to NRTIs (lamivudine and zidovudine) combined with protease inhibitors (ritonavir and saquinavir) throughout gestation was reported in 2000 (15). A male infant was delivered at 38 weeks' gestation. He received postnatal prophylaxis with lamivudine and zidovudine for 4 weeks until the agents were discontinued because of anemia. Other adverse effects that were observed in the infant (age at onset) were hypocalcemia (shortly after birth), Group B streptococcal sepsis, ventricular extrasystoles, prolonged metabolic acidosis, and lactic acidemia (8 weeks), a mild elevation of long chain fatty acids (9 weeks), and neutropenia (3 months). The metabolic acidosis required treatment until 7 months of age, whereas the elevated plasma lactate resolved over 4 weeks. Cerebrospinal fluid lactate was not determined nor was a muscle biopsy conducted. Both the neutropenia and the cardiac dysfunction had resolved by 1 year of age. The elevated plasma fatty acid level was confirmed in cultured fibroblasts, but other peroxisomal functions (plasmalogen biosynthesis and catalase staining) were normal. Although mitochondrial dysfunction has been linked to NRTIs, the authors were unable to identify the

cause of the combined abnormalities in the infant. The child was reported to be healthy and developing normally at 26 months of age (15).

A case of life-threatening anemia following in utero exposure to antiretroviral agents was described in 1998 (16). A 30-year-old woman with HIV infection was treated with zidovudine, didanosine, and trimethoprim/sulfamethoxazole (three times weekly) during the 1st trimester. Vitamin supplementation was also given. Because of an inadequate response, didanosine was discontinued and lamivudine and zalcitabine were started in the 3rd trimester. Two weeks before delivery the HIV viral load was undetectable. At term, a pale, male infant was delivered who developed respiratory distress shortly after birth. Examination revealed a hyperactive precordium and hepatomegaly without evidence of hydrops. The hematocrit was 11% with a reticulocyte count of zero. An extensive work-up of the mother and infant failed to determine the cause of the anemia. Bacterial and viral infections, including HIV, parvovirus B19, cytomegalovirus, and others, were excluded. The infant received a transfusion and was apparently doing well at 10 weeks of age. Because no other cause of the anemia could be found, the authors attributed the condition to bone marrow suppression, most likely to zidovudine. A contribution of the other agents to the condition, however, could not be excluded (16).

Two reviews, one in 1996 and the other in 1997, concluded that all women currently receiving antiretroviral therapy should continue to receive therapy during pregnancy and that treatment of the mother with monotherapy should be considered inadequate therapy (17,18). The same conclusion was reached in a 2003 review with the added admonishment that therapy must be continuous to prevent emergence of resistant viral strains (19). In 2009, the updated United States Department of Health and Human Services guidelines for the use of antiretroviral agents in HIV type 1 (HIV-1) infected patients continued the recommendation that therapy, with the exception of efavirenz, should be continued during pregnancy (20). If indicated, lamivudine should not be withheld in pregnancy because the expected benefit to the HIV-positive mother outweighs the unknown risk to the fetus.

A review published in 2000 described seven clinical trials that have been effective in reducing perinatal transmission, five with zidovudine alone, one with zidovudine plus lamivudine, and one with nevirapine (22). Six of the trials were in less-developed countries. Prolonged use of zidovudine in the mother and infant was the most effective for preventing vertical transmission, but also was the most expensive. The combination of lamivudine and zidovudine, consisting of antepartum, intrapartum, and postpartum maternal therapy with continued

therapy in the infant for 1 week, may have been as effective as prolonged zidovudine (22). The updated guidelines for the use of antiretroviral drugs to reduce perinatal HIV-1 transmission were released in 2010 (21). Women receiving antiretroviral therapy during pregnancy should continue the therapy but, regardless of the regimen, zidovudine administration is recommended during the intrapartum period to prevent vertical transmission of HIV to the newborn (21).

Required Statement: “The Registry’s analytic approach is to evaluate specific classes of antiretroviral drugs (FIs [fusion inhibitor(s)], NRTIs [nucleoside analog reverse transcriptase inhibitor(s)], NNRTIs [nonnucleoside reverse transcriptase inhibitor(s)], NtRTIs [nucleotide reverse transcriptase inhibitors], and PIs [protease inhibitor(s)]). The following specific drugs have large enough groups of exposed women to warrant a separate analysis: abacavir, didanosine, efavirenz, lamivudine, lopinavir, nelfinavir, nevirapine, ritonavir, stavudine, tenofovir, and zidovudine.

No increases in risk of overall birth defects or specific defects have been detected to date. For lamivudine and zidovudine sufficient numbers of 1st trimester exposures have been monitored to detect at least a 1.5-fold increase in risk of overall birth defects and a twofold increase in risk of birth defects in the more common classes, cardiovascular and genitourinary systems. No such increases have been detected to date. For abacavir, efavirenz, nelfinavir, nevirapine, ritonavir, and stavudine sufficient numbers of 1st trimester exposures have been monitored to detect at least a twofold increase in risk of overall birth defects. No such increases have been detected to date. Although no pattern of birth defects has been detected with didanosine, the Committee continues to monitor the apparent increased frequency of defects among infants exposed to didanosine in the 1st trimester of gestation.

To date, the Registry has not demonstrated an increased prevalence of birth defects overall, or in the specific classes studied, or among women exposed to abacavir, efavirenz, lamivudine, nelfinavir, nevirapine, ritonavir, stavudine, or zidovudine individually or in combination during the 1st trimester when compared with observed rates for “early diagnoses” in population-based birth defects surveillance systems. While the Registry to date has not detected a major teratogenic signal overall or within classes of drugs or the individual drugs analyzed separately, the population exposed and monitored to date is not sufficient to detect an increase in the risk of relatively rare defects. These findings should provide some assurance when counseling patients.”

BREASTFEEDING SUMMARY

Lamivudine is excreted into breast milk. In 10 women on lamivudine monotherapy (300 mg/day), the mean drug concentrations in maternal serum and breast milk were 0.55 and 1.22 mcg/mL, respectively (5). The infants were not allowed to breastfeed.

Reports on the use of lamivudine during breastfeeding are unlikely because the antiviral agent is used in the treatment of HIV infection. HIV-1 is transmitted in milk, and in developed countries, breastfeeding is not recommended (17,18,20,23–25). In developing countries, breastfeeding is undertaken, despite the risk, because there are no affordable milk substitutes available. Until 1999, no studies had been published that examined the effect of any antiretroviral therapy on HIV-1 transmission in milk. In that year, a study involving zidovudine

was published that measured a 38% reduction in vertical transmission of HIV-1 infection despite breastfeeding when compared with controls (see Zidovudine).

LAMOTRIGINE

Anticonvulsant

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Women with epilepsy may have a higher risk of delivering an infant with a malformation than those who do not have this condition. Reproduction studies with lamotrigine in two animal species showed evidence, in the presence of maternal toxicity, of developmental toxicity (growth restriction, behavioral deficits, and death) but not structural anomalies. Moreover, at least two reviews have concluded that this anticonvulsant may be associated with a lower risk of teratogenicity (1,2). However, a recent report has shown a significant risk for oral clefts following 1st trimester exposure (3). A 2012 review concluded that the absolute risk of lamotrigine-induced cleft lip and palate or cleft palate alone was between 0.1% and 0.4% (4). In addition, a significant increase in the risk for major defects has been reported when lamotrigine was combined with valproate (5).

FETAL RISK SUMMARY

Lamotrigine is an anticonvulsant, chemically unrelated to existing antiepileptic drugs, that is used as adjunctive therapy for the treatment of partial seizures in patients with epilepsy. It is also indicated for the maintenance treatment of bipolar disorder to delay the time to occurrence of mood episodes. Protein binding is moderate (about 55%) and the agent is metabolized to inactive metabolites (6).

Lamotrigine was not teratogenic in animal reproductive studies involving mice, rats, and rabbits using oral doses that were 1.2, 0.5, and 1.1 times, respectively, the highest usual human maintenance dose (500 mg/day) based on BSA (HUHMD). However, maternal toxicity and secondary fetal toxicity

consisting of reduced fetal weight and/or delayed ossification were observed at these doses in mice and rats but not in rabbits. Behavioral deficits were observed in the offspring of rats dosed with 0.1 and 0.5 times the HUHMD during organogenesis. No structural defects were observed after IV bolus doses in rats and rabbits, but an increased incidence of intrauterine fetal death occurred in rats dosed at 0.6 times the HUHMD. Similarly, an increase in fetal deaths occurred in rats dosed orally at 0.1, 0.14, or 0.3 times the HUHMD during the latter part of gestation. These doses were maternally toxic (decreased food consumption and weight). Postnatal deaths also were observed with the two highest doses (6).

No evidence of carcinogenicity was observed in 2-year studies in mice and rats. In multiple other tests, there was no evidence of mutagenicity or clastogenicity, and no impairment of fertility in rats (6).

Lamotrigine reduces fetal folate levels in rats, an effect known to be associated with malformations in animals and humans (6). Human fetal folate levels have apparently not been investigated, but in studies with nonpregnant humans, the drug's inhibitory action of dihydrofolate reductase did not significantly reduce folate levels (7). Serum folate and red blood cell folate concentrations were within the 95% confidence interval (CI) of the baseline values.

Lamotrigine crosses the human placenta (8–10). A 24-year-old woman had been treated before and throughout gestation with the anticonvulsant (300 mg/day) in combination with valproic acid (8). The latter drug was discontinued during the 3rd week of pregnancy. Her lamotrigine serum levels decreased from 17.8 mcg/mL (2 weeks after her last dose of valproic acid) to 2.52 mcg/mL at week 34, but she remained seizure-free throughout pregnancy. She delivered a healthy, 3620-g male infant at 39 weeks' gestation. The umbilical cord blood lamotrigine concentration was 3.26 mcg/mL, indicating a probable cord:maternal serum ratio of 1 (maternal serum level at delivery not reported). On the second day after delivery and a few hours after commencing suckling, the serum concentrations in the infant and mother were 2.79 and 3.88 mcg/mL, respectively, a ratio of 0.7. A 1997 case report found that maternal lamotrigine plasma levels decreased during pregnancy (9). The woman in that case delivered a healthy infant (weight and sex not given) at term. At delivery, the umbilical cord:maternal plasma ratio was 1.2.

In a 2000 report, maternal and cord plasma concentrations of lamotrigine were determined at term delivery in nine women (10 pregnancies; 1 woman with 2 pregnancies also reported in reference 3) (10). Maternal and cord

plasma levels were similar. At 72 hours postpartum, median lamotrigine plasma levels in the infants were 75% of the cord plasma levels (range 50%–100%). The placental transfer is consistent with the low molecular weight (about 256). Moreover, during the first 2 weeks after delivery, the median increase in maternal plasma concentration/dose ratio was 170%, a significant increase (10).

A 2004 report described 12 pregnancies in which women were treated with lamotrigine monotherapy for epilepsy (11). An increase in seizure frequency and/or severity occurred in nine pregnancies, attributed to a gradual decrease in the serum-to-dose ratio to 40% of baseline. Consequently, the doses were increased in seven pregnancies. Three to ten days after delivery, toxic symptoms (dizziness, diplopia, or ataxia) occurred in three of the women with dose increases. Lamotrigine serum levels were 12–14 mcg/mL, a high normal range. The symptoms resolved when the dose was decreased (11).

A 2005 abstract reported 62 pregnancy outcomes after exposure to gabapentin, lamotrigine, or topiramate (12). The study included a blinded dysmorphology examination. Nineteen women used lamotrigine, one of whom had a major malformation: coarctation of the aorta with anomalous left coronary artery, frontal hair upsweep, and a long philtrum (monotherapy for seizures). Of the nine infants examined by a dysmorphologist, none had more than one feature consistent with anticonvulsant embryopathy (12).

The Lamotrigine Pregnancy Registry, an ongoing project conducted by the manufacturer, was closed to new enrollments in June 2009 and the final report was issued in July 2010 (5). The final report covers pregnancy exposures from September 1992 through March 2010. There were 3416 pregnancies registered prospectively (reported to the Registry before the pregnancy outcome was known), 2444 were closed with known outcomes, and 972 (28.5%) were lost to follow-up. In the 2444 known pregnancy outcomes, there were 43 sets of twins, 1 set of triplets and 1 set of quadruplets, for a total of 2492 fetal outcomes. Among the 1817 fetal outcomes involving lamotrigine monotherapy, there were 1636 live births (defects not reported but cannot be ruled out), 98 spontaneous abortions (SABs), 33 elective abortions (EABs), and 10 fetal deaths without defects. Major birth defects were observed in 36 live births, 3 EABs, and 1 fetal death. Excluding SABs, EABs, and fetal deaths without defects, the earliest exposure by trimester was 1554 (1st), 95 (2nd), 18 (3rd), and 5 not specified. Major birth defects were observed in 35 1st trimester exposures (31 live births, 1 fetal death, and 3 EABs), 4 live births in the 2nd trimester, and 1 live birth in the 3rd trimester. The rate of major birth

defects in the 1st trimester exposures was 2.2% (35/1558 excluding fetal deaths and EABs without defects). The sample size of 1558 was sufficient to detect, with 80% power, at least a 1.39- to 1.48-fold increase over baseline in the overall rate of major birth defects (5).

Polytherapy (lamotrigine plus at least one other AED) with valproate involved 173 outcomes: 159 live births, 6 SABs, 6 EABs, and 2 fetal deaths. Among 161 1st trimester exposures, there were 14 live births and 2 EABs with birth defects, 6 SABs, and 139 outcomes without defects (134 live births, 4 EABs, and 1 fetal death). Excluding the 6 SABs, and the 4 EABs and 1 fetal death without defects, the rate of birth defects in the 1st trimester exposures was 10.7% (16/150). Polytherapy without valproate involved 502 outcomes: 457 live births, 22 SABs, 20 EABs, and 3 fetal deaths. Among 474 1st trimester exposures, there were 11 live births and 1 EAB with birth defects, 22 SABs, and 440 outcomes without defects (418 live births, 19 EABs, and 3 fetal deaths). Excluding the 22 SABs, and the 10 EABs and 3 fetal deaths without defects, the rate of birth defects in the 1st trimester exposures was 2.8% (12/430) (5).

The Registry listed the major birth defects observed in the monotherapy and polytherapy groups and concluded that there was no consistent pattern among the defects. Although the data were insufficient to reach a definite conclusion, the Registry found no evidence of a dose–response effect with daily doses of lamotrigine up to 1200 mg/day (5).

Retrospective cases (reported to the Registry after the pregnancy outcome was known) are often biased (only adverse outcomes are reported), but they are useful in identifying specific patterns of anomalies suggestive of a common cause. There were 164 pregnancies with birth defects reported retrospectively to the Registry, 142 involving earliest exposure to lamotrigine in the 1st trimester, 4 with earliest exposure in the 2nd trimester, and 18 with an unspecified trimester of exposure. Lamotrigine monotherapy was used in 94 pregnancies, while 70 involved polytherapy (5).

As of 1996, the FDA had received three disparate reports of birth defects, in which lamotrigine was used in combination with other anticonvulsants during the affected pregnancy (F. Rosa, personal communication, FDA, 1996).

A 1998 noninterventional, observational cohort study described the outcomes of pregnancies in women who had been prescribed ≥ 1 of 34 newly marketed drugs by general practitioners in England (13). Data were obtained by questionnaires sent to the prescribing physicians one month after the expected or possible date of delivery. In 831 of the pregnancies (78%), a newly

marketed drug was thought to have taken during the 1st trimester with birth defects noted in 14 (2.5%) singleton births of the 557 newborns (10 sets of twins). In addition, two birth defects were observed in aborted fetuses. However, few of the aborted fetuses were examined. Lamotrigine was taken during the 1st trimester in 59 pregnancies. The outcomes of these pregnancies included 10 SABs, 1 missed abortion, 9 EABs, 35 normal newborns (4 premature), and 4 newborns with congenital malformations. The malformations observed were ventricular septal defect; congenital respiratory stridor; palatal cleft (soft palate only), hypospadias, and undescended testes (mother had convulsions early in gestation); and abdominal distension with possible congenital intestinal obstruction. In three of these cases, lamotrigine was given in various combinations with other anticonvulsants (e.g., carbamazepine, phenytoin, phenobarbital, and/or sodium valproate). In addition, the study lacked the sensitivity to identify minor anomalies because of the absence of standardized examinations. Late-appearing major defects may also have been missed due to the timing of the questionnaires (13).

A significant association between lamotrigine and isolated, nonsyndromic oral clefts has been reported (3). The findings were published in May 2006 and presented at the June 2006 annual meeting of the Teratology Society in Tucson, Arizona. The cases were collected between 1997 and 2006 by the North American Antiepileptic Drug Pregnancy Registry (North American AED Pregnancy Registry). Among 564 infants (including live births, stillbirths, and elective terminations for anomalies) exposed to lamotrigine monotherapy in the 1st trimester, 15 had major malformations. The prevalence was 2.7% (95% CI 1.5%–4.3%) compared with 1.62% in an unexposed comparison group (N = 221,746 births) (relative risk [RR] 1.7; 95% CI 1.0–2.7). Five infants in the lamotrigine-exposed group had oral clefts (8.9/1000 births): three isolated cleft palate and two isolated cleft lip. None had a recognized syndrome (3).

In the comparison group, the prevalence of the two defects was 1:6160 (0.16/1000) and 1:4820 (0.21/1000), respectively. The RRs attributed to lamotrigine for cleft palate and cleft lip were 32.8 (95% CI 10.6–101.3) and 17.1 (95% CI 4.3–68.2), respectively. The authors thought that the low rates of oral clefts in the comparison group reflected the limited identification of syndromes associated with cleft lip and/or palate. In five other registries that reported 1623 lamotrigine-exposed infants, four infants had oral clefts for a frequency of 2.5/1000 compared with 0.37/1000 in the comparison group. The combined findings showed a significant risk of oral clefts following 1st trimester exposure to lamotrigine monotherapy (3).

An update to the North American AED Pregnancy Registry was published in 2008 (14). Among 684 infants exposed in utero to lamotrigine monotherapy, 16 (2.3%) had major malformations identified at birth, well within the normal background rate. However, five infants (7.3/1000) had oral clefts: three with isolated cleft palate and one each with isolated cleft lip or cleft lip and palate. The rate was 10.4 times the rate among a comparison group of 206,224 unexposed infants (0.7/1000). A comparison also was made with 1623 infants exposed to lamotrigine monotherapy who had enrolled in five other registries. In that group there were four infants with oral clefts (2.5/1000) (RR 3.8, 95% CI 1.4–10.0) (14).

In a population-based case–control study, the EUROCAT Antiepileptic Drug Working Group evaluated data for 3.9 million births from 19 registries covering the period 1995–2005 (15). The data included congenital anomalies among live births, stillbirths, and terminations of pregnancy after prenatal diagnosis. Cases were 5511 nonsyndromic oral clefts, 4571 of whom were isolated oral clefts. In these, there were 1969 cases of cleft palate, 1532 of whom were isolated cleft palate. Controls were 80,052 nonchromosomal, nonepileptic, non-AED-use pregnancies. In the cases, there were 40 pregnancies exposed to lamotrigine monotherapy. Comparisons were made between the monotherapy and the control group for oral clefts relative to other malformations, for isolated oral clefts, cleft palate, and isolated cleft palate. None of the comparisons reached statistical significance. However, when the same comparisons were made between any AED use and no AED use, significant results were found for oral clefts relative to other malformations, cleft palate, and isolated cleft palate (15).

An editorial discussed the results from the above two studies, noting the small number of oral cleft cases in the two reports (five in the North American Registry and three in the EUROCAT) study (16). The editorial also listed the limitations in both. The conclusion was that although the overall risk for oral clefts from lamotrigine monotherapy was low, there was a specific signal that required clarification by additional studies.

A 2013 study reported dose-dependent associations with reduced cognitive abilities across a range of domains at 6 years of age after fetal valproate exposure (17). Analysis showed that IQ was significantly lower for valproate (mean 97, 95% CI 94–101) than for carbamazepine (mean 105, 95% CI 102–108; $p = 0.0015$), lamotrigine (mean 108, 95% CI 105–110; $p = 0.0003$), or phenytoin (mean 108, 95% CI 104–112; $p = 0.0006$). Mean IQs were higher in children whose mothers had taken folic acid (mean 108, 95% CI 106–111)

compared with children whose mothers had not taken the vitamin (mean 101, 95% CI 98–104; $p = 0.0009$) (17).

In a 2009 case report, a 38-year-old woman took lamotrigine during the latter portion of one pregnancy and throughout another pregnancy (18). Both infants appeared to be normal, although a benign peripheral pulmonary stenosis was discovered at 16 days of age in the second infant. This infant also had an apneic episode and became cyanotic (see Breastfeeding Summary).

A 2006 review of prophylactic therapy of bipolar disorder briefly described the effects in pregnancy and breastfeeding of a number of drugs, including lamotrigine (19). Untreated pregnant and nursing women with the disorder are at an increased risk of poor obstetrical outcomes and relapse of affective symptoms. Although the limited data prevented conclusions on the relative safety of the drugs, the author did state that each case needed to be considered separately (19).

A study published in 2009 examined the effect of AEDs on the head circumference in newborns (20). Significant reductions in mean birth-weight-adjusted mean head circumference (bw-adj-HC) was noted for monotherapy with carbamazepine and valproic acid. No effect on bw-adj-HC was observed with gabapentin, phenytoin, clonazepam, and lamotrigine. A significant increase in the occurrence of microcephaly (bw-adj-HC smaller than 2 standard deviations below the mean) was noted after any AED polytherapy but not after any monotherapy, including carbamazepine and valproic acid. The potential effects of these findings on child development warrant study (20).

The pharmacokinetics of lamotrigine were described in 2002 (21). The clearance of the drug increases by >50% starting early in pregnancy and reverts to the nonpregnant state quickly after delivery. Lamotrigine blood levels should be checked before, during, and after pregnancy.

BREASTFEEDING SUMMARY

Lamotrigine is excreted into breast milk (6,8–10,18,22–25). A 24-year-old mother who had been treated throughout gestation with lamotrigine (see details above) began nursing her infant on the 2nd day after delivery (8). At this time, she was taking 300 mg/day, decreased to 200 mg/day approximately 6 weeks postpartum to lessen the drug exposure of the infant. From day 2 to day 145 after delivery, 11 maternal serum and 9 milk samples (about 2–3 hours after the morning dose) were drawn, with lamotrigine serum concentrations ranging from 3.59 to 9.61 mcg/mL and milk levels ranging from 1.26 to 6.51 mcg/mL. The mean milk:serum ratio was 0.56 with a high correlation ($r = 0.959$, p

<0.01) between the serum and milk. The infant's serum levels (about 1–2 hours after breastfeeding), determined at the same times as the mother's, ranged from <0.2 mcg/mL (during weaning) to 2.79 mcg/mL. No adverse effects were observed in the nursing infant either during breastfeeding or during weaning (8).

A 60-kg woman took lamotrigine 200 mg/day throughout gestation and during nursing (9). Two weeks after delivery, the milk:maternal plasma ratio was 0.6. The infant's plasma level, which had been similar to the mother's at birth, was now 25% of the maternal levels. No adverse effects were observed in the nursing infant (9).

In a 2000 report, nine women (10 pregnancies, one woman with two pregnancies also reported in reference 3) received lamotrigine throughout gestation (see Fetal Risk Summary above) and continued the drug during breastfeeding (10). The median milk:maternal plasma ratio 2–3 weeks after delivery was 0.61 (range 0.47–0.77). The lamotrigine plasma concentrations in the infants were approximately 30% (range 23%–50%) of the corresponding maternal plasma levels. The estimated infant lamotrigine dose was ≥ 0.2 –1 mg/kg/day, assuming a milk intake of 150 mL/kg/day, about 9% of the weight-adjusted maternal daily dose. Because of the slow elimination in the infant (most likely due to reduced hepatic glucuronidation capacity), the marked increase in maternal plasma lamotrigine concentrations that occurred after birth (see Fetal Risk Summary above), and the fact that infant drug levels may not have reached steady-state concentrations, the infant exposure could eventually result in therapeutic plasma lamotrigine levels. No adverse effect in the nursing infants was observed (10).

A 38-year-old woman took lamotrigine throughout her third pregnancy for a seizure disorder caused by a pilocytic astrocytoma 6 years earlier (18). Although the brain tumor had been removed surgically, she had residual epilepsy that was treated with lamotrigine. In her second pregnancy, she started daily lamotrigine 550 mg toward the end of the pregnancy, and then gradually reduced the dose while breastfeeding to 425 mg. The highest serum concentration, measured at 45 days postpartum, was 8.96 mcg/mL. No adverse effects were observed in the fully breastfed infant. In her third pregnancy, the mother's daily dose was increased from 450 mg (pregestation) to 875 mg (term). The dose at term was 10.9 mg/kg/day. Serum concentrations during this interval were 5.12 mcg/mL (pregestation), 3.30 mcg/mL (3rd trimester), and 4.53 mcg/mL (day of birth). She had a focal epileptic seizure during the 5th gestational month and a generalized tonic–clonic seizure shortly after delivery. She took her last 875-mg dose 20.5 hours before

giving birth to a full-term, 4200-g male infant with Apgar scores of 9 and 9. Because of the latest seizure, a dose reduction was not started until the 2nd week. The infant was exclusively breastfed. His lamotrigine concentration approximately 12.5 hours after birth was 7.71 mcg/mL (proposed pediatric therapeutic range 1–5 mcg/mL). At age 3 days, his serum concentration was 5.81 mcg/mL. At 16 days of age, his breathing became irregular and strenuous and he had a brief episode of apnea. Three hours after the first apneic episode, he became cyanotic while nursing. The mother, a physician, successfully resuscitated him and took him to the hospital. On admission, his lamotrigine serum concentration was 4.87 mcg/mL (4 hours after the mother's 850-mg dose and 3 hours after nursing). Except for periodic sinus tachycardia (170–180 beats/minute) and a benign peripheral pulmonary stenosis, his examination and laboratory tests were normal. Breastfeeding was discontinued on postpartum day 17. The mother's lamotrigine serum concentration at this time was 14.93 mcg/mL. Her dose was decreased to 600 mg on postpartum day 22, and then gradually reduced to 525 mg by day 64. Using a milk concentration of 7.68 mcg/mL obtained on day 22, the theoretical infant dose (1.15 mg/kg/day) as a percentage of the mother's weight-adjusted dose was 13%. The milk:plasma ratio determined 4 times during postpartum days 22–64 was 0.79–0.96. Based on blood samples obtained 22 and 25 days after birth, the estimated lamotrigine half-life in the infant was 56 hours, about twice that seen in adults. The infant had no further apneic or cyanotic episodes and was developing normally at 7 months of age. The authors could not determine why the infant developed apnea but concluded that lamotrigine was the probable cause (18).

A 2004 study reported lamotrigine serum concentrations in four nursing infants, all of whom had been exposed throughout pregnancy (22). All the women had full-term deliveries of healthy babies. The doses on day 10 postpartum, the sampling day, were 200–800 mg/day. The infant: maternal plasma concentration ratios were 0.2, 0.2, 0.43, and ≤ 0.17 (infant < 1 mcg/mL and maternal 5.2 mcg/mL), respectively. For the first two cases, sampling was repeated at 2 months of age with nearly identical ratios of 0.22 and 0.23, respectively, but both nursing infants were being supplemented with formula 2–3 times per day. No adverse effects were observed in the infants, but the authors were concerned because of the drug concentrations reaching “therapeutic ranges” (22).

A 2005 case report described a woman treated for epilepsy with partial seizures with 300 mg/day lamotrigine throughout pregnancy and during

breastfeeding (23). The healthy, 3.3-kg male infant was spontaneously delivered at term with Apgar scores of 8 and 9. Development of the infant was normal during the first 4 breastfed months and no toxicity was observed (23).

A 2006 report quantified the amount of lamotrigine in the breast milk of six mothers and in the plasma of their breast-fed infants (mean age 4.1 months; range 0.4–5.1 months) (24). The mothers, who obtained the milk samples by hand expression, were taking a mean dose of 400 mg/day (range 75–800 mg) for epilepsy (N = 5) or bipolar disorder (N = 1). The duration of treatment before the study was not stated. The mean maternal dose based on body weight was 6.3 mg/kg/day, whereas the mean absolute infant dose was 0.45 mg/kg/day. The daily infant dose relative to the mother's weight-adjusted dose was 7.6%. The mean infant plasma concentration of lamotrigine was 0.60 mg/L, a level that was a mean of 18% of the maternal plasma concentration. The mothers and physicians observed no adverse effects in the infants (24).

A 2008 report described steady-state lamotrigine concentrations in 26 women who were breastfeeding while taking the drug (25). The mean age of the infants was 13.0 weeks and the mean maternal dose was 5.93 mg/kg/day. The mean breast milk concentration was 3.38 mcg/mL (based on sampling from one breast every 4 hours for 24 hours) and the milk:plasma ratio was 0.413. The mean theoretical infant dose was 0.51 mg/kg/day and the relative infant dose was 9.2%. No adverse events were noted among the mothers or their nursing infants, but seven infants had elevated platelet counts without adverse clinical consequences (25).

As with any drug, a mother who must take lamotrigine to control her disease and who chooses to nurse her infant should carefully monitor the infant for adverse effects. Some anticonvulsants have produced adverse effects in nursing infants (see Phenobarbital and Primidone); whereas others are considered compatible with breastfeeding. (See Carbamazepine, Phenytoin, and Valproic Acid.) No adverse effects have been seen in nursing infants of mothers taking lamotrigine. Monitoring infant lamotrigine concentrations should be considered, as well as close monitoring for sedation and rash (26).

In a 2010 study, 199 children who had been breastfed while their mothers were taking a single antiepileptic drug (carbamazepine, lamotrigine, phenytoin, or valproate) were evaluated at 3 years of age cognitive outcome (27). Mean adjusted IQ scores for exposed children were 99 (95% CI 96–103), whereas the mean adjusted IQ scores of nonbreastfed infants were 98 (95% CI 95–101).

Because of the potential for therapeutic serum concentrations in the infant,

the American Academy of Pediatrics classifies lamotrigine as a drug for which the effect on a nursing infant is unknown but may be of concern (28).

LANSOPRAZOLE

Gastrointestinal Agent (Antisecretory)

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

The human and animal data for proton pump inhibitors (PPIs) suggest that this class of drugs can be considered low risk in pregnancy, but the human pregnancy experience for lansoprazole alone is still limited. A study showing an association between in utero exposure to gastric acid-suppressing drugs and childhood allergy and asthma requires confirmation. Birth defects, including cardiac defects, have been reported in pregnancies exposed to a PPI (see also Omeprazole), but there is no evidence of a causal association. Most likely, the observed defects were the result of many factors, including possibly the severity of the disease and concurrent use of other drugs. The data do warrant continued investigation. In addition, the studies lacked the sensitivity to detect minor anomalies because of the absence of standardized examinations. Late-appearing major defects may also have been missed due to the timing of some data collection. If lansoprazole is required or if inadvertent exposure does occur early in gestation, the known risk to the embryo–fetus appears to be low. Long-term follow-up of offspring exposed during gestation is warranted.

FETAL RISK SUMMARY

Lansoprazole is a PPI that blocks gastric acid secretion by a direct inhibitory effect on the gastric parietal cell (1). It is used for the treatment of gastric and duodenal ulcer, erosive esophagitis, gastroesophageal reflux disease (GERD), and pathologic hypersecretory conditions, such as Zollinger-Ellison syndrome. It is also used in combination with amoxicillin and/or clarithromycin for *Helicobacter pylori* eradication to reduce the risk of duodenal ulcer recurrence. Lansoprazole is in the same class of PPIs as dexlansoprazole, esomeprazole, omeprazole, pantoprazole, and rabeprazole.

Reproductive studies have been conducted in pregnant rats and rabbits at oral doses ≤ 40 and 16 times, respectively, the recommended human dose based on BSA (1). No evidence was found that these doses impaired fertility or caused fetal harm. Similar to other PPIs, lansoprazole is carcinogenic in mice and rats, producing dose-related gastric, testicular, and liver tumors (1). In addition, positive results were seen with lansoprazole in the in vitro human lymphocyte chromosomal aberration assays, but the Ames mutation assay and other genotoxic animal tests were negative (1).

In a study published in 1990, lansoprazole at a dose of 50 or 300 mg/kg was not teratogenic in pregnant rats, but a decrease in fetal weight occurred (2). Schardein also cited a 1990 study, which appears to be similar to the one cited above, that found no evidence of teratogenicity in rats and rabbits (3).

It is not known if lansoprazole crosses the human placenta. The molecular weight (about 369) is low enough that passage to the fetus should be expected. Another PPI, omeprazole, has a molecular weight (about 345) and chemical structure that are very similar to lansoprazole, and it is known to cross the human placenta (see Omeprazole).

A 1998 noninterventional, observational cohort study described the outcomes of pregnancies in women who had been prescribed ≥ 1 of 34 newly marketed drugs by general practitioners in England (4). Data were obtained by questionnaires sent to the prescribing physicians one month after the expected or possible date of delivery. In 831 (78%) of the pregnancies, a newly marketed drug was thought to have been taken during the 1st trimester, with birth defects noted in 14 (2.5%) singleton births of the 557 live newborns (10 sets of twins). In addition, two birth defects were observed in aborted fetuses. However, few of the aborted fetuses were examined. Lansoprazole was taken during the 1st trimester in six pregnancies. Seven healthy newborns (one premature; one set of twins) were delivered (4).

Data from the Swedish Medical Birth Registry were presented in 1998 (5). A total of 553 infants (6 sets of twins) were delivered from 547 women who had used acid-suppressing drugs early in pregnancy. The odds ratio (OR) for malformations after PPI exposure was 0.91, 95% confidence interval (CI) 0.45–1.84. Of the 19 infants with birth defects, 10 had been exposed to PPIs alone and 1 was also exposed to ranitidine. Lansoprazole was the only acid-suppressing drug exposure in 13 infants. Two of these infants had birth defects: an atrial septum defect and an undescended testicle (see Omeprazole for additional details of this study (5)).

In a study published in 1999, investigators linked data from a Danish

prescription database to a birth registry to evaluate the risks of PPIs for congenital malformations, low birth weight, and preterm delivery (<37 weeks') (6). From a total of 51 women who had filled a prescription for these drugs sometime during pregnancy, 38 (omeprazole N = 35, lansoprazole N = 3) had done so during the interval of 30 days before conception to the end of the 1st trimester. A control group, consisting of 13,327 pregnancies in which the mother had not obtained a prescription for reimbursed medication from 30 days before conception to the end of her pregnancy, was used for comparison. The prevalence of major congenital anomalies in controls was 5.2%. Three major birth defects (7.9%), two of which were cardiovascular anomalies, were observed from the 38 pregnancies possibly exposed in the 1st trimester (specific drug exposure not given): ventricular septum defect; pyloric stenosis; and one case of patent ductus arteriosus, atrial septum defect, hydronephrosis, and agenesis of the iris. In comparison with controls, the adjusted (for maternal age, birth order, gestational age, and smoking, but not for alcohol abuse) relative risks for the three outcomes were congenital malformations 1.6 (95% CI 0.5–5.2), low birth weight 1.8 (95% CI 0.2–13.1), and preterm delivery (not adjusted for gestational age) 2.3 (95% CI 0.9–6.0). Although the study found no elevated risks for the three outcomes, the investigators cautioned that more data were needed to assess the possible association between PPIs and cardiac malformations or preterm delivery (6).

A 2002 study conducted a meta-analysis involving the use of PPIs in pregnancy (7). In the five cohort studies analyzed, there were 593 infants, mostly exposed to omeprazole, but also including lansoprazole and pantoprazole. The relative risk (RR) for major malformations was 1.18, 95% CI 0.72–1.94 (7).

A 2005 study by the European Network of Teratology Information Services reported the outcomes of pregnancies exposed to omeprazole (N = 295), lansoprazole (N = 62), or pantoprazole (N = 53) (8). In the pantoprazole group, the median duration of treatment was 14 days (range 7–23 days) and the dose used was 40 mg/day. The outcomes consisted of one spontaneous abortion (SAB), three elective abortions (EABs) (none for congenital anomalies), one stillbirth, and 48 live births. One infant exposed early in gestation (week 2 for 8 days) had congenital toxoplasmosis. Compared with a nonexposed control group, there was no difference in the rate of major malformations between the lansoprazole and control groups (RR 1.04, 95% CI 0.25–4.21). Similar results were observed for omeprazole and pantoprazole (8).

A 2007 case report described the use of lansoprazole in a woman with

Zollinger-Ellison syndrome (9). In the 1st trimester, she underwent a left lobectomy of the liver to remove a gastrin-secreting neuroendocrine tumor. Lansoprazole (30 mg three times a day) was taken throughout gestation. Ultrasound scans revealed a single umbilical artery and bilateral choroid plexus cysts with no other malformations. In the 38th week, she gave birth to a 3.370-kg male infant with Apgar scores of 8 and 10. A routine physical examination of the infant was normal. At the time of the report, the woman was in her second pregnancy and receiving the same oral treatment (9).

A population-based observational cohort study formed by linking data from three Swedish national healthcare registers over a 10-year period (1995–2004) was reported in 2009 (10). The main outcome measures were a diagnosis of allergic disease or a prescription for asthma or allergy medications. The drug types included in the study were gastric acid suppressors, including H₂-receptor antagonists, prostaglandins, PPIs, combinations for eradication of *Helicobacter pylori*, and drugs for peptic ulcer and GERD. Of 585,716 children, 29,490 (5.0%) met the diagnosis and 5645 (1%) had been exposed to gastric acid suppression therapy in pregnancy. Of these children, 405 (0.07%) were treated for allergic disease. For developing allergy, the odds ratio (OR) was 1.43, 98% CI 1.29–1.59, irrespective of the drug, time of exposure during pregnancy, and maternal history of allergy. For developing childhood asthma, but not other allergic diseases, the OR was 1.51, 95% CI 1.35–1.69, irrespective of the type of acid-suppressive drug and the time of exposure in pregnancy. The authors proposed three possible mechanisms for their findings: (a) exposure to increased amounts of allergens could cause sensitization to digestion-labile antigens in the fetus; (b) maternal Th2 cytokine pattern could promote an allergy-prone phenotype in the fetus; and (c) maternal allergen-specific IgE could cross the placenta and sensitize fetal immune cells to food- and airborne allergens. Several limitations of the study that might have affected their findings were identified, including a general increase in childhood asthma but not necessarily an increase in allergic asthma (10). The study requires confirmation.

A second meta-analysis of PPIs in pregnancy was reported in 2009 (11). Based on 1530 exposed compared with 133,410 not exposed pregnancies, the OR for major malformations was 1.12, 95% CI 0.86–1.45. There also was no increased risk for SABs (OR 1.29, 95% CI 0.84–1.97) or preterm birth (OR 1.13, 95% CI 0.96–1.33) (11).

In a 2010 study from Denmark, covering the period 1996–2008, there were 840,968 live births among whom 5082 were exposed to PPIs between 4 weeks

before conception to the end of the 1st trimester (12). In the exposed group, there were 174 (3.4%) major malformations compared with 21,811 (2.6%) not exposed to PPIs (adjusted prevalence odds ratio [aPOR] 1.23, 95 CI 1.05–1.44). When the analysis was limited to exposure in the 1st trimester, there were 118 (3.2%) major malformations among 3651 exposed infants (aPOR 1.10, 95% CI 0.91–1.34). For exposure to lansoprazole in the 1st trimester, there were 28 (3.5%) major birth defects among 794 live births (aPOR 1.13, 95% CI 0.77–1.67) (see Esomeprazole, Omeprazole, Pantoprazole, and Rabeprazole for their data). The data showed that exposure to PPIs in the 1st trimester was not associated with a significantly increased risk of major birth defects (12). An accompanying editorial discussed the strengths and weaknesses of the study (13).

In a 2012 publication, the National Birth Defects Prevention study, a multi-site population-based case–control study, examined whether nausea/vomiting of pregnancy (NVP) or its treatment were associated with the most common noncardiac defects (nonsyndromic cleft lip with or without cleft palate [CL/P], cleft palate alone [CP], neural tube defects [NTDs], and hypospadias) (14). PPI exposure included esomeprazole, lansoprazole, and omeprazole. There were 4524 cases and 5859 controls. NVP was not associated with cleft palate or NTDs, but modest risk reductions were observed for CL/P and hypospadias. Increased risks were found for PPIs (N = 7) and hypospadias (adjusted OR [aOR] 4.36, 95% CI 1.21–15.81), steroids (N = 10) and hypospadias (aOR 2.87, 95% CI 1.03–7.97), and ondansetron (N = 11) and CP (aOR 2.37, 95% CI 1.18–4.76) (14).

Another 2012 reference, using the Danish nationwide registries, evaluated the risk of hypospadias after exposure to PPIs during the 1st trimester and throughout gestation (15). The study period, 1997 through 2009, included all liveborn boys that totaled 430,569, of whom 2926 were exposed to maternal PPI use. Hypospadias was diagnosed in 20 (0.7%) exposed boys, whereas 2683 (0.6%) of the nonexposed had hypospadias (adjusted prevalence ratio [aPR] 1.1, 95% CI 0.7–1.7). For the 5227 boys exposed throughout pregnancy, 32 (0.6%) had hypospadias (PR 1.0, 95% CI 0.7–1.4). When the analysis was restricted to mothers with 2 or more PPI prescriptions, the aPR of overall hypospadias was 1.7, 95% CI 0.9–3.3) and 1.6, 95% CI 0.7–3.9 for omeprazole. The authors concluded that PPIs were not associated with hypospadias (15).

A large retrospective cohort study from Israel covering 1998–2009 was published in 2012 (16). Among 114,960 live births, there were 110,783

singletons and 1239 EABs. Major malformations were observed in 6037 (5.5%) singletons and in 468 abortuses. Exposure to a PPI (lansoprazole, omeprazole, or pantoprazole) during the 1st trimester occurred in 1186 (1159 infants and 27 abortuses). In the exposed infants and abortuses, 80 (6.7%) had a major malformation compared with 6425 (5.9%) not exposed (adjusted OR [aOR] 1.06, 95% CI 0.84–1.33). In the 233 infants–abortuses exposed to lansoprazole, 13 (5.6%) had a major malformation compared with 6753 (6.1%) not exposed (aOR 0.83, 95% CI 0.48–1.46). The data showed that exposure to PPIs during the 1st trimester was not associated with an increased risk of major defects. Moreover, additional analysis revealed that exposure during the 3rd trimester was not associated with increased risk of perinatal mortality, premature delivery, low birth weight, or low Apgar scores (16).

Five reviews on the treatment of GERD have concluded that PPIs can be used in pregnancy with relative safety (17–21). Because there is either very limited or no human pregnancy data for the three newest agents in this class (dexlansoprazole, esomeprazole, and rabeprazole), other drugs in the class are preferred.

BREASTFEEDING SUMMARY

No reports describing the use of lansoprazole during human lactation have been located. The molecular weight (about 369) is low enough that excretion into breast milk should be expected. Because of the carcinogenicity observed in animals, and the potential for suppression of gastric acid secretion in the nursing infant, the use of lansoprazole during lactation is best avoided.

LANTHANUM CARBONATE

Antidote (Phosphate Binder)

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of lanthanum carbonate in human pregnancy have been located. The indication for the drug suggests that human pregnancy experience will be very limited. The systemic bioavailability is minimal and should have no effect on the embryo or fetus.

FETAL RISK SUMMARY

Lanthanum carbonate, an oral phosphate binder, is indicated to reduce serum phosphate in patients with end-stage renal disease. In the acid environment of the upper gastrointestinal tract, lanthanum ions are released to bind dietary phosphate from food during digestion. The resulting lanthanum phosphate complexes are highly insoluble. The systemic bioavailability of lanthanum carbonate is very low (<0.002%) with a mean plasma concentration of 0.6 ng/mL. The drug is practically insoluble in water. Lanthanum carbonate is not metabolized. Plasma protein binding is >99% and the plasma elimination half-life is 53 hours. However, lanthanum is bound to bone and is slowly released with an estimated half-life of 2.0–3.6 years (1).

Reproduction studies have been conducted in rats and rabbits. In rats, oral doses up to 3.4 times the maximum recommended daily human dose (MRDHD) resulted in no evidence of fetal harm. When the highest dose was given from implantation through lactation, offspring had delayed eye opening, reduction in body weight gain, and delayed sexual development (preputial separation and vaginal opening). In rabbits, doses up to 5 times the MRDHD were maternal toxic (reduced body weight gain and food consumption) and were associated with increased postimplantation loss, reduced fetal weights, and delayed fetal ossification (1).

In long-term studies, lanthanum carbonate was not carcinogenic in rats but was associated with an increased incidence of glandular stomach adenomas in male mice. The drug did not cause mutagenicity or chromosomal aberrations in multiple tests. Fertility of male and female rats was not affected by doses up to 3.4 times the MRDHD (1).

It is not known if lanthanum carbonate crosses the human placenta. The molecular weight (about 458 for anhydrous form) is low enough, but the very low systemic bioavailability and high plasma protein binding suggest that exposure of the embryo–fetus will not be clinically significant.

BREASTFEEDING SUMMARY

No reports describing the use of lanthanum carbonate during human lactation have been located. The very low systemic bioavailability (<0.002%) and high plasma protein binding (>99%) suggest that insignificant amounts of the drug will be excreted into breast milk. Moreover, even the minimal amounts that might be excreted would bind with milk phosphate, resulting in a nonabsorbable complex. The effect of this binding on infant bone growth is unknown but is probably not clinically significant.

LAPATINIB

Antineoplastic (Tyrosine Kinase Inhibitor)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

The human pregnancy experience with lapatinib is very limited. The animal reproduction studies suggest moderate risk. The no-observed-effect-level (NOEL) in animals was ≤ 1 times the human clinical exposure based on AUC (HCE). Although the near absence of human pregnancy experience prevents a complete assessment of the embryo–fetal risk, the drug should be avoided in pregnancy. If it must be administered for the mother’s benefit, avoiding the period of organogenesis should be considered.

FETAL RISK SUMMARY

Lapatinib is an intracellular tyrosine kinase inhibitor that is indicated, in combination with capecitabine (see Capecitabine), for the treatment of patients with advanced or metastatic breast cancer whose tumors overexpress human epidermal receptor type 2 (HER2) and who have received prior therapy, including an anthracycline, a taxane, and trastuzumab. There are no other agents in this subclass (see Appendix). Lapatinib is extensively metabolized to inactive metabolites. Plasma protein binding to albumin and α -1 acid glycoprotein is $>99\%$. The terminal phase half-life following repeated dosing is 24 hours (1).

Reproduction studies have been conducted in rats and rabbits. Pregnant rats were given doses during organogenesis and through lactation that produced systemic exposures that were about 6.4 times the HCE. At this exposure, 91% of the pups died by the 4th day after birth, but this dose also caused maternal toxicity. When half of the dose was used (about 3.3 times the HCE), 34% of the pups died. The NOEL was about equal to the HCE. There were no teratogenic effects at the highest exposure, but minor anomalies observed were left-sided umbilical artery, cervical rib, and precocious ossification. In rabbits, maternal toxicity was observed at doses resulting in exposures that

were about 0.07 and 0.2 times the HCE. Decreased fetal body weights and minor skeletal variations were noted at both doses, and abortions were observed at the higher dose (1).

Carcinogenicity studies have not been completed. Lapatinib was not clastogenic or mutagenic in a variety of assays. There were no effects on mating or fertility in female and male rats given doses producing exposures that were 6.4 and 2.6 times the HCE, respectively. However, in female rats, this exposure during breeding and through the first 6 days of gestation was associated with a significant decrease in the number of live fetuses. At about 3.3 times the HCE, there was a significant decrease in fetal body weights (1).

It is not known if lapatinib crosses the human placenta. Although the high plasma protein binding will inhibit transfer, the molecular weight (about 926 for the nonhydrated form) and the prolonged half-life suggest that embryo–fetus exposure will occur.

A 44-year-old woman with breast cancer conceived while being treated in a phase I clinical trial with lapatinib (2). During the previous 10 years, she had been treated with a number of antineoplastic agents, including cyclophosphamide, doxorubicin, fluorouracil, paclitaxel, trastuzumab, and vinorelbine. She also had undergone a left modified radical mastectomy, regional radiation, and 10 years of tamoxifen. When cancer was discovered in her right breast, she was enrolled in the clinical trial. She was initially treated with lapatinib 1500 mg/day, but the dose was reduced by 50% because of diarrhea and rash. Pregnancy was diagnosed at about 14 weeks' gestation; conception was thought to have occurred in the 3rd or 4th week of study drug. A modified radical mastectomy was conducted to avoid further antineoplastic treatment. Because of disease progression, labor was induced, and the woman gave birth to a healthy, 2.6-kg female infant with Apgar scores of 8 and 9 at 1 and 5 minutes, respectively. At 18 months of age, the infant was doing well, having reached all developmental milestones on schedule (2).

BREASTFEEDING SUMMARY

No reports describing the use of lapatinib during lactation have been located. Although the high plasma protein binding (>99%) should inhibit excretion, the molecular weight (about 926 for the nonhydrated form) and the prolonged half-life (24 hours) suggest that the drug will be excreted into breast milk. Women receiving lapatinib should not breastfeed because of the potential for toxicity in a nursing infant. The most common toxicities in adults were severe diarrhea, nausea and vomiting, and rash.

LARONIDASE

Endocrine/Metabolic Agent (Enzyme)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity (≤ 7 Days after Birth) Probably Compatible (>7 Days after Birth)

PREGNANCY SUMMARY

One report of laronidase in human pregnancy has been located, and that case involved exposure before the onset of organogenesis. The animal reproduction data, although based on body weight, suggest low risk. However, the absence of human pregnancy experience during organogenesis and later prevents a more complete assessment. Nevertheless, the benefits (improved pulmonary function and walking capacity) of treatment with laronidase to a pregnant woman with mucopolysaccharidosis I (MPS I) appear to outweigh the unknown risks to the embryo and/or fetus. Therefore, if a woman requires this therapy, it should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Laronidase, a polymorphic variant of the human enzyme, α -L-iduronidase, is a glycoprotein prepared by recombinant DNA technology. It is indicated for patients with the Hurler and Hurler-Scheie forms of MPS I and for patients with the Scheie form who have moderate-to-severe symptoms. The predicted amino acid sequence of laronidase is identical to the polymorphic form of human α -L-iduronidase. Laronidase is given as a once-weekly 3–4 hour IV infusion. The mean elimination half-life ranges from 1.5 to 3.6 hours (1).

Hypersensitivity reactions, including anaphylaxis, may occur during laronidase IV infusions. Patients should receive antipyretics and/or antihistamines 60 minutes before the infusion. Hypotension was observed in 9% (2/22) of the patients receiving an infusion of laronidase in a placebo-controlled study (1). This adverse effect in a pregnant woman could have deleterious effects on placental perfusion, resulting in embryo and fetal harm.

Reproduction studies have been conducted in rats. No evidence of fetal harm was observed with a dose that was 6.2 times the human dose (assumed to be based on body weight). In addition, the same dose had no effect on male and female rat fertility (1).

It is not known if laronidase crosses the human placenta. The molecular weight is high (about 83,000), suggesting that the glycoprotein will not cross to the embryo or fetus.

A 2006 case report described a 21-year-old woman with MPS I, who became pregnant while receiving weekly infusions (100 U/kg) of laronidase (2). Exposure appears to have been no longer than 4 weeks. Further laronidase treatment was stopped. The woman went into spontaneous premature labor at 29 weeks' gestation and delivered a healthy, normal 1250-g female infant. Although the cause of the preterm labor was unknown, the authors speculated that it might have been secondary to the disease (2).

BREASTFEEDING SUMMARY

No reports describing the use of laronidase during human lactation have been located.

The high molecular weight (about 83,000) suggests that the glycoprotein will not be excreted into breast milk. However, many proteins (e.g., immunoglobulins) are excreted into milk and absorbed by the infant in the first few days after birth. Thus, laronidase could potentially be excreted and absorbed.

If laronidase is excreted into milk, one strategy to reduce the exposure of a nursing infant, especially during the first week after birth, involves using the pharmacokinetics and dosing schedule of the drug. Laronidase has a short elimination half-life (1.5–3.6 hours) and is infused once weekly over 3–4 hours. The woman could nurse immediately before the start of the infusion, and then pump and dump her milk for about 8–12 hours after the end of the infusion. During this period, the infant could be fed breast milk stored earlier. This strategy should markedly reduce laronidase exposure of the nursing infant. Nevertheless, if a woman receiving laronidase therapy chooses to nurse, especially during the first week after birth, her infant should be closely monitored for the adverse effects most commonly observed in adults (skin rash, upper respiratory tract infection, hyperreflexia, paresthesia, chest pain, edema, and hypotension).

LATANOPROST

Ophthalmic (Prostaglandin Agonist)

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Neither the limited human pregnancy experience nor the animal reproduction data suggest that latanoprost is a clinically significant risk to the embryo–fetus. The amount of drug in the systemic circulation after ophthalmic use of the recommended dose is likely minimal. The limited data suggest that, if indicated, latanoprost should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Latanoprost, a prostaglandin F_{2α} analog, is a topical ophthalmic solution indicated for the reduction of elevated intraocular pressure in patients with open-angle glaucoma or ocular hypertension. It is in the same class as bimatoprost, tafluprost, and travoprost. Latanoprost is a prostanoid selective FP receptor agonist, which is believed to reduce the intraocular pressure by increasing the outflow of aqueous humor. Latanoprost is a prodrug that is hydrolyzed by esterases in the cornea to the biologically active acid. Metabolites of the active acid are inactive. The elimination half-life of the active acid form is 17 minutes (1,2).

Reproduction studies have been performed in rats and rabbits. In rabbits, 4 of 16 dams had no viable fetuses at a dose that was about 80 times the maximum human dose (MHD) (assumed to be based on body weight). The no-effect dose for embryo death in rabbits was about 15 times the MHD (1,2). No information on studies conducted in pregnant rats was provided.

Latanoprost was not carcinogenic in mice and rats at doses up to 2800 times the MHD. Mutagenicity studies were also negative in multiple assays, but the drug did cause chromosome aberrations in an in vitro assay with human

lymphocytes. The drug had no effect on male or female fertility in animal studies (1,2).

It is not known if latanoprost or its active acid crosses the human placenta. The molecular weight of the prodrug (about 433) is low enough, but plasma concentrations are probably very low and have a very short elimination half-life. These properties suggest that clinically significant exposure of the embryo–fetus is unlikely.

Prostaglandin F_{2α} has been used for pregnancy termination in humans via intrauterine extra-amniotic infusion to treat missed abortion or intrauterine death. However, there is no evidence that at doses given to reduce elevated ophthalmic pressure, an increased risk for uterine contractions would be seen (3,4).

Eleven 1st trimester latanoprost-exposed pregnancies were identified by a teratology information service in Italy (5). Exposure in the 1st trimester occurred for 4–70 days. Three women continued therapy throughout gestation and one discontinued the drug in the 3rd trimester. One pregnancy was lost to follow-up, one ended in a spontaneous abortion 2 weeks after therapy was discontinued (in a 46-year-old woman), and nine women gave birth at term to normal, healthy infants (5).

BREASTFEEDING SUMMARY

No reports describing the use of latanoprost during human lactation have been located. The molecular weight of the prodrug (about 433) is low enough, but plasma concentrations are probably very low and have a very short elimination half-life (17 minutes). These properties suggest that clinically significant amounts will not be excreted into breast milk.

LEFLUNOMIDE

Immunologic Agent (Antirheumatic)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Leflunomide is an animal teratogen and its use in pregnancy is contraindicated. The drug and its active metabolite are eliminated from the body very slowly and may take up to 2 years to reach nondetectable plasma metabolite levels. Nevertheless, the limited human pregnancy experience has not shown an increased risk of major or minor anomalies. Moreover, the risk of preterm delivery and lower birth weight of full-term infants appears to be related to the disease (rheumatoid arthritis) or concurrent drug therapy other than leflunomide. In women of childbearing age, pregnancy should be excluded and the woman should be on a reliable contraceptive before starting therapy. In the event of inadvertent conceptions, a drug elimination procedure using cholestyramine has been developed and is included in the product information. However, the procedure for preventing embryo exposure to therapeutic levels in unplanned pregnancies might be clinically ineffective. In inadvertent pregnancies, the procedure, to be at least partially effective, should be initiated no later than the time of the first missed menstrual period (1). Pregnancy loss and anomalies occurring early in organogenesis would still be a risk, but drug-induced microcephaly and mental retardation would be prevented (2). A pregnancy registry and cohort study has been established to monitor fetal outcomes of pregnant women exposed to leflunomide for the treatment of rheumatoid arthritis (RA) (3). Healthcare providers are encouraged to register their patients by calling the toll-free number (877-311-8972) (1).

FETAL RISK SUMMARY

Leflunomide, a pyrimidine synthesis inhibitor, is indicated for the treatment of

active RA to reduce signs and symptoms and retard structural damage. The drug is metabolized to an active metabolite that has an elimination half-life of about 2 weeks (1).

Leflunomide is contraindicated in pregnancy because it has exhibited dose-related teratogenicity and embryo–fetal toxicity in animals at doses that resulted in systemic exposures at or below those obtained in humans. Therefore, in women of childbearing age, leflunomide should not be started until pregnancy has been excluded and the use of reliable contraception has been confirmed (1).

In reproduction studies with pregnant rats during organogenesis, an oral dose that produced systemic exposure approximately 10% of the human exposure level based on AUC (HE) was teratogenic (anophthalmia or microphthalmia and internal hydrocephalus). This dose also resulted in an increase in embryo death and a decrease in maternal and surviving fetuses' body weight. In rabbits, an oral dose equivalent to the maximum HE during organogenesis resulted in fused, dysplastic sternebrae. No teratogenic effects were noted at lower doses in either species. In rats treated with doses 1% of the HE for 14 days before mating and continued until the end of lactation, >90% of the offspring failed to survive the postnatal period (1).

Leflunomide was not carcinogenic in rats, but mice exhibited dose-related increases in lymphoma (males) and bronchoalveolar adenomas and carcinomas combined (females). The incidence of the lung tumors, however, was within the spontaneous range for the mouse strain. The drug was not mutagenic or clastogenic in various assays, although a minor metabolite (4-trifluoromethylaniline) was in some tests. Because of the very low amounts of this metabolite, the results were not thought to be clinically significant (1).

It is not known if leflunomide crosses the human placenta. The molecular weight (about 270) is low enough that passage to the fetus should be expected. It also is not known if the active metabolite can cross the placenta or if the fetus can metabolize the parent compound to the active metabolite.

Because it may take ≤ 2 years to reach nondetectable plasma levels (<0.02 mcg/mL) of the active metabolite, the manufacturer has developed a drug elimination procedure in the event that a woman taking leflunomide becomes pregnant: (a) administer cholestyramine 8 g 3 times daily for 11 days (not necessarily consecutive unless there is a need to lower the plasma level rapidly); (b) verify plasma levels <0.02 mcg/mL by two tests = 14 days apart. If plasma levels are >0.02 mcg/mL, additional cholestyramine treatment should be considered (1).

Information relating to the risks of leflunomide use in human pregnancy has been published. A 2000 review on the treatment of rheumatic diseases briefly mentioned the agent, stating that it was contraindicated in pregnancy (4). It also reviewed the drug elimination procedure in the manufacturer's product literature. A 2001 reference thoroughly reviewed the reproductive risks of leflunomide and provided detailed information on counseling of men and women who might have been exposed to the agent and were either contemplating fathering a child, were pregnant, or were planning a pregnancy (2). The drug blood level considered safe was 0.03 mcg/mL, which was 123 and 136 times lower than the no-effect blood levels in rats and rabbits, respectively. The safe concentration was about 0.1% of the average steady-state plasma level of the active metabolite. The author mentioned that approximately 30 women had become pregnant on leflunomide, 29 of whom were exposed to therapeutic levels of the drug during early organogenesis despite initiating the drug elimination protocol as soon as pregnancy was diagnosed. Only three pregnancies were continuing (no outcome data available), however, as 27 women had elected to undergo termination (2).

A survey of 600 members of the American College of Rheumatology, conducted partially to determine the outcomes of pregnancies exposed to disease-modifying antirheumatic drugs (DMARDs) (etanercept, infliximab, leflunomide, and methotrexate), was published in 2003 (5). From the 175 responders, the outcomes of 10 pregnancies exposed to leflunomide were two full-term healthy infants, one preterm delivery, one spontaneous abortion, two elective abortions, two unknown outcomes, and two women still pregnant. Cholestyramine was definitely used in two pregnancies and may have been used in all (5).

A 2004 study reported data from the manufacturer's database of pregnancies exposed to infliximab (see Infliximab for details of this study) (6). One woman had received infliximab and leflunomide before conception and in pregnancy and delivered an infant with intestinal malrotation (6).

An Italian teratogen information service described the outcomes of five pregnancies in women exposed to leflunomide and one case of paternal exposure (7). Exposures in three women who had elective abortions were until 1.5 months before conception, and until 5 weeks' and 9 weeks' gestation, respectively. A woman exposed until 6.5 months before conception gave birth to a normal 2600-g male infant at 39 weeks' and another woman exposed until the 9th week of gestation had a normal 2200-g male infant at 36 weeks'. The paternal exposure started 6 months before conception and continued

throughout pregnancy without a condom being worn during intercourse. A normal 3350-g male infant was born at 38 weeks'. All three births were by cesarean section. None of six cases had a washout procedure (7).

In a 2007 case report from England, a 43-year-old woman with RA became pregnant about 8 months after starting leflunomide 20 mg/day (8). At 21 weeks', the drug was discontinued and cholestyramine treatment was started. A male infant was born 9 weeks prematurely and was found to be blind in the right eye, and to have cerebral palsy with left-sided spasticity. The mother's three previous pregnancies had involved a neonatal death within 24 hours of birth due to a congenital heart defect, a healthy daughter, and a son diagnosed with autism (8).

In a 2004 abstract, preliminary results of the on-going Organization of Teratology Information Specialists (OTIS) Rheumatoid Arthritis in Pregnancy study were reported (9). As of January, 2004, 168 infant outcomes were known: 43 exposed to leflunomide, 78 RA controls without leflunomide exposure, and 47 nondiseased controls. The proportion of major and minor malformations was similar between the groups. However, both RA groups were significantly more likely to deliver preterm infants than nondiseased controls: leflunomide group, adjusted odds ratio (OR) 12.0, 95% confidence interval (CI) 2.5–59.2; and RA group, OR 10.1, 95% CI 2.2–47.3. The mean birth weight of full-term infants also was significantly lower in both RA groups than in nondiseased controls: 3158, 3336, and 3487 g, respectively. The results suggested that RA itself, with a possible contribution from other medications, such as corticosteroids, was responsible for the increased rate of preterm delivery and lower birth weight of full-term infants (9).

In a continuation of the above prospective cohort study, 250 pregnancy outcomes were known: 64 exposed to leflunomide (61 [95.3%] of who received cholestyramine), 108 RA controls, and 78 healthy pregnant women (10). Women exposed to methotrexate or cyclophosphamide at any time during pregnancy were excluded. The number of live births in the three groups was 56, 95, and 72, respectively. Of these, 51 (91.1%), 90 (94.7%), and 65 (90.3%) were examined by a pediatric dysmorphologist blinded to the groups. There was no significant difference in the number of major defects in all pregnancies (live births plus losses): 4.8%, 6.6%, and 4.0%, respectively. The three major anomalies in the leflunomide-exposed infants were occult spinal dysraphism, unilateral uretero pelvic junction obstruction and multicystic kidney disease, and microcephaly. There also was no difference between the groups in terms of functional problems, but significantly more exposed infants had

minor defects ($p = 0.05$) and a higher proportion of three or more minor defects (47.1% vs. 32.2% vs. 29.2%, $p = 0.10$). There was no specific pattern of major or minor anomalies. Infants in both RA groups were born smaller and earlier than infants from healthy mothers, but there were no significant differences between the RA groups. In addition, among 19 infants from leflunomide-treated mothers who were not eligible for the cohort study for various reasons, 2 had major anomalies: aplasia cutis congenita in a surviving twin; and multiple defects including the Pierre-Robin sequence, cleft of the soft palate, and chondrodysplasia punctata (mother treated for systemic lupus erythematosus). The data indicated that there was no substantial risk of adverse pregnancy outcome among leflunomide-treated women who undergo the cholestyramine elimination procedure early in pregnancy (10).

A 2010 report described a 22-year-old woman with Takayasu's arteritis who conceived while taking leflunomide 10 mg/day, adalimumab 40 mg SC every 4 weeks, prednisolone 5 mg/day, and dalteparin 500 IU/day (11). Leflunomide was discontinued by the patient at 8 weeks' gestation but the other agents were continued throughout pregnancy. At 37 weeks', a cesarean section was performed to deliver a healthy 2550-g male infant with Apgar scores of 9, 9, and 10 at 1, 5, and 10 minutes, respectively (11).

BREASTFEEDING SUMMARY

No reports describing the use of leflunomide during lactation have been located. The molecular weight (about 270) is low enough that excretion into breast milk should be expected. The effects of this exposure on a nursing infant are unknown. Because of the potential for serious adverse effects and without information on the amount of drug in milk, nursing mothers receiving this drug should probably not breastfeed (2).

LENALIDOMIDE

Immunomodulator

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of lenalidomide in human pregnancy have been located. Thalidomide is a well-known potent human teratogen (see Thalidomide). As an analog of thalidomide, lenalidomide is contraindicated in human pregnancy and in women capable of becoming pregnant. It is available only under a restricted distribution program (RevAssist) (1).

FETAL RISK SUMMARY

Lenalidomide is an analog of thalidomide that is used for its immunomodulatory and antiangiogenic properties. It is indicated for the treatment of transfusion-dependent anemia due to low- or intermediate-1-risk myelodysplastic syndrome (MDS) associated with a deletion 5q cytogenetic abnormality with or without additional cytogenetic abnormalities. It also is indicated, in combination with dexamethasone, for the treatment of multiple myeloma patients who have received at least prior therapy. The only other immunomodulator with a similar indication is thalidomide. Lenalidomide is partly metabolized (about one-third), but the metabolites have not been characterized. Plasma protein binding also is low (about 30%) and the elimination half-life is about 3 hours. The pharmacokinetics in MDS patients has not been studied, but in multiple myeloma patients the exposure (AUC) was 57% higher than in healthy male volunteers (1).

Reproduction studies have been conducted in rats and rabbits. In pregnant rats, no evidence of teratogenicity was observed with daily doses up to about 600 times the human dose of 10 mg based on BSA (HD). Minimal maternal toxicity (slight, transient decrease in mean body weight gain and food intake) was observed at doses that were about 120–600 times the HD. Male offspring of pregnant rats given daily doses \leq 600 times the HD exhibited slightly delayed

sexual maturation. Female offspring had slightly lower body weight gains during gestation when bred with male offspring. In pregnant rabbits, a dose that was about 120 times the HD had an embryocidal effect (1).

Carcinogenicity studies have not been conducted with lenalidomide. The drug was not mutagenic in several assays. In studies in rats, doses up to about 600 times the HD had no effect on fertility (1).

It is not known if lenalidomide crosses the human placenta. The molecular weight (about 259), moderate metabolism and plasma protein binding, and the elimination half-life suggest that the drug will cross to the embryo and/or fetus.

Lenalidomide is contraindicated in pregnancy and in women who might become pregnant. However, when there is no other alternative, the drug can be used in women of reproductive age if specific conditions to avoid pregnancy are met. These conditions include abstention from heterosexual intercourse, or the use of two methods of reliable birth control. One of the birth control methods should be considered highly effective (e.g., intrauterine device, hormonal contraception, tubal ligation, or partner's vasectomy), whereas the second method should be considered effective (e.g., latex condom, diaphragm, or cervical cap). The birth control methods should be used continuously for 4 weeks before starting therapy, during therapy, during therapy delay, and for 4 weeks after the end of therapy. Pregnancy testing should be conducted within 10–14 days and a second test within 24 hours of starting therapy and then weekly during the 1st month. After the first month, pregnancy testing should be conducted monthly in women with regular menstrual cycles or every 2 weeks in women with irregular menstrual cycles.

BREASTFEEDING SUMMARY

No reports describing the use of lenalidomide during human lactation have been located.

The molecular weight (about 259), moderate metabolism (about one-third) and plasma protein binding (about 30%), and the elimination half-life (about 3 hours) suggest that the drug will be excreted into breast milk. The effects of this exposure on a nursing infant are unknown. However, serious toxicity has been observed in adult patients with del 5q MDS who were treated with lenalidomide. The most serious toxicities were neutropenia, thrombocytopenia, deep venous thrombosis, and pulmonary embolism, but other commonly observed ($\geq 20\%$) adverse effects included pruritus, rash, diarrhea, constipation, nausea, nasopharyngitis, fatigue, pyrexia, peripheral edema, arthralgia, and back pain. Because of the uncertainty regarding the amount of

drug in milk and the potential for severe toxicity, women being treated with lenalidomide should not breastfeed.

LEPIRUDIN

Hematologic Agent (Thrombin Inhibitor)

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

The animal data suggest low risk, but the near absence of human pregnancy experience prevents a more complete assessment of embryo/fetal risk. The passage of lepirudin across the rat placenta suggests that the agent might also cross the human placenta. The effects of this potential exposure on a human embryo or fetus, including hemorrhage, are unknown. However, if a pregnant woman requires lepirudin therapy for heparin-induced thrombocytopenia (HIT), the benefits to her appear to outweigh the theoretical risks to her embryo–fetus.

FETAL RISK SUMMARY

The polypeptide lepirudin (rDNA) is a recombinant hirudin derived from yeast cells that is indicated for anticoagulation in patients with HIT and associated thromboembolic disease. It is composed of 65 amino acids and is administered as a continuous IV infusion. Lepirudin binds to thrombin to directly block the thrombogenic activity of thrombin (1).

Reproduction studies with lepirudin have been conducted in rats and rabbits. In pregnant rats, IV doses up to 1.2 times the maximum recommended daily human dose based on BSA (MRHD) during organogenesis and the perinatal–postnatal period revealed no evidence of fetal harm. However, increased rat maternal mortality from undetermined causes was noted. Studies with pregnant rabbits at IV doses up to 2.4 times the MRHD also found no evidence of embryo or fetal harm (1).

Despite the high molecular weight of lepirudin (about 6970), the drug crosses the placenta of pregnant rats (1). Because of the similarities between rat and human placentas, exposure of the human embryo–fetus might occur.

Several case reports (2–6) and a review (7) have described the successful use of lepirudin for the treatment of HIT in pregnancy. In another case report, lepirudin was used in the 3rd trimester when heparin-induced thrombosis occurred (8). Developmental toxicity was not observed in any of these cases.

BREASTFEEDING SUMMARY

One report has described the use of lepirudin (recombinant hirudin) during lactation. A 34-year-old woman, breastfeeding a 7-week-old infant, developed a deep vein thrombosis in her calf and was treated with low-molecular-weight heparin (9). She developed HIT on day 20 of treatment. Therapy was changed to lepirudin 50 mg twice daily. Although therapeutic levels of hirudin were measured in her plasma (0.5–1.0 mg/L), it was not detected in her milk (detection level 0.1 mg/L). The woman continued breastfeeding for the next 6 months while being treated with lepirudin. No adverse effects were observed in the mother or infant (9).

The above report is consistent with the high molecular weight (about 6970) of lepirudin that suggests excretion into milk does not occur. Even if small amounts are excreted, the polypeptide probably would be digested in the stomach of the infant.

LETROZOLE

Antineoplastic

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No published reports describing the use of letrozole in human pregnancy have been located.

The animal data suggest risk. However, several reports and reviews have described the use of letrozole for ovulation stimulation, an off-label indication. In a 2005 letter from Novartis to healthcare professionals, the manufacturer warned that the drug should not be used for pregnancy induction because it was teratogenic (Novartis issues breast cancer drug warning. December 1, 2005). Novartis was aware of 13 women exposed to the drug during pregnancy resulting in two spontaneous abortions and two infants with birth defects (no additional details are available). Because the drug inhibits estrogen synthesis in all tissues, it is contraindicated during pregnancy.

FETAL RISK SUMMARY

Letrozole is an aromatase inhibitor indicated for postmenopausal women as (a) adjuvant treatment with hormone receptor positive breast cancer; (b) extended adjuvant treatment of early breast cancer in those who have received prior standard adjuvant tamoxifen therapy; and (c) first- and second-line treatment of those with hormone receptor positive or unknown advanced breast cancer. It also has been used off-label to induced ovulation in infertile women. Letrozole inhibits the aromatase enzyme, resulting in a reduction of estrogen synthesis in all tissues. It is metabolized to inactive metabolites, weakly bound to plasma proteins, and the terminal elimination half-life is about 2 days (1).

Reproduction studies have been conducted in rats and rabbits. In rats, doses during organogenesis that were ≥ 0.01 times the daily maximum recommended human dose based on BSA (MRHD) caused increased resorptions and postimplantation loss, decreased numbers of live fetuses, and fetal anomalies

including absence and shortening of renal papilla, dilation of ureter, edema, and incomplete ossification of frontal skull and metatarsals. Doses that were 0.1 times MRHD caused fetal domed head and cervical/centrum vertebral fusion. In rabbits, doses that were 0.0001–0.00001 times the MRHD caused embryo–fetal toxicity and anomalies that included incomplete ossification of the skull, sternebrae, and fore- and hindlegs (1).

In 2-year studies, letrozole was carcinogenic in mice and rats. The drug was not mutagenic but was a potential clastogen in an in vitro test but not in an in vivo test. In mice, rats, and dogs, letrozole caused sexual inactivity in females and atrophy of the reproductive tract in male and female animals (1).

It is not known if letrozole crosses the human placenta. The molecular weight (about 285), low plasma protein binding, and long terminal elimination half-life suggest that exposure of the embryo and/or fetus will occur.

A number of studies (2–14) and reviews (15–20) have reported the use of letrozole, alone or with gonadotropins, follicle-stimulating hormone, or metformin for ovarian stimulation. The effectiveness of letrozole for this use was comparable to other agents. No increase in the incidence of congenital malformations was observed and pregnancy outcomes were comparable or better than when clomiphene citrate was used.

BREASTFEEDING SUMMARY

No reports describing the use of letrozole during human lactation have been located. Such reports are unlikely because of its indication for breast cancer. Moreover, the molecular weight (about 285), low plasma protein binding, and long terminal elimination half-life (about 2 days) suggest that it will be excreted into breast milk. Women requiring this agent should not breastfeed.

LEUCOVORIN

Vitamin

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Leucovorin (folinic acid) is an active metabolite of folic acid (1). It has been used for the treatment of megaloblastic anemia during pregnancy (2). See Folic Acid.

BREASTFEEDING SUMMARY

Leucovorin (folinic acid) is an active metabolite of folic acid (1). See Folic Acid.

LEUPROLIDE

Antineoplastic/Hormone

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Although the human data are limited, daily injections of leuprolide early in gestation do not appear to be associated with an increased risk of spontaneous abortions (SABs), intrauterine growth restriction (IUGR), or major congenital malformations.

FETAL RISK SUMMARY

Leuprolide is a synthetic nonapeptide analog of naturally occurring gonadotropin-releasing hormone that inhibits the secretion of gonadotropin when given continuously and in therapeutic doses.

Leuprolide causes a dose-related increase in the incidence of major malformations in pregnant rabbits, but not in rats (1). The most frequently observed malformations in rabbits were vertebral anomalies and hydrocephalus (J.D. Miller, personal communication, Tap Pharmaceuticals, Inc., 1992). The doses tested were 1/300th to 1/3rd of the typical human dose. Increased fetal mortality and decreased fetal weights were observed in both animal species with the higher test doses.

In humans, SABs or IUGR are theoretically possible because leuprolide suppresses endometrial proliferation. The risk of these adverse outcomes is considered greater than the risk of congenital malformations because the affected organs in animal studies do not depend on the presence of gonadal steroids for normal development (J.D. Miller, personal communication, Tap Pharmaceuticals, Inc., 1992).

A 1991 case report described a woman who was treated with leuprolide from days 21 to 38 after her last menstrual period (2). She had received the drug in preparation for in vivo fertilization. At 38 weeks' gestation, she delivered a healthy, 3300-g male infant who was doing well at 6 months of age (2).

The manufacturer is maintaining a registry of inadvertent human exposures

during pregnancy to leuprolide and currently has more than 100 such cases (J.D. Miller, personal communication, Tap Pharmaceuticals, Inc., 1992). No cases of congenital defects attributable to the drug have been reported, although the numbers are too small to draw conclusions as to the risk for perinatal mortality, low birth weight, or teratogenicity.

The outcomes of 18 pregnancies in 17 women who had been exposed to leuprolide early in gestation were described in a 1993 report (3). The outcomes included five 1st trimester SABs, one of which was a fetus with trisomy 18, and the loss of a normal fetus at 20 weeks' because of cervical incompetence. The other 12 cases involved delivery of normal infants; 11 at term and 1 at 36 weeks'. The results suggested no increased risk for birth defects or pregnancy wastage (3).

BREASTFEEDING SUMMARY

No reports describing the use of leuprolide during human lactation have been located.

LEVALLORPHAN

[Withdrawn from the market. See 8th edition.]

LEVALBUTEROL

Respiratory Drug (Bronchodilator)

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of levalbuterol (levosalbutamol), an (R)-enantiomer of racemic albuterol, in human pregnancy have been located. However, racemic albuterol is considered compatible in pregnancy, and there is no apparent reason not to classify levalbuterol the same. If levalbuterol is used in pregnancy for the treatment of asthma, healthcare professionals are encouraged to call the toll-free number (877-311-8972) for information about patient enrollment in an Organization of Teratology Specialists (OTIS) study.

FETAL RISK SUMMARY

Levalbuterol (levosalbutamol) is a β_2 -adrenergic receptor agonist that acts as a bronchodilator. It is an (R)-enantiomer of the racemic albuterol. Levalbuterol inhalation is indicated for the treatment or prevention of bronchospasm in adults, adolescents, and children ≥ 6 years of age with reversible obstructive airway disease. It is in the same subclass of β_2 -adrenergic bronchodilators as albuterol, arformoterol, formoterol, metaproterenol, pirbuterol, salmeterol, and terbutaline. The drug is partially metabolized to an inactive metabolite before elimination. The plasma elimination half-life in adults after four doses was 4.0 hours (1).

Reproduction studies have been conducted in rabbits. Oral doses up to 110 times the maximum recommended daily inhalation dose were not teratogenic. However, racemic albuterol was teratogenic in mice and rabbits (see also Albuterol).

Studies for carcinogenicity and fertility have not been conducted with levalbuterol (see Albuterol). Levalbuterol was not mutagenic in two assays (1).

It is not known if levalbuterol crosses the human placenta. The molecular weight (about 240 for the free base) and elimination half-life suggest that the drug will cross to the embryo–fetus. However, the plasma concentrations after inhalation are very low.

BREASTFEEDING SUMMARY

No reports describing the use of levalbuterol during human lactation have been located. The molecular weight (about 240 for the free base) and elimination half-life (4 hours) suggest that the drug will be excreted into breast milk. However, the plasma concentrations (ng/mL) after inhalation are very low. The effect of this exposure on a nursing infant is unknown, but the drug is probably compatible with breastfeeding.

LEVETIRACETAM

Anticonvulsant

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The animal data suggest risk, but the limited human pregnancy experience with levetiracetam has not shown an increased risk of major congenital malformations. Although confirmation is needed, severe growth restriction has been observed. Additional data are required before a more complete assessment of embryo–fetal risk can be derived. It is not known if levetiracetam causes folic acid deficiency, but it will usually be combined with other anticonvulsants, some of which may cause folic acid deficiency. Therefore, daily supplementation with 4–5 mg of folic acid, combined with multivitamins that include adequate amounts of other B vitamins, is recommended. If a pregnant patient is receiving levetiracetam, clinicians are encouraged to register her, before pregnancy outcome is known, in the Antiepileptic Drug Pregnancy Registry by calling the toll-free number (888-233-2334) (1).

FETAL RISK SUMMARY

Levetiracetam is an anticonvulsant used as adjunctive therapy in the treatment of partial-onset seizures in epilepsy. It is chemically unrelated to other anticonvulsant agents. Levetiracetam is minimally protein bound (<10%) and is not metabolized by the liver (1,2). Major metabolism occurs by enzymatic hydrolysis of the acetamide group to produce the carboxylic acid metabolite (1). Levetiracetam does not inhibit and is not a high affinity substrate for epoxide hydrolase (1). Reports describing the effects (if any) of levetiracetam on folic acid have not been located.

In reproduction studies with pregnant rats, maternal doses approximately equivalent to the maximum recommended human dose (3000 mg) based on

BSA (MRHD) administered throughout pregnancy and lactation were associated with an increased incidence of minor fetal skeletal abnormalities and restricted growth prenatally and postnatally (1). When doses six times the MRHD were used, increased pup mortality and behavioral alterations were observed. The developmental no-effect dose administered throughout pregnancy and lactation was 0.2 times the MRHD. Dosing at 12 times the MRHD given only during organogenesis resulted in reduced fetal weights and an increased incidence of fetal skeletal variations. The developmental no-effect dose during organogenesis was four times the MRHD. No evidence of fetal or neonatal harm was observed with doses up to six times the MRHD during the last third of pregnancy and throughout lactation. None of the studied doses produced maternal toxicity (1).

In pregnant rabbits, increased embryo/fetal mortality and an increased incidence of minor skeletal abnormalities were observed at maternal doses four times the MRHD administered during organogenesis. When a dose 12 times the MRHD was used, decreased fetal weight and increased incidences of fetal malformations were noted, but maternal toxicity was also evident at this dose. The developmental no-effect dose was 1.3 times the MRHD (1).

It is not known if levetiracetam crosses the human placenta. The low molecular weight (about 170) and the lack of protein binding suggest that exposure of the embryo and fetus should be expected.

An estimated 20%–30% of epileptic patients have seizures not well controlled by monotherapy and require anticonvulsant polytherapy (2). Clinical studies of levetiracetam have demonstrated efficacy in partial-onset seizures with a good tolerability profile. In addition, its lack of hepatic metabolism and low protein binding result in a low risk of interaction with other drugs, including other anticonvulsants and oral contraceptives. Although comparison studies with other adjunctive anticonvulsants (e.g., felbamate, gabapentin, lamotrigine, tiagabine, topiramate, and vigabatrin) have not been conducted, it should be added to the list of agents to consider in cases of treatment-refractory partial-onset seizures (2).

A 2005 report described the outcomes of 11 pregnancies exposed to levetiracetam that were enrolled in the European Registry of Antiepileptic Drugs and Pregnancy (3). Levetiracetam was used alone in two pregnancies and combined with other antiepileptic agents in nine. The outcomes were one spontaneous abortion, one elective abortion, and nine infants without birth defects. However, three of the infants, one of whom was premature, had very low birth weight (≤ 5 th percentile) (3).

The Lamotrigine Pregnancy Registry, an ongoing project conducted by the manufacturer, was first published in January 1997 (4). The final report was published in July 2010. The Registry is now closed. Among 57 prospectively enrolled pregnancies exposed to levetiracetam and lamotrigine, with or without other anticonvulsants, 54 were exposed in the 1st trimester resulting in 48 live births without birth defects, 3 SABs, 1 fetal death, and 2 birth defects. There were three exposures in the 2nd/3rd trimesters resulting in live births without defects (4).

BREASTFEEDING SUMMARY

No reports describing the use of levetiracetam during lactation have been located. The molecular weight (about 170) and low protein binding (<10%) suggest that levetiracetam will be excreted into breast milk. The effects of this exposure on a nursing infant are unknown. Of note, however, other anticonvulsants (see Carbamazepine, Phenytoin, and Valproic Acid) are classified as compatible with breastfeeding by the American Academy of Pediatrics.

LEVOCETIRIZINE

Antihistamine

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of levocetirizine in human pregnancy have been located. The animal reproduction data suggest low risk, but the absence of human pregnancy experience prevents a more complete assessment of the embryo–fetal risk. There are no data suggesting that antihistamines, in general, are associated with human developmental toxicity, and the embryo–fetal risk from exposure levocetirizine appears to be low, if it exists at all. Nevertheless, if an antihistamine is required during pregnancy, agents with human pregnancy experience, such as chlorpheniramine or diphenhydramine, appear to be a better choice.

FETAL RISK SUMMARY

The antihistamine levocetirizine is a H₁-receptor antagonist. It is the (R)-enantiomer and principal pharmacologically active component of the racemic compound cetirizine. (See also Cetirizine.) Levocetirizine is indicated for the relief of symptoms associated with allergic rhinitis (seasonal and perennial) and, for the treatment of uncomplicated skin manifestations of chronic idiopathic urticaria, both indications in adults and children 6 years of age or older. The drug is only partially metabolized (<14%) but plasma protein binding is high (91%–92%). The plasma half-life is about 8–9 hours (1,2).

Reproduction studies have been conducted in pregnant rats and rabbits. In these species, oral doses up to 320 and 390 times, respectively, the maximum recommended daily dose in adults based on BSA (MRDD), were not teratogenic (1,2).

Although carcinogenicity studies have not been conducted with levocetirizine, they have been with cetirizine. This drug was not carcinogenic in 2-year studies

in rats. In a similar study in mice, cetirizine caused an increased incidence of benign hepatic tumors in males. Levocetirizine was not mutagenic or clastogenic in multiple assays. The antihistamine had no effect on fertility and general reproductive performance in mice at a dose that was about 25 times the MRDD (1,2).

It is not known if levocetirizine crosses the human placenta. The molecular weight (about 390 for the free base), minimum metabolism, and long plasma half-life suggest that the drug will reach the embryo–fetus, but the high plasma protein binding might lessen the amount crossing the placenta.

BREASTFEEDING SUMMARY

No reports describing the use of levocetirizine during human lactation have been located. The molecular weight (about 390 for the free base), minimum metabolism, and long plasma half-life suggest that the drug will be excreted into breast milk, but the high plasma protein binding might lessen the amount excreted. The effects of this exposure on a nursing infant are unknown, but sedation or irritability is a potential minor adverse effect.

Antihistamines are a large pharmacologic class of drugs, only one of which, when used alone, has been associated with major toxicity in a nursing infant. (See Clemastine.) Milk concentrations have been determined for only four antihistamines (see Fexofenadine, Loratadine, Terfenadine, and Triprolidine), and these four agents are considered compatible with breastfeeding by the American Academy of Pediatrics. The theoretical infant dose, as a percentage of the mother’s weight-adjusted dose, was calculated for three of drugs and was $\leq 0.45\%$. Because there is no reason to believe that levocetirizine should be any different, the drug probably is compatible with breastfeeding.

LEVODOPA

Antiparkinson Agent

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Levodopa-induced teratogenicity and dose-related toxicity have been observed in animals, but no adverse outcomes associated with this drug have been observed in a limited number of human pregnancies. Although conditions requiring the use of levodopa during the childbearing years are relatively uncommon, exposure to this agent during gestation does not appear to present a major risk to the fetus. (See also Carbidopa.) However, evaluation of the effect of chronic in utero exposure to dopamine, the active metabolite of levodopa, on neurodevelopment is warranted.

FETAL RISK SUMMARY

Levodopa, a metabolic precursor to dopamine, is primarily used for the treatment and prevention of symptoms related to Parkinson's disease. The active agent for this purpose is thought to be dopamine, which is formed in the brain after metabolism of levodopa. Levodopa crosses the blood–brain barrier, but dopamine does not. Combination with carbidopa (see also Carbidopa), an agent that inhibits the decarboxylation of extracerebral levodopa, allows for lower doses of levodopa, fewer adverse drug effects related to peripheral dopamine, and higher amounts of levodopa available for passage to the brain and eventual conversion to dopamine.

Levodopa, either alone or in combination with carbidopa, has caused visceral and skeletal malformations in rabbits (1). Doses of 125 or 250 mg/kg/day in pregnant rabbits produced malformations of the fetal circulatory system (2). This teratogenicity was not observed at 75 mg/kg/day, but all three doses produced fetal toxicity manifested by decreased litter weight and an increased incidence of stunted and resorbed fetuses. In mice, no teratogenicity was observed with doses of 125, 250, and 500 mg/kg/day, but at the highest dose,

fetuses were significantly smaller than controls (2). A similar, significant decrease in the weights of newborn mice was observed in a study in which pregnant mice were fed levodopa 40 mg/g of food, but not at lower doses (3). The number of pregnancies and the number of newborns were also significantly decreased in those treated at 40 mg/g of food compared with those treated with 0, 10, or 20 mg/g of food.

Levodopa, in oral doses of 1–1000 mg/kg/day administered to pregnant rats during the 1st week of gestation, produced a dose-related occurrence in brown fat (interscapular brown adipose tissue) hemorrhage and vasodilation in the newborns (4). A similar response was observed with dopamine. The addition of carbidopa (MK-486) to levodopa resulted in a significant decrease in this toxicity, implying that the causative agent was dopamine.

A study published in 1978 examined the effect of carbidopa (20 mg/kg SC every 12 hours × 7 days) and levodopa plus carbidopa (200/20 mg/kg SC every 12 hours × 7 days) on the length of gestation in pregnant rats (5). Only the combination had a statistically significant effect on pregnancy duration, causing a delay in parturition of 12 hours. The results were thought to be consistent with dopamine inhibition of oxytocin release.

Because Parkinson's disease is relatively uncommon in women of childbearing age, only a few reports, some involving uses other than for parkinsonism, have been located that describe the use of levodopa, with or without carbidopa, in human pregnancy.

Placental transfer of levodopa at term was documented in a 1989 report (6). A 34-year-old multiparous woman, with a 6-year history of Parkinson's disease, was treated with a proprietary combination of levodopa and benserazide (Madopar, not available in the United States), three 250-mg tablets/day. When pregnancy was diagnosed (15th day postconception), the combination therapy was discontinued and treatment with levodopa (≤ 500 mg/day) alone was started. After 5 months, because of worsening parkinsonism, she was again treated with levodopa/benserazide (six 250-mg tablets/day). She eventually gave birth to a normal, 3070-g female infant who had no signs or symptoms of toxicity from the drug therapy during the first 8 days of life. Her 1-minute Apgar score was 2; then improved to 7 and 10 at 3 and 5 minutes, respectively. The cord plasma level of levodopa was 0.38 mcg/mL compared with 2.7 mcg/mL in the mother's plasma, a ratio of 0.14.

A 1995 reference described the placental transfer of levodopa and the possible fetal metabolism of the drug to dopamine, its active metabolite (7). A 34-year-old woman with juvenile Parkinson's disease was treated with

carbidopa/levodopa (200/800 mg/day) during two pregnancies (see also Carbidopa). Both pregnancies were electively terminated, one at 8 weeks' gestation and the other at 10 weeks' gestation. Mean concentrations of levodopa (expressed as ng/mg protein) in the maternal serum, placental tissue (including umbilical cord), fetal peripheral organs (heart, kidney, muscle), and fetal neural tissue (brain and spinal cord) were 8.5, 33.6, 7.4, and 7.7, respectively. Corresponding mean concentrations of dopamine at these sites were 0.10, <0.03, 0.29, and 1.01, respectively. The levels in the placentas and fetuses for both levodopa and dopamine were much higher than those measured in control tissue. Moreover, the relatively high concentrations of dopamine in fetal peripheral organs and neural tissue implied that the fetuses had metabolized levodopa. The investigators cautioned that, because neurotransmitters were known to alter early neural development in animals and in cultured cells, the increased amounts of dopamine found in their study suggested that chronic use of levodopa during gestation could induce long-term damage (7).

The pregnancy outcomes of two women who were treated with levodopa or carbidopa/levodopa during three pregnancies were described in a 1985 paper (8). The first woman, with at least a 7-year history of parkinsonism, conceived while being treated with carbidopa/levodopa (five 25/250-mg tablets/day) and amantadine (100 mg twice daily). She had delivered a normal male infant approximately 6 years earlier, but no medical treatment had been given during that pregnancy. Amantadine was immediately discontinued when the current pregnancy was diagnosed. Other than slight vaginal bleeding in the 1st trimester, there were no maternal or fetal complications. She gave birth to a normal-term infant (sex and weight not specified) who was doing well at 1.5 years of age. The second patient, a 32-year-old woman with parkinsonism first diagnosed at age 23, was being treated with levodopa (4 g/day) when a pregnancy of about 6 months' duration was diagnosed. Attempts to lower her levodopa dose were unsuccessful. She delivered a term, male, 7-lb 2-oz (about 3235-g) infant. Two years later, while still undergoing treatment with levodopa, she delivered a term, female, 2951-g infant. Both children were alive and well at 7 and 5 years, respectively.

A 1987 retrospective report described the use of carbidopa/levodopa, starting before conception, in five women during seven pregnancies, one of which was electively terminated during the 1st trimester (9). A sixth woman, taking levodopa plus amantadine, had a miscarriage at 4 months. All of the other pregnancies went to term (newborn weights and sexes not specified).

Maternal complications in three pregnancies included slight 1st trimester vaginal bleeding, nausea, and vomiting during the 8th and 9th months (the only patient who reported nausea and vomiting after the 1st trimester) and depression that resolved postpartum, and preeclampsia. One infant, whose mother took amantadine and carbidopa/levodopa and whose pregnancy was complicated by preeclampsia, had an inguinal hernia. No adverse effects or congenital anomalies were noted in the other five newborns and all remained healthy at follow-up (approximately 1–5 years of age).

A 27-year-old woman, with a history of chemotherapy and radiotherapy for non-Hodgkin's lymphoma occurring approximately 4 years earlier had developed a progressive parkinsonism syndrome that was treated with a proprietary preparation of carbidopa/levodopa (co-careldopa, Sinemet Plus; 375 mg/day) (10). She conceived 5 months after treatment began and eventually delivered a healthy, 3540-g male infant at term. Apgar scores were both 9 at 1 and 10 minutes. Co-careldopa had been continued throughout her pregnancy.

A brief case report, published in 1997, described a normal outcome in the 3rd pregnancy of a woman with levodopa-responsive dystonia (Segawa's type) who was treated throughout gestation with 500 mg/day of levodopa alone (11). The male infant weighed 2350 g at birth and was developing normally at the time of the report. Two previous pregnancies had occurred while the woman was being treated with daily doses of levodopa 100 mg and carbidopa 10 mg. Spontaneous abortions had occurred in both pregnancies; one at 6 weeks and the other at 12 weeks. An investigation failed to find any cause for the miscarriages (11).

A successful pregnancy in a 27-year-old woman with Segawa disease was reported in 2009 (12). The woman was treated throughout gestation with levodopa 1250 mg/day and, at 36 weeks', gave birth to a healthy, 2298-g male infant with an Apgar score of 9 at 5 minutes. The infant was doing well at 6 months of age. The authors cited eight other cases of the disease in five pregnant women. Five of the pregnancies were treated with levodopa monotherapy and ended in healthy newborns. In one of those patients, her first two pregnancies were treated with carbidopa/levodopa and both ended in abortions (see reference 11 above). The ninth pregnancy was not treated with any agent and the severely asphyxiated newborn died after birth (12).

Two 1998 case reports described the use of levodopa, in combination with selegiline and benserazide, during human pregnancy (see Selegiline for details) (13,14). In another 1998 case report, a woman took levodopa/carbidopa

(Sinemet CR 50/200) four times daily throughout gestation (15). Healthy male infants were delivered in all three pregnancies.

A brief 1996 communication included data obtained from a manufacturer (the Roche Drug Safety database) on the effects of levodopa on the fetus during human pregnancy (16). This database, current up to March 31, 1995, had six reports involving the use of levodopa/benserazide during gestation. The outcomes of these pregnancies included two elective terminations, one spontaneous abortion, two normal outcomes, and one lost to follow-up. No information was available on the condition of the fetuses in the three abortions. Another normal pregnancy outcome, without further details, from a mother who used levodopa/benserazide during gestation, was also cited (17). To the knowledge of these authors, two of whom were representatives of the manufacturer, no reports of human birth defects resulting from use of levodopa had been discovered.

A woman with a 12-year history of Parkinson's disease was treated throughout gestation with levodopa, carbidopa, entacapone, and bromocriptine (18). She gave birth at term to a 3175-g female infant, without deformities, with Apgar scores of 9, 10, and 10. Generalized seizures occurred in the infant 1 hour after birth, followed by repeated episodes of shivering throughout the first day that responded to diazepam. Slowly improving hypotonia also was observed during the first week. Pneumonia was diagnosed, but an extensive workup for the cause of seizures was negative. The child was developing normally at 1 year of age and has not had any other seizures (18).

A 2002 case report described the use of levodopa/ pergolide in a 35-year-old woman throughout gestation (19). The woman was started on levodopa (200 mg/day) and pergolide (3 mg/day) about 3 years before conception. She continued these doses until delivery of a normal-term infant (sex and weight not specified), with Apgar scores of 9 (assumed to mean 9 and 9 at 1 and 5 minutes, respectively). The healthy child was developing normally at 13 months of age (19).

In a 2005 report, a woman with Parkinson's disease took levodopa/carbidopa 330 mg/day and cabergoline 1 mg/day throughout an uncomplicated pregnancy and gave birth at term to a healthy baby girl (20). A few years later, now at age 34 and receiving levodopa/carbidopa 625 mg/day and cabergoline 4 mg/day, she became pregnant again. At 32 weeks', she underwent a cesarean section because of placenta abruption. The baby girl was doing well (20).

A study designed to investigate the inhibitory effect of levodopa on prolactin

levels in late pregnancy was reported in 1973 (21). Four women in the 3rd trimester of pregnancy were given a single oral dose of levodopa, 1000 mg. A statistically significant decrease in serum prolactin occurred, with the lowest levels measured 4 hours after the dose, but 2 hours later the levels had returned to pretreatment values, similar to nontreated controls. No further decreases in prolactin were measured during the next 3 days. All of the treated women eventually delivered normal infants at or near term.

Levodopa has been used in the treatment of coma resulting from fulminant hepatic failure occurring during pregnancy (22,23). A 22-year-old woman, in her 6th month of pregnancy, had severe viral hepatitis with a grade IV coma (22). She was successfully treated with levodopa, 1 g orally every 6 hours, neomycin, vitamins, and parenteral hydrocortisone (1000 mg/day). Recovery from the coma occurred 24–48 hours after the start of levodopa. Approximately 3 months later, she delivered a full-term infant (details of the infant and its condition were not included). In the second case, a 30-year-old woman in her 5th month of gestation was treated for 1 week with levodopa, 1 g orally every 6 hours (23). This patient, who also had viral hepatitis, began to recover consciousness 1 hour after the first dose of levodopa and was fully awake within 24–48 hours. She delivered a term, healthy infant (sex and weight not specified).

Angiotensin pressor responsiveness (vascular sensitivity) was decreased by the administration of levodopa in pregnancy (mean 29–30 weeks, range 24–36 weeks' gestation) (24). Five patients were treated with a single 500-mg oral dose and 16 received 1000 mg. Only the higher dose produced a significant decrease in angiotensin sensitivity. The authors hypothesized that chronic treatment with levodopa might not only decrease angiotensin sensitivity but also decrease pregnancy-induced hypertension. No data were provided on the outcome of these pregnancies following the study. The effect of levodopa on plasma prolactin secretion and inhibition of the renin–aldosterone axis was reported in a subsequent paper by this same group of investigators (25). Using methods and a patient population nearly identical with those of their previous study, the investigators found that a 1000-mg oral dose of levodopa produced a significant decrease in serum prolactin, plasma renin activity, and plasma aldosterone.

BREASTFEEDING SUMMARY

Levodopa is excreted into breast milk. A 1998 case report described a woman who took levodopa/carbidopa (Sinemet CR 50/200) four times daily throughout

gestation (15). She continued the therapy after delivery and during breastfeeding. At about 5 months postpartum, the peak concentration of levodopa in milk (based on 5-mL milk samples) was 1.6 nmol/mL, 3 hours after a dose. The milk:plasma ratio, based on AUC (6 hours for plasma and milk) was 0.28. When the dose was changed to two tablets of Sinemet 25/100 four times daily, the peak milk concentration (3 hours after a dose) was 3.47 nmol/mL and the milk:plasma ratio was 0.32. With both tablet strengths, the milk concentrations returned to baseline in 6 hours. The authors estimated that the nursing infant was ingesting 0.127–0.181 mg/day (0.016–0.023 mg/kg/day) of levodopa. No adverse effects were observed in the infant and he was developing normally at 2 years of age (15).

Levodopa inhibits prolactin release in both animals (26) and humans (21,25). In lactating rats, levodopa injected intraperitoneally in doses of 1.25, 2.5, 5, and 10 mg/100 g body weight produced a dose-related inhibition of milk ejection (26). Doses of 5 and 10 mg/100 g body weight, but not lower doses, prevented the release of prolactin induced by suckling. Small doses of oxytocin given immediately before suckling produced a normal milk-ejection response, indicating that the mechanism of inhibition by levodopa was not caused by mammary gland response but to an increase in catecholamines at the hypothalamic–hypophysial axis (26).

In one study, four women in the 3rd trimester of pregnancy received a single 1000-mg oral dose of levodopa (21). A significant decrease in serum prolactin occurred with the lowest concentration at 4 hours. Two hours later, the level had returned to pretreatment values. After delivery at or near term, all of the women had completely normal lactation. A second study also found that a single 1000-mg oral dose of levodopa produced a significant decrease in serum prolactin (25).

Clinical evidence of lactation inhibition was provided in a 1974 study (27). Ten female patients with a history of inappropriate galactorrhea were treated orally with levodopa, 500–3500 mg/day. Partial-to-complete suppression of lactation was observed in the women, but when treatment was stopped, lactation returned to normal levels.

LEVOFLOXACIN

Anti-infective (Quinolone)

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Although only a few reports describing the use of levofloxacin during human gestation have been located, the available evidence for other members of this class suggests that the risk of major malformations is low. However, a causal relationship with birth defects cannot be excluded (see Ofloxacin), although the lack of a pattern among the anomalies is reassuring (see Ciprofloxacin). Because of these concerns and the available animal data, levofloxacin should be used cautiously during pregnancy, especially during the 1st trimester. A 1993 review on the safety of fluoroquinolones concluded that these antibacterials should be avoided during pregnancy because of the difficulty in extrapolating animal mutagenicity results to humans and because interpretation of this toxicity is still controversial (1). The authors of this review were not convinced that fluoroquinolone-induced fetal cartilage damage and subsequent arthropathies were a major concern, even though this effect had been demonstrated in several animal species after administration to both pregnant and immature animals and in occasional human case reports involving children (1). Others have also concluded that fluoroquinolones should be considered contraindicated in pregnancy, because safer alternatives are usually available (2). A 2013 review stated that fluoroquinolones are usually avoided in pregnancy because of concerns for fetal cartilage damage, but there were no human studies to validate this concern (3).

FETAL RISK SUMMARY

Levofloxacin is a synthetic, broad-spectrum antibacterial agent that is the optical isomer of ofloxacin. As a fluoroquinolone, it is in the same class as ciprofloxacin, enoxacin, lomefloxacin, norfloxacin, ofloxacin, and sparfloxacin.

Nalidixic acid is also a quinolone drug. Levofloxacin undergoes limited metabolism and plasma protein binding only is 24%–38%. The mean terminal plasma elimination half-life is about 6–8 hours (4).

Reproduction studies have been conducted in rats and rabbits. In rats given oral and IV doses that were ≤ 4.2 and ≤ 1.2 times the maximum recommended human dose based on BSA (MRHD), respectively, no evidence of impaired fertility or reproductive performance was noted. No teratogenicity was observed in pregnant rats with oral and IV doses that were ≤ 9.4 and ≤ 1.9 times the MRHD, respectively. However, an oral dose 9.4 times the MRHD caused decreased fetal weight and increased fetal mortality. In pregnant rabbits, no teratogenicity was observed with oral and IV doses that were ≤ 1.1 and ≤ 0.5 times the MRHD, respectively (4).

A 2005 study measured the amount of three fluoroquinolones (ciprofloxacin, ofloxacin, levofloxacin) that crossed the perfused human placenta (5). All three agents crossed the placenta from the maternal to the fetal compartment, but the amounts crossing were small: 3.2%, 3.7%, and 3.9%, respectively. The transfer of levofloxacin across the placenta is consistent with the molecular weight (about 370). Moreover, in vivo transfer should be expected because of the low metabolism and plasma protein binding, and the moderately long plasma elimination half-life.

In a 2010 study, 12 women scheduled for a cesarean section were given IV levofloxacin 500 mg over 60 minutes (6). The transplacental passage rate calculated as a percentage of fetal venous concentration to maternal blood concentration was about 67%, whereas the transfetal passage rate calculated as a percentage of fetal arterial drug concentration to fetal venous concentration was about 84% (6).

A second study by the same group as above, measured levofloxacin amniotic fluid concentrations in 10 women given a 500-mg oral dose about 2 hours before amniocentesis (7). The study was conducted between the 16th and 20th gestational weeks. The mean concentrations of levofloxacin in maternal blood and amniotic fluid were 3.95 mcg/mL and 0.60 mcg/mL, an amniotic fluid passage rate of about 16% (7).

In a prospective follow-up study conducted by the European Network of Teratology Information Services (ENTIS), data on 549 pregnancies exposed to fluoroquinolones (none to levofloxacin; 93 to ofloxacin) (see also Ofloxacin) were described in a 1996 reference (2). Data on another 116 prospective and 25 retrospective pregnancy exposures to the antibacterials were also included. Of the 666 cases with known outcome, 32 (4.8%) of the embryos, fetuses, or

newborns had congenital malformations. From previous epidemiologic data, the authors concluded that the 4.8% frequency of malformations did not exceed the background rate. Finally, 25 retrospective reports of infants with anomalies, who had been exposed in utero to fluoroquinolones, were described, but no specific patterns of major congenital malformations were detected (2).

The authors of the above study concluded that pregnancy exposure to quinolones was not an indication for termination, but that this class of antibacterials should still be considered contraindicated in pregnant women. Moreover, this study did not address the issue of cartilage damage from quinolone exposure and the authors recognized the need for follow-up studies of this potential toxicity in children exposed in utero. Because of their own and previously published findings, they further recommended that the focus of future studies should be on malformations involving the abdominal wall and urogenital system and on limb reduction defects (2).

BREASTFEEDING SUMMARY

When first marketed, the use of levofloxacin during lactation was not recommended because of the potential for arthropathy and other serious toxicity in the nursing infant (4). Phototoxicity has been observed with quinolones when exposure to excessive sunlight (i.e., ultraviolet [UV] light) has occurred. Well-differentiated squamous cell carcinomas of the skin has been produced in mice who were exposed chronically to some fluoroquinolones and periodic UV light (e.g., see Lomefloxacin), but studies to evaluate the carcinogenicity of ofloxacin in this manner have not been conducted (4).

Levofloxacin is excreted into breast milk (8). A lactating woman received levofloxacin 500 mg/day during the first 23 days postpartum. Milk samples were collected at various times at steady state. The peak concentration in milk, 8.2 mcg/mL, occurred 5 hours after a dose. The pharmacokinetics in milk was similar to those in the plasma. Minimal levels of the drug were detectable 65 hours after the last dose. The infant was not allowed to breastfeed (8). The effect of this exposure on a nursing infant is unknown, but other fluoroquinolones are classified as compatible with breastfeeding by the American Academy of Pediatrics (see Ofloxacin and Ciprofloxacin).

LEVORPHANOL

Narcotic Agonist Analgesic

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 3rd Trimester

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The use of levorphanol during labor should be expected to produce neonatal depression to the same degree as other narcotic analgesics (1). If levorphanol is used in pregnancy, healthcare professionals are encouraged to call the toll-free number (800-670-6126) for information about patient enrollment in the Motherisk study.

FETAL RISK SUMMARY

No reports linking the use of levorphanol with human congenital defects have been located. A single oral dose of 25 mg/kg was teratogenic in mice (2). At this dose, nearly 50% of the mouse embryos died.

BREASTFEEDING SUMMARY

No reports describing the use of levorphanol during lactation have been located. The molecular weight (about 444) is low enough that passage into breast milk should be expected. Moreover, the drug is structurally similar to morphine, which is excreted into milk (see Morphine). The potential for long-term effects on neurobehavior and development in a nursing infant from exposure to levorphanol in milk are unknown but warrant study.

LEVOTHYROXINE

Thyroid

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Levothyroxine (T4) is compatible with all stages of pregnancy. Untreated or undertreated maternal hypothyroidism is associated with low birth weight secondary to medically indicated preterm delivery, preeclampsia or placental abruption (1), and with lower neuropsychological development of their offspring (2).

FETAL RISK SUMMARY

T4 is a naturally occurring thyroid hormone produced by the mother and the fetus. It is used during pregnancy for the treatment of hypothyroidism (see also Liothyronine [T3] and Thyroid). Earlier investigations concluded that there was negligible transplacental passage of T4 at physiologic serum concentrations (3–8), but a 1989 study found that sufficient amounts of T4 cross the placenta to protect the congenital hypothyroid fetus and newborn (see below) (9). A 1994 review summarized the evidence that T4 crosses to the embryo and fetus throughout gestation (10).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 554 newborns had been exposed to levothyroxine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 25 (4.5%) major birth defects were observed (24 expected). Specific data were available for six defect categories, including (observed/expected) 5/6 cardiovascular defects, 0/1 oral clefts, 0/0.3 spina bifida, 1/2 polydactyly, 1/1 limb reduction defects, and 1/1 hypospadias. These data do not support an association between the drug and congenital defects.

In a study of 25 neonates born with an autosomal recessive disorder that completely prevents iodination of thyroid proteins and thus the synthesis of T4, the thyroid hormone was measured in their cord serum in concentrations

ranging from 35 to 70 nmol/L (9). Because the newborns were unable to synthesize the hormone, the T4 must have come from the mothers. The investigators then studied 15 newborns with thyroid agenesis and measured similar cord levels of T4. The mean serum half-life of T4 in the neonates was only 3.6 days, indicating that T4 would be below the level of detection between 8 and 19 days after birth. Although the amounts measured were below normal values of T4 (80–170 nmol/L), the amounts were sufficient to protect the infants initially from impaired mental development. A possible mechanism for this protection may involve increased conversion of T4 to T3 in the cerebral cortex in hypothyroid fetuses, and when combined with a decreased rate of T3 degradation, the net effect is to normalize intracellular levels of the active thyroid hormone in the brain (9).

Several reports have described the direct administration of T4 to the fetus and amniotic fluid (2,7,9,11–15). In almost identical cases, two fetuses were treated in the 3rd trimester with IM injections of T4, 120 mcg, every 2 weeks for four doses in an attempt to prevent congenital hypothyroidism (2,7). Their mothers had been treated with radioactive iodine (I^{131}) at 13 and 13.5 weeks' gestation. Both newborns were hypothyroid at birth and developed respiratory stridor, but neither had physical signs of cretinism. At the time of the reports, one child had mild developmental retardation at 3 years of age (7). The second infant was stable with a tracheostomy tube in place at 6 months of age (11). In a third mother who inadvertently received I^{131} at 10–11 weeks' gestation, intra-amniotic T4, 500 mcg, was given weekly during the last 7 weeks of pregnancy (12). Evidence was found that the T4 was absorbed by the fetus. A male infant who developed normally was delivered. In a study to determine the metabolic fate of T4 in utero, 700 mcg of T4 were injected intra-amniotically 24 hours before delivery in five full-term healthy patients (13). Serum T4 levels were increased in all infants. Intra-amniotic T4, 200 mcg, was given to eight women in whom premature delivery was inevitable or was indicated to enhance fetal lung maturity (14). The patients ranged in gestational age between 29 and 32 weeks. No respiratory distress syndrome was found in the eight newborn infants. Delivery occurred 1–49 days after the injection. The dimensions of a large fetal goiter, secondary to propylthiouracil, were decreased but not eliminated within 5 days of an intra-amniotic 200-mcg dose of T4 administered at 34.5 weeks' gestation (15). Serial lecithin:sphingomyelin (L:S) ratios before and after the injection demonstrated no effect of T4 on fetal lung maturity.

In a large prospective study, 537 mother–child pairs were exposed to levothyroxine and thyroid (desiccated) during the 1st trimester (16, pp. 388–

400). For use anytime during pregnancy, 780 exposures were reported (16, p. 443). After 1st trimester exposure, possible associations were found with cardiovascular anomalies (nine cases), Down's syndrome (three cases), and polydactyly in blacks (three cases). Because of the small numbers involved, the statistical significance of these findings is unknown and independent confirmation is required. Maternal hypothyroidism itself has been reported to be responsible for poor pregnancy outcome (17–19). Others have not found this association, claiming that fetal development is not directly affected by maternal thyroid function (20). However, untreated maternal hypothyroidism during pregnancy has been shown to result in lower scores relating to intelligence, attention, language, reading ability, school performance, and visual–motor performance in children 7–9 years of age (21).

Combination therapy with thyroid–antithyroid drugs was advocated at one time for the treatment of hyperthyroidism but is now considered inappropriate (see Propylthiouracil).

BREASTFEEDING SUMMARY

Levothyroxine (T4) is excreted into breast milk in low concentrations. The effect of this hormone on the nursing infant is controversial (see also Liothyronine and Thyrotropin). Two reports have claimed that sufficient quantities are present to partially treat neonatal hypothyroidism (22,23). A third study measured high T4 levels in breastfed infants but was unsure of its significance (24). In contrast, four competing studies have found that breastfeeding does not alter either T4 levels or thyroid function in the infant (25–28). Although all of the investigators on both sides of the issue used sophisticated available methods to arrive at their conclusions, the balance of evidence weighs in on the side of those claiming lack of effect because they have relied on increasingly refined means to measure the hormone (29–31). The reports are briefly summarized below.

In 19 healthy euthyroid mothers not taking thyroid replacement therapy, mean milk T4 concentrations in the 1st postpartum week were 3.8 ng/mL (22). Between 8 and 48 days, the levels rose to 42.7 ng/mL and then decreased to 11.1 ng/mL after 50 days postpartum. The daily excretion of T4 at the higher levels is about the recommended daily dose for hypothyroid infants (22). An infant was diagnosed as athyrotic shortly after breastfeeding was stopped at age 10 months (23). Growth was at the 97th percentile during breastfeeding, but the bone age remained that of a newborn. In this study, mean levels of T4 in breast milk during the last trimester (12 patients) and within 48 hours of delivery (22 patients) were 14 and 7 ng/mL, respectively (23). A 1983 report

measured significantly greater serum levels of T4 in 22 breastfed infants than those in 25 formula-fed babies, 131.1 vs. 118.4 ng/mL, respectively (24). The overlap between the two groups, however, casts doubt on the physiologic significance of the differences.

In 77 euthyroid mothers, measurable amounts of T4 were found in only 5 of 88 milk specimens collected over 43 months of lactation, with 4 of the positive samples occurring within 4 days of delivery. Concentrations ranged from 8 to 13 ng/mL (25). A 1980 report described four exclusively breastfed infants with congenital hypothyroidism who were diagnosed between the ages of 2 and 79 days. Breastfeeding did not hinder making the diagnosis (26). Another report, evaluating clinical and biochemical thyroid parameters in hypothyroid infants, found no differences between breastfed (N = 12) and bottle-fed (N = 33) babies. These results lead to the conclusion that breast milk does not offer protection against the effects of congenital hypothyroidism (27). In a 1985 study, serum concentrations of T4 were similar in breastfed and bottle-fed infants at 5, 10, and 15 days postpartum (28).

The discrepancies described above can be partially explained by the various techniques used to measure milk T4 concentrations. Japanese researchers failed to detect milk T4 using four different methods of radioimmunoassay (RIA) (29). Using three competitive protein-binding assays, highly variable T4 levels were recovered from milk and a standard solution. Although the RIA methods were not completely reliable because recovery from a standardized solution exceeded 100% with one method, the researchers concluded that milk T4 concentrations must be very low and had no influence on the pituitary–thyroid axis of normal babies. No difficulty was encountered with measuring serum T4 levels, which were not significantly different between breastfed and bottle-fed infants (29). Swedish investigators using RIA methods also failed to find T4 in milk (30). A second group of Swedish researchers used a gas chromatography–mass spectrometry technique to determine that the concentration of T4 in milk was <4 ng/mL (31).

Levothyroxine breast milk levels, as determined by modern laboratory techniques, are too low to protect a hypothyroid infant completely from the effects of the disease. The levels are also too low to interfere with neonatal thyroid screening programs (28). The American Academy of Pediatrics classifies levothyroxine as compatible with breastfeeding (32).

LIDOCAINE

Local Anesthetic/Cardiac Drug

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Lidocaine is a local anesthetic that also is used for the treatment of cardiac ventricular arrhythmias. The majority of the information on the drug in pregnancy derives from its use as a local anesthetic during labor and delivery. Reproduction studies have revealed no evidence of fetal harm in pregnant rats at doses up to 6.6 times the human dose (1).

FETAL RISK SUMMARY

Lidocaine rapidly crosses the placenta to the fetus, appearing in the fetal circulation within a few minutes after administration to the mother. Cord:maternal serum ratios range between 0.50 and 0.70 after IV and epidural anesthesia (2–12). In 25 women just before delivery, a dose of 2–3 mg/kg was given by IV infusion at a rate of 100 mg/minute (2). The mean cord:maternal serum ratio in 9 patients who received 3 mg/kg was 0.55. A mean ratio of 1.32 was observed in nonacidotic newborns following local infiltration of the perineum for episiotomy (13). A similarly elevated ratio was measured in an acidotic newborn (14). The infant had umbilical venous/arterial pH values of 7.23/7.08 and a lidocaine cord:maternal serum ratio of 1.32 following epidural anesthesia. Because lidocaine is a weak base, the high ratio may have been caused by ion trapping (14).

Both the fetus and the newborn are capable of metabolizing lidocaine (8,9). The elimination half-life of lidocaine in the newborn following maternal epidural anesthesia averaged 3 hours (8). After local perineal infiltration for episiotomy, lidocaine was found in neonatal urine for at least 48 hours after delivery (13).

A number of studies have examined the effect of lidocaine on the newborn. In one report, offspring of mothers receiving continuous lumbar epidural blocks had significantly lower scores on tests of muscle strength and tone than did

controls (15). Results of other tests of neurobehavior did not differ from those of controls. In contrast, four other studies failed to find adverse effects on neonatal neurobehavior following lidocaine epidural administration (10–12,16). Continuous infusion epidural analgesia with lidocaine has been used without effect on the fetus or newborn (17).

Lidocaine may produce central nervous system depression in the newborn with high serum levels. Of eight infants with lidocaine levels greater than 2.5 mcg/mL, four had Apgar scores of 6 or less (3). Three infants with levels above 3.0 mcg/mL were mildly depressed at birth (3). A 1973 study observed fetal tachycardia (3 cases) and bradycardia (3 cases) after paracervical block with lidocaine in 12 laboring women (18). The authors were unable to determine whether these effects were a direct effect of the drug. Accidental direct injection into the fetal scalp during local infiltration for episiotomy led to apnea; hypotonia; and fixed, dilated pupils 15 minutes after birth in one infant (19). Lidocaine-induced seizures occurred at 1 hour. The lidocaine concentration in the infant's serum at 2 hours was 14 mcg/mL. The heart rate was 180 beats/minute. Following successful treatment, physical and neurologic examinations at 3 days and again at 7 months were normal.

Lidocaine is the treatment of choice for ventricular arrhythmias (20,21). A 1984 report described the use of therapeutic lidocaine doses (100 mg IV injection followed by 4 mg/minute infusion) in a woman who was successfully resuscitated after a cardiac arrest at 18 weeks' gestation (22). A normal infant was delivered at 38 weeks' gestation. Neurologic development was normal at 17 months of age, but growth was below the 10th percentile.

The Collaborative Perinatal Project monitored 50, 282 mother–child pairs, 293 of whom had exposure to lidocaine during the 1st trimester (23, pp. 358–363). No evidence of an association with large classes of malformations was found. Greater than expected risks were found for anomalies of the respiratory tract (three cases), tumors (two cases), and inguinal hernias (eight cases), but the statistical significance is unknown and independent confirmation is required (23, pp. 358–363, 477). For use anytime during pregnancy, 947 exposures were recorded (23, pp. 440, 493). From these data, no evidence of an association with large categories of major or minor malformations or to individual defects was found.

BREASTFEEDING SUMMARY

Small amounts of lidocaine are excreted into breast milk (24). A 37-year-old, lactating woman was treated with intravenous lidocaine for acute-onset

ventricular arrhythmia secondary to chronic mitral valve prolapse. The woman had been nursing her 10-month-old infant up to the time of treatment. She was treated with lidocaine, 75 mg over 1 minute, followed by a continuous infusion of 2 mg/minute (23 mcg/kg/minute). A second 50-mg dose was given 5 minutes after the first bolus dose. The woman's serum lidocaine level 5 hours after initiation of therapy was 2 mcg/mL. The drug concentration in a milk sample, obtained 2 hours later when therapy was stopped, was 0.8 mcg/mL (40% of maternal serum). Although the infant was not allowed to nurse during and immediately following the mother's therapy, the potential for harm of the infant from exposure to lidocaine in breast milk is probably very low. The American Academy of Pediatrics classifies lidocaine as compatible with breastfeeding (25).

LINACLOTIDE

Gastrointestinal Agent (Laxative)

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of linaclotide during human pregnancy have been located. Although the animal reproduction data are reassuring, the comparisons to human doses were based on body weight and may not be interpretable. Nevertheless, the absence of quantifiable plasma concentrations of linaclotide and its active metabolite suggest that clinically significant amounts of these agents will not cross to the embryo or fetus.

FETAL RISK SUMMARY

Linaclotide, guanylate cyclase-C agonist, and its active metabolite act locally on the luminal surface of the intestinal epithelium. The parent drug is a 14-amino-acid peptide. Linaclotide is indicated in adults for treatment of irritable bowel syndrome with constipation and for chronic idiopathic constipation. Both linaclotide and its active metabolite are minimally absorbed with plasma concentrations below the limit of quantitation (1).

Reproduction studies have been conducted in rats, rabbits, and mice. In rats and rabbits, oral doses up to 20,000 and 8000 times, respectively, the maximum recommended human dose of about 5 mcg/kg/day based on a 60-kg body weight (MRHD) produced no maternal toxicity and no effects on embryo–fetal development. In mice, oral doses at least 8000 times the MRHD caused severe maternal toxicity including death, reduction of gravid uterine and fetal weights, and effects on fetal morphology. A dose 1000 times the MRHD in mice was not maternal toxic and caused no adverse effects on embryo–fetal development (1).

In 2-year studies, linaclotide was not carcinogenic in rats and mice. Assays for mutagenicity also were negative and the drug had no effect on fertility or

reproductive function in male and female rats (1).

It is not known if linaclotide or its active metabolite cross the human placenta. The molecular weight of the parent drug (about 1527) and the absence of quantifiable concentrations of either agent suggest that exposure of the embryo or fetus will be nil. However, both agents are proteolytically degraded within the intestinal lumen to smaller peptides and naturally occurring amino acids and these may be absorbed and cross the placenta.

BREASTFEEDING SUMMARY

No reports describing the use of linaclotide during human lactation have been located. The molecular weight of the parent drug (about 1527) and the absence of quantifiable plasma concentrations of linaclotide or its active metabolite suggest that excretion into breast milk of clinically significant amounts of either agent is unlikely. However, both agents are proteolytically degraded within the intestinal lumen to smaller peptides and naturally occurring amino acids and these may be absorbed and excreted into milk. Nevertheless, the use of linaclotide during breastfeeding appears to be compatible.

LINAGLIPTIN

Antidiabetic Agent

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of linagliptin in human pregnancy have been located. The animal reproduction data suggest low risk, but the absence of human pregnancy experience prevents a complete assessment of the embryo–fetal risk. Although the use of linagliptin may help decrease the incidence of fetal and newborn morbidity and mortality in developing countries where the proper use of insulin is problematic, insulin still is the treatment of choice for this disease during pregnancy. Moreover, insulin does not cross the placenta, which eliminates the additional concern that the drug therapy will adversely affect the fetus. Carefully prescribed insulin therapy will provide better control of the mother’s blood glucose, thereby preventing the fetal and neonatal complications that occur with this disease. High maternal glucose levels, as might occur in diabetes mellitus, are associated with a number of maternal and fetal adverse effects, including fetal structural anomalies if the hyperglycemia occurs early in gestation. To prevent this toxicity, the American College of Obstetricians and Gynecologists recommends that insulin be used for types 1 and 2 diabetes occurring during pregnancy and, if diet therapy alone is not successful, for gestational diabetes (1,2). If a woman becomes pregnant while taking linagliptin, changing the therapy to insulin should be considered.

FETAL RISK SUMMARY

Linagliptin is an oral antidiabetic agent. It is in same class of dipeptidyl peptidase-4 (DPP-4) inhibitors as saxagliptin and sitagliptin. Linagliptin is indicated as an adjunct to diet and exercise to improve glycemic control in adults with type 2 diabetes mellitus. Linagliptin undergoes minimal metabolism

to inactive metabolites. Plasma protein binding at steady state is 70%–80%. Although the terminal half-life is >100 hours, relating to saturable binding to DPP-4, the effective half-life is about 12 hours (3).

Reproduction studies have been conducted in rats and rabbits. No teratogenic effects were observed when the drug was given to these species during organogenesis in doses up to about 49 and 1943 times, respectively, the human clinical dose based on AUC exposure (HCD). In rats, a dose that was 1000 times HCD caused maternal toxicity and developmental delays in skeletal ossification and slightly increased embryo–fetal loss. When the maternal toxic dose was administered to rats from gestation day 6 to lactation day 21, decreased body weight and delays in physical and behavioral development in male and female offspring were observed. No functional, behavioral, or reproductive toxicity was observed in the offspring of rats exposed to 49 times the HCD. In rabbits, a dose 1943 times the HCD caused increased fetal resorptions and visceral and skeletal variations. The drug crossed the placenta in pregnant rats and rabbits (3).

In 2-year carcinogenesis studies, linagliptin did not increase the incidence of tumors in male and female rats and mice, but a higher dose in female mice did increase the incidence of lymphoma. Mutagenic clastogenic effects were not observed in various assays. In fertility studies with rats, no adverse effects on early embryonic development, mating, fertility, or bearing live young were observed with doses up to about 943 times the HCD (3).

It is not known if linagliptin crosses the human placenta. The molecular weight (about 473), minimal metabolism, moderate plasma protein binding, and long elimination half-life all suggest that the drug will cross to the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use of linagliptin during human lactation have been located. The molecular weight of the parent compound (about 473), minimal metabolism, moderate plasma protein binding (70%–80%), and effective half-life (about 12 hours) suggest that linagliptin will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown. Single doses of linagliptin up to 600 mg (120 times the maximum recommended human dose in healthy adults) caused no dose-related adverse reactions (3). Thus, hypoglycemia in a nursing infant might be unlikely but should be monitored. The most common ($\geq 5\%$) adverse reaction in adults receiving monotherapy was nasopharyngitis (3).

LINCOMYCIN

Antibiotic

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No reports linking the use of lincomycin with congenital defects have been located.

FETAL RISK SUMMARY

Lincomycin crosses the placenta, achieving cord serum levels about 25% of the maternal serum level (1,2). Multiple IM injections of 600 mg did not result in accumulation in the amniotic fluid (2). No effects on the newborn were observed.

The progeny of 302 patients treated at various stages of pregnancy with oral lincomycin, 2 g/day for 7 days, were evaluated at various intervals up to 7 years after birth (3). As compared with a control group, no increases in malformations or in delayed developmental defects were observed.

BREASTFEEDING SUMMARY

Lincomycin is excreted into breast milk. Six hours following oral dosing of 500 mg every 6 hours for 3 days, serum and milk levels in nine patients averaged 1.37 and 1.28 mcg/mL, respectively, a milk:plasma ratio of 0.9 (1). Much lower milk:plasma ratios of 0.13–0.17 have also been reported (4). Although no adverse effects have been reported, three potential problems exist for the nursing infant: modification of bowel flora, direct effects on the infant, and interference with the interpretation of culture results if a fever workup is required.

LINDANE

Scabicide/Pediculicide

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

If maternal treatment is required, the manufacturers recommend using lindane no more than twice during a pregnancy (1,2). However, because of lindane's potentially serious toxicity, the CDC recommends, in pregnant women, permethrin or pyrethrins with piperonyl butoxide for the treatment of lice infestations and permethrin for the treatment of scabies (see Permethrin and Pyrethrins with Piperonyl Butoxide) (3).

FETAL RISK SUMMARY

Lindane (γ -benzene hexachloride) is used topically for the treatment of lice and scabies. Small amounts are absorbed through the intact skin and mucous membranes (4).

No published reports linking the use of this drug with toxic or congenital defects have been located, but one reference suggested that it should be used with caution because of its potential to produce neurotoxicity, convulsions, and aplastic anemia (5). Animal studies have not shown a teratogenic effect (6,7) and in one, lindane seemed to have a protective effect when given with known teratogens (8). Multigeneration reproduction studies in mice, rats, rabbits, pigs, and dogs at oral doses up to 10 times the human dose have revealed no evidence of impaired fertility or fetal harm (1).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 1417 newborns had been exposed to topical lindane during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 64 (4.5%) major birth defects were observed (60 expected). Specific data were available for six defect categories, including (observed/expected) 17/14 cardiovascular defects, 4/2 oral clefts,

0/0.7 spina bifida, 1/4 polydactyly, 2/2 limb reduction defects, and 7/3 hypospadias. Only with the latter defect is there a suggestion of a possible association, but other factors, including concurrent drug use and chance, may be involved.

BREASTFEEDING SUMMARY

Lindane is excreted into breast milk after ingestion of the agent from treated foods (1). Concentrations in milk ranged from 0 to 113 parts per billion.

No reports describing the use of lindane in lactating women have been located. Based on theoretical considerations, a manufacturer estimated the upper limit of lindane levels in breast milk to be approximately 30 ng/mL after maternal application (E.D. Rickard, personal communication, Reed & Carnrick Pharmaceuticals, 1983). A nursing infant consuming 1000 mL of milk/day would thus ingest about 30 mcg/day of lindane. This is in the same general range that the infant would absorb after direct topical application (E.D. Rickard, personal communication, 1983). These amounts are probably clinically insignificant. Waiting 4 days after discontinuing lindane lotion, however, should prevent exposure of a nursing infant to any drug in the milk (1).

LINEZOLID

Anti-infective

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo/Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential
Toxicity

PREGNANCY SUMMARY

No reports describing the use of linezolid during human pregnancy have been located. Because of the lack of human pregnancy data, other antibiotics with this experience should be used if possible. If no other alternatives are available and linezolid must be used, the maternal benefit appears to outweigh the unknown fetal risk.

FETAL RISK SUMMARY

Linezolid is a synthetic, oxalodinone class, antibacterial agent that is indicated for the treatment of gram-positive bacteria, including vancomycin-resistant enterococcus (VRE). It is available in both oral and IV formulations.

Reproduction studies have been conducted in pregnant mice and rats (1). No evidence of teratogenicity was seen in mice and rats at doses that were 4 and 1 times the expected human exposure based on AUC (EHE), respectively. However, in mice, embryo and fetal toxicity (embryo death, including total litter loss, decreased fetal weight, and an increased incidence of costal cartilage fusion) and maternal toxicity (clinical signs and reduced weight gain) were seen at this dose. In pregnant rats, doses 0.13 and 0.64 times the EHE resulted in slight fetal toxicity (reduced fetal weight and ossification of sternebrae). The higher dose (0.64 times the EHE) caused slight maternal toxicity consisting of reduced body weight gain. When this dose was given during pregnancy and lactation, pup survival was decreased on postnatal days 1 to 4. In addition, when surviving pups reached maturity and were mated, they had decreased fertility as evidenced by an increase in preimplantation loss (1).

It is not known if linezolid crosses the human placenta. The molecular weight (about 337) is low enough that transfer to the fetus should be expected.

BREASTFEEDING SUMMARY

No reports describing the use of linezolid during human lactation have been located. The molecular weight (about 337) is low enough that excretion into breast milk should be expected. The effects of this exposure on a nursing infant are unknown, but myelosuppression and reversible thrombocytopenia are potential complications. Women taking linezolid should probably not breastfeed.

LIOTHYRONINE

Thyroid

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Liothyronine (T3) is compatible with all stages of pregnancy. Untreated or undertreated maternal hypothyroidism is associated with low birth weight secondary to medically indicated preterm delivery, preeclampsia, or placental abruption (1) and with lower neuropsychological development of their offspring (2).

FETAL RISK SUMMARY

T3 is a naturally occurring thyroid hormone produced by the mother and the fetus. It is used during pregnancy for the treatment of hypothyroidism (see also Levothyroxine and Thyroid). Although early studies found little or no transplacental passage of T3 at physiologic serum concentrations (3–5), as well as limited passage following very high doses (6,7), a 1994 review cited evidence that small amounts of T3 do cross the human placenta (8).

In a large prospective study, 34 mother–child pairs were exposed to T3 during the 1st trimester. No association between the drug and fetal defects was found (9). Maternal hypothyroidism itself has been reported to be responsible for poor pregnancy outcome (10). Others have not found this association, claiming that fetal development is not directly affected by maternal thyroid function (11). However, untreated maternal hypothyroidism during pregnancy has been shown to result in lower scores relating to intelligence, attention, language, reading ability, school performance, and visual–motor performance in children 7–9 years of age (2).

Combination therapy with thyroid–antithyroid drugs was advocated at one time for the treatment of hyperthyroidism but is now considered inappropriate (see Propylthiouracil).

BREASTFEEDING SUMMARY

T3 is excreted into breast milk in low concentrations. The effect on the nursing infant is not thought to be physiologically significant, although at least one report concluded otherwise (12). An infant was diagnosed as athyrotic shortly after breastfeeding was stopped at age 10 months. Growth was at the 97th percentile during breastfeeding, but the bone age remained that of a newborn. Mean levels of T3 in breast milk during the last trimester (12 patients) and within 48 hours of delivery (22 patients) were 1.36 and 2.86 ng/mL, respectively (12).

A 1978 study reported milk concentrations varying between 0.4 and 2.38 ng/mL (range 0.1–5 ng/mL) from the day of delivery to 148 days postpartum (13). No T3 was detected in a number of samples. Levels in three instances, collected 16, 20, and 43 months postpartum, ranged from 0.68 to 4.5 ng/mL with the highest concentration measured at 20 months. From the first week through 148 days postdelivery, the calculated maximum amount of T3 that a nursing infant would have ingested was 2.1–2.6 mcg/day, far less than the dose required to treat congenital hypothyroidism. However, it was concluded that this was enough to mask the symptoms of the disease without halting its progression (13).

In a study comparing serum T3 levels between 22 breastfed and 29 formula-fed infants, significantly higher levels were found in the breastfeeding group. The levels, 2.24 and 1.79 ng/mL, were comparable with previous reports and probably were of doubtful clinical significance (14).

A 1980 report described four exclusively breastfed infants with congenital hypothyroidism who were diagnosed between the ages of 2 and 79 days. Breastfeeding did not hinder making the diagnosis (15). Another report, evaluating clinical and biochemical thyroid parameters in hypothyroid infants, found no differences between breastfed (N = 12) and bottle-fed (N = 33) babies. These results lead to the conclusion that breast milk does not offer protection against the effects of congenital hypothyroidism (16). As reported in a 1985 paper, serum concentrations of T3 were similar in breastfed and bottle-fed infants at 5, 10, and 15 days postpartum. The levels were too low to interfere with neonatal thyroid screening programs (17).

Japanese researchers found a T3 milk:plasma ratio of 0.36 (18). No correlation was discovered between serum T3 and milk T3 or total daily T3 excretion, nor was there a correlation between milk T3 levels and milk protein concentration or daily volume of milk. They concluded that breastfeeding has no influence on the pituitary–thyroid axis of normal babies (18). A Swedish investigation measured higher levels of T3 in milk 1–3 months after delivery as

compared with T3 levels in early colostrum (19). The concentrations were comparable with those in the studies cited above.

T3 breast milk concentrations are too low to protect a hypothyroid infant completely from the effects of the disease.

LIOTRIX

Thyroid

Liotrix is a synthetic combination of levothyroxine and liothyronine (see Levothyroxine and Liothyronine).

LIPIDS

Nutrient

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Based on limited clinical experience, IV lipids apparently do not pose a significant risk to the mother or fetus, although two cases of fetal death indicate that the therapy is not without danger. Standard precautions, as taken with nonpregnant patients, should be followed when administering these solutions during pregnancy.

FETAL RISK SUMMARY

Lipids (IV fat emulsions) are a mixture of neutral triglycerides, primarily unsaturated fatty acids, prepared from either soybean or safflower oil. Egg yolk phospholipids are used as an emulsifier. Most fatty acids readily cross the placenta to the fetus (1,2).

A number of reports have described the use of lipids during pregnancy in conjunction with dextrose/amino acid solutions (see Hyperalimentation, Parenteral) (3–14). However, one investigator concluded in 1977 that lipid infusions were contraindicated during pregnancy for several reasons: (a) an excessive increase in serum triglycerides, often with ketonemia, would result because of the physiologic hyperlipemia present during pregnancy; (b) premature labor would occur; and (c) placental infarctions would occur from fat deposits and cause placental insufficiency (15). A brief 1986 correspondence also stated that lipids were contraindicated because of the danger of inducing premature uterine contractions with the potential for abortion or premature delivery (16). This conclusion was based on the observation that lipids contain arachidonic acid, a precursor to prostaglandins E_2 and $F_{2\alpha}$ (16). However, another investigator concluded that concentrations of arachidonic acid must arise from decidual membranes or amniotic fluid (i.e., must be very close to the myometrium) to produce this effect (17).

A 1986 report described four women in whom parenteral hyperalimentation was used during pregnancy, two of whom also received lipids, and, in addition, reviewed the literature for both total parenteral nutrition and lipid use during gestation (18). These authors concluded that there was no evidence that lipid emulsions had an adverse effect on pregnancy (18).

The effect of oral administration of a triglyceride emulsion on the fetal breathing index was described in a 1982 publication (19). Six women, at 32 weeks' gestation, ingested 100 mL of the emulsion containing 67 g of triglycerides and were compared with six women, also at 32 weeks' gestation, who drank mineral water. No correlation was noted between the fetal breathing index and plasma free fatty acids, glucose, insulin, glucagon, total cortisol, free cortisol, or triglyceride levels (19).

Cardiac tamponade, resulting in maternal and fetal death, was reported in a woman receiving central hyperalimentation with lipids for severe hyperemesis gravidarum (20) (see Hyperalimentation, Parenteral, for details of this case).

A stillborn male fetus was delivered at 22 weeks' gestation from a 31-year-old woman with hyperemesis gravidarum who had been treated with total IV hyperalimentation and lipid emulsion for 8 weeks (21). The tan-yellow placenta showed vacuolated syncytial cells and Hofbauer cells that stained for fat. The placental fat deposits, the first to be described with parenteral lipids, were thought to be the cause of the fetal demise.

BREASTFEEDING SUMMARY

Although there are no reports describing the use of IV lipids during lactation, there does not appear to be any risk to the nursing infant.

LIRAGLUTIDE

Antidiabetic Agent

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible (NEW)

PREGNANCY SUMMARY

No reports describing the use of liraglutide in human pregnancy have been located. The drug caused developmental toxicity (decreased body weight and structural anomalies) in two animal species at systemic exposures less than the human exposure. The absence of human pregnancy experience prevents a complete assessment of the embryo–fetal risk. Until such data are available, the best course is to avoid liraglutide in pregnancy.

FETAL RISK SUMMARY

Liraglutide is a glucagon-like peptide-1 receptor agonist that enhances glucose-dependent insulin secretion, suppresses inappropriately elevated glucagon secretion and slows gastric emptying. It is in the same subclass of antidiabetic agents as exenatide. Liraglutide is indicated as an adjunct to diet and exercise to improve glycemic control in adults with type 2 diabetes mellitus. It is given as an SC injection once daily. The low metabolism is similar to large proteins without a specific organ as a major route of elimination. The drug is extensively bound to plasma protein (>98%) and the elimination half-life is about 13 hours (1).

Reproduction studies have been conducted in rats and rabbits. Rats were given daily SC doses beginning 2 weeks before mating to gestation day 17 that resulted in estimated systemic exposures that were 0.8–11 times the human exposure resulting from the maximum recommended human dose based on plasma AUC (MRHD). The highest dose caused maternal toxicity (reduced body weight gain and food consumption). All doses were associated with fetal abnormalities and variations in kidneys and blood vessels, irregular ossification of the skull, and a more complete state of ossification. The incidences of

misshapen oropharynx and/or narrowed opening into the larynx, and umbilical hernia were increased at the lowest dose. At the highest dose, the number of early embryonic deaths increased slightly, and mottled liver and minimally kinked ribs were observed. Daily SC doses given from gestation day 6 through weaning or termination of nursing on lactation day 24 were associated with a slight delay in parturition and a decrease in group mean body weight of neonatal rats. Bloody scabs and agitated behavior occurred in male rats descended from dams treated with the highest dose. A nonsignificant trend toward lower group mean body weight from birth to postpartum day 14 was seen in F₂ generation rats (1).

Pregnant rabbits were given three different daily SC doses from gestation days 6 through 18 that resulted in estimated systemic exposures that were all less than the MRHD. Decreased fetal weight and a dose-dependent increase in fetal abnormalities were observed at all doses. The malformations involved the kidneys, scapula, eyes, forelimb, brain, tail, sacral vertebrae, major blood vessels, heart, umbilicus, sternum, and parietal bones. Irregular ossification and/or skeletal abnormalities occurred in the skull and jaw, vertebrae and ribs, sternum, pelvis, tail, and scapula. Dose-dependent minor skeletal variations also were observed. Visceral abnormalities occurred in blood vessels, lung, liver, and esophagus, and bilobed or bifurcated gallbladder (1).

Studies for carcinogenicity potential have been conducted in mice and rats. In both of these species, a dose-related increase in benign thyroid C-cell adenomas and malignant C-cell carcinomas were observed. Thyroid C-cell tumors are rare findings during carcinogenicity testing in mice and rats. Liraglutide was negative with and without metabolic activation in multiple tests for mutagenicity and clastogenicity. In rats, the drug had no effect on male fertility. In female rats, a maternal toxic dose that was 11 times the MRHD caused an increase in early embryonic deaths.

It is not known if liraglutide crosses the human placenta. The high molecular weight (about 3751) and plasma protein binding suggest that the agent will not cross in clinically significant amounts, but the low metabolism and long elimination half-life are favorable factors for exposure of the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use of liraglutide during human lactation have been located. The high molecular weight (about 3751) and plasma protein binding (>98%) suggest that clinically significant amounts of the agent will not be excreted into breast milk. However, the low metabolism and long elimination

half-life (about 13 hours) might increase these amounts. What little is excreted will probably be digested in the stomach of the nursing infant. Therefore, although the effect of the exposure on a nursing infant is unknown, the risk appears to be negligible. Nevertheless, blood glucose monitoring of the infant should be considered.

LISDEXAMFETAMINE

Central Stimulant

PREGNANCY RECOMMENDATION: Human and Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of lisdexamfetamine in human pregnancy have been located. However, the prodrug is rapidly metabolized upon absorption to dextroamphetamine (see Amphetamine for human data).

FETAL RISK SUMMARY

Lisdexamfetamine is a prodrug that is rapidly metabolized upon absorption to dextroamphetamine (see Amphetamine) and l-lysine. It is indicated for the treatment of attention deficit hyperactivity disorder. The average plasma elimination half of lisdexamfetamine is <1 hour (1).

Animal reproduction studies have not been conducted with lisdexamfetamine. Studies have been conducted with amphetamine (D- to L-enantiomer ratio of 3:1) in rats, rabbits, and mice, but comparisons to the recommended human dose based on BSA or AUC was not given. No adverse effects on embryo–fetal morphological development or survival were observed in rats and rabbits given the drug throughout organogenesis. In mice, fetal malformations and death resulted from parenteral doses that caused severe maternal toxicity (1).

Several studies in animals, using doses similar to those used clinically, have shown that prenatal or early postnatal exposure can result in long-term neurochemical and behavioral alterations (learning and memory deficits, altered locomotor activity, and changes in sexual function) (1).

Carcinogenicity studies have not been conducted with lisdexamfetamine, but no evidence of carcinogenicity was found in mice and rats with dl-amphetamine. Several studies for mutagenic or clastogenic effects with lisdexamfetamine were negative. Amphetamine (d- to l-enantiomer ratio of 3:1) did not adversely affect fertility or early embryonic development in rats (1).

It is not known if lisdexamfetamine crosses the human placenta. The

molecular weight of the dimesylate formulation (about 456) is low enough, but the prodrug is rapidly metabolized to dexamphetamine (molecular weight about 135) and this agent probably crosses to the embryo–fetus.

There are numerous reports of amphetamine use in human pregnancy (see Amphetamine).

BREASTFEEDING SUMMARY

No reports describing the use of the prodrug lisdexamfetamine during human lactation have been located. However, the prodrug is rapidly metabolized upon absorption to dextroamphetamine and this agent is concentrated in breast milk (see Amphetamine for human data).

LISINOPRIL

Antihypertensive

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in the 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The fetal toxicity of lisinopril in the 2nd and 3rd trimesters is similar to other angiotensin-converting enzyme (ACE) inhibitors. The use of this drug during the 2nd and 3rd trimesters may cause teratogenicity and severe fetal and neonatal toxicity. Fetal toxic effects may include anuria, oligohydramnios, fetal hypocalvaria, intrauterine growth restriction (IUGR), prematurity, and patent ductus arteriosus. Stillbirth or neonatal death may occur. Anuria-associated oligohydramnios may produce fetal limb contractures, craniofacial deformation, and pulmonary hypoplasia. Severe anuria and hypotension, which is resistant to both pressor agents and volume expansion, may occur in the newborn following in utero exposure. Newborn renal function and blood pressure should be closely monitored.

FETAL RISK SUMMARY

Lisinopril is a long-acting ACE inhibitor used for the treatment of hypertension. The drug is not teratogenic in mice, rats, and rabbits treated with doses ≤ 55 , 33, and 0.15 times, respectively, the maximum recommended human daily dose based on BSA (1).

Use of lisinopril limited to the 1st trimester does not appear to present a significant risk to the fetus, but fetal exposure after this time has been associated with teratogenicity and severe toxicity in the fetus and newborn, including death. The pattern of fetal toxicity, including teratogenicity, appears to be similar to that experienced with captopril and enalapril.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 15 newborns had been exposed to lisinopril during the 1st trimester (F. Rosa, personal

communication, FDA, 1993). Two (13.3%) major birth defects were observed (0.6 expected), one of which was polydactyly (none expected). No anomalies were observed in five other categories of defects (cardiovascular defects, oral clefts, spina bifida, limb reduction defects, and hypospadias) for which specific data were available.

Two cases of lisinopril-induced perinatal renal failure in newborns were published in a 1991 abstract (2). Additional details were not provided other than that both infants had been exposed in utero to the agent. The authors noted, however, that the effects of ACE inhibitors in the newborn are prolonged unless removed by dialysis, because 95% of the active metabolites are eliminated by renal excretion (2).

In a 2000 report, a woman with normal amniotic fluid volume and fetal measurements by ultrasound consistent with 18 weeks' gestation presented with severe chronic hypertension (3). She had been treated before conception and during the first 16 weeks with lisinopril but had self-stopped therapy 2 weeks before presentation. Because a combination of methyldopa, nifedipine, and labetalol failed to control her blood pressure, lisinopril was re-added to her regimen. At 22 weeks' gestation, the amniotic fluid index was 8 but declined to 0 at 24 weeks'. A cesarean section was performed at about 27 weeks' because of deteriorating maternal and fetal condition. The growth restricted, 680-g (3rd percentile) female infant had minimal respiratory distress syndrome. Severe renal impairment (maximum urine output 0.3 mL/kg/hr) was present during the first 6 days before improving after corrective surgery for bowel perforations secondary to necrotizing enterocolitis. She was discharged home on day 102 (3).

An 18-year-old woman received lisinopril, 10 mg/day, throughout gestation for the treatment of essential hypertension (4). No mention of amniotic fluid levels during pregnancy was made in this brief report. She delivered a premature, 1.48-kg, anuric infant at 33 weeks' gestation. Fetal calvarial hypoplasia was present. The normal-sized kidneys showed no evidence of perfusion on renal ultrasonography. An open biopsy at 11 weeks of age showed extensive atrophy and loss of tubules with interstitial fibrosis. The findings were compatible with exposure to a nephrotoxic agent. Peritoneal dialysis was instituted on day 8. Measurements of the drug in the dialysate indicated that removal of lisinopril was occurring. At 12 months of age, the infant continued to require dialysis (4).

Three cases of in utero exposure to ACE inhibitors, one of which was lisinopril, were reported in a 1992 abstract (5). The infant, delivered at 32

weeks' gestation because of severe oligohydramnios and fetal distress, suffered from IUGR, hypocalvaria, renal tubular dysplasia, and persistent renal insufficiency. The profound neonatal hypotension and anuria observed at birth improved only after dialysis. At the time of the report, the 15-month-old infant was maintained on dialysis.

Six pregnancies treated with lisinopril were reported in a 1997 study of 19 pregnancies exposed to ACE inhibitors (6). Lisinopril therapy was stopped in the 1st trimester in four pregnancies and at 20 and 25 weeks', respectively, in the others. No congenital anomalies or renal dysfunction were noted in the six neonates (6).

A case of lisinopril-induced fetopathy and hypocalvaria was included in a study examining the causes of fetal skull hypoplasia (7). Among 14 known cases of hypocalvaria or acalvaria, 5 were caused by ACE inhibitors. The authors speculated that the underlying pathogenetic mechanism in these cases is fetal hypotension (7).

A 1991 article examining the teratogenesis of ACE inhibitors cited evidence linking fetal calvarial hypoplasia with the use of these agents after the 1st trimester (8). The proposed mechanism was drug-induced oligohydramnios that allowed the uterine musculature to exert direct pressure on the fetal skull. This mechanical insult, combined with drug-induced fetal hypotension, could inhibit peripheral perfusion and ossification of the calvaria (8).

A retrospective study using pharmacy-based data from the Tennessee Medicaid program identified 209 infants, born between 1985 and 2000, that had 1st trimester exposure to ACE inhibitors (9). Infants of mothers with evidence of diabetes, either before or during pregnancy, were excluded, as were those exposed to angiotensin-receptor antagonists (ARBs), ACE inhibitors, or other antihypertensives beyond the 1st trimester, and those exposed to known teratogens. Two comparison groups, other antihypertensives (N = 202) and no antihypertensives (N = 29,096), were formed. The number of major birth defects in each of the three groups was 18 (8.6%), 4 (2%), and 834 (2.9%), respectively. Compared with the no-antihypertensives group, exposure to ACE inhibitors was associated with a significantly increased risk of major defects (relative risk [RR] 2.71, 95% confidence interval [CI] 1.72–4.27). When the analysis was conducted by the type of defect, the highest rates were with cardiovascular defects, 9, 2, and 294 respectively, RR 3.72, 95% CI 1.89–7.30, and with CNS defects, 3, 0, and 80, respectively, RR 4.39, 95% CI 1.37–14.02. The major defects observed in the subject group were as follows: atrial septal defect (N = 6) (includes three with pulmonic stenosis and/or three with

patent ductus arteriosus (PDA), renal dysplasia (N = 2), PDA alone (N = 2), and one each of ventricular septal defect, spina bifida, microcephaly with eye anomaly, coloboma, hypospadias, intestinal and choanal atresia, Hirschsprung disease, and diaphragmatic hernia (9). In an accompanying editorial, it was noted that neither previous reports of 1st trimester exposure to ACE inhibitors nor the animal studies had observed an increased risk of birth defects (10). It also was noted that no mechanism for ACE inhibitor-induced teratogenicity was known. A subsequent communication raising concerns about the validity of the study in terms of adequate exclusion of diabetes, charting and coding errors in busy medical practices, and the effects of maternal obesity (11), was addressed by the investigators (12).

Lisinopril and other ACE inhibitors are human teratogens when used in the 2nd and 3rd trimesters, producing fetal hypocalvaria and renal defects. The cause of the defects and other toxicity is probably related to fetal hypotension and decreased renal blood flow. The compromise of the fetal renal system may result in severe, and at times fatal, anuria, both in the fetus and in the newborn. Anuria-associated oligohydramnios may produce pulmonary hypoplasia, limb contractures, persistent PDA, craniofacial deformation, and neonatal death (13,14). IUGR, prematurity, and severe neonatal hypotension may also be observed. Two reviews of fetal and newborn renal function indicated that both renal perfusion and glomerular plasma flow are low during gestation and that high levels of angiotensin II are physiologically necessary to maintain glomerular filtration at low perfusion pressures (15,16). Lisinopril prevents the conversion of angiotensin I to angiotensin II and, thus, may lead to in utero renal failure. Since the primary means of removal of the drug is renal, the impairment of this system in the newborn prevents elimination of the drug resulting in prolonged hypotension. Newborn renal function and blood pressure should be closely monitored. If oligohydramnios occurs, stopping lisinopril may resolve the problem but may not improve infant outcome because of irreversible fetal damage (13). In those cases in which lisinopril must be used to treat the mother's disease, the lowest possible dose should be used combined with close monitoring of amniotic fluid levels and fetal well-being. Guidelines for counseling exposed pregnant patients have been published and should be of benefit to health professionals faced with this task (8,13).

The observation in Tennessee Medicaid data of an increased risk of major congenital defects after 1st trimester exposure to ACE inhibitors raises concerns about teratogenicity that have not been seen in other studies (10). Medicaid data are a valuable tool for identifying early signals of teratogenicity,

but are subject to a number of shortcomings and their findings must be considered hypotheses until confirmed by independent studies.

A 2012 review of the use of ACE inhibitors and ARBs in the 1st trimester concluded that there may be an elevated teratogenic risk, but the risk appeared to be related to other factors (17). The factors, that typically coexist with hypertension in pregnancy, included diabetes, advanced maternal age, and obesity.

BREASTFEEDING SUMMARY

No reports describing the use of lisinopril during human lactation have been located. The molecular weight (about 442) is low enough that excretion into breast milk should be expected. Two similar agents (captopril and enalapril) are present in milk in low concentrations and are classified by the American Academy of Pediatrics as compatible with breastfeeding (see Captopril and Enalapril).

LITHIUM

Antipsychotic

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

If possible, lithium should be avoided during pregnancy, especially during the period of organogenesis. In those cases in which 1st trimester use is unavoidable, adequate screening tests, including level II ultrasound and fetal echocardiography (e.g., at 18–20 weeks' gestation [1]), should be performed (1–3). Serum levels should also be monitored. Daily folic acid (5 mg/day) is also recommended. Use of the drug near term may produce severe toxicity in the newborn, which is usually reversible. The long-term effects of in utero lithium exposure on postnatal development are unknown but warrant investigation.

FETAL RISK SUMMARY

Lithium is used for the treatment of manic episodes of manic-depressive illness. The drug is available as either lithium carbonate or lithium citrate.

The use of lithium during the 1st trimester may be related to an increased incidence of congenital defects, particularly of the cardiovascular system. A 1987 review of psychotherapeutic drugs in pregnancy evaluated several reproduction studies of lithium in animals, including mice, rats, rabbits, and monkeys, and observed no teratogenicity except in rats (4).

Lithium freely crosses the placenta, equilibrating between maternal and cord serum (4–9). Amniotic fluid concentrations exceed cord serum levels (6).

A 1992 report described the outcomes of 11 women taking lithium during pregnancy, five of whom had two pregnancies (10). All gave birth to healthy babies.

Frequent reports have described the fetal effects of lithium, the majority from data accumulated by the Lithium Baby Register (4,5,11–19). The Register, founded in Denmark in 1968 and later expanded internationally, collects data on

known cases of 1st trimester exposure to lithium (17). By 1977, the Register included 183 infants, 20 (11%) with major congenital anomalies. Of the 20 malformed infants, 15 involved cardiovascular defects, including 5 with the rare Ebstein's anomaly. Others have also noted the increased incidence of Ebstein's anomaly in lithium-exposed babies (20). Two new case reports bring the total number of infants with cardiovascular defects to 17, or 77% (17 of 22) of the known malformed children (21,22). Ebstein's anomaly has been diagnosed in the fetus during the 2nd trimester by echocardiography (23). Details on 16 of the malformed infants are given below.

| Author | Case No. | Defect |
|------------------------------|----------|--|
| Weinstein and Goldfield (16) | 1 | Coarctation of aorta |
| | 2 | High intraventricular septal defect |
| | 3 | Stenosis of aqueduct with hydrocephalus, spina bifida with sacral meningo-myelocoele, bilateral talipes equinovarus with paralysis; atonic bladder, patulous rectal sphincter and rectal prolapse (see also reference 7) |
| | 4 | Unilateral microtia |

| | | |
|-------------------|----|--|
| | 5 | Mitral atresia, rudimentary left ventricle without inlet or outlet, aorta and pulmonary artery arising from right ventricle, patent ductus arteriosus, left superior vena cava |
| | 6 | Mitral atresia |
| | 7 | Ebstein's anomaly |
| | 8 | Single umbilical artery, bilateral hypoplasia of maxilla |
| | 9 | Ebstein's anomaly |
| | 10 | Atresia of tricuspid valve |
| | 11 | Ebstein's anomaly |
| | 12 | Patent ductus arteriosus, ventricular septal defect |
| | 13 | Ebstein's anomaly |
| Rane et al. (21) | 14 | Dextrocardia and situs solitus, patent ductus arteriosus, juxtaductal aortic coarctation |
| Weinstein (17) | 15 | Ebstein's anomaly |
| Arnon et al. (22) | 16 | Massive tricuspid regurgitation, atrial flutter, congestive heart failure |

In 60 of the children born without malformations, follow-up comparisons with nonexposed siblings did not show an increased frequency of physical or mental anomalies (24).

The fetal toxicity of lithium, particularly in regard to cardiac abnormalities and the Ebstein's anomaly, was discussed in two 1988 references (25,26). As an indication of the rarity of Ebstein's anomaly, only approximately 300 cases of the defect have been recorded in the literature since Ebstein first described it approximately 100 years ago (25). One author concluded that the majority of tricuspid valve malformations, such as Ebstein's anomaly, are not related to drug therapy and, thus, the association between lithium and Ebstein's anomaly is weak (26).

A 1996 case report described multiple anomalies in an aborted male fetus of

a woman treated with lithium carbonate monotherapy for a schizodepressive disorder (27). Maternal plasma levels before pregnancy varied between 0.58 and 0.73 mmol/L, but were not determined during gestation. Following diagnosis of multiple defects, the pregnancy was terminated at 22 weeks. The findings in the fetus were deep-set ears, clubfeet, bilateral agenesis of the kidneys (Potter's syndrome), and a septal defect with transposition of the great vessels (26). In addition, the placenta had portions that were poorly vascularized and villi of different sizes. A causal association in this case between lithium and the defects cannot be determined. Moreover, Potter's syndrome is thought to be a genetic defect (28).

A prospective study published in 1992 gathered data from four teratogen information centers in Canada and the United States on lithium exposure in pregnancy (2). A total of 148 pregnant women using lithium (mean daily dose 927 mg) during the 1st trimester were matched by age with 148 controls. Ten women using lithium were lost to postnatal follow-up, but information was available on the fetal echocardiograms performed. The number of live births in the two groups was 76% (105/138) and 83% (123/148), respectively. One stillbirth, in the exposed group, was observed. Other outcomes (figures based on 148 women in each group) included spontaneous abortion (9% vs. 8%), therapeutic abortion (10% vs. 6%), and ectopic pregnancy (1 case vs. 0 case). None of these differences were statistically significant. However, the birth weight of lithium-exposed infants was significantly higher than that of controls, 3475 vs. 3383 g, $p = 0.02$), even though significantly many of their mothers smoked cigarettes than did controls (31.8% vs. 15.5%, $p = 0.002$). Three exposed infants and three controls had congenital malformations. The defects observed after lithium exposure were two infants with neural tube defects (hydrocephalus and meningomyelocele—also exposed to carbamazepine during the 1st trimester—spina bifida and tethered cord) and one with meromelia who was delivered at 23 weeks' gestation and died shortly after birth. Defects in the offspring of control mothers were a ventricular septal defect (one), congenital hip dislocation (one), and cerebral palsy and torticollis (one). In addition to the above cases, one of the therapeutic abortions in the lithium group was a pregnancy terminated at 16 weeks' gestation for a severe form of Ebstein's anomaly. The mother had also taken fluoxetine, trazodone, and L-thyroxine in the 1st trimester. Ebstein's anomaly has an incidence of 1 in 20,000 in the general population; thus, the appearance of this case is consistent with an increased risk for the heart defect among infants of women using lithium. However, a larger sample size is still needed to define the actual magnitude of

the risk. The investigators concluded that lithium is not an important human teratogen and that, because it is beneficial in the therapy of major affective disorders, women may continue the drug during pregnancy. They cautioned, however, that adequate screening tests, including level II ultrasound and fetal echocardiography, were required when lithium is used during gestation (2).

A 1994 reference evaluated the teratogenic risk of 1st trimester exposure to lithium and summarized the treatment recommendations for lithium use in women with bipolar disorder (3). Included in their assessment were four case-controlled studies in which no cases of Ebstein's anomaly occurred among 207 lithium-exposed pregnancies as compared with 2 cases of the defects among 398 nonexposed controls. These data led them to the conclusion that the risk of teratogenicity after 1st trimester exposure to lithium was lower than previously reported (3). Reaching a similar conclusion, another review, published in 1995, concluded that the risk of teratogenicity with lithium was low in women with carefully controlled therapy, but that therapy should probably be avoided during the period of cardiac organogenesis (2nd–4th month of pregnancy) (29).

Concerning nonteratogenic effects, lithium toxicity in the fetus and newborn has been reported frequently:

Cyanosis (6,21,30–35)

Hypotonia (6,15,30–38)

Bradycardia (21,31,34,35,37,39)

Thyroid depression with goiter (6,15,38)

Atrial flutter (40)

Hepatomegaly (34,35)

Hyperbilirubinemia (42)

Electrocardiogram abnormalities (T-wave inversion) (31,39)

Cardiomegaly (32,34,35,40,42)

Gastrointestinal bleeding (39)

Diabetes insipidus (6,34,35,41,42)

Hypoglycemia (42)

Polyhydramnios (35,41)

Polyuria (42)

Poor respiratory effort (42)

Seizures (35)

Shock (34)

Most of these toxic effects are self-limiting, returning to normal in 1–2 weeks. This corresponds with the renal elimination of lithium from the infant. The serum

half-life of lithium in newborns is prolonged, averaging 68–96 hours, as compared with the adult value of 10–20 hours (7,21). Two of the reported cases of nephrogenic diabetes insipidus persisted for 2 months or longer (6,34).

Premature labor, loss of fetal cardiac variability and acceleration, an unusual fetal heart rate pattern (double phase baseline), and depression at birth (Apgar scores of 4 and 7 at 1 and 5 minutes, respectively) were observed in a comatose mother and her infant after an acute overdose of an unknown amount of lithium and haloperidol at 31 weeks' gestation (43). Because of progressive premature labor, the female, 1526-g infant was delivered about 3 days after the overdose. The lithium concentrations of the maternal plasma, amniotic fluid, and cord vein plasma were all greater than 4 mmol/L (severe toxic effect >2.5 mmol/L), while the maternal level of haloperidol at delivery was about 1.6 ng/mL. The effects observed in the fetus and newborn were attributed to cardiac and cerebral manifestations of lithium intoxication. No follow-up on the infant was reported (43).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 62 newborns had been exposed to lithium during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Two (3.2%) major birth defects were observed (three expected), one of which was a polydactyly (0.2 expected). No anomalies were observed in five other categories of defects (cardiovascular defects, oral clefts, spina bifida, limb reduction defects, and hypospadias) for which specific data were available.

A 2014 case study described the use of phenelzine (105 mg/day), lithium (900 mg/day), and quetiapine (600 mg/day) in a 31-year-old woman with bipolar affective disorder (44). She was also taking metformin (1 g/day) for polycystic ovarian syndrome with oligomenorrhea. Her pregnancy was confirmed at 17 weeks' gestation. A glucose tolerance test was negative at 26 weeks'. Lithium was suspended 24–48 hours before induction of labor at 39 weeks'. Because of obstructed labor, a cesarean section was performed to give birth to a 4.2-kg male infant with Apgar scores of 5 and 9 at 1 and 5 minutes, respectively. The baby required initial resuscitation during the first 10 minutes. He was discharged home with the mother on day 5 and, at 10 weeks of age, his growth and development were normal (44).

Fetal red blood cell choline levels are elevated during maternal therapy with lithium (45). The clinical significance of this effect on choline, the metabolic precursor to acetylcholine, is unknown but may be related to the teratogenicity

of lithium because of its effect on cellular lithium transport (45). In an in vitro study, lithium had no effect on human sperm motility (46).

A review published in 1995 used a unique system to assess the reproductive toxicity of lithium in animals and humans (47). Following an extensive evaluation of the available literature, for both experimental animals and humans, up through the early 1990s, a committee concluded that lithium, at concentrations within the human therapeutic range, could induce major malformations (particularly cardiac) and may be associated with neonatal toxicity. The evaluation included an assessment of human reproductive toxicity from lithium exposure in food, mineral supplements, swimming pools and spas, and drinking water, as well as from other environmental or occupational exposures. Because a linear relationship between lithium and toxicity was assumed, these exposures, which produce concentrations of lithium well below therapeutic levels, were not thought to produce human toxicity (47).

In the mother, renal lithium clearance rises during pregnancy, returning to prepregnancy levels shortly after delivery (48). In four patients, the mean clearance before delivery was 29 mL/minute, declining to 15 mL/minute 6–7 weeks after delivery, a statistically significant difference ($p < 0.01$). These data emphasize the need to monitor lithium levels closely before and after pregnancy (48).

BREASTFEEDING SUMMARY

Lithium is excreted into breast milk (9,31,49–52). Milk levels are approximately 40%–50% of the maternal serum concentration (31,50,51). Infant serum and milk levels are approximately equal. In a 2003 study, milk lithium levels were determined in 11 lactating women (daily dose 600–1500 mg) that were taking the drug for the management of bipolar disorder (52). No adverse effects were observed in the infants. The estimated infant dose from milk ranged from 0% to 30% of the mother's weight adjusted dose. These data suggested that monitoring lithium levels in milk and/or the infant's blood, combined with close observation of the nursing infant for adverse effects, was a rational approach (52).

Although no toxic effects in the nursing infant have been reported, long-term effects from this exposure have not been studied. Because of the near therapeutic blood concentrations in infants, the American Academy of Pediatrics classifies lithium as a drug that should be given to nursing mothers with caution (53).

LODOXAMIDE

Ophthalmic (Mast Cell Stabilizer)

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of lodoxamide in human pregnancy have been located. The animal data suggest low risk. Moreover, the drug is available as an ophthalmic solution and such use has not resulted in detectable levels in the plasma. The drug appears to be compatible in pregnancy.

FETAL RISK SUMMARY

Lodoxamide is a mast cell stabilizer that is available as an ophthalmic 0.1% solution. It is indicated in the treatment of ocular disorders referred to by the terms vernal keratoconjunctivitis, vernal conjunctivitis, and vernal keratitis. In healthy adult volunteers, administration of one drop in each eye four times daily for 10 days did not result in measurable lodoxamide plasma concentrations (detection limit 2.5 ng/mL) (1).

Reproduction studies have been conducted in rats and rabbits. Oral doses in these species that were more than 5000 times the proposed human clinical dose produced no evidence of developmental toxicity (1)

No evidence of carcinogenicity was observed in long-term studies with oral doses in rats. There also was no evidence of mutagenicity or genetic damage in multiple assays or evidence of impaired reproductive function in laboratory animal studies (1).

It is not known if lodoxamide crosses the human placenta. The molecular weight (about 554) is low enough, but the absence of detectable plasma levels suggests that embryo–fetal exposure will be very low or nil.

BREASTFEEDING SUMMARY

No reports describing the use of lodoxamide during lactation have been located. The molecular weight (about 554) is low enough for excretion into breast milk, but the absence of detectable plasma levels suggests that the effects on a nursing infant are probably nil.

LOMEFLOXACIN

Anti-infective (Quinolone)

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Although no reports describing the use of lomefloxacin during human gestation have been located, the available evidence for other members of this class suggests that the risk of major malformations is low. However, a causal relationship with birth defects cannot be excluded (see Ciprofloxacin or Ofloxacin), although the lack of a pattern among the anomalies is reassuring. Because of these concerns and the available animal data, the use of lomefloxacin should be limited in pregnancy, especially during the 1st trimester. A 1993 review on the safety of fluoroquinolones concluded that these antibacterials should be avoided during pregnancy because of the difficulty in extrapolating animal mutagenicity results to humans and because interpretation of this toxicity is still controversial (1). The authors of this review were not convinced that fluoroquinolone-induced fetal cartilage damage and subsequent arthropathies were a major concern, even though this effect had been demonstrated in several animal species after administration to both pregnant and immature animals and in occasional human case reports involving children. Others have also concluded that fluoroquinolones should be considered contraindicated in pregnancy, because safer alternatives are usually available (2).

FETAL RISK SUMMARY

Lomefloxacin is an oral, synthetic, broad-spectrum antibacterial agent. As a fluoroquinolone, it is in the same class of agents as ciprofloxacin, enoxacin, levofloxacin, norfloxacin, ofloxacin, and sparfloxacin. Nalidixic acid is also a quinolone drug.

Reproductive studies have been conducted in rats, rabbits, and monkeys. No evidence of impaired fertility, in male or female rats, or fetal harm in pregnant

rats was observed at doses up to 8 times the recommended human dose (RHD) based on BSA (RHD-BSA) (34 times the RHD based on body weight [RHD-BW]). In rabbits, maternal and fetal toxicity was evident at a dose twice the RHD-BSA, consisting of reduced placental weight and variations of the coccygeal vertebrae. Pregnant monkeys dosed at 3–6 times the RHD-BSA (6–12 times the RHD-BW) had an increased incidence of fetal loss, but no teratogenic effects were observed. As with other quinolones, multiple doses of lomefloxacin produced permanent lesions and erosion of cartilage in weight-bearing joints, leading to lameness in immature rats and dogs (3).

It is not known whether lomefloxacin crosses the placenta to the human fetus, but the molecular weight (about 388) is low enough that transfer to the fetus should be expected. No reports describing the use of the antibacterial in human gestation have been located.

In a prospective follow-up study conducted by the European Network of Teratology Information Services (ENTIS), data on 549 pregnancies exposed to fluoroquinolones (none to lomefloxacin) were described in a 1996 reference (2). Data on another 116 prospective and 25 retrospective pregnancy exposures to the antibacterials were also included. Of the 666 cases with known outcome, 32 (4.8%) of the embryos, fetuses, or newborns had congenital malformations. From previous epidemiologic data, the authors concluded that the 4.8% frequency of malformations did not exceed the background rate (2). Finally, 25 retrospective reports of infants with anomalies, who had been exposed in utero to fluoroquinolones, were analyzed, but no specific patterns of major congenital malformations were detected.

The authors of the above study concluded that pregnancy exposure to quinolones was not an indication for termination, but that this class of antibacterial agents should still be considered contraindicated in pregnant women. Moreover, this study did not address the issue of cartilage damage from quinolone exposure and the authors recognized the need for follow-up studies of this potential toxicity in children exposed in utero. Because of their own and previously published findings, they further recommended that the focus of future studies should be on malformations involving the abdominal wall and urogenital system and on limb reduction defects (2).

BREASTFEEDING SUMMARY

When first marketed, the administration of lomefloxacin during breastfeeding was not recommended because of the potential for arthropathy and other serious toxicity in the nursing infant, such as phototoxicity and the eventual

development of squamous cell carcinoma of the skin that had been observed in mice (3).

No reports describing the use of lomefloxacin in human lactation have been located. Other quinolones are excreted into milk and, because of its relatively low molecular weight (about 388), the passage of lomefloxacin into milk should be expected. The American Academy of Pediatrics classifies ciprofloxacin and ofloxacin as compatible with breastfeeding (see Ciprofloxacin and Ofloxacin).

LOMITAPIDE

Antilipemic Agent (Miscellaneous)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest High Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of lomitapide in human pregnancy have been located. The animal data suggest risk, but the absence of human pregnancy experience prevents a more complete assessment of the embryo–fetal risk. The manufacturer classifies the drug as contraindicated because of the toxicity observed in three animal species.

FETAL RISK SUMMARY

Lomitapide is an oral synthetic lipid-lowering agent that directly binds and inhibits microsomal triglyceride transfer protein. It is indicated as an adjunct to a low-fat diet and other lipid-lowering treatments, including low-density lipoprotein (LDL) apheresis where available, to reduce LDL cholesterol, total cholesterol, apolipoprotein B, and non-high-density lipoprotein cholesterol in patients with homozygous familial hypercholesterolemia. It is extensively metabolized by the liver to inactive metabolites. The drug is highly (99.8%) bound to plasma protein and the mean terminal half-life is about 40 hours (1).

Reproduction studies have been conducted in rats, rabbits, and ferrets. In rats, oral doses that were ≥ 2 times the human exposure at the maximum recommended human dose of 60 mg based on AUC (MRHD-AUC) given from gestation day 6 through organogenesis caused fetal malformations. The defects included umbilical hernia, gastroschisis, imperforate anus, alterations in heart shape and size, limb malrotations, skeletal malformations of the tail, and delayed ossification of cranial, vertebral and pelvic bones. When given from gestation day 7 through termination of nursing on lactation day 20, systemic exposures that were equivalent to the human exposure at the MRND-AUC were associated with malformations. Increased pup mortality occurred at 4 times the

MRHD-AUC. In rabbits, exposures up to 3 times the MRHD based on BSA (MRHD-BSA) from gestational day 6 through organogenesis were not associated with adverse effects. However, exposures that were ≥ 6 times the MRHD-BSA resulted in embryo–fetal death. In ferrets given the drug from gestation day 12 through organogenesis, exposures that were < 1 –5 times the human exposure at the MRHD-AUC were associated with maternal toxicity and fetal malformations. Defects included umbilical hernia, medially rotated or short limbs, absent or fused digits on paws, cleft palate, open eye lids, low-set ears, and kinked tail (1).

In a 2-year dietary carcinogenicity study in mice, lomitapide caused significant increases of liver adenomas and small intestine carcinomas in males and combined adenomas and carcinomas in females. In 2-year studies in rats, there were no statistically significant drug-related increases in tumor incidences. Various assays for mutagenicity were negative. The drug had no effects on fertility in male and female rats at exposures up to 4–5 times the MRHD-AUC (1).

It is not known if lomitapide crosses the human placenta. The molecular weight (about 790) and high plasma protein binding suggest that exposure of the embryo–fetus will be limited, but the long terminal half-life might allow the drug to cross.

BREASTFEEDING SUMMARY

No reports describing the use of lomitapide during human lactation have been located. The molecular weight (about 790) and high (99.8%) plasma protein binding suggest that excretion of the drug into breast milk will be limited, but the long terminal half-life (about 40 hours) might allow excretion of the drug into milk. The effect of the exposure on a nursing infant is unknown. The potential for tumorigenicity in a mouse study suggests that the drug should not be used during breastfeeding. However, if a mother receiving the drug chooses to breastfeed, the infant should be monitored for the most common (incidence $\geq 28\%$) adverse effect seen in adults. These effects include diarrhea, nausea, vomiting, dyspepsia, and abdominal pain (1).

LOPERAMIDE

Antidiarrheal

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

The animal data suggest low risk, but the human pregnancy experience is too limited to allow a more complete assessment of embryo/fetal risk. Nevertheless, an abstract suggests that the human risk also is low.

FETAL RISK SUMMARY

Loperamide is a synthetic opioid analog that is used for the treatment of diarrhea. It is available without a prescription. No published reports linking the use of loperamide with congenital defects have been located.

Reproduction studies with rats and rabbits at doses up to 30 times the human dose have revealed no evidence of impaired fertility, teratogenicity, or other fetal harm (1).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 108 newborns had been exposed to loperamide during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Six (5.6%) major birth defects were observed (five expected), three of which were cardiovascular defects (one expected). No anomalies were observed in five other defect categories (oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available. The number of cardiovascular defects suggests a possible association, but other factors, including the mother's disease, concurrent drug use, and chance, may be involved.

In a 1999 abstract, the pregnancy outcomes of 89 women exposed to loperamide in the 1st trimester were compared with matched controls (2). There were no significant differences between the groups in terms of major and minor malformations, spontaneous abortions, elective abortions, preterm

delivery, and birth weights. However, in 21 mothers who took loperamide throughout gestation, birth weights tended to be lower (200 g) (ns) (2).

BREASTFEEDING SUMMARY

No reports describing the use of loperamide during lactation have been located. However, one study investigated loperamide oxide, a pharmacologically inactive prodrug that is reduced to loperamide as it progresses through the intestinal tract, during lactation (3). Six women in the immediate postpartum period, who were not nursing, were given two 4-mg oral doses of loperamide oxide 12 hours apart. Simultaneous plasma and milk samples were collected 12 hours after the first dose, and 6 and 24 hours after the second dose. Small amounts of loperamide oxide were measured in some of the plasma samples, but the mean loperamide oxide milk concentrations were <0.10 ng/mL (detection limit) at each sampling time. Mean loperamide milk concentrations for the three samples were 0.18, 0.27, and 0.19 ng/mL, respectively, corresponding to milk:plasma ratios of 0.50, 0.37, and 0.35, respectively (3). The American Academy of Pediatrics classifies loperamide as compatible with breastfeeding (4).

LOPINAVIR

Antiviral

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo/Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

The human pregnancy experience with lopinavir, always in combination with ritonavir and other antiretroviral agents, suggests that the embryo–fetal risk is low. The animal data are suggestive of moderate risk because the exposure for lopinavir was less than the human therapeutic exposure. If indicated, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Lopinavir, an inhibitor of HIV protease, prevents cleavage of the Gag-Pol polyproteins, resulting in the production of immature, noninfectious viral particles. The agent is only available in a fixed combination (200 mg lopinavir/50 mg ritonavir per capsule; 80 mg lopinavir/20 mg ritonavir per mL oral solution). Ritonavir is a potent inhibitor of CYP3A isozyme from the hepatic cytochrome P450 system that is responsible for the metabolism of lopinavir, thereby increasing the plasma levels of lopinavir. The plasma levels of ritonavir are very low; therefore, the antiviral activity of the combination is due to lopinavir. Plasma protein binding of lopinavir is high (98%–99%), primarily by α_1 -acid glycoprotein, but some is bound to albumin. The average half-life of lopinavir over a 12-hour dosing interval is 5–6 hours (1).

Reproduction studies have been conducted in rats and rabbits. In rats, doses producing systemic exposures that were approximately 0.7 (lopinavir)/1.8 (ritonavir) times the human exposure obtained with the recommended dose of 400/100 mg twice daily based on AUC (HE) resulted in embryonic and fetal toxicity (early resorption, decreased fetal viability and body weight, increased incidences of skeletal variations and skeletal ossification delays). This dose was maternal toxic. Developmental toxicity (decreased pup survival) also was observed in a perinatal and postnatal rat study at doses producing exposures

equal to or greater than about 0.3 (lopinavir)/0.7 (ritonavir) times the HE. In rabbits, maternal toxic doses (0.6 [lopinavir]/1.0 [ritonavir]) did not result in embryonic or fetal development toxicity (1).

Consistent with the molecular weight (about 629) and lipid solubility, lopinavir crosses the human placenta. A 2006 study using the ex vivo human cotyledon perfusion model found that placental transfer of lopinavir (combined with ritonavir) was compatible with passive diffusion, even in the presence of physiologic concentrations of human albumin (2). The amount entering the fetal compartment was well above the 50% inhibitory concentration (2). In an earlier study, the cord:maternal blood ratio 12.25 hours after lopinavir (533 mg twice daily in combination with lamivudine and abacavir) in a woman delivering at term (38 weeks) was <0.1 (<250 ng/mL/3105 ng/mL) (3,4).

The Antiretroviral Pregnancy Registry reported, for January 1989 through July 2009, prospective data (reported before the outcomes were known) involving 4702 live births that had been exposed during the 1st trimester to one or more antiretroviral agents (5). Congenital defects were noted in 134, a prevalence of 2.8% (95% confidence interval [CI] 2.4–3.4). In the 6100 live births with earliest exposure in the 2nd/3rd trimesters, there were 153 infants with defects (2.5%, 95% CI 2.1–2.9). The prevalence rates for the two periods did not differ significantly. There were 288 infants with birth defects among 10,803 live births with exposure anytime during pregnancy (2.7%, 95% CI 2.4–3.0). The prevalence rate did not differ significantly from the rate expected in a nonexposed population. There were 1794 outcomes exposed to lopinavir (526 in the 1st trimester and 1268 in the 2nd/3rd trimesters) in combination with other antiretroviral agents. There were 39 birth defects (9 in the 1st trimester and 30 in the 2nd/3rd trimesters). In reviewing the birth defects of prospective and retrospective (pregnancies reported after the outcomes were known) registered cases, the Registry concluded that, except for isolated cases of neural tube defects with efavirenz exposure in retrospective reports, there was no other pattern of anomalies (isolated or syndromic) (5). (See Lamivudine for required statement.)

In 1998, a public health advisory was issued by the FDA on the association between protease inhibitors and diabetes mellitus (6). Because pregnancy is a risk factor for hyperglycemia, there was concern that these antiretroviral agents would exacerbate this risk. The manufacturer's product information also notes the potential risk for new-onset diabetes, exacerbation of preexisting diabetes, and hyperglycemia in HIV-infected patients receiving protease inhibitor therapy (1). An abstract published in 2000 described the results of a study involving

34 pregnant women treated with protease inhibitors compared with 41 controls that evaluated the association with diabetes (7). No association between protease inhibitors and an increased incidence of gestational diabetes was found.

Two reviews, one in 1996 and the other in 1997, concluded that all women currently receiving antiretroviral therapy should continue to receive therapy during pregnancy and that treatment of the mother with monotherapy should be considered inadequate therapy (8,9). The same conclusion was reached in a 2003 review with the added admonishment that therapy must be continuous to prevent emergence of resistant viral strains (10). In 2009, the updated U.S. Department of Health and Human Services guidelines for the use of antiretroviral agents in HIV type 1 (HIV-1)-infected patients continued the recommendation that therapy, with the exception of efavirenz, should be continued during pregnancy (11). If indicated, therefore, protease inhibitors, including lopinavir, should not be withheld in pregnancy because the expected benefit to the HIV-positive mother outweighs the unknown risk to the fetus. Pregnant women taking protease inhibitors should be monitored for hyperglycemia. Updated guidelines for the use of antiretroviral drugs to reduce perinatal HIV-1 transmission also were released in 2010 (12). Women receiving antiretroviral therapy during pregnancy should continue the therapy but, regardless of the regimen, zidovudine administration is recommended during the intrapartum period to prevent vertical transmission of HIV to the newborn (12).

BREASTFEEDING SUMMARY

No reports have been located that describe the use of the combination product, lopinavir/ritonavir, during human lactation. The molecular weights of lopinavir (about 629) and ritonavir (about 721), combined with their lipid solubility, suggest that the drugs will be excreted into human breast milk, although the extensive plasma protein binding (98%–99%) should limit this excretion. The effects of this exposure on a nursing infant are unknown.

However, reports on the use of lopinavir/ritonavir during lactation are unlikely because the combination is indicated in the treatment of patients with HIV. HIV-1 is transmitted in milk, and in developed countries, breastfeeding is not recommended (8,9,11,13–16). In developing countries, breastfeeding is undertaken, despite the risk, because there are no affordable milk substitutes available.

LORACARBEF

[Withdrawn from the market. See 9th edition.]

LORATADINE

Antihistamine

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

No evidence of increased teratogenicity has been found in animals or humans. The human pregnancy experience is adequate to show that the drug is not a major human teratogen. Moreover, a significant increase in loratadine-induced congenital malformations would be unusual, as no other antihistamine has been shown to be a major human teratogen. If an oral antihistamine agent is required during pregnancy, first-generation agents such as chlorpheniramine or tripeleennamine should be considered. Previous reviews published before the availability of the studies discussed below concluded that loratadine and cetirizine were acceptable alternatives, except during the 1st trimester, if a first-generation drug was not tolerated (1–3).

FETAL RISK SUMMARY

Loratadine, a second-generation histamine H₁-receptor antagonist, is used for the treatment of symptoms related to seasonal allergic rhinitis. Studies with rats and rabbits with oral doses up to 75 and 150 times, respectively, the maximum recommended human daily oral dose based on BSA found no evidence of teratogenicity (4). Treatment of pregnant rats from gestational day 7 through postpartum day 4 with doses up to 26 times the human clinical exposure revealed no evidence of antiandrogenic activity, as demonstrated by a lack of effect on androgen-dependent development in male offspring (5).

It is not known if loratadine crosses the human placenta. The molecular weight (about 383) is low enough that passage to the fetus should be expected.

The FDA has received six reports of adverse outcomes following exposure

during pregnancy, including two cases of cleft palate, and one case each of microtia and microphthalmia, deafness, tricuspid dysplasia, and diaphragmatic hernia (F. Rosa, personal communication, FDA, 1996). A relationship, if any, between loratadine and the outcomes cannot be determined from these data.

A 1998 noninterventional, observational cohort study described the outcomes of pregnancies in women who had been prescribed one or more of 34 newly marketed drugs by general practitioners in England (6). Data were obtained by questionnaires sent to the prescribing physicians one month after the expected or possible date of delivery. In 831 (78%) of the pregnancies, a newly marketed drug was thought to have been taken during the 1st trimester with birth defects noted in 14 (2.5%) singleton births of the 557 newborns (10 sets of twins). In addition, two birth defects were observed in aborted fetuses. However, few of the aborted fetuses were examined. Loratadine was taken during the 1st trimester in 18 pregnancies. The outcomes of these pregnancies included 2 elective abortions and 16 normal, term infants (6).

A 2002 study found no increased risk of teratogenicity or other pregnancy or newborn complications for antihistamines when used in early pregnancy for the treatment of nausea and vomiting (N = 12,394) and allergy (N = 5041) (7). In the study, 1769 women used loratadine.

A collaborative 2003 report gathered data from four teratology information services (Canada, Israel, Italy, and Brazil) pertaining to 1st trimester loratadine exposures in 161 pregnancies (8). The outcomes of these pregnancies were compared with 161 nonexposed controls. The average daily dose of loratadine was 11.3 mg. The live birth rate, gestational age at delivery, and birth weight in the two groups were similar. There were five congenital malformations (kidney defect, aortic valve stenosis, unspecified chromosomal abnormalities, bilateral inguinal hernia, and congenital hip dislocation) in the loratadine group and six in the controls. The sample size had an 80% power to detect a 3.5-fold increase in the overall rate of defects (8).

In 2004, the CDC summarized their analysis of data from The National Birth Defects Prevention Study that examined the association between loratadine and hypospadias (9). The study population consisted of 563 male infants with hypospadias and 1444 male infants with no major birth defects. Cases and controls were born between October 1997 and June 2001. In the cases, 46 (8.2%) had multiple congenital malformations that were not recognized as phenotypes, and in 517 (91.8%) hypospadias was an isolated defect. Exposure to loratadine occurred in 11 cases and 22 controls (adjusted odds ratio [OR] 0.96, 95% confidence interval [CI] 0.41–2.22). For nonsedating (including

loratadine) and sedating antihistamines, the OR (and 95% CI) were 0.95 (0.48–1.89) and 1.02 (0.68–1.53), respectively. Thus, neither type of antihistamine was associated with hypospadias (9).

BREASTFEEDING SUMMARY

Loratadine and its metabolite, descarboethoxyloratadine, are excreted into human milk (4,10). Six lactating women were given a single 40-mg dose (10). The peak milk concentration, 29.2 ng/mL, occurred within 2 hours of the dose, whereas the peak plasma level, 30.5 ng/mL, was measured 1 hour after the dose. The mean milk:plasma area under the concentration curve (AUC) ratios for the parent compound and the active metabolite, measured during 48 hours, were 1.17 and 0.85, respectively (4,10). During 48 hours, the mean amounts of loratadine and metabolite recovered from the milk were 4.2 mcg (0.010% of the dose) and 6.0 mcg (equivalent to 7.5 mcg of loratadine; 0.019% of the dose), respectively. A 4-kg infant ingesting this milk would have received a dose equivalent to 0.46% of the mother's dose on an mg/kg basis (10). Based on this estimate, and the fact that the dose used in the study was four times the current recommended dose, there is probably little clinical risk to a nursing infant whose mother was taking 10 mg of loratadine per day. The American Academy of Pediatrics classifies loratadine as compatible with breastfeeding (11).

LORAZEPAM

Sedative

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in the 1st and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible* *Potential toxicity if combined with other CNS depressants

PREGNANCY SUMMARY

Lorazepam is a benzodiazepine indicated for the treatment of status epilepticus and as a preanesthetic sedative. One report found a significant association with anal atresia. When used close to delivery, “floppy infant” syndrome has been reported. The long-term effects of in utero exposure on neurobehavior, especially when the exposure occurs in the latter half of pregnancy, have not been studied but are of concern.

FETAL RISK SUMMARY

Reproduction studies with lorazepam have been conducted in mice, rats, and two strains of rabbits. Occasional, non-dose-related malformations (reduction of tarsals, tibia, metatarsals, malrotated limbs, gastroschisis, malformed skull, and microphthalmia) were observed in rabbits, but these defects have also randomly occurred in controls. Fetal resorptions and increased fetal loss occurred in rabbits at oral (40 mg/kg) and IV (4 mg/kg) doses and higher (1).

Lorazepam crosses the placenta, achieving cord levels similar to maternal serum concentrations (2–5). Placental transfer is slower than that of diazepam, but high IV doses may produce the “floppy infant” syndrome (3). (See Diazepam for a description of this syndrome.)

A case reported in 1996 described an otherwise healthy male infant, exposed throughout gestation to lorazepam (7.5–12.5 mg/day) and clozapine (200–300 mg/day), who developed transient, mild floppy infant syndrome after delivery at 37 weeks’ gestation (6). The mother had taken the combination therapy for the treatment of schizophrenia. The hypotonia, attributed to lorazepam because of the absence of such reports in pregnancies exposed to clozapine alone, resolved 5 days after birth.

An abstract published in 1999 found an association between lorazepam and anal atresia (7). Using data from a French pregnancy registry, the investigators reported that among infants exposed to benzodiazepines 5 of 6 cases of anal atresia were exposed to lorazepam ($p = 0.01$).

Lorazepam has been used in labor to potentiate the effects of narcotic analgesics (8). Although not statistically significant, a higher incidence of respiratory depression occurred in the exposed newborn infants.

BREASTFEEDING SUMMARY

Lorazepam is excreted into breast milk in low concentrations (9,10). In one study, no effects on the nursing infant were reported (9), but the slight delay in establishing feeding was a cause for concern (11). Milk:plasma ratios in four women who had received 3.5 mg orally of lorazepam 4 hours earlier ranged from 0.15 to 0.26 (9). The mean milk concentration was 8.5 ng/mL. In another study, 5 mg of oral lorazepam was given 1 hour before labor induction and the effects on feeding behavior were measured in the newborn infants (12). During the first 48 hours, no significant effect was observed on volume of milk consumed or duration of feeding.

The effects of exposure to benzodiazepines during breastfeeding were reported in a 2012 study (13). In a 15-month period spanning 2010–2011, 296 women called the Motherisk Program in Toronto, Ontario, seeking advice on the use of these drugs during lactation and 124 consented to the study. The most commonly used benzodiazepines were lorazepam (52%), clonazepam (18%), and midazolam (15%). Neonatal sedation was reported in only two infants. Lorazepam was not used by either mother. There was no significant difference between the characteristics of these 2 and the 122 that reported no sedation in terms of maternal age, gestational age at birth, daily amount of time nursing, amount of time infant slept each day, and the benzodiazepine dose (mg/kg/day). The only difference was in the number of CNS depressants that the mothers were taking: 3.5 vs. 1.7 ($p = 0.0056$). The investigators concluded that their results supported the recommendation that the use benzodiazepines was not a reason to avoid breastfeeding (13).

The American Academy of Pediatrics classifies the effects of lorazepam on the nursing infant as unknown but may be of concern if exposure is prolonged (14).

LORCASERIN

Anorexiant

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of lorcaserin in human pregnancy have been located. The animal reproduction data suggest moderate risk, but the absence of human pregnancy experience prevents a more complete assessment of embryo–fetal risk. However, the manufacturer classifies the drug as contraindicated in pregnancy because weight loss offers no potential benefit to a pregnant woman and may result in fetal harm (1).

FETAL RISK SUMMARY

Lorcaserin is an oral selective agonist of serotonin 2C receptors that are located in the hypothalamus. It is indicated as an adjunct to a reduced-calorie diet and increased physical activity for chronic weight management in adult patients with an initial body mass index (BMI) of 30 kg/m² or greater (obese) or 27 kg/m² or greater (overweight) in the presence of at least one weight-related comorbid condition (e.g., hypertension, dyslipidemia, and type 2 diabetes). Lorcaserin is extensively metabolized to inactive metabolites. The drug is moderately (about 70%) bound to plasma proteins and has a plasma half-life of about 11 hours (1).

Reproduction studies have been conducted in rats and rabbits. In these species, plasma exposures during organogenesis that were 44 and 19 times, respectively, the human exposure (HE) revealed no evidence of teratogenicity or embryoletality. In a separate study, rats were given the drug from gestation through postnatal day 21 with doses resulting in exposures up to about 44 times the HE. The highest dose resulted in stillborns and lower pup viability, but all doses lowered pup body weight at birth, which persisted to adulthood. However, no developmental abnormalities or effects on reproductive performance in the offspring were observed at any dose (1).

Two-year carcinogenicity studies in mice were negative. In a similar study in rats, mammary adenocarcinoma and mammary fibroadenoma occurred in females. These findings may have been associated with drug-induced changes in prolactin homeostasis and their relevance to humans is unknown. In male rats, treatment-related neoplastic changes were noted in the subcutis (fibroadenoma, Schwannoma), the skin (squamous cell carcinoma), mammary gland, and the brain (astrocytoma). Lorcaserin was not mutagenic or genotoxic in multiple assays. No effects on fertility in male and female rats were observed (1).

It is not known if lorcaserin crosses the human placenta. The molecular weight (about 197 for the free base), moderate plasma protein binding, and the long plasma half-life suggest that the drug will cross to the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use of lorcaserin during human lactation have been located. The molecular weight (about 197 for the free base), moderate (about 70%) plasma protein binding, and the long (about 11 hours) plasma half-life suggest that the drug will be excreted into breast milk. The effect of the exposure on a nursing infant is unknown. The most common (>5%) adverse effects in nondiabetic patients were headache, dizziness, fatigue, nausea, dry mouth, and constipation (1). If a woman is receiving lorcaserin and chooses to nurse, her infant should be monitored for these adverse effects.

LOSARTAN

Antihypertensive

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in the 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The antihypertensive mechanisms of action of losartan and angiotensin-converting enzyme (ACE) inhibitors are very close. That is, the former selectively blocks the binding of angiotensin II to AT₁ receptors, whereas the latter prevents the formation of angiotensin II itself. Therefore, use of this drug during the 2nd and 3rd trimesters may cause teratogenicity and severe fetal and neonatal toxicity that is identical to that seen with ACE inhibitors (e.g., see Captopril or Enalapril). Fetal toxic effects may include anuria, oligohydramnios, fetal hypocalvaria, intrauterine growth restriction (IUGR), prematurity, and patent ductus arteriosus. Anuria-associated oligohydramnios may produce fetal limb contractures, craniofacial deformation, and pulmonary hypoplasia. Severe anuria and hypotension, which is resistant to both pressor agents and volume expansion, may occur in the newborn following in utero exposure to losartan. Newborn renal function and blood pressure should be closely monitored.

FETAL RISK SUMMARY

Losartan is a selective angiotensin II receptor blocker (ARB) that is used, either alone or in combination, with other antihypertensive agents, for the treatment of hypertension. Losartan, and its active metabolite, block the vasoconstrictor and aldosterone-secreting effects of angiotensin II by preventing angiotensin II from binding to AT₁ receptors.

Reproduction studies have been conducted in pregnant rats (1–3). At oral doses greater than three times the maximum recommended human dose of 100 mg based on BSA (MRHD), reduced body weight, delayed physical and behavioral development, mortality, and renal toxicity were observed in rat

fetuses and neonates (1–3). These adverse effects were attributed to exposure during late pregnancy (gestational days 15–20) and/or during lactation (1,2). The irreversible renal abnormalities in the newborn pups included dilatation of the renal pelvis, edema of the renal papilla, medial hypertrophy of intracortical arterioles, chronic renal inflammation, and irregular scarring of the renal parenchyma (2).

In fertility and reproductive performance studies, a significant decrease in fetal implants in rats was noted at a maternally toxic oral dose, approximately 24 times the MRHD. No effects on implants/pregnant female, percent postimplantation loss, or live pups/litter at parturition were observed at an oral dose approximately 12 times the MRHD (1–3).

It is not known if losartan or its active metabolite crosses the human placenta to the fetus. Because the molecular weight of losartan (about 461) is low enough, passage to the human fetus should be expected.

A postmarketing safety surveillance study of losartan, published in 1999, described the outcomes of four human pregnancies (4). Three of the pregnancies were exposed to the drug in the 1st trimester and the fourth pregnancy was diagnosed about 2 months after stopping the drug. In the first case, the woman became pregnant while taking losartan and the drug was discontinued at approximately 8 weeks' gestation. Because of worsening renal failure, dialysis was required during pregnancy. She delivered a growth-restricted infant at 29 weeks who died at 9 days of age. In the second case, losartan was stopped 6 weeks after the last menstrual period. The woman delivered prematurely at 30 weeks because of preeclampsia. The infant was reported to be doing well. The third pregnancy ended with a spontaneous abortion (no specific embryo data) at 6–8 weeks' gestation while the woman was receiving losartan. Finally, a spontaneous abortion (no specific embryo data) occurred at 6 weeks' gestation in a woman who had stopped losartan about 2 months before the pregnancy was diagnosed. Because of the timing of the exposures, none of the outcomes appear to be related to the use of losartan. They are probably a consequence of the women's severe hypertension (4).

In a 2001 case report, anhydramnios was diagnosed at 31 weeks' gestation in a 31-year-old woman with periarteritis nodosa (5). Hypertension had developed at 17 weeks' gestation and losartan, 50 mg/day, had been started. Therapy was changed to methyldopa (750 mg/day), but 2 days later the woman noticed no fetal movements. Ultrasound confirmed intrauterine fetal death and she delivered a stillborn 1592-g male infant the next day. The infant

had facial and limb deformities characteristic of oligohydramnios. At autopsy, pulmonary hypoplasia and hypoplastic skull bones with wide sutures were observed, but no other apparent abnormalities, including the kidneys and urinary tract, were noted. The anhydramnios and resulting fatal fetal abnormalities were attributed to losartan (5).

A 42-year-old woman was treated with losartan (dose not specified), hydrochlorothiazide, felodipine, and metoprolol throughout gestation (6). Oligohydramnios was diagnosed at 33 weeks' gestation. A 2180-g female infant was born at 36 weeks' with limb deformities (varus of left foot, right clubfoot, and fixed external rotation of the right knee). Potter's facies, pulmonary hypertension, and anuria were present and the infant died of respiratory distress on day 4. Autopsy revealed a patent ductus arteriosus and abnormal kidneys (6).

In another case, a 35-year-old woman with hypertension was treated with losartan (50 mg/day) throughout gestation (7). An examination at 22 weeks' was normal, but oligohydramnios was noted at 34 weeks'. Losartan was stopped and an amnioinfusion was given, but the woman developed signs of infection and a hypotonic male infant (weight not given) was delivered. Apgar scores were 1, 4, and 4 at 1, 5, and 10 minutes, respectively. The infant had persistent hypotension, anuria, and multivisceral failure and died on day 4 (7).

In an unusual case, a 45-year-old woman with type 2 diabetes and chronic hypertension developed anhydramnios (amniotic fluid index [AFI] 0) at about 28 weeks' gestation while receiving losartan (8). Losartan was discontinued and 4 days later, a transabdominal amnioinfusion produced an AFI of 6. Normal amniotic fluid levels were maintained for the remainder of the pregnancy. At 32 weeks', ultrasound revealed a thrombus in the fetal vena cava at the level of the right renal vein. Labor was induced at 38 weeks' to deliver 2960-g male infant with Apgar scores of 8 and 9 at 1 and 5 minutes, respectively. Further ultrasound studies revealed an inclusive inferior vena cava thrombus with up to three collateral vessels providing flow around the clot. At 10 days of age, additional examination of the asymptomatic infant revealed a single dominant collateral vessel (8).

A 41-year-old woman with hypertension was treated throughout gestation with losartan (9). At 29 weeks' gestation, anhydramnios was detected. A cesarean section delivered a 1223-g (50th–60th percentile) female infant was delivered with Apgar scores of 2, 5, and 7 at 1, 5, and 10 minutes, respectively. The flaccid newborn had apnea, bradycardia, and was cyanotic. The neonatal course was complicated by marked renal impairment,

hypotension, respiratory depression, joint contractures, and a large anterior fontanelle with widely separated sutures. Follow-up at 7 months of age revealed a growth-restricted infant (≤ 5 th percentile) and renal disease, including apparent renal tubular acidosis (9).

A brief teratogen update in 2005 summarized the adverse outcomes of pregnancies exposed to losartan and three other similar agents (10). Exposure in the second half of pregnancy resulted in fetal toxicity that was very similar to that observed with ACE inhibitors. Although the number of reported 1st trimester exposures was limited, there was no suggestion of an increased risk of major congenital defects (10).

A 2009 report described two cases of losartan exposure before and during pregnancy (11). The drug was used to treat hypertension and was stopped at 8 and 23 weeks' gestation, respectively. The pregnancy outcome in the first patient was a healthy, 3.730-kg female infant born at 39 weeks. In the second woman, pregnancy woman was diagnosed at 25 weeks' and losartan was stopped, but oligohydramnios was noted on ultrasound. A repeat ultrasound 1 week later showed worsening oligohydramnios (AFI 1.5). At 27 weeks', she spontaneously gave birth to a 1.040-kg female infant with Apgar scores of 9 and 9. In addition to the complications of prematurity, impaired renal function was noted but spontaneously resolved by day 6 of age. A renal ultrasound on day 9 was normal. The infant was discharged home on day 52, at which time a small umbilical hernia was discovered. A neurological examination revealed slightly increased muscle tone and mild tremor (11).

A 2012 review of the use of ACE inhibitors and ARBs in the 1st trimester concluded that there may be an elevated teratogenic risk, but the risk appeared to be related to other factors (12). The factors, which typically coexist with hypertension in pregnancy, included diabetes, advanced maternal age, and obesity.

BREASTFEEDING SUMMARY

No reports describing the use of losartan during human lactation have been located. Because the molecular weight (about 461) of losartan is low enough, excretion into human breast milk should be expected. The effects of this exposure on a nursing infant are unknown. The American Academy of Pediatrics, however, classifies ACE inhibitors, a closely related group of antihypertensive agents, as compatible with breastfeeding (see Captopril or Enalapril).

LOVASTATIN

Antilipemic Agent

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Infants with malformations following in utero exposure to lovastatin have been described in published and unpublished reports. A causal relationship between the drug and some of the defects is possible, but some might have occurred by chance. Additional data are needed. Because there is apparently no maternal benefit for the use of lovastatin during gestation and because of the human cases and the teratogenicity observed in one animal species, the drug should be avoided during pregnancy.

FETAL RISK SUMMARY

Lovastatin, a 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitor (“statins”) that is lipophilic, is used to lower elevated levels of cholesterol. It has the same mechanism of action as other available drugs in this class, atorvastatin, fluvastatin, pitavastatin, pravastatin, rosuvastatin, and simvastatin (cerivastatin was withdrawn from the market in 2001).

The drug is teratogenic in mice and rats, producing decreased fetal weight and skeletal malformations in exposed fetuses, at doses of 800 mg/kg/day (40 and 80 times the maximum recommended human dose based on BSA [MRHD], respectively) (1,2). However, the skeletal malformations were thought to be due to maternal toxicity that involved gastric lesions and not due to the drug (3). No teratogenic effects were observed in rabbits administered doses ≤ 15 mg/kg/day (3 times the MRHD), the maximum tolerated dose (1,2).

A surveillance study of lovastatin and simvastatin exposures during pregnancy, conducted by the manufacturer, was reported in 1996 (2) and updated in 2005 (4). Of the 477 reports, all involving 1st trimester exposure, 386 were prospective (67 lovastatin, 319 simvastatin) and 91 were retrospective (38 lovastatin, 53 simvastatin). The pregnancy outcomes were known for 225 (58%) of the prospective reports. There were congenital defects

in five liveborn and one stillborn, all involving simvastatin. (See Simvastatin.) Other outcomes were 18 spontaneous abortions (SABs), 49 elective abortions (EABs), 4 fetal deaths, and 148 live births without defects. All of the outcomes, with the exception of fetal deaths, were similar to the population background rate. Although the number of fetal deaths was increased, there was no specific pattern to suggest a common cause. One death involved a nuchal cord and another was a trisomy 18. No congenital defects were reported in the SABs or EABs (4).

There were 13 cases of congenital defects in retrospective reports; 7 involving lovastatin and 6 with simvastatin (4). The details of the congenital defects after exposure to lovastatin (daily dose and exposure in weeks from last menstrual period) were as follows:

- (a) atrial and ventricular septal defect, aortic hypoplasia, infant died on day 32 (40 mg, 0–5 weeks)
- (b) features of VATER association with other abnormalities, mother also took dextroamphetamine at the same time (10 mg, 6–11 weeks)
- (c) spina bifida, EAB (20 mg, 1st trimester)
- (d) rudimentary right thumb, skull defects (40 mg, 0–4 weeks)
- (e) “severe deformity” (dose and exposure not reported)
- (f) open neural tube defect, duplication of spinal cord, cleft palate, EAB (20 mg, 0–18 weeks)
- (g) deformed right ear, no auditory canal (microtia) (dose not reported, 0–8 weeks)

The case involving the VATER association is also described below. There was no specific patterns observed in the above reports (4).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 3 newborns had been exposed to lovastatin during the 1st trimester (F. Rosa, personal communication, FDA, 1993). One (33.3%) major birth defect was observed (none expected), a cardiovascular defect. Eight other exposures to lovastatin occurred after the 1st trimester without apparent fetal harm (5).

Three retrospective spontaneous reports of birth defects suspected of being associated with 1st trimester use of lovastatin have been received by the FDA (5). The anomalies described were aortic hypoplasia, ventricular septal defect with cerebral dysfunction, death (one case); anal atresia and renal dysplasia (one case); and short forearm, absent thumb, and thoracic scoliosis (one case).

A 1992 case report described the use of lovastatin in a human pregnancy (6). A woman was treated for 5 weeks with lovastatin and dextroamphetamine, starting approximately 6 weeks from her last menstrual period, for progressive weight gain and hypercholesterolemia. Therapy was discontinued when her pregnancy was diagnosed at 11 weeks' gestation. A female infant was delivered by cesarean section at 39 weeks' gestation. Gestational age was confirmed by an ultrasound examination at 21 weeks' gestation and the Dubowitz score at birth. The infant had a constellation of malformations termed the VATER association (vertebral anomalies, anal atresia, tracheoesophageal fistula with esophageal atresia, renal and radial dysplasias). Specific anomalies included an asymmetric chest, thoracic scoliosis, absent left thumb, foreshortened left forearm, left elbow contracture, fusion of the ribs on the left, butterfly vertebrae in the thoracic and lumbar spine, left radial aplasia, and a lower esophageal stricture. Chromosomal analysis was normal, and the family history was noncontributory (6). This case is also described above (see reference 2).

The cause of the defects in the above infant is unknown, but drug-induced teratogenicity cannot be excluded as in utero exposure to both drugs occurred during organogenesis. Experiments with mice and rabbits indicated that amphetamines are teratogenic, but the anomalies primarily involve the heart and CNS (7). Moreover, the use of amphetamines during human pregnancy for medical indications has not been found to present a significant risk to the fetus in terms of fetotoxicity or teratogenicity (see Amphetamines).

A 1995 abstract reported an extensive NTD in a fetus exposed during the 1st trimester to lovastatin (8). A causal relationship could not be established.

A 2004 report evaluated 20 cases of adverse pregnancy outcomes reported to the FDA after exposures to statins (9). The cases were among 178 cases of 1st trimester pregnancy exposure to cholesterol-lowering statin drugs reported to the FDA. There were 52 cases suitable for evaluation after exclusion for spontaneous abortions, elective abortions, pregnancy loss due to maternal diseases, fetal genetic disorders, transient neonatal disorders, or loss to follow-up. In the 52 cases, there were 20 reports of malformation as follows (drug, dose, and exposure time in weeks after last menstrual period shown in parentheses):

CNS

- (a) Holoprosencephaly (cerivastatin, 0.25 mg/day, 0–8 weeks)
- (b) Holoprosencephaly (see reference 10) (defective septum separating lateral cerebral ventricles), atrial septal defect, aortic hypoplasia, death

- at 1 month of age (lovastatin, 40 mg/day, 0–7 weeks)
- (c) Aqueductal stenosis with hydrocephalus, limb deficiency (right banded, atretic thumb) (lovastatin, 40 mg/day, 0–4.5 weeks)
- (d) NTD, myelocoele, duplication of spinal cord, cerebellar herniation with hydrocephalus, apparent agenesis of palate (lovastatin, 20 mg/day, 1st trimester)
- (e) spina bifida, right arm abnormality (mother also type 1 diabetic) (atorvastatin, unknown dose, until pregnancy recognized)

Limb deficiency

- (a) same as c above
- (b) right leg fibula and tibia 9% shorter than left side, agenesis of one tarsal bone, right foot 16% shorter than left (reported at 4 years of age) (simvastatin, 20 mg/day, 0–6 weeks)
- (c) left leg femur 16% shorter than right, foot with aplasia of metatarsals and phalanges 3, 4, and 5, additional VACTERL defects—left renal dysplasia, reversed laterality of aorta, disorganized lumbosacral vertebrae, single umbilical artery, additional findings—clitoral hypertrophy, vaginal and uterine agenesis (mother also took drug similar to progesterone 10 days/month, 0–13 weeks) (simvastatin, 10 mg/day, 0–13 weeks)
- (d) left arm aplasia of radius and thumb, shortened ulna, additional VACTERL defects—left arthrogryposis, thoracic scoliosis, fusion of ribs on left, butterfly vertebrae in thoracic and lumbar region, esophageal stricture, anal atresia, renal dysplasia, additional findings—hemihypertrophy of entire left side, craniofacial anomalies (including asymmetric ears, ptosis of eyelids, high arched palate), torticollis (mother also took dextroamphetamine, 6–11 weeks) (lovastatin, 10 mg/day, 6–11 weeks)
- (e) limb reduction deficiency, transverse deficiency of otherwise normal radius and ulna superior to wrist structures, with aplasia of all distal structures (atorvastatin, 10 mg/day, 0–9 weeks) (9)

The other 11 cases of malformations were simvastatin: cleft lip with intrauterine growth restriction; cleft lip; polydactyly; duodenal atresia; hypospadias; clubfoot; and unspecified major abnormalities; atorvastatin: cleft palate; esophageal atresia; lovastatin: microtia with absent auditory canal and severe unspecified deformity (9). All of the 20 defects involved a lipophilic statin (i.e., atorvastatin, cerivastatin, lovastatin, and simvastatin). There were no

malformations in the 14 cases of exposure to pravastatin, a hydrophilic agent with low tissue penetration that is not related to reproductive toxicity in animals (see Pravastatin). Because of the voluntary nature of the reports to the FDA, the authors thought that the reports were likely to be biased toward severe outcomes. However, the nature of some of the CNS and limb deficiency malformations (i.e., primarily the cases of holoprosencephaly and VACTERL association) might be consistent with the inhibition of cholesterol biosynthesis (9,10).

In 2005, the authors of the above study reexamined the clinical report of the case listed as holoprosencephaly (CNS, case b) and discovered a coding error (11). The infant had a “ventricular septal defect,” not a “defective septum separating lateral cerebral ventricles,” thus reducing the number of lovastatin fetuses with midline CNS anomalies from three to two (11).

BREASTFEEDING SUMMARY

No human studies describing the use of lovastatin during lactation have been located. Because there is potential for adverse effects in the infant, the drug should not be used by women who are nursing.

LOXAPINE

Antipsychotic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

There is limited human pregnancy experience with loxapine. Animal reproductive data suggest risk. Because of the very limited human pregnancy experience with atypical antipsychotics, the American College of Obstetricians and Gynecologists does not recommend the routine use of these agents in pregnancy, but a risk–benefit assessment may indicate that such use is appropriate (1). Because loxapine is indicated for severe debilitating mental disease, the benefits to the mother appear to outweigh the unknown risk. A 1996 review on the management of psychiatric illness concluded that patients with histories of chronic psychosis represent a high-risk group (for both the mother and the fetus) and should be maintained on pharmacologic therapy before and during pregnancy (2). Folic acid 4 mg/day has been recommended for women taking atypical antipsychotics because they may have a higher risk of NTDs due to inadequate folate intake and obesity (3). Moreover, neonates exposed to antipsychotic drugs in the 3rd trimester are at risk of extrapyramidal and/or withdrawal symptoms (4).

FETAL RISK SUMMARY

Loxapine is an atypical antipsychotic that is indicated for the treatment of schizophrenia (4). The drug is extensively metabolized to apparently inactive metabolites. The manufacturer did not state the amount of plasma protein binding or the elimination half-life, but did state that loxapine was rapidly removed from the plasma and distributed in tissues (4). Loxapine belongs to the antipsychotic subclass of dibenzapine derivatives that includes asenapine, clozapine, olanzapine, and quetiapine.

In reproductive studies with rats, rabbits, and dogs, no embryotoxicity or teratogenicity was observed. However, with the exception of one rabbit study, the dose used was ≤ 2 times the maximum recommended human dose (presumably based on weight) (4,5). Renal papillary abnormalities were found in offspring of rats treated from mid-gestation with doses approximately equivalent to the usual human dose (4).

It is not known if loxapine crosses the human placenta. The molecular weight (about 328 for the free base) suggests that it will cross to the embryo–fetus.

A 2009 review cited information received from the manufacturer regarding the outcomes of three pregnancies exposed to loxapine (6). The retrospective outcomes were one baby with achondroplasia; one with multiple unspecified anomalies; and one infant, exposed throughout pregnancy, with tremors at 15 weeks of age (6). However, achondroplasia is a known autosomal dominant inheritance defect and is not related to drug exposure.

BREASTFEEDING SUMMARY

No reports describing the use of loxapine during human lactation have been located. The relatively low molecular weight of loxapine (about 328 for the free base) suggests that the drug will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown. The American Academy of Pediatrics classifies other antipsychotics (e.g., see Clozapine) as drugs whose effect on the nursing infant is unknown but may be of concern (7). Because of the very limited human experience with atypical antipsychotics, the American College of Obstetricians and Gynecologists does not recommend the routine use of these agents during lactation, but a risk–benefit assessment may indicate that such use is appropriate (1).

LUBIPROSTONE

Gastrointestinal Agent (Laxative)

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The human pregnancy experience with lubiprostone is limited. In animal reproduction studies, no teratogenicity was observed in two species. In a third species, the drug caused fetal loss, but the cause of the loss is unknown because systemic absorption of lubiprostone, at least in humans, is minimal, although one metabolite is absorbed systemically. The limited human data prevent a complete assessment of the embryo–fetal risk.

FETAL RISK SUMMARY

Lubiprostone, a locally acting chloride channel activator, increases intestinal fluid secretion that results in increased motility of the intestine, thereby increasing the passage of stool and alleviating symptoms associated with constipation (1). It is a prostaglandin E₁ derivative (2). Lubiprostone is indicated for the treatment of chronic idiopathic constipation in adults. It has low systemic bioavailability with plasma concentrations below the level of quantitation (10 pg/mL). Rapid and extensive metabolism occurs in the stomach and jejunum. One of the metabolites, M3, is absorbed into the plasma, but at very low levels (peak plasma concentration about 42 pg/mL). The plasma elimination half-life of M3 ranges from 0.9 to 1.4 hours. In vitro studies indicate that lubiprostone is about 94% bound to human plasma proteins (1).

Reproduction studies have been conducted in rats, rabbits, and guinea pigs. In pregnant rats and rabbits, oral doses up to about 332 and 32 times, respectively, the recommended human dose based on BSA (RHD) revealed no evidence of teratogenicity. In pregnant guinea pigs, repeated doses that were two and six times, respectively, the RHD caused fetal loss (1).

Long-term (2-year) carcinogenicity studies were conducted in mice and rats.

Doses up to about 42 times the RHD in mice were not associated with a significant increase in any tumor incidences. In rats at the highest dose tested (about 68 times the RHD), there was a significant increase in the incidence of interstitial cell adenoma of the testes in male rats. Hepatocellular adenomas were observed at the highest dose in female rats. Lubiprostone was not genotoxic in several tests, and had no effect on male and female fertility or on reproductive function at daily doses that were about 166 times the RHD (1).

It is not known if lubiprostone or the metabolite M3 crosses the human placenta. The molecular weight of the parent compound (about 391) is low enough, but plasma levels are below the level of quantitation. M3 has been detected in the plasma at low levels and may cross to the embryo–fetus. However, the very short elimination half-life and presumably high plasma protein binding should limit the amount crossing the placenta.

In clinical trials, four women became pregnant while taking the recommended human dose of 24 mg twice daily. Therapy was stopped when the pregnancies were detected. Three of the women gave birth to healthy infants, but the fourth woman, with an apparent normal pregnancy, was lost to follow-up (1).

The manufacturer recommends that before treatment, women of reproductive age should have a negative pregnancy test and should use effective contraception during treatment (1,3). However, based on the pharmacokinetics of lubiprostone, the embryo–fetal risk from inadvertent exposure during pregnancy appears to be low.

BREASTFEEDING SUMMARY

No reports describing the use of lubiprostone during human lactation have been located.

It is not known if lubiprostone or the metabolite M3 is excreted into human breast milk. The molecular weight of the parent compound (about 391) is low enough, but plasma levels are below the level of quantitation. M3 has been detected in the plasma at low levels and may be excreted into milk. However, the very short elimination half-life (0.9–1.4 hours) and presumably high plasma protein binding (parent drug 94%) should limit the amount excreted. Although the risk to a nursing infant probably is very low, if it exists at all, nursing women taking lubiprostone should monitor their infants for adverse effects commonly observed in adults (e.g., headache, nausea, and diarrhea).

LURASIDONE

Antipsychotic

PREGNANCY RECOMMENDATION: No Human Data—Potential Risk in the 3rd Trimester

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of lurasidone in human pregnancy have been located. The animal data suggest low risk in early pregnancy, but the absence of human pregnancy experience prevents further assessment of the embryo–fetal risk. The use of other atypical antipsychotics during the 3rd trimester has been associated with a risk of abnormal muscle movements (extrapyramidal symptoms) and withdrawal symptoms in newborns. Symptoms may be self-limiting and include agitation, feeding disorder, hypertonia, hypotonia, respiratory distress, somnolence, and tremor (1,2).

FETAL RISK SUMMARY

Lurasidone is an atypical antipsychotic indicated for the treatment of schizophrenia. The drug is in the benzoisothiazol subclass of antipsychotics. There are no other approved drugs in this class. The activity of the agent is primarily due to the parent drug, but it is metabolized to two active metabolites. Lurasidone is highly bound (about 99%) to plasma proteins. The mean elimination half-life is 18 hours (1).

Reproduction studies have been conducted in rats and rabbits. When these species were given lurasidone during organogenesis, no evidence of teratogenicity was observed at doses up to 3 and 12 times, respectively, the maximum recommended human dose of 80 mg/day based on BSA (MRHD). There was no evidence of adverse developmental effects in rats given doses up to approximately equal to the MRHD during organogenesis and continued through weaning (1).

In carcinogenicity studies, significant increases in the incidences of malignant

mammary gland tumors and pituitary gland adenomas were observed in female mice. Similar increases in mammary gland carcinomas were seen in female rats. No increases in these tumors were observed in male mice or rats. These neoplastic changes are considered to be prolactin mediated with chronic administration of atypical antipsychotics. It is not known whether this increased risk of the tumors is relevant to human risk. Lurasidone was not genotoxic in multiple assays. Estrous cycle irregularities were seen in female rats and fertility was reduced but reversible. Fertility was not affected in male rats (1).

It is not known if lurasidone or its active metabolites cross the human placenta. The molecular weight of the parent drug (about 493 for the free base) and the elimination half-life suggest that the drug will cross to the embryo–fetus. However, the very high plasma protein binding may limit the exposure.

BREASTFEEDING SUMMARY

No reports describing the use of lurasidone during human lactation have been located. The molecular weight of the parent drug (about 493 for the free base) and the elimination half-life (18 hours) suggest that the drug will be excreted into human milk, although the very high plasma protein binding (about 99%) might limit excretion. However, lurasidone is a weak base, and when used during lactation, accumulation in the milk may occur with concentrations significantly greater than corresponding plasma levels. The American Academy of Pediatrics classifies other antipsychotics as agents whose effect on the nursing infant is unknown but may be of concern (3). Lurasidone should be classified the same way.

LYNESTRENOL

[Withdrawn from the market. See 9th edition.]

LYPRESSIN

[Withdrawn from the market. See 9th edition.]

LYSERGIC ACID DIETHYLAMIDE

Hallucinogen

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

The available data suggest that pure lysergic acid diethylamide (LSD) does not cause chromosomal abnormalities, spontaneous abortions, or congenital malformations. There have been no cases published of fetal anomalies when only pure LSD was administered under medical supervision. Early descriptions of congenital abnormalities involved patients who had used or were using illicit LSD and are believed to be examples of reporting bias, the effects of multiple drugs, or other nondrug factors. However, long-term follow-up of exposed infants has never been reported. This is an area that warrants additional research.

FETAL RISK SUMMARY

LSD (lysergide) is a chemical used for its hallucinogenic properties. The drug does not have a legal indication in the United States. Illicitly obtained LSD is commonly adulterated with a variety of other chemicals (e.g., amphetamines) (1,2). In some cases, doses sold illicitly as LSD may contain little or none of the chemical; as a result, the actual amount of LSD ingested cannot be determined (1). In addition, persons consuming the hallucinogen often consume multiple abuse drugs simultaneously, such as marijuana, opiates, alcohol, amphetamines, STP (2,5-dimethoxy-4-methylamphetamine, or DOM, a synthetic hallucinogen), barbiturates, cocaine, and other prescription and nonprescription substances. Further complicating the situation are the lifestyles that some of these persons live, which are often not conducive to good fetal health. As a consequence, the effects of pure LSD on the human fetus can only be evaluated by examining those cases in which the chemical was administered under strict medical supervision. These cases, however, are few in number. Most data are composed of sample populations who ingested the chemical in an unsupervised environment. Correct interpretation of this latter material is

extremely difficult and, although cited in this monograph, must be viewed cautiously.

The passage of LSD across the human placenta has not been studied. The molecular weight of the chemical (about 323) is low enough that passage to the fetus should be expected. LSD has been shown to cross the placenta in mice with early 1st trimester fetal levels averaging five times the levels measured in late gestation (3).

Concerns with fetal exposure to LSD have primarily focused on chromosomal damage (both chromatid-type and chromosome-type abnormalities), an increased risk of spontaneous abortions, and congenital malformations. These topics are discussed in the sections below.

A 1967 report was the first to claim that the use of LSD could cause chromosomal abnormalities in human leukocytes (4). Because these abnormalities could potentially result in carcinogenic, mutagenic, and teratogenic effects in current or future generations, at least 25 studies were published in the next 7 years. These studies were the subject of three reviews published in the 1970s with all three arriving at similar conclusions (2,5,6). First, in the majority of studies, the addition of LSD to cells in vitro caused chromosomal breakage, but a dose–response relationship was not always apparent. The clinical relevance of the in vitro studies was questionable because pure LSD was used, usually with much higher levels than could be achieved in humans, and the in vitro systems lacked the normal protective mechanisms of metabolism and excretion that are present in the body. Second, only a slight transitory increase in chromosomal breaks was seen in a small percentage (14%) of the subjects administered pure LSD. A much higher percentage of persons (49%) consuming illicit LSD was observed to have chromosomal damage. The abnormalities in this latter group were probably related to the effects of multiple drug abuse and not to LSD alone. Four prospective studies found no definitive evidence that LSD damages lymphocyte chromosomes in vitro (2). Third, there was no evidence that the chromosomal defects observed in illicit LSD users were expressed as an increased incidence of leukemias or other neoplasia. Fourth, mutagenic changes were only observed in experimental organisms (e.g., *Drosophila*) when massive doses (2000–10,000 mcg/mL) were used. Because of this, LSD was believed to be a weak mutagen, but mutagenicity was thought to be unlikely after exposure to any concentration used by humans (5). Finally, the reviewers found no compelling evidence for a teratogenic effect of LSD, either in animals or in humans.

A 1974 investigation involving 50 psychiatric patients, who had been treated for varying intervals under controlled conditions with pure LSD, provided further confirmation that the chemical does not cause chromosomal damage (7). Chromosomal analyses of these patients were compared with those of 50 nonexposed controls matched for age, sex, and marital status. The analysis was blinded so that the investigators did not know the origin of the samples. No significant difference between the groups in chromosomal abnormalities was observed. In another 1974 reference (not included in the previously cited reviews), involving only two subjects, no evidence of chromosomal damage was found in their normal offspring (8). The two women had been treated medically with pure LSD before pregnancy. Thus, the predominance of evidence indicates that LSD does not induce chromosomal aberrations, and even if it did, it has no clinical significance to the fetus.

The question of whether fetal wastage could be induced by LSD exposure was investigated in a study published in 1970 (9). This investigation involved 148 pregnancies (81 patients) in which either the father (N = 60) or the mother (N = 21) had ingested LSD. In 12 pregnancies, exposure occurred both before and during pregnancy. In the 136 pregnancies in which the exposure occurred only before conception, 118 involved the administration of pure LSD (the medical group) and 18 involved both medical and illicit LSD exposure (the combined group). The spontaneous abortion rates for these two populations were 14% (17 of 118) and 28% (5 of 18), respectively. In 83 of the pregnancies, only the father had been exposed to LSD. Excluding these, the incidences of fetal loss for the medical and combined groups are 26% (11 of 43) and 40% (4 of 10), respectively. In the 12 pregnancies in which LSD was consumed both before and during gestation, 3 were in the medical group and 9 were in the combined group. The frequency of spontaneous abortions in these cases was 33% (1 of 3) and 56% (5 of 9). In the combined sample, however, one woman accounted for five abortions and one liveborn infant. If she is excluded, the incidence of fetal wastage in the combined group is zero.

In the medical group, the number of women (12 of 46; 26%) with fetal wastage was high. However, 25 of these pregnancies occurred in women undergoing psychotherapy, and 21 occurred in an experimental setting (9). The number of spontaneous abortions in the psychotherapy group (N = 9, 36%) was more than twice the incidence in the experimental sample (N = 3, 14%). The authors speculated that the greater frequency of fetal wastage in the women undergoing psychotherapy may have been caused by the greater emotional stress that often accompanies such therapy. The increased rate in

the combined sample (9 of 19; 47%) was probably caused by the use of multiple abuse drugs, other nondrug factors, and the inclusion of one woman with five abortions and one live birth. Exclusion of this latter patient decreases the combined sample incidence to 31% (4 of 13). Thus, although other studies examining the incidence of spontaneous abortions in LSD-exposed women have not been located, it appears unlikely that pure LSD administered in a controlled condition is an abortifacient. The increased rate of fetal wastage that was observed in the 1970 study was probably caused by a combination of factors, rather than only to the ingestion of LSD.

A number of case reports have described LSD use in pregnancies ending with poor outcomes since the first report in 1967 of an exposed infant with major malformations (10–25). All of these reports, however, are biased in the respect that malformed infants exposed in utero to LSD are much more likely to be reported than exposed normal infants and are also more frequently reported than nonexposed malformed infants (2). Most of the reports either involved multiple drug exposures, including abuse drugs, or other drug exposures could probably be deduced because of the illicit nature of LSD. With these cautions, the reports are briefly described below.

The first mention of an anomaly observed in an infant exposed in utero to LSD appeared in a 1967 editorial (10). The editorial, citing a report in a lay publication, briefly described a case of LSD exposure in a pregnancy that ended in a malformed infant with megacolon. Apparently, details of this case have never been published in the medical literature.

The first case report in the medical literature also appeared in 1967 and involved a female infant with unilateral fibular aplastic syndrome (11,12). The mother had taken LSD four times between the 25th and 98th days of gestation with one dose occurring during the time of most active lower limb differentiation (11). Defects in the infant, which were characteristic of the syndrome, included absence of the fibula and lateral rays of the foot, anterior bowing of the shortened tibia, shortening of the femur, and dislocated hip. A second case involving limb defects and LSD exposure was published in 1968 (13). The infant, with a right terminal transverse acheiria defect (absence of the hand), was the offspring of a woman who had taken LSD both before and during early gestation. She had also smoked marijuana throughout the pregnancy and had taken a combination product containing dicyclomine, doxylamine, and pyridoxine for 1st trimester nausea. Another infant with a terminal transverse deficit, also exposed to LSD and marijuana, was described in 1969 (14). The defect involved portions of the fingers on the left hand, syndactyly of the right hand

with shortened fingers, and talipes equinovarus of the left foot. Two of these same authors described another exposed infant with amputation deformities of the third finger of the right hand and the third toe of the left foot (15). A critique of these latter three case histories concluded that the defects in the infants could have been caused by amniotic band syndrome (26). Limb defects and intrauterine growth restriction were observed in an offspring of a malnourished mother who had used LSD, marijuana, methadone, and cigarettes during gestation (16). The anomalies consisted of partial adactyly of the hands and feet, syndactyly of the remaining fingers, and defective formation of the legs and forearms.

In a study of 140 women using LSD and marijuana followed up through 148 pregnancies, 8 of 83 liveborn infants had major defects as did 4 of 14 embryos examined after induced abortion (17). The incidence of defects in this sample was 8.1% (12/148) and may have been higher if the other abortuses had been examined. Only one of the liveborn infants had a limb defect (absence of both feet) combined with spina bifida occulta and hemangiomas. Defects in the other seven infants were as follows: myelomeningocele with hydrocephalus in three (one with clubfoot); tetralogy of Fallot; hydrocephalus; right kidney neuroblastoma; and hydrocephalus and congestive heart failure. A limb defect was one of several anomalies found in a male infant whose mother ingested LSD both before and during gestation (18). The abnormalities included absent left arm, syndactyly, anencephaly with ectopic placenta, cleft lip and palate, coloboma of the iris, cataract, and corneal opacity with vascularization. At least one author thought that the limb and cranial defects in this latter case may have been caused by amniotic band syndrome (27). This opinion was contested by the original authors, who stated that the limb defects were true aplasia and not an amputation deformity (28). Similarly, they claimed that the cranial anomaly was not a form of encephalocele, which an amniotic band could have caused, but a true anencephaly (28). Congenital anomalies were observed in 11 of 120 liveborn infants in a previously cited study that examined the effects of LSD on spontaneous abortions and other pregnancy outcomes (9). Nine of the 11 infants had limb defects that were, in most cases, easily correctable with either special shoes or casts. None of the 11 cases appear to be related to LSD exposure. The defects were (the number of cases and possible causes are shown in parentheses): turned-in feet (6 cases, 4 familial, 2 unknown); "crimped" ureter (1 case, familial); tibial rotation (2 cases, 2 familial); pyloric stenosis (1 case, possibly genetic); bone deformity of legs and deafness (1 case, postrubella syndrome) (9).

Other infants with ocular defects, in addition to the case mentioned immediately above, have been described. A mother who ingested LSD, marijuana, meprobamate, amphetamines, and hydrochlorothiazide throughout pregnancy delivered an infant with generalized hypotonia, a high-pitched cry, brachycephaly with widely separated sutures, bilateral cephalohematomas, a right eye smaller than the left and with a cataract, and overlapping second and third toes (19). Two other cases of ocular defects were published in 1978 and 1980 (20,21). In one case, a premature female infant was delivered from a 16-year-old mother who had consumed LSD, cocaine, and heroin during the 1st trimester (20). The infant, who died 1 hour after birth, had microphthalmos, intraocular cartilage, cataract, persistent hyperplastic primary vitreous, and retinal dysplasia. A hypoplastic left lung and a defect in the diaphragm were also noted. The second case involved another premature female infant born to a mother enrolled in a methadone program who also used LSD (21). The infant had left anophthalmia but no other defects.

Various other malformations have been reported after in utero LSD exposure (22–25). Complete exstrophy of the bladder, epispadias, widely separated pubic rami, and bilateral inguinal hernias were observed in a newborn exposed to LSD, marijuana, and mephentermine (22). The mother had consumed LSD 12–15 times during an interval extending from 2 months before conception to 2.5 months into pregnancy. A mother, who ingested LSD at the time of conception, produced a female infant with multiple defects, including a short neck, left hemithorax smaller than the right, protuberant abdomen because of a severe thoracolumbar lordosis, a thoracolumbar rachischisis, craniolacunia, long fingers, clubfeet, and defects of the urinary tract and brain (23). The infant died at 41 days of age. Other drug exposures consisted of cigarettes, an estrogen preparation (type not specified) that was used unsuccessfully to induce menstruation, and medroxyprogesterone for 1st trimester bleeding. Because the case resembled a previously described cluster of unusual defects (i.e., spondylothoracic dysplasia and Jarcho–Levin syndrome), which is caused by an autosomal recessive mode of inheritance, the authors could not exclude this mechanism. In a case of a female infant with multiple anomalies compatible with trisomy 13 with D/D translocation, the mother had last used LSD 9 months before conception (24). She had also used marijuana, barbiturates, and amphetamines throughout gestation and, presumably, before conception. The authors theorized that the defect may have been caused by LSD-induced damage to maternal germ cells before fertilization. A 1971 study evaluated 47 infants born to parents who had used LSD (25). Maternal use of the drug could

be documented in only 30 of the cases and multiple other abuse drugs were consumed. Abnormalities observed in 8 (17%) of the infants were transient hearing loss and ventricular septal defect, cortical blindness, tracheoesophageal fistula, congenital heart disease (type not specified), congenital neuroblastoma, spastic diplegia, and seizure disorders in 2 infants.

Two other case reports involving the combined use of LSD and marijuana with resulting adverse fetal outcomes do not appear to have any relationship to either drug (29,30). One of these involved a report of six infants with persistent ductus arteriosus, one of whom was exposed to LSD and marijuana during early gestation (29). The history of maternal drug use was coincidental. The second case described an infant who died at 2.5 months of age of a bilateral in utero cerebral vascular accident and resulting porencephaly (30). The mother had used LSD, marijuana, alcohol, and other abuse drugs, including cocaine. This latter drug was thought to be the causative agent.

In contrast to the above reports, a large body of research has been published describing the maternal (and paternal) ingestion of LSD without apparent fetal consequences (1,7–9,31–36). A number of reviews have also examined the teratogenic potential of the chemical and have concluded that a causal relationship between congenital malformations and LSD does not exist (2,5,6,37–45). (See reference 6 for an excellent critique of the early investigations in laboratory animals.)

BREASTFEEDING SUMMARY

No reports have been located concerning the passage of lysergic acid diethylamide into breast milk. Because the drug has a relatively low molecular weight (about 323), which should allow its transfer into milk, and because its psychotomimetic effects are produced at extremely low concentrations, the use of LSD during lactation is contraindicated.

L-LYSINE

Nutrient (Amino Acid)

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

L-Lysine is an essential amino acid that has been occasionally used for the treatment and prophylaxis of herpes simplex infections (the effectiveness of this indication is questionable). No reports on the use of the commercial formulation in human pregnancy have been located.

FETAL RISK SUMMARY

L-Lysine is actively transported across the human placenta to the fetus with a steady-state fetal:maternal ratio of approximately 1.6:1 (1,2). Fetal tissues retain most of the essential amino acids, including l-lysine, in preference to the nonessential amino acids (3).

One published case has been located that described a woman with familial hyperlysinemia because of deficiency of the enzymes lysine ketoglutarate reductase and saccharopine dehydrogenase (4). The woman gave birth to a normal child. No details of the pregnancy or the child were provided other than that the child was normal. Serum lysine levels, which were regularly >10 mg/dL and may have been as high as 20 mg/dL or more when the disorder was detected, were not measured during the pregnancy or in the baby.

BREASTFEEDING SUMMARY

No reports describing the use of l-lysine during human lactation have been located.

M

MAFENIDE

Anti-infective

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of mafenide during human pregnancy have been located. The cream formulation is absorbed into the systemic circulation and exposure of the embryo–fetus probably occurs. The anti-infective did not cause fetal toxicity in the only animal species tested. Although the mechanism of action is different from the sulfonamides, it is closely related to that class of agents (see also Sulfonamides). Because of its indication for severe burns, it should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Mafenide is an anti-infective available as a topical 11.2% cream or 5% solution. The cream is indicated for adjunctive therapy of patients with second- and third-degree burns. The solution is indicated for use as an adjunctive topical antimicrobial agent to control bacterial infection when used under moist dressings over meshed autografts on excised burn wounds. The mechanism of action of mafenide is not known but is different from the sulfonamides. In addition, it is not known if there is cross-sensitivity to other sulfonamides. (See also Sulfonamides.) The cream formulation is absorbed into the systemic circulation where the agent is converted to an inactive metabolite. Peak blood concentrations ranged from 26 to 197 mcg/mL 2 hours after application (1,2).

A reproduction study has been conducted in rats. In pregnant rats given oral

doses of mafenide up to 600 mg/kg/day, no evidence of fetal harm was observed. No animal studies evaluating the potential for carcinogenicity or for effects on fertility have been conducted. However, the drug was not mutagenic in one assay (1).

It is not known if mafenide crosses the human placenta. The molecular weight of the free base (about 186) is low enough that passage to the embryo–fetus should be expected.

BREASTFEEDING SUMMARY

No reports describing the use of mafenide during human lactation have been located. The molecular weight of the free base (about 186) is low enough that excretion into breast milk should be expected. Although the mechanism of action is different from the sulfonamides, it is closely related to that class of agents (see also Sulfonamides). Mafenide and its metabolite inhibit carbonic anhydrase, which has caused metabolic acidosis in patients treated with the drug. Hemolytic anemia, presumably related to glucose-6-phosphate dehydrogenase deficiency, has also been reported during treatment. Because the indications for this agent suggest long-term exposure from milk that could increase the possibility of toxicity, nursing is best avoided if the mother requires treatment.

MAGNESIUM SULFATE

Anticonvulsant/Laxative

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

The administration of magnesium sulfate to the mother for anticonvulsant or tocolytic effects does not usually pose a risk to the fetus or newborn. Long-term infusions of magnesium may be associated with sustained hypocalcemia in the fetus resulting in congenital rickets. Neonatal neurologic depression may occur with respiratory depression, muscle weakness, and loss of reflexes. The toxicity is not usually correlated with cord serum magnesium levels. Offspring of mothers treated with this drug close to delivery should be closely observed for signs of toxicity during the first 24–48 hours after birth. Caution is also advocated with the use of aminoglycoside antibiotics during this period.

FETAL RISK SUMMARY

Magnesium sulfate (MgSO_4) is commonly used as an anticonvulsant for toxemia and as a tocolytic agent for premature labor during the last half of pregnancy. Concentrations of magnesium, a natural constituent of human serum, are readily increased in both the mother and fetus following maternal therapy with cord serum levels ranging from 70% to 100% of maternal concentrations (1–6). Elevated levels in the newborn may persist for up to 7 days with an elimination half-life of 43.2 hours (2). The elimination rate is the same in premature and full-term infants (2). IV magnesium sulfate did not cause lower Apgar scores in a study of women treated for pregnancy-induced hypertension, although the magnesium levels in the newborns reflected hypermagnesemia (6). The mean cord magnesium level, 5.3 mEq/dL, was equal to the mean maternal serum level.

No reports linking the use of magnesium sulfate with congenital defects have been located. The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 141 of which had exposure to magnesium sulfate during pregnancy

(7). No evidence was found to suggest a relationship to congenital malformations.

In a 1987 report, 17 women, who had been successfully treated with IV magnesium sulfate for preterm labor, were given 1 g of magnesium gluconate every 4 hours after the IV magnesium had been discontinued (8). A mean serum magnesium level before any therapy was 1.44 mg/dL. Two hours after an oral dose (12–24 hours after discontinuation of IV magnesium) the mean magnesium serum level was 2.16 mg/dL, a significant increase ($p < 0.05$). A group of 568 women was randomly assigned to receive either 15 mmol of magnesium-aspartate hydrochloride ($N = 278$) or 13.5 mmol of aspartic acid ($N = 290$) per day (9). Therapy was started as early as possible in the pregnancies, but not later than 16 weeks' gestation. Women receiving the magnesium tablets had fewer hospitalizations ($p < 0.05$), fewer preterm deliveries, and less frequent referral of the newborn to the neonatal intensive care unit ($p < 0.01$) (9). In a double-blind randomized, controlled clinical study, 374 young women (mean age approximately 18 years) were treated with either 365 mg of elemental magnesium/day (provided by six tablets of magnesium-aspartate hydrochloride each containing 60.8 mg of elemental magnesium) ($N = 185$) or placebo tablets containing aspartic acid only ($N = 189$) (10). Treatment began at approximately a mean gestational age of 18 weeks (range 13–24 weeks). In addition, both groups received prenatal vitamins containing 100 mg of elemental magnesium. In contrast to the reference cited above, the magnesium therapy did not improve the outcome of the pregnancies as judged by the nonsignificant differences between the groups in incidences of preeclampsia, fetal growth restriction, preterm labor, birth weight, gestational age at delivery, or number of infants admitted to the special care unit (10).

Most studies have been unable to find a correlation between cord serum magnesium levels and newborn condition (2,5,11–15). In a study of 7000 offspring of mothers treated with $MgSO_4$ for toxemia, no adverse effects from the therapy were noted in fetuses or newborns (5). Other studies have also observed a lack of toxicity (16,17). A 1983 investigation of women at term with pregnancy-induced hypertension compared newborns of magnesium-treated mothers with newborns of untreated mothers (15). No differences in neurologic behavior were observed between the two groups except that exposed infants had decreased active tone of the neck extensors on the first day after birth.

Newborn depression and hypotonia have been reported as effects of maternal magnesium therapy in some series, but intrauterine hypoxia could not always be eliminated as a potential cause or contributing factor

(2,11,12,18–20). In a study reporting on the effects of IV magnesium on Apgar scores, the most common negative score was assigned for color, rather than for muscle tone (6).

A 1971 report described two infants with magnesium levels >8 mg/dL who were severely depressed at birth (13). Spontaneous remission of toxic symptoms occurred after 12 hours in one infant, but the second had residual effects of anoxic encephalopathy. In a 1982 study, activities requiring sustained muscle contraction, such as head lag, ventral suspension, suck reflex, and cry response, were impaired up to 48 hours after birth in infants exposed in utero to magnesium (14). A hypertensive woman, treated with 11 g of magnesium sulfate within 3.5 hours of delivery, gave birth to a depressed infant without spontaneous respirations, movement, or reflexes (21). An exchange transfusion at 24 hours reversed the condition. In another study, decreased gastrointestinal motility, ileus, hypotonia, and patent ductus arteriosus occurring in the offspring of mothers with severe hypertension were thought to be caused by maternal drug therapy, including magnesium sulfate (22). However, the authors could not relate their findings to any particular drug or drugs and could not completely eliminate the possibility that the effects were caused by the severe maternal disease.

A mild decrease in cord calcium concentrations has been reported in mothers treated with magnesium (3,13,15). In contrast, a 1980 study reported elevated calcium levels in cord blood following magnesium therapy (4). No newborn symptoms were associated with either change in serum calcium concentrations. However, long-term maternal tocolysis with IV magnesium sulfate may cause injury to the newborn as described below.

In an investigation of five newborn infants whose mothers had been treated with IV magnesium sulfate for periods ranging from 5 to 14 weeks, radiographic bony abnormalities were noted in two of the infants (18). One of the mothers, a class C diabetic who had been insulin-dependent for 12 years, was treated with IV magnesium, beginning at 21 weeks' gestation, for 14 weeks. A 2030-g female infant was delivered vaginally at 35 weeks' gestation following spontaneous rupture of the mother's membranes. The maternal histories of this and another mother treated for 6 weeks were described in 1986 (19). The infant had frank rachitic changes of the long bones and the calvaria. Serum calcium at 6 hours of age was normal. The infant was treated with IV calcium gluconate for 3 days, then given bottle feedings without additional calcium or vitamin D. Scout films for an IV pyelogram taken at 4 months of age because of a urinary tract infection showed no bony

abnormalities. Growth over the first 3 years has been consistently at the 3rd percentile for height, weight, and head circumference. Dental enamel hypoplasia, especially of the central upper incisors, was the only physical abnormality noted at 3 years of age. The second infant's mother had been treated with IV magnesium for 9 weeks beginning at 25 weeks' gestation. The 2190-g female infant was delivered vaginally at 34 weeks because of spontaneous rupture of membranes. Hypocalcemia (5.8 mg/dL, normal 6.0–10.0 mg/dL) was measured at 6 hours of age. A chest radiograph taken on the 1st day revealed lucent bands at the distal ends of the metaphyses (18). She was treated with IV calcium for 5 days and then given bottle feedings without additional calcium or vitamin D. A scout film for an IV pyelogram at 5 months of age showed no bony abnormalities. In the remaining three cases, the mothers had been treated with IV magnesium for 4–6 weeks, and their infants were normal on examination. The authors hypothesized that the fetal hypermagnesemia produced by the long-term maternal administration of magnesium caused a depression of parathyroid hormone release that resulted in fetal hypocalcemia (18).

In another study of long-term IV magnesium tocolysis, 22 women were treated for an average of 26.3 days (maximum duration in any patient was 75 days) (20). Two infants delivered from this group were noted to have wide-spaced fontanelles and parietal bone thinning. These effects returned to normal with time. A third newborn, delivered from a mother belonging to an intermediate group treated with IV magnesium for an average of 6.3 days, suffered a parietal bone fracture during an instrumental delivery and developed spastic quadriplegia (20).

More recent studies have also described the adverse effects of prolonged magnesium therapy on fetal bone mineralization (23–27). The mechanism of this reaction appears to be increased and persistent urinary calcium losses in the mother and her fetus (26,27). In one investigation, increases in 1,25-dihydroxyvitamin D and parathyroid hormone in both the mother and the fetus may have prevented more severe hypocalcemia (27).

Clinically significant drug interactions have been reported, one in a newborn and three in mothers, after maternal administration of $MgSO_4$. In one case, an interaction between in utero acquired magnesium and gentamicin was reported in a newborn 24 hours after birth (28,29). The mother had received 24 g of $MgSO_4$ during the 32 hours preceding birth of a neurologically depressed female infant. Gentamicin, 2.5 mg/kg IM every 12 hours, was begun at 12 hours of age for presumed sepsis. The infant developed respiratory arrest

following the second dose of gentamicin, which resolved after the antibiotic was stopped. Animal experiments confirmed the interaction. The maternal cases involved an interaction between magnesium and nifedipine (30,31). One report described two women who were hospitalized at 30 and 32 weeks' gestation, respectively, for hypertension (30). In both cases, oral methyldopa, 2 g, and IV MgSO₄, 20 g, daily were ineffective in lowering the mother's blood pressure. Oral nifedipine, 10 mg, was given and a marked hypotensive response occurred 45 minutes later. The blood pressures before nifedipine in the women were 150/110 and 140/105 mmHg, respectively, and decreased to 80/50 and 90/60 mmHg, respectively, after administration of the calcium channel blocker. Blood pressure returned to previous levels 25–30 minutes later. Both infants were delivered following the hypotensive episodes, but only one survived. In the third maternal case, a woman in premature labor at 32 weeks' gestation was treated with oral nifedipine, 60 mg over 3 hours, then 20 mg every 8 hours (31). Because uterine contractions returned, intravenous MgSO₄ was begun 12 hours later followed by the onset of pronounced muscle weakness after 500 mg had been administered. Her symptoms included jerky movements of the extremities, difficulty in swallowing, paradoxical respirations, and an inability to lift her head from the pillow. The magnesium was stopped and the symptoms resolved in the next 25 minutes. The reaction was attributed to nifedipine potentiation of the neuromuscular blocking action of magnesium.

Maternal hypothermia with maternal and fetal bradycardia apparently caused by IV magnesium sulfate has been reported (32). The 30-year-old woman, at about 31 weeks' gestation, was being treated for premature labor. She had received a single, 12-mg IM dose of betamethasone at the same time that magnesium therapy was started. Her oral temperature fell from 99.8°F to 97°F 2 hours after the infusion had been increased from 2 to 3 g/hr. Twelve hours after admission to the hospital, her heart rate fell to 64 beats/minute (baseline 80 beats/minute), whereas the fetal heart rate decreased to 110 beats/minute (baseline 140–150 beats/minute). A rectal temperature at this time was 95.8°F and the patient complained of lethargy and diplopia. Her serum magnesium level was 6.6 mg/dL. Magnesium therapy was discontinued and all signs and symptoms returned to baseline values within 6 hours. Neither the mother nor the fetus suffered adversely from the effects attributed to magnesium.

BREASTFEEDING SUMMARY

Magnesium salts may be encountered by nursing mothers using over-the-counter laxatives. A study in which 50 mothers received an emulsion of

magnesium and liquid petrolatum or mineral oil found no evidence of changes or frequency of stools in nursing infants (33). In 10 preeclamptic patients receiving magnesium sulfate 1 g/hr IV during the first 24 hours after delivery, magnesium levels in breast milk were 64 mcg/mL as compared with 48 mcg/mL in nontreated controls (34). Twenty-four hours after stopping the drug, magnesium levels in breast milk in treated and nontreated patients were 38 and 32 mcg/mL, respectively. By 48 hours, the levels were identical in the two groups. Milk:plasma ratios were 1.9 and 2.1 in treated and nontreated patients, respectively. The American Academy of Pediatrics classifies magnesium sulfate as compatible with breastfeeding (35).

MANDELIC ACID

[Withdrawn from the market. See 9th edition.]

MANNITOL

Diuretic

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Mannitol is an osmotic diuretic. No reports of its use in pregnancy following IV administration have been located. Mannitol, given by intra-amniotic injection, has been used to induce abortion (1).

BREASTFEEDING SUMMARY

No reports describing the use of mannitol during human lactation have been located.

MAPROTILINE

Antidepressant

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

No published reports linking the use of maprotiline with congenital defects have been located.

FETAL RISK SUMMARY

Maprotiline is a tetracyclic antidepressant. Animal studies have failed to demonstrate teratogenicity, carcinogenicity, mutagenicity, or impairment of fertility (1,2).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 13 newborns had been exposed to maprotiline during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Two (15.4%) major birth defects were observed (0.6 expected), one of which was an oral cleft (none expected). No anomalies were observed in five other defect categories (cardiovascular defects, spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available. The number of exposures is too small for an assessment of the embryo–fetal risk.

In a 1996 descriptive case series, the European Network of the Teratology Information Services (ENTIS) prospectively examined the outcomes of 689 pregnancies exposed to antidepressants (3). Multiple drug therapy occurred in about two-thirds of the mothers. Maprotiline was used in 107 pregnancies. The outcomes of these pregnancies were 17 elective abortions, 11 spontaneous abortions, 2 stillbirths, 72 normal newborns (includes 7 premature infants), 3 normal infants with neonatal disorder (hypotonia in 2; diabetes associated disorder in 1), and 2 infants with congenital defects. The defects (all exposed in the 1st trimester or longer; both exposed to multiple other agents) were facial

dysmorphism, nasal hypoplasia, bone immaturity; and bilateral talipes.

A 2002 prospective study compared two groups of mother–child pairs exposed to antidepressants throughout gestation (46 exposed to tricyclics or tetracyclics—1 to maprotiline; 40 to fluoxetine) with 36 nonexposed, not depressed controls (4). Offspring were studied between the ages 15 and 71 months for effects of antidepressant exposure in terms of IQ, language, behavior, and temperament. Exposure to antidepressants did not adversely affect the measured parameters, but IQ was significantly and negatively associated with the duration of depression, and language was negatively associated with the number of depression episodes after delivery (4).

BREASTFEEDING SUMMARY

Maprotiline is excreted into breast milk (5). Milk:plasma ratios of 1.5 and 1.3 have been reported following a 100-mg single dose and 150 mg in divided doses for 120 hours. Multiple dosing resulted in milk concentrations of unchanged maprotiline of 0.2 mcg/mL. Although this amount is low, the significance to the nursing infant is not known.

MARAVIROC

Antiviral

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Although the animal data suggest low risk, the absence of detailed human pregnancy experience prevents an assessment of the embryo–fetal risk. If indicated, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Maraviroc, a cellular chemokine receptor (CCR5) antagonist, is in the same antiviral subclass of entry inhibitors as enfuvirtide. It is indicated for combination antiretroviral treatment of adults infected with only CCR5-tropic detectable HIV-1, who have evidence of viral replication and HIV-1 strains resistant to multiple antiretroviral agents. The drug is metabolized to inactive compounds by the cytochrome P450 system and is moderately (76%) bound to plasma proteins, including both albumin and α_1 -acid glycoprotein. The terminal half-life at steady state is 14–18 hours (1).

Reproduction studies have been conducted in rats and rabbits. No increase in the incidence of fetal variations and malformations was observed in these species at exposures (AUC) that were 20 and 5 times, respectively, the human exposure from the recommended daily dose (HE). No effects of the exposure were observed in the offspring during prenatal and postnatal development studies, including fertility and reproductive performance (1).

Carcinogenicity studies have been conducted in mice and rats and no drug-related increases in tumor incidence were observed. Maraviroc was not genotoxic in multiple assays and did not impair mating or fertility of male and female rats at exposures that were about 20 times the HE (1).

Consistent with the molecular weight (514), moderate protein binding, and long elimination half-life, maraviroc crosses the human placenta. A woman with HIV became pregnant and was treated with multiple antiviral agents (2).

Maraviroc (150 mg twice daily) was started at 29 weeks' gestation. At 38 weeks', a cesarean section gave birth to a baby with no abnormalities. At birth, maraviroc concentrations in the maternal plasma and cord blood, 13 hours after a dose, were 186 and 69 ng/mL, respectively, a ratio of 0.37 (2). Another study using an ex vivo human cotyledon perfusion model also found that the drug crosses the human placenta (3).

The Antiretroviral Pregnancy Registry has reported one 2nd/3rd trimester exposure to maraviroc. An apparently normal outcome was observed (4).

Two reviews, one in 1996 and the other in 1997, concluded that all women receiving antiretroviral therapy should continue to receive the therapy during pregnancy and that treatment of the mother with monotherapy should be considered inadequate (5,6). The same conclusion was reached in a 2003 review with the added admonishment that therapy must be continuous to prevent emergence of resistant viral strains (7). In 2009, the updated U.S. Department of Health and Human Services guidelines for the use of antiretroviral agents in HIV-1 infected patients continued the recommendation that therapy, with the exception of efavirenz, should be continued during pregnancy (8). If indicated, maraviroc should not be withheld in pregnancy because the expected benefit to the HIV-positive mother outweighs the unknown risk to the fetus. Updated guidelines for the use of antiretroviral drugs to reduce perinatal HIV transmission also were released in 2010 (9). Women receiving antiretroviral therapy during pregnancy should continue the therapy but, regardless of the regimen, zidovudine administration is recommended during the intrapartum period to prevent vertical transmission of HIV to the newborn (9). Physicians are encouraged to register exposed patients in the Antiretroviral Pregnancy Registry by calling 1-800-258-4263 (1).

BREASTFEEDING SUMMARY

No reports have been located that describe the use of maraviroc during human lactation. The molecular weight (about 514) and long elimination half-life (14–18 hours) suggest that the drug will be excreted into breast milk. The effect on a nursing infant is unknown.

Reports on the use of maraviroc during human lactation are unlikely because the drug is used in the treatment of HIV infections. HIV is transmitted in milk, and in developed countries, breastfeeding is not recommended (5,6,8–12). In developing countries, breastfeeding is undertaken, despite the risk, because milk substitutes are not affordable. Until 1999, no studies had been published that examined the effect of any antiretroviral therapy on HIV transmission in

milk. In that year, a study involving zidovudine was published that measured a 38% reduction in vertical transmission of HIV-1 infection despite breastfeeding when compared with controls. (See Zidovudine.)

MARIJUANA

Hallucinogen

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

The use of marijuana in pregnancy has produced conflicting reports on the length of gestation, the quality and duration of labor, fetal growth, congenital defects, and neurobehavior in the newborn. These effects have been the subject of a number of reviews. A meta-analysis and a longitudinal study could not find associations between marijuana and low birth weight or growth in adolescents, but an association with lower birth weight and length was found when biomarkers were used to document maternal exposure. The possible association of in utero marijuana exposure with leukemia in children should be a major concern of any woman who chooses to use this drug during pregnancy. No pattern of malformations has been observed that could be considered characteristic of in utero marijuana exposure. However, there is evidence that marijuana might potentiate the fetal effects of alcohol and may be associated with an increased risk of ventricular septal defects. Two research centers have concluded that prenatal marijuana use adversely affects neurobehavior in infants and adolescents. In the neonatal period, exposed infants may have symptoms similar to mild narcotic withdrawal. In older children, the negative effects included decreased problem-solving ability, inattention, increased hyperactivity, impulsivity and delinquency, and externalization of problems. Some of these results were found even after controlling for the home environment. In most studies, the use of marijuana is closely associated with the use of nicotine and alcohol; and the abuse of other drugs, both prescription and illicit, occurs frequently. Moreover, maternal self-reporting of the amounts and timing of the exposures to marijuana and other abuse substances is common. Separating the effects of these confounding exposures from the effects of marijuana is a daunting task. In addition, failure to account for the varying concentrations of delta-9-tetrahydrocannabinol (Δ -9-THC, THC) contained in the natural product, the presence of contaminants, and the

underreporting of maternal marijuana use could very well have changed the findings of many studies. Therefore, the associations with structural and neurobehavior defects require continued study.

FETAL RISK SUMMARY

Marijuana (cannabis; hashish) is a natural substance that is smoked for its hallucinogenic properties. (One marijuana cigarette is commonly referred to as a “joint.”) Hashish is a potent concentrated form of marijuana. The main psychoactive ingredient, THC is also available in a commercial oral formulation (dronabinol) for use as an antiemetic agent. Natural preparations of marijuana may vary widely in their potency and, except for the commercial preparation, no standardization exists either for the THC content or for the presence of contaminants. Only the commercially available oral formulation can be legally used in the United States.

The use of marijuana by pregnant women is common. Most investigators have reported incidences of 3%–16% (1–17). Other researchers have proposed that even these figures represent underreporting, especially in the 1st month when pregnancy may not be suspected (18–20). Because of the illicit nature of marijuana, many women will simply not admit to its use (4,8). Data from the Ottawa Prenatal Prospective Study in Canada indicated that 20% of their patients used marijuana during the year before pregnancy with the incidence declining to about 10% after the women knew they were pregnant (13). In addition, heavy marijuana usage (>5 joints/week or the use of hashish), when compared with alcohol or nicotine usage, was the least reduced of the three agents during pregnancy (21).

Although the use of marijuana by pregnant women is common, the effects of this use on the pregnancies and the fetuses are unclear. Part of this problem is attributable to the close association between marijuana, alcohol, cigarette smoking, other abuse drugs, and lifestyles that may increase perinatal risk (1–3,6,7). Moreover, studies have relied on maternal self-reporting of the amount and timing of exposures to marijuana and the other substances. Controlling for these confounders becomes a daunting task of almost all studies. However, sufficient data appear to be available to allow classification of the major concerns surrounding exposure to marijuana during pregnancy. These concerns are

- Placental passage of Δ -9-THC
- Pregnancy complications

- Length of gestation
- Quality and duration of labor
- Effect on maternal hormone levels
- Fetal or newborn complications
 - Intrauterine growth
 - Structural defects
 - Neurobehavioral defects
- Leukemia
- Miscellaneous effects

Placental Passage

Δ -9-THC and a metabolite, 9-carboxy-THC, cross the placenta to the fetus at term (4,22). Data for other periods of gestation and for other metabolites are not available. A 1982 study found measurable amounts of 9-carboxy-THC, but not THC, in two cord blood samples but did not quantify the concentrations (4). In a study of 10 women who daily smoked up to five marijuana cigarettes, maternal serum samples were drawn 10–20 minutes before corresponding cord blood samples (22). The time interval between last exposure and sampling ranged from 5 to 26 hours. This is well beyond the time of peak THC levels that occur 3–8 minutes after beginning to smoke (23). Maternal levels of THC were below the limit of sensitivity (0.2 ng/mL) in five samples and ranged from 0.4 to 6 ng/mL in the others. Measurable cord blood concentrations of THC were found in three samples and varied between 0.3 and 1.0 ng/mL. The maternal plasma:cord blood ratios for these three samples were 2.7, 4, and 6. The metabolite, 9-carboxy-THC, which was measured in all maternal and cord blood samples, ranged between 2.3 and 125 ng/mL and 0.4 and 18 ng/mL, respectively. Plasma:cord blood ratios for the metabolite varied from 1.7 to 7.8.

Pregnancy Complications

LENGTH OF GESTATION Marijuana-induced complications of pregnancy are controversial, with different studies producing conflicting results. One of these areas of controversy involves the effect of marijuana on length of gestation. A 1980 prospective study of 291 women found no relationship between maternal use of marijuana and gestational length (3). Similar results were reported from two studies, one in 1982 involving 1690 women (24) and one in 1989 with 1226 women (25). Of interest, marijuana use by the women in the later study was confirmed with urine assays (25). A significantly shorter gestational period was

found in 1246 users in a retrospective study of 12,424 pregnancies, but this difference disappeared when the data were controlled for nicotine exposure, demographic characteristics, and medical and obstetric histories (9).

In contrast to the above reports, three groups of investigators associated regular marijuana use with shorter gestations (1,10,14) and one group with longer gestations (26). In 36 women using marijuana ≥ 2 times/week, 9 (25%) delivered prematurely, a rate much higher than the 5.1% for users of marijuana ≤ 1 /week and the 5.6% for nonusers (1). Investigation of 583 women who delivered single live births, a continuation of the 1980 study mentioned above, now revealed that heavy use of marijuana (more than five marijuana cigarettes/week) was significantly associated with a reduction of 0.8 week's gestational length after adjustment for the mother's prepregnancy weight (10). A total of 84 women (14.4%) used marijuana in this population, 18 of whom were classified as heavy users. A large prospective study of 3857 pregnancies ending in singleton live births found that regular marijuana use (2–3 times/month or more) was associated with an increased risk of preterm (<37 weeks) delivery for white women but not for nonwhite women (14). For the 122 regular white users, 8.2% delivered prematurely compared with 3.8% of 105 occasional users (one marijuana cigarette or less/month) and 4.0% of 2778 nonusers. In the nonwhite groups, the incidences of shortened gestation for the 86 regular, 53 occasional, and 706 nonusers were 10.5%, 11.3%, and 8.8%, respectively. In a population of lower socioeconomic-status women, the total amount of marijuana used during pregnancy was positively correlated with an average 2 days' prolongation of gestation (26). However, the authors of this study noted that their evidence for a longer gestational period was weak in terms of magnitude.

QUALITY AND DURATION OF LABOR A second pregnancy complication examined frequently is the effect of marijuana on the quality and duration of labor. No association between marijuana and duration of labor, including precipitate labor and the type of presentation at birth, was found in the Ottawa Prenatal Prospective Study (3,5,8) or in another study (26). In contrast, other investigators found a significant difference in precipitate labor (<3 hours total) between users (29%) and nonusers (3%) (4,27). Although not significant, 31% of users (11 of 35) had prolonged, protracted, or arrested labor as compared with 19% (7 of 36) nonusers (4,27). Because of the dysfunctional labor, 57% of the newborn infants in the user group had meconium staining vs. 25% among nonusers, a situation that probably resulted in the observation that 41% of newborn infants of users required resuscitation compared with 21% of infants

of nonusers. Adjustment of the data for race, income, smoking, alcohol use, and first physician visit did not change the findings. A second study by these latter investigators using a different group of patients produced similar results in the incidence of dysfunctional labor, precipitate labor, and meconium staining, but the differences between users and nonusers were not significant (7).

MATERNAL HORMONE LEVELS In nonhuman primates, marijuana disrupts the menstrual cycle by inhibiting ovulation through its effects on the pituitary trophic hormones (luteinizing hormone and follicle-stimulating hormone), prolactin, and resulting decreases in estrogen and progesterone levels (16). Tolerance to these effects has been reported (16). Similar effects have been observed in human clinical studies (16).

Thirteen pregnant women, who were regular users of marijuana (once/month to 4 times/day), were matched with controls (28). No effect of this exposure was measured on the levels of human chorionic gonadotropin (hCG), pregnancy-specific β -1-glycoprotein, placental lactogen, progesterone, 17-hydroxyprogesterone, estradiol, and estriol.

Fetal or Newborn Complications

Concerns with the fetal complications arising from maternal marijuana use center around the effects on intrauterine growth restriction, structural anomalies, and neurobehavioral complications in the newborn infant. A recent report indicates that induction of leukemia in childhood must also be considered. As with pregnancy complications, conflicting reports are common.

INTRAUTERINE GROWTH Data of the Ottawa Prenatal Prospective Study indicated no significant reduction in birth weight or head circumference (after adjustment for other factors) in babies of marijuana users (3,5,8,10,13). Compared with infants of nonusers, birth weight actually increased by an average of 67 g in irregular users (one marijuana cigarette/week or less) and 117 g in moderate users (two to five/week), whereas heavy use (more than five/week) was associated with a nonsignificant reduction of 52 g (10). Other studies observed no effect on growth after adjustment of their data (1,7,9,26,29–33). However, in one study, a reduction of 0.55 cm in infant length, but not head circumference, was correlated with maternal use of three marijuana cigarettes/day in the 1st trimester (26). Use during the remainder of pregnancy or the total amount smoked during pregnancy did not significantly affect the infants' length or head circumference. One study, however, did find a significantly smaller head size in offspring of mothers who were heavy marijuana users (32). In addition, one group of investigators found no

association between marijuana and preterm delivery or abruptio placentae (30).

A number of researchers have reported positive correlations with reduced intrauterine growth (after adjustment). In one study, use of <3 joints/week was associated with a significant decrease in birth weight of 95 g compared with that of controls, and use of ≥ 3 cigarettes/week was associated with a significant reduction of 139 g (24,34). A related 1989 study found that marijuana use during pregnancy, when confirmed by positive urine assays, was independently associated with impaired fetal growth, and that the effects of cocaine abuse were additive but not synergistic (25). However, they could not demonstrate a cause-and-effect relationship with marijuana because of other factors, such as the markedly elevated blood levels of carbon monoxide that occur with marijuana use (blood carboxyhemoglobin levels after smoking marijuana are about 5 times those observed after smoking tobacco) (25). Of 1226 mothers who were studied, 331 (27%) used marijuana during gestation as determined by history and positive urine assay. Only 278 (84%) of these would have been detected by history alone. After controlling for potential confounding variables, infants of marijuana users with positive urine assays (N = 202), compared with infants of nonusers (N = 895), were found to have significantly lower birth weight (79 g) and length (0.52 cm) but not head circumference. The birth weight and length measurements did not differ statistically if only self-reported marijuana use was considered, demonstrating the importance of a biologic marker in studies involving this drug (25).

A study, conducted from 1975 to 1983 in two phases, found decreased birth weight only in the second phase (17). The two phases, involving 1434 and 1381 patients, respectively, differed primarily in their assessment of marijuana use early in pregnancy. In the first phase, 9.3% used marijuana, with consumption of two to four joints/month associated with a significant increase in birth weight. No trend was observed with more or less frequent use. The second phase, with 10.3% users, found weight reductions in all classifications of marijuana exposure: 127 g for two to three joints/week, 143 g for four to six joints/week, and 230 g for daily use (17). The authors speculated that the difference between the groups may have been related to the use of other abuse drugs (e.g., cocaine) or changes in the composition or contaminants of marijuana. In a 1986 study, regular marijuana use (2 to 3 times/month or more) was correlated with an increased risk of low-birth-weight (<2500 g) and small-for-gestational-age (SGA) infants in whites only (14). The rates of low-birth-weight and SGA infants in users (N = 122) and nonusers (N = 3490) were 8.2% vs. 2.7%, and 12.5% vs. 4.9%, respectively. In 845 nonwhites, no differences between users

and nonusers were observed. In a 1984 report, examination of 462 infants, 16% of whom were exposed to marijuana and alcohol during early gestation, revealed a significant correlation between maternal marijuana use and decreased body length at 8 months of age (11). Body weight and head circumference were not significantly affected.

In three case reports on the same five infants, low birth weight (all <2500 g) with reduced head circumference and length were observed (35–37). Two of the infants were premature (<37 weeks). The mothers of these infants smoked 2–14 marijuana cigarettes/day during pregnancy with one also using alcohol, cocaine, and nicotine, and two mothers also using nicotine. In a 1999 study, positive pregnancy test urine samples were screened for several drugs, including marijuana (38). Those testing positive for marijuana had babies with significantly lower birth weight, an increased risk of prematurity, and a lower gestational age at delivery.

A 1997 meta-analysis on the effect of marijuana on birth weight identified 10 studies in which the results were adjusted for cigarette smoking and 5 of these met their criteria for analysis (39). The pooled odds ratio (OR) for any use of marijuana and low birth weight was 1.09 (95% confidence interval [CI] 0.94–1.27). They concluded that, in the amounts typically used by pregnant women, there was insufficient evidence that marijuana caused low birth weight (39). In a 2001 study, exposure to marijuana during pregnancy was not associated with any growth measurement or timing of pubertal milestones in a group of 152 adolescents (13- to 16-year-olds) that had been followed longitudinally since birth (40).

STRUCTURAL DEFECTS

Animal research in the 1960s and 1970s yielded inconclusive evidence on the teratogenicity of marijuana and its active ingredients unless high doses were used in certain species (41–44). In humans, most investigators and reviewers have concluded either that marijuana does not produce structural defects or that insufficient data exist to reach any conclusion (1,13,25,26,29,45–56). However, one reviewer cautioned that marijuana-induced birth defects could be rare and easily missed (55), and another observed that marijuana could potentiate known teratogens by lowering the threshold for their effects (49). A previously mentioned study that used urine assays to document marijuana exposure found that the drug was not associated with minor (either singly or as a constellation of three) or major congenital anomalies (25).

Because marijuana use is so common in women during pregnancy, and

because of its frequent association with alcohol and other abuse drugs, it is not surprising that a number of studies and case reports have described congenital malformations in infants whose mothers were smoking marijuana. With some exceptions, most of these investigators did not attribute the observed defects to marijuana, but they are chronicled here mainly for a complete record.

Several reports have described the combined maternal use of marijuana and lysergic acid diethylamide (LSD) in cases ending with poor fetal outcome (57–65). A 1968 report described an infant with right terminal transverse acheiria (absence of hand) (57). The mother had taken LSD early in gestation before she knew she was pregnant. She had also smoked marijuana throughout the pregnancy and had taken a combination product containing dicyclomine, doxylamine, and pyridoxine for 1st trimester nausea. A second infant with a terminal transverse deficit, who was also exposed to the two hallucinogens, was described in 1969 (58). The defect involved portions of fingers of the left hand. Syndactyly of the right hand with shortened fingers and talipes equinovarus of the left foot were also present. A critique of these case reports and others concluded that the defects in the two infants might have been caused by amniotic band syndrome (59). Complete exstrophy of the bladder, epispadias, widely separated pubic rami, and bilateral inguinal hernias were observed in a newborn exposed to LSD, marijuana, and mephentermine (60). Marijuana was allegedly used only twice by the mother. In another case, a female infant with multiple anomalies compatible with trisomy 13 with D/D translocation was delivered from a 22-year-old mother who had last used LSD 9 months before conception (61). The mother used marijuana, barbiturates, and amphetamines throughout gestation and, presumably, before conception. The authors speculated that the defect may have been caused by LSD-induced damage of maternal germ cells before fertilization. A 1972 case report described an infant with multiple eye and central nervous system defects consisting of brachycephaly with widely separated sutures, bilateral cephalohematomas, a right eye smaller than the left, a possible cataract, and multiple brain anomalies (62). The mother had taken marijuana, LSD, and other drugs throughout pregnancy. In a study of 140 women using LSD and marijuana followed through 148 pregnancies, 8 of 83 liveborn infants had major defects as did 4 of 14 embryos examined after induced abortion (63). The incidence of defects in this sample is high (8.1%), but many of the women were using multiple other abuse drugs and had lifestyles that probably were not conducive to good fetal health. Two other reports involving the combined use of marijuana and LSD with resulting adverse fetal outcomes do not appear to have any

relationship to either drug (64,65). One of these involved a report of six cases of persistent ductus arteriosus, one of which involved exposure to marijuana in utero (64). The history of maternal marijuana use was coincidental. The second case described an infant who died at 2.5 months of age of a bilateral in utero cerebral vascular accident and resulting porencephaly (65). The mother had used marijuana, LSD, alcohol, and other abuse drugs, including cocaine. This latter drug was thought to be the causative agent.

In one of two fatal cases of congenital hypothalamic hamartoblastoma tumor, an infant exposed to marijuana also had congenital heart disease and skeletal anomalies suggestive of the Ellis-von Creveld syndrome (i.e., chondroectodermal dysplasia syndrome) (66). In addition to marijuana, the mother had used cocaine and methaqualone during early pregnancy, but the authors did not attribute the defects to a particular agent. In a report of an infant with a random pattern of amputations and constrictions consistent with the amniotic band sequence, the mother's occasional use of marijuana was coincidental (67).

In contrast to the above case reports, in which marijuana use was apparently not related to structural defects, studies have reported possible associations with the drug (9,24,35–37,68,69). In a large study involving 12,424 women of whom 1246 (10%) used marijuana during pregnancy, a crude association between one or more major malformations and marijuana was discovered; no association was found with minor malformations (9). Logistic regression was used to control confounding variables, and although the OR (1.36) was suggestive, the association between marijuana and the defects was not significant. In 1690 mother–child pairs, women who smoked marijuana, but who only drank small amounts of alcohol, were 5 times more likely than nonusers to deliver an infant with features compatible with the fetal alcohol syndrome (see Ethanol) (24). The relative risk for this defect in marijuana users was 12.7 compared with 2.0 in nonusers. In a series of case reports, five infants were described with congenital defects suggestive of the fetal alcohol syndrome (35–37). In addition to daily marijuana use by the mothers, one used alcohol, cocaine, and nicotine; two used nicotine only; and two denied the use of other drugs (35). One study compared 25 marijuana users with 25 closely matched nonusing controls in a search for minor anomalies (68). Infants were examined at a mean age of 28.8 months. No relationship between the drug and minor malformations was found, but the authors could not exclude the existence of a possible relationship at birth because some minor anomalies disappear with age. Of interest, three infants had severe epicanthal folds, three had true

ocular hypertelorism, and all were the offspring of heavy users (more than five joints/week) (68).

A 2004 report from the Atlanta Birth Defects Case–Control Study identified an association between maternal marijuana use and ventricular septal defects (VSD) in the offspring (69). The cases, 122 infants with isolated simple VSD, were compared with 3029 control infants. Maternal marijuana use was determined by self-report combined with paternal proxy-reports of the mother's exposure. The OR for maternal use of marijuana and VSD, after adjustment, was 1.90, 95% CI 1.29–2.81. The risk of VSD increased with regular (≥ 3 days/week) marijuana use. A similar analysis for heavy (≥ 10 drinks/week) maternal alcohol consumption produced an OR of 2.10, 95% CI 0.75–5.87 (69).

Strabismus was diagnosed in 24% (7 of 29) of the infants delivered from mothers maintained on methadone throughout pregnancy in a 1987 report (70). This percentage was approximately 4–8 times the expected incidence of the eye defect in the general population. Two (29%) of the seven infants were also exposed in utero to marijuana vs. three (14%) of the nonaffected infants. Although use of other abuse drugs was common, the authors attributed the eye condition to low birth weight and, possibly, an unknown contribution from methadone (70). However, in the Ottawa Prenatal Prospective Study, 35% of the marijuana-exposed infants compared with 6% of the controls had significantly more than one of the following eye problems: myopia, strabismus, abnormal oculomotor functioning, or unusual discs (13). The examiner was blinded to the prenatal histories of the infants.

NEUROBEHAVIOR DEFICITS Significant alterations in neurobehavior in offspring of regular marijuana users were noted in the Ottawa Prenatal Prospective Study (3,5,13,15,71–80). After adjustment for nicotine and alcohol use, in utero exposure to marijuana was associated with increased tremors and exaggerated startles, both spontaneous and in response to minimal stimuli (13,15). Decreased visual responses, including poorer visual habituation to light, were also observed in these infants. In addition, a slight increase in irritability was noted. In early data from the Ottawa group, a distinctive shrill, high-pitched, cat-like cry, reminiscent of the cry considered to be symptomatic of drug withdrawal, was heard from a large number of the offspring of regular users (3). No differences were noted between exposed and nonexposed infants in terms of lateralization, muscle tone, hand-to-mouth behavior, general activity, alertness, or lability of states (3). On follow-up examinations, the abnormalities in neonatal neurobehavior apparently did not result in poorer performance on

cognitive and motor tests at 18 and 24 months (13). The investigators cautioned that they were unable to determine whether the follow-up results were truly indicative of a return to normal or were related to insensitivity of the available tests (13).

In a longitudinal analysis of exposed offspring, a series of additional reports from the Ottawa Prenatal Prospective Study appeared covering the period 1989–2001 (71–80). Offspring exposed prenatally to marijuana were evaluated at 9 and 30 days of age (71). Exposure was associated with symptoms similar to those of mild narcotic withdrawal (tremors associated with Moro reflex, increased fine tremor, and startles). Children exposed in utero were evaluated by a series of tests at 12 and 24 months of age (72). A positive association was found between maternal use of marijuana and the cognitive composite score at 12 months but not at 24 months. At 36- and 48-month follow-up, significantly lower scores in verbal and memory were associated with maternal use of the drug during pregnancy (73). However, no association was found with lower verbal or cognitive scores at 60- and 72-month evaluation (74), although in the latter evaluation, a dose–response association was found with a possible deficit in sustained attention and a higher rating by the mothers on the impulsive/hyperactive scale (75). In children 6–9 years of age, parental ratings of behavior problems, visuoperceptual tasks, language comprehension, and distractibility, after adjustment for the home environment condition, were not associated with marijuana exposure (76). No association was found between marijuana and reading or language outcomes in children 9–12 years of age (77). Although subsequent analysis found no association between exposure and global or verbal intelligence, it did find a negative association with executive function tasks that require impulse control and visual analysis/hypothesis testing (78). Prenatal marijuana exposure did not adversely affect basic visuoperceptual tasks in 9–12-year-olds, but a negative association was found with performance in visual problem solving situations (79). This latter finding could be explained by marijuana’s negative impact on problem-solving situations requiring integration, analysis, and synthesis (i.e., executive functions) (79). In 13–16-year-olds, prenatal marijuana exposure was associated with the stability of attention over time (increased errors of omissions) (80). This finding was similar to what was found in 6-year-olds (75). Several reviews by the above investigators have summarized their findings (81–86).

A 1984 report examining maternal drinking and neonatal withdrawal found that marijuana use had no effect on the signs of withdrawal in their patients (87). In another study, no increase in startles, tremors, or other

neurobehavioral measures at birth was noted in exposed infants (26). Marijuana exposure also had no effect on muscle tone. Evaluation at 1 year of age found no significant differences in growth or in mental and motor development between infants exposed in utero to either none or varying amounts of the drug (26).

A 1994 study of children exposed to marijuana during the 1st and 2nd trimesters found significant negative effects on the performance of 3-year-old children on the Stanford-Binet Intelligence Scale (88). Although the effects were small, they indicated that, on average, exposed children had a lower IQ compared with nonexposed children. In another study, infants were assessed at 9 and 19 months of age (88). At 9 months, 3rd trimester marijuana use (>1 joint/day) was associated with delayed mental development, but not on infants at 19 months of age (89). In a third study from this group, children exposed prenatally were evaluated at 10 years of age (90). A significant relationship between prenatal exposure to marijuana and increased hyperactivity, impulsivity, inattention, increased delinquency, and externalizing problems was found.

Leukemia

The development of leukemia in children exposed to marijuana during gestation was suggested in a 1989 report (91). In a multicenter study conducted between 1980 and 1984 by the Childrens Cancer Study Group, in utero marijuana exposure was significantly related to the development of acute nonlymphoblastic leukemia (ANLL). Of the 204 cases that were analyzed, marijuana use was found in 10 mothers, only 1 of whom used other (LSD) mind-altering drugs. An 11th case mother used methadone. Only 1 of the 203 closely matched healthy controls was exposed to abuse drugs. The 10-fold risk induced by marijuana exposure was statistically significant. The mean age of ANLL diagnosis was significantly younger in the exposed children than in nonexposed children: 37.7 vs. 96.1 months, respectively. Based on the French–American–British system of classification, the morphology of the leukemias also differed significantly, with 70% of the exposed cases presenting with monocytic (M5) or myelomonocytic (M4) morphology compared with 31% of the nonexposed cases. Additionally, only 10% of the exposed children had M1 or M2 (myelocytic) morphology vs. 58% of the nonexposed children. The authors were able to exclude reporting bias but could not exclude the possibility that the association was related to other factors, such as the presence of herbicides or pesticides on the marijuana (91).

Miscellaneous Effects

Early concerns (92,93) that marijuana-induced chromosomal damage could eventually lead to congenital defects have been largely laid to rest (46,55,56). The clinical significance of any drug-induced chromosomal abnormality is doubtful (55). Finally, heavy marijuana use in males has been associated with decreased sperm production (16,93). However, the clinical significance of this finding has been questioned because no evidence indicates that the reduction in sperm counts is related to infertility (16,93).

Review Articles

A number of reviews have examined the conflicting reports on the association between marijuana and developmental toxicity (16,42,43,45–49,52–56,81–86,94–96).

BREASTFEEDING SUMMARY

THC, the main active ingredient of marijuana (cannabis, hashish), is excreted into breast milk (26,49,97,98). Analyses of THC and its two metabolites, 11-hydroxy-THC and 9-carboxy-THC, were conducted on the milk of two women who had been nursing for 7 and 8 months and who smoked marijuana frequently (97). A THC concentration of 105 ng/mL, but no metabolites, was found in the milk of the woman smoking one pipe of marijuana daily. In the second woman, who smoked seven pipes/day, concentrations of THC, 11-hydroxy-THC, and 9-carboxy-THC were 340 ng/mL, 4 ng/mL, and none, respectively. The analysis was repeated in the second mother, approximately 1 hour after the last use of marijuana, using simultaneously obtained samples of milk and plasma. Concentrations (in ng/mL) of the active ingredient and metabolites in milk and plasma (ratios shown in parenthesis) were 60.3 and 7.2 (8.4), 1.1 and 2.5 (0.4), and 1.6 and 19 (0.08), respectively. The marked differences in THC found between the milk samples was thought to be related to the amount of marijuana smoked and the interval between smoking and sample collection. A total fecal sample from the infant yielded levels of 347 ng of THC, 67 ng of 11-hydroxy-THC, and 611 ng of 9-carboxy-THC. Because of the large concentration of metabolites, the authors interpreted this as evidence that the nursing infant was absorbing and metabolizing the THC from the milk. Despite the evidence that the fat-soluble THC was concentrated in breast milk, both nursing infants were developing normally (97).

In animals, THC decreases the amount of milk produced by suppressing the production of prolactin and, possibly, by a direct action on the mammary glands

(49). Human data on this effect are not available.

Two studies have examined the long-term effects of marijuana exposure on nursing infants (26,98).

A 1985 study evaluated 27 infants at 1 year of age who were exposed to marijuana via the milk (26). Compared with 35 nonexposed infants, no significant differences were found in terms of age at weaning, growth, and mental or motor development. In contrast, a 1990 study that evaluated the development at 1 year of age of 68 breastfed infants exposed to marijuana in the mother's milk in the first month postpartum compared with 68 infants not exposed, found that the exposure appeared to be associated with a decrease in infant motor development (98). Based on these reports, additional research on the long-term effects of marijuana exposure from breast milk is warranted. The American Academy of Pediatrics classifies marijuana as a drug that should not be used by nursing mothers (99).

MEBENDAZOLE

Anthelmintic

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

A 1985 review of intestinal parasites and pregnancy concluded that treatment of the pregnant patient should only be considered if the “parasite is causing clinical disease or may cause public health problems” (1). When indicated, mebendazole was recommended for the treatment of *Trichuris trichiura* (whipworm) occurring during pregnancy. A 1986 review recommended mebendazole therapy, when indicated, for the treatment of *Ascaris lumbricoides* (roundworm) and *Enterobius vermicularis* (threadworm, seatworm, or pinworm) (2), although another review recommended piperazine for this purpose, despite the known poor absorption of mebendazole (3).

FETAL RISK SUMMARY

Mebendazole is a synthetic anthelmintic agent. Although embryotoxic and teratogenic in rats at single oral doses approximately equal to the human dose based on BSA (4), this effect has not been observed in multiple other animal species (5).

One manufacturer has reports of 1st trimester mebendazole exposure in 170 pregnancies going to term without an identifiable teratogenic risk (4). There was also no increased risk of spontaneous abortion following 1st trimester exposure. Earlier, another manufacturer knew of only one malformation, a digital reduction of one hand, in 112 infants exposed in utero to the drug (6).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 64 newborns had been exposed to mebendazole during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Four (6.3%) major birth defects were observed (three expected), one of which was a limb reduction defect (none expected).

No anomalies were observed in five other defect categories (cardiovascular defects, oral clefts, spina bifida, polydactyly, and hypospadias) for which specific data were available.

During a 1984 outbreak of trichinosis (*Trichinella spiralis*) in Lebanon, four pregnant patients were treated with mebendazole and corticosteroids (7). Two women, both in the 1st trimester, had miscarriages. The authors did not mention if this was caused by the disease or the drug. Neither fetus was examined. The remaining two patients, both in the 3rd trimester, delivered healthy infants. In a separate case, a pregnant patient, also with trichinosis, was treated with mebendazole and delivered a normal infant (8). The period of pregnancy when the infection and treatment occurred was not specified.

In Sri Lanka, *Necator americanus*, one of the two known causes of hookworm, is endemic and it is an important contributor to iron-deficiency anemia in pregnancy (9). Consequently, the routine use of mebendazole is recommended in the 2nd trimester of pregnancy. A study published in 1999 compared the pregnancy outcomes of women treated with mebendazole (N = 5275) to a control group (N = 1737) that was not treated. There was no significant difference in the rate of major congenital malformations for exposures anytime during pregnancy, 1.8% (97 of 5275) vs. 1.5% (26 of 1737), odds ratio (OR) 1.24, 95% confidence interval (CI) 0.8–1.91. For 1st trimester exposure, the incidence was 2.5% (10 of 407), OR 1.66, 95% CI 0.81–3.56, $p = 0.23$. In other comparisons between the two groups, significant decreases occurred in the exposed group in the incidence of stillbirths and perinatal deaths (1.9% vs. 3.3%, $p = 0.0004$), and low (≤ 1500 g) birth weights (1.1% vs. 2.3%, $p = 0.0003$). The researchers concluded that although there was no significant increase in the number of major defects associated with mebendazole, the agent should not be used during the 1st trimester, and a small increased risk of defects could not be excluded (9).

A 2003 prospective controlled cohort study reported the outcomes of 192 pregnancies exposed to mebendazole, most of which (71.5%) involved 1st trimester exposure (10). The rate of major birth defects, spontaneous abortions, and median birth weight did not differ significantly between the exposed and matched control groups, 3.3% vs. 1.7%, 11.5% vs. 9.4%, and 3222 g vs. 3258 g, respectively. However, more pregnancies were electively terminated in the study group than in controls, 11.5% vs. 1.6%. There was no pattern in the defects to suggest a single cause. Moreover, the timing of the exposures made a causative association with the malformations implausible (10).

BREASTFEEDING SUMMARY

A nursing woman, in her 10th week of lactation, was treated with mebendazole (100 mg twice daily for 3 days) for a roundworm infection (11). Immediately before this, she had been treated for 7 days with metronidazole for genital *Trichomonas vaginalis*. Milk production decreased markedly on the 2nd day of mebendazole therapy and stopped completely within 1 week. Although no mechanism was suggested, the author concluded that the halt in lactation was mebendazole induced.

In contrast to the above report, a 1994 reference described no effect on lactation or breastfeeding in four postpartum women treated with mebendazole, 100 mg twice daily for 3 days, for various intestinal parasites (12). In one of the patients, the maternal plasma concentration of mebendazole at the end of therapy was <20 ng/mL, and milk levels were undetectable. The decreased milk production in the above case was attributed to maternal anxiety from having passed a roundworm per rectum (12).

Based on the more recent data, breastfeeding should not be withheld during mebendazole therapy. Only about 2%–10% of an oral dose is absorbed (13) and, as expected, the amounts of the drug excreted into milk are below the level of detection and appear to be clinically insignificant.

MECAMLAMINE

[Withdrawn from the market. See 9th edition.]

MECHLORETHAMINE

Antineoplastic

PREGNANCY RECOMMENDATION: Contraindicated—1st Trimester

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Mechlorethamine is an alkylating antineoplastic agent. Other agents in this class (e.g., see also Busulfan, Chlorambucil, and Cyclophosphamide) are known to be human teratogens and, combined with the animal data, strongly suggest that mechlorethamine should not be given in the 1st trimester.

FETAL RISK SUMMARY

Mechlorethamine produced congenital malformations in rats and ferrets when given as a single SC injection of 1 mg/kg (2–3 times the maximum recommended human dose) (1).

Mechlorethamine has been used in pregnancy, usually in combination with other antineoplastic drugs. Most reports have not shown an adverse effect in the fetus even when mechlorethamine was given during the 1st trimester (2–6). However, structural anomalies and toxicity were observed in two infants exposed to mechlorethamine during the 1st trimester: oligodactyly of both feet with webbing of the third and fourth toes, four metatarsals on the left, three on the right, bowing of the right tibia, and cerebral hemorrhage (7); and malformed kidneys that were markedly reduced in size and malpositioned (8). The relationship between these outcomes and the drug is uncertain.

Data from one review indicated that 40% of the infants exposed to anticancer drugs were of low birth weight (4). Long-term studies of growth and mental development in offspring exposed to mechlorethamine during the 2nd trimester, the period of neuroblast multiplication, have not been conducted (9).

Ovarian function has been evaluated in 27 women previously treated with mechlorethamine and other antineoplastic drugs (10). Excluding 3 patients who received pelvic radiation, 13 (54%) maintained regular cyclic menses and, overall, 13 normal children were born after therapy. Other successful

pregnancies have been reported following combination chemotherapy with mechlorethamine (11–17). Ovarian failure is apparently often gradual in onset and is age related (10). Mechlorethamine therapy in males has been observed to produce testicular germinal cell depletion and azoospermia (15,16,18,19).

Occupational exposure of the mother to antineoplastic agents during pregnancy may present a risk to the fetus. A position statement from the National Study Commission on Cytotoxic Exposure and a research article involving some antineoplastic agents are presented in the monograph for cyclophosphamide (see Cyclophosphamide).

BREASTFEEDING SUMMARY

No reports describing the use of mechlorethamine during lactation have been located. The low molecular weight (about 157 for the free base) suggests that the drug passes into milk. Although it undergoes rapid chemical transformation in water and body fluids, it is not known if exposure to this biologic alkylating agent in breast milk poses a significant risk to a nursing infant. Because of the potential for serious adverse reactions, however, breastfeeding should be discontinued while the mother is receiving therapy.

MECLIZINE

Antihistamine/Antiemetic

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Meclizine is a piperazine antihistamine that is frequently used as an antiemetic (see also Buclizine and Cyclizine). In general, antihistamines are considered low risk in pregnancy. However, exposure near birth of premature infants has been associated with an increased risk of retrolental fibroplasia.

FETAL RISK SUMMARY

Meclizine is teratogenic in animals, causing cleft palates in rats at 25–50 times the human dose, but apparently not in humans (1). Since late 1962, the question of meclizine's effect on the fetus has been argued in numerous communications, the bulk of which are case reports and letters (2–28). Three studies involving large numbers of patients have concluded that meclizine is not a human teratogen (29–31).

The Collaborative Perinatal Project (CPP) monitored 50,282 mother–child pairs, 1014 of whom had exposure to meclizine in the 1st trimester (29, p. 328). For use anytime during pregnancy, 1463 exposures were recorded (29, p. 437). In neither group was evidence found to suggest a relationship to large categories of major or minor malformations. Several possible associations with individual malformations were found (see below), but their statistical significance is unknown (29, pp. 328, 437, 475). Independent confirmation is required to determine the actual risk.

- Respiratory defects (7 cases)
- Eye and ear defects (7 cases)
- Inguinal hernia (18 cases)
- Hypoplasia cordis (3 cases)
- Hypoplastic left heart syndrome (3 cases)

The CPP study indicated a possible relationship to ocular malformations, but the authors warned that the results must be interpreted with extreme caution (32). The FDA's Over-The-Counter Laxative Panel, acting on the data from the CPP study, concluded that meclizine was not teratogenic (33). A second large prospective study covering 613 1st trimester exposures supported these negative findings (30). No harmful effects were found in the exposed offspring as compared with the total sample. Finally, in a 1971 report, significantly fewer infants with malformations were exposed to antiemetics in the 1st trimester as compared with controls (31). Meclizine was the third most commonly used antiemetic.

An association between exposure during the last 2 weeks of pregnancy to antihistamines in general and retrolental fibroplasia in premature infants has been reported. See Brompheniramine for details.

BREASTFEEDING SUMMARY

No reports describing the use of meclizine during lactation have been located. The molecular weight (about 464) is low enough that passage into milk should be anticipated. The potential effects of this exposure on a nursing infant are unknown. Some agents in this class (e.g., see Brompheniramine and Diphenhydramine) have been classified by their manufacturers as contraindicated during nursing because of the increased sensitivity of newborn or premature infants to antihistamines.

MECLOFENAMATE

Nonsteroidal Anti-inflammatory

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 1st and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Constriction of the ductus arteriosus in utero is a pharmacologic consequence arising from the use of prostaglandin synthesis inhibitors during pregnancy, as is inhibition of labor, prolongation of pregnancy, and suppression of fetal renal function (see also Indomethacin) (1). Persistent pulmonary hypertension of the newborn may occur if these agents are used in the 3rd trimester close to delivery (1,2). Women attempting to conceive should not use any prostaglandin synthesis inhibitor, including meclofenamate, because of the findings in a variety of animal models that indicate these agents block blastocyst implantation (3,4). Moreover, nonsteroid anti-inflammatory drugs (NSAIDs) have been associated with spontaneous abortions (SABs) and congenital malformations. The risk for these defects, however, appears to be small.

FETAL RISK SUMMARY

The NSAID, meclofenamate sodium, is used in the treatment of acute and chronic pain, arthritis, and primary dysmenorrhea. It is in the same NSAID subclass (fenamates) as mefenamic acid.

Reproduction studies in mice, rats, and rabbits during organogenesis found no teratogenic effects (5–7), but postimplantation losses were observed in rats (7). Although apparently not reported, animal reproductive toxicities, such as prolonged gestation, dystocia, intrauterine growth restriction, and decreased fetal and neonatal survival, which were observed with other agents in the class, should also be expected with meclofenamate.

It is not known if meclofenamate crosses the human placenta. The molecular weight of the free acid (about 313) is low enough that passage to the embryo

and fetus should be expected.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 166 newborns had been exposed to meclofenamate during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Six (3.6%) major birth defects were observed (seven expected), including one cardiovascular defect (two expected) and one oral cleft (three expected). No anomalies were observed in four other categories of defects (spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available. These data do not support an association between the drug and congenital defects.

A combined 2001 population-based observational cohort study and a case–control study estimated the risk of adverse pregnancy outcome from the use of NSAIDs (8). The use of NSAIDs during pregnancy was not associated with congenital malformations, preterm delivery, or low birth weight, but a positive association was discovered with SABs. A similar study, also published in 2001, failed to find a relationship, in general, between NSAIDs and congenital malformations, but did find a significant association with cardiac defects and orofacial clefts (9). In addition, a 2003 study found a significant association between exposure to NSAIDs in early pregnancy and SABs (10). (See Ibuprofen for details on these three studies.)

A brief 2003 editorial on the potential for NSAID-induced developmental toxicity concluded that NSAIDs, and specifically those with greater COX-2 affinity, had a lower risk of this toxicity in humans than aspirin (11).

Two reviews, both on antirheumatic drug therapy in pregnancy, recommended that if a NSAID was needed, agents with short elimination adult half-lives should be used at the maximum tolerated dosage interval, using the lowest effective dose, and that therapy should be stopped within 8 weeks of the expected delivery date (12,13). Meclofenamate has a short plasma elimination half-life (2 hours), but other factors, such as its toxicity profile, need to be considered.

BREASTFEEDING SUMMARY

No reports describing the use of meclofenamate sodium during lactation have been located. The molecular weight of the free acid (about 313) suggests that the drug will be excreted into breast milk. The effects of this exposure on a nursing infant are unknown, but other NSAIDs are classified as compatible with breastfeeding by the American Academy of Pediatrics (see Ibuprofen and Indomethacin).

MEDROXYPROGESTERONE

Progestogenic Hormone

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Medroxyprogesterone acetate (MPA) demonstrates dose-related teratogenicity and toxicity in animals. Although the hormone is contraindicated in human pregnancy, inadvertent exposure to therapeutic doses does not appear to represent a significant risk of structural defects. Fetal growth restriction might be a low-risk complication if MPA is administered within 4 weeks of conception. However, confirmation of this finding is needed.

FETAL RISK SUMMARY

MPA is a derivative of progesterone that is available in both parenteral and oral formulations. The indications for this hormone include contraception (either alone or in combination with an estrogen), secondary amenorrhea and abnormal uterine bleeding due to hormonal imbalance in the absence of organic pathology, and in combination with estrogens for the treatment of vasomotor symptoms associated with menopause, vulvar and vaginal atrophy, and the prevention of osteoporosis. There are no pregnancy-related indications for this hormone.

A 1977 report described reproduction tests conducted with MPA in mice, rats, and rabbits (1). In each species, once daily SC doses of 0.1–3000 mg/kg/day were given during organogenesis for 3, 6, or 9 consecutive days. Untreated controls were used for each species. No congenital defects attributable to the hormone were observed in mice and rats. In two breeds of rabbits, however, a dose-related increase in cleft palate was observed at doses of 3, 10, and 30 mg/kg/day. The absence of a significant dose–response relationship at doses >30 mg/kg/day was thought to be due to the mortality caused by the higher doses (1).

In an attempt to explain the teratogenic effects observed in rabbits, the same

investigative group examined the binding of MPA to glucocorticoid receptors in appropriate rat and rabbit target tissues (2). Their results indicated that, in rabbits but not in rats, MPA was as effective as natural glucocorticoids in competing for selected binding sites. They theorized that the MPA-induced cleft palates in their original experiment might have been caused by the hormone binding to specific glucocorticoid receptors and by its progestational activity (2).

An experiment to determine a possible mechanism for progestogen-induced hypospadias was reported in 1982 (3). Pregnant rats were given MPA at doses of 1, 10, and 100 times, respectively, the human contraceptive dose equivalent based on body weight (HCDE) on days 13–20 of gestation. Norethisterone, alone or in combination with ethnylestradiol, was also given to other pregnant rats at similar doses. Compared with untreated controls, no effect was observed from these agents on dehydroepiandrosterone metabolism by fetal Wolffian ducts. Inhibition of this testosterone precursor had been shown previously to cause severe hypospadias in male rats and was thought to be a possible mechanism for similar defects in human males (3).

Mice given SC MPA (5–900 mg/kg) before implantation (day 2 of pregnancy) had sporadic increases in dead and resorbed fetuses, decreased fetal weight, and an increase in the incidence of cleft palate and malformed fetuses (4). These effects were not dose-related. Treatment with 30 mg/kg on gestational day 9 was associated with increased rates of respiratory and urinary tract defects. In addition, increased incidences of cleft palate were observed with this dose on several days between gestational days 1 and 12 (4). The methods used in this animal study have been criticized and its findings considered to have questionable relevancy (5) and defended (6).

The fetal effects of IM MPA were studied in pregnant baboons given doses during organogenesis that were 1, 10, and 40 times the HCDE (7). Only the two highest doses were teratogenic, causing anomalies only in the target organs: male external genitalia (short penis, hypospadias, underdeveloped glans and prepuce, bilateral cryptorchidism), female external genitalia (clitoral hypertrophy, labial fusion, female pseudohermaphroditism), and adrenal gland hypoplasia (only at 40 times the HCDE) (7).

Pregnant mice were treated during organogenesis with subdermal pellets that delivered MPA at daily doses 25, 250, and 2500 times the human dose equivalent (HDE) (8). No increase in nongenital malformations was noted at any dose, but the two highest doses caused embryotoxicity (resorptions and decreased weight). In addition, no evidence was found for limb reduction defects even when endochondral bone growth was inhibited (8).

An in vivo model in pregnant mice of intrauterine inflammation was developed using lipopolysaccharide (LPS) from *Escherichia coli* (9). At a gestational length corresponding to about 28–29 weeks in human, the animals were pretreated with either MPA or progesterone before LPS was infused into the uterus. The preterm delivery rates were 91% (LPS alone), 63% (LPS + progesterone), and 0% (LPS + MPA). All of the undelivered fetuses in the first two groups died within 48 hours, whereas most fetuses survived in the LPS + MPA group. The investigators concluded that the progestational and anti-inflammatory properties of MPA prevented inflammation-induced preterm parturition and preserved fetal viability (9).

Although the FDA mandated deletion of pregnancy-related indications from all progestins years ago because of concerns for congenital anomalies, MPA was once used to prevent early abortions. A 1964 report described the use of the hormone for that purpose in 239 women (10). Of the 203 women who went to term, 172 were treated with MPA (oral or IM) before the 12th week of gestation. The average daily dose was 5–50 mg orally with a total dose ranging from <50 to >7000 mg. In six cases, MPA (IM) was the only agent used. Among the 174 infants (2 sets of twins), there were 92 males and 82 females. The outcomes included one stillborn, one newborn with congenital heart disease (no details provided), and one case of mild, transient clitoral enlargement. The infant's mother had received oral MPA 25 mg/day for 7 days during the 6th week of gestation. At 6 months of age, the clitoral hypertrophy had resolved (10).

An unusual cluster of multiple anomalies was observed in a newborn female exposed in utero during the 1st trimester to MPA (for 1st trimester bleeding), lysergic acid diethylamide (LSD), and cigarette smoking (11). The authors of the report could not exclude an autosomal recessive mode of inheritance as a cause of the defects (see Lysergic Acid Diethylamide).

A total of 259 1st trimester exposures to MPA were reported in a 1975 letter (12). Pregnancies exposed to estrogens or progesterones were identified prospectively over a 3-year period (1966–1968). Women were interviewed during pregnancy about early drug use and their outcomes were compared with women who were not exposed to sex hormones. Of those exposed to MPA, 30 infants had congenital malformations, some of which were minor anomalies. Among major defects, there were eight cases involving male genitalia (undescended testis [N = 4], hypospadias [N = 2], and hydrocele [N = 2]), four infants with talipes, two heart defects, and three infants with defects of blood-vessel development (hemangioma, telangiectasia [N = 2]). No causal

association could be determined because of the nature of indications for the hormones (e.g., threatened or previous abortions) (12).

As of 1981, 14 cases of ambiguous genitalia of the fetus had been reported to the FDA, although the literature is more supportive of the 19-nortestosterone derivatives (see Norethindrone, Norethynodrel) (13). Moreover, a 1979 review proposed that the use of progestins during the 1st trimester was a possible cause of hypospadias (14).

A brief 1982 correspondence described the use of oral MPA (40 mg/day) to support an in vitro fertilization procedure (15). The drug was given for 10 days after fertilization was confirmed and restarted about 3 weeks later for threatened abortion (vaginal bleeding and a fall in basal temperature). The second course was continued until 16 weeks' gestation by menstrual dates. A 2340-g male infant was delivered at term that, except for growth restriction, was otherwise healthy (15). The potential adverse consequences of the drug therapy on female (virilization) and male (hypospadias) fetuses were the subject of later correspondence on this report (16).

The Collaborative Perinatal Project monitored 866 mother–child pairs with 1st trimester exposure to progestational agents, including 130 with exposure to MPA (17, p. 389). An increase in the expected frequency of cardiovascular defects (also see FDA data below) and hypospadias was observed for the progestational agents as a group (17, p. 394). The cardiovascular defects included a ventricular septal defect and tricuspid atresia (18). Reevaluation of these data in terms of timing of exposure, vaginal bleeding in early pregnancy, and previous maternal obstetric history, however, failed to support an association between female sex hormones and cardiac malformations (19). Other studies have also failed to find any relationship with nongenital malformations (20,21).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 407 newborns had been exposed to MPA during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 15 (3.7%) major birth defects were observed (13 expected), including (observed/expected) 7/4 cardiovascular defects and 1/1 oral clefts. No malformations were observed in four other defect categories (spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available. Only the number of cardiovascular defects is suggestive of an association, but other factors, including the mother's disease, concurrent drug use, and chance, may be involved.

One infant of a set of triplets was found to have an additional lumbar rib and hemi vertebrae at two levels of the spinal column (22). In addition, the infant had a small, deformed right ear. The pregnancy had resulted from in vitro fertilization following ovulation induction with clomiphene citrate. Because of threatened abortion, the mother had been treated with oral MPA (80 mg/day) from the 4th week after embryo transfer throughout the 30 weeks' gestation. The authors thought the combination of ear, spinal, and rib malformations was probably consistent with the Goldenhar syndrome (oculoauriculovertebral anomaly) (22).

A 1985 study described 2754 infants born to mothers who had vaginal bleeding during the 1st trimester (23). Of the total group, 1608 of the newborns were delivered from mothers treated during the 1st trimester with either oral MPA (20–30 mg/day), 17-hydroxyprogesterone (500 mg/week by injection), or a combination of the two. MPA was used exclusively in 1274 (79.2%) of the study group. The control group consisted of 1146 infants delivered from mothers who bled during the 1st trimester but who were not treated. There were no differences between the study and control groups in the overall rate of malformations (120 vs. 123.9/1000, respectively) or in the rate of major malformations (63.4 vs. 71.5/1000, respectively) (23). Another 1985 study compared 988 infants exposed in utero to various progesterones with a matched cohort of 1976 unexposed controls (24). Only 60 infants were exposed to MPA. No association between progestins, primarily progesterone and 17-hydroxyprogesterone, and fetal malformations was discovered.

A 1988 report from Thailand described the outcomes of pregnancies of 1229 women who had used MPA before the index pregnancy compared with 4023 women who had used no contraception (controls) and 3038 who had used oral contraceptives (pill) (25). No differences were observed between the groups in terms of stillbirths, multiple pregnancies, or birth weight. Women who had used MPA had a similar incidence of major and minor malformations and deformations as controls, but both groups had significantly increased incidences of these outcomes compared with pill users. There was a significantly increased association of polysyndactyly in the MPA group compared with the other two groups (rate per 1000: 8.1 vs. 1.7 and 1.2). However, only 3 of the 10 cases had exposure to MPA during gestation and in 5 cases, the last injection of the hormone had occurred more than 9 months before conception. Thus, a causal association between MPA and syndactyly was thought to be unlikely. Another unexpected finding was an increase in the number of chromosomal anomalies (N = 5) found in the MPA group relative to

the controls (N = 3) and pill users (N = 2). Adjustment by maternal age did not affect these results. Because of the unrelated nature of the defects, the lack of confirming studies, and the distant timing of the exposure in some cases, the authors concluded that the association had occurred by chance (25).

Using the same population base as above, the same investigators studied the effects of in utero exposure to steroid contraceptives on birth weight (26). A total of 1573 pregnancies were exposed to injectable MPA (830 accidental pregnancies and 743 infants conceived before the use of the steroid), 601 to oral contraceptives, and 2578 planned pregnancies (controls). Both the injectable and oral contraceptive groups had increased risks for low-birth-weight infants (<2500 g), but this result was thought to be partial due to confounders. However, the risk of low-birth-weight infants was significantly increased in accidental pregnancies when MPA was given within 4 weeks of conception (odds ratio [OR] 1.9, 95% confidence interval [CI] 1.4–3.2) (26). The researchers then investigated the effect of steroid contraceptives on neonatal and infant survival (27). As above, three groups were formed consisting of 1431 children of women who had received injectable MPA during pregnancy, 565 children exposed in utero to oral contraceptives, and 2307 control infants with no exposure to hormonal contraceptives. After adjustment (including adjustment for birth weight), the neonatal and infant death rates in those exposed to MPA were nonsignificant. However, there was a relation between shorter injection-to-conception intervals and an increased risk of death: OR 2.5 (95% CI 1.1–5.7), interval ≤ 4 weeks; OR 2.1 (95% CI 1.0–4.6), interval 5–8 weeks, and OR 0.9 (95% CI 0.4–2.4), interval ≥ 9 weeks (27). The investigators concluded that infants of pregnancies that occur 1–2 months after an injection of MPA might be at increased risk of low birth weight and death (26,27).

A commentary on the methodology used in the above two studies raised concerns about the validity of the results (28). In particular, criticism involved the comparison groups, establishing the timing of conception, and the biologic plausibility of the effects on birth weight. The authors, however, defended the methods used in the studies and their findings (29).

In the fourth study from the research group in Thailand, no increased risk of impaired growth in height, after adjustment for socioeconomic factors, was found in children (up to the age of 17 years) exposed to MPA during pregnancy (N = 1207) and/or during breastfeeding (N = 1215) (30). However, there was a delay in the onset of reported pubic hair growth among girls exposed to MPA during pregnancy. No other effects on attainment of puberty (i.e., menarche

and breast development) were observed (30).

Another 1988 report focused on the potential teratogenicity of MPA (31). Three groups of women were formed: subfertile women with a history of recurrent spontaneous abortion (N = 180) or threatened abortion (N = 269), and matched subfertile controls (N = 464). The women in the first groups were treated with oral MPA (80–120 mg/day) from the 5th or 7th week of pregnancy until the 18th week. The number of pregnancies in each group was 199, 309, and 508, respectively, and the total number of infants was 161, 205, and 428, respectively. Early pregnancy wastage was high in all groups. Congenital malformations were noted in 15/366 (4.1%) in the treated groups and 15/428 (3.5%) in the controls (difference not significant). Of note, there were two cases of hypospadias, one in the treated group and one in controls. The investigators concluded that MPA was not teratogenic (31).

A possible association between MPA and epispadias, with or without bladder exstrophy, was reported in 1991 (32). Among 20,650 infants delivered at one hospital over a 5-year period, 4 male infants had epispadias and 2 of the 4 also had bladder exstrophy. In each case, MPA had been given to the mother to prevent 1st trimester threatened abortion. The infants were delivered at term with a mean birth weight of 2980 g. The cluster of these rare defects suggested to the authors that a relationship to the drug was possible (32).

BREASTFEEDING SUMMARY

Medroxyprogesterone (MPA) has not been shown to affect lactation adversely (33,34). A 1981 review concluded that use of the drug by the mother would not have a significant effect on the nursing infant (35). Milk production and duration of lactation may be increased if the drug is given in the puerperium. This effect might be secondary to the increase in basal serum prolactin levels that has been shown to occur with depot-MPA (36). If breastfeeding is desired, MPA may be used safely (37,38). A 1996 study found no effect on the urine hormonal profiles of male infants nursing from mothers receiving a depot injection of MPA (38). The American Academy of Pediatrics classifies MPA as compatible with breastfeeding (39).

MEFENAMIC ACID

Nonsteroidal Anti-inflammatory

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 1st and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Constriction of the ductus arteriosus in utero is a pharmacologic consequence arising from the use of prostaglandin synthesis inhibitors during pregnancy, as is inhibition of labor, prolongation of pregnancy, and suppression of fetal renal function (see also Indomethacin) (1). Persistent pulmonary hypertension of the newborn may occur if these agents are used in the 3rd trimester close to delivery (1,2). Women attempting to conceive should not use any prostaglandin synthesis inhibitor, including mefenamic acid, because of the findings in a variety of animal models that indicate these agents block blastocyst implantation (3,4). Moreover, nonsteroidal anti-inflammatory drugs (NSAIDs) have been associated with spontaneous abortions (SABs) and congenital malformations. The risk for these defects, however, appears to be small.

FETAL RISK SUMMARY

Mefenamic acid, a NSAID, is used for the short-term treatment of pain and for primary dysmenorrhea. It is in the same NSAID subclass (fenamates) as meclofenamate.

Although mefenamic acid causes toxic effects in pregnant animals similar to those produced by other agents in this class (decreased fertility, delayed parturition, increase in the number of resorptions, and decreased pup survival), no congenital malformations were observed in studies involving rats, rabbits, and dogs at doses up to 10 times those used in humans (5). In one study of pregnant rats, inhibition of parturition by mefenamic acid appeared to be dose-related (6).

Consistent with its low molecular weight (about 241), mefenamic acid

crosses the human placenta to the fetus. Fetal concentrations of the drug, 40–180 minutes after a 500-mg dose administered to 13 women at 15–22 weeks' gestation, were 32%–54% of the maternal plasma concentrations (7).

A combined 2001 population-based observational cohort study and a case–control study estimated the risk of adverse pregnancy outcome from the use of NSAIDs (8). The use of NSAIDs during pregnancy was not associated with congenital malformations, preterm delivery, or low birth weight, but a positive association was discovered with SABs. A similar study, also published in 2001, failed to find a relationship, in general, between NSAIDs and congenital malformations, but did find a significant association with cardiac defects and orofacial clefts (9). In addition, a 2003 study found a significant association between exposure to NSAIDs in early pregnancy and SABs (10). (See Ibuprofen for details on these three studies.)

A brief 2003 editorial on the potential for NSAID-induced developmental toxicity concluded that NSAIDs, and specifically those with greater COX-2 affinity, had a lower risk of this toxicity in humans than aspirin (11).

Mefenamic acid, 500 mg 3 times a day, was used as a tocolytic in a double-blind, randomized human study (12). Compared with controls, preterm delivery occurred less in the mefenamic acid group (15% vs. 40%, $p < 0.005$), and birth weights were higher. No adverse effects were observed in the newborns exposed in utero to mefenamic acid.

An infant, delivered by urgent cesarean section at 34 weeks' gestation, had marked cyanosis after in utero exposure to mefenamic acid used to prevent premature delivery (13). Echocardiography of the infant demonstrated a small (1- to 2-mm) patent ductus arteriosus. The authors concluded that the maternal drug therapy was responsible for the premature closure of the ductus.

BREASTFEEDING SUMMARY

Small amounts of mefenamic acid are excreted into breast milk and absorbed by the nursing infant (14). Ten nursing mothers in the immediate postpartum period were given a 500-mg oral loading dose followed by 250 mg 3 times daily for 3 days. Blood and milk samples were obtained 2 hours after the first daily dose on postpartum days 2–4. Blood and urine samples were obtained from the infants 1 hour after nursing on postpartum day 4. The averages of the mean daily concentrations of mefenamic acid in maternal plasma and milk were 0.94 and 0.17 mcg/mL, respectively, corresponding to a milk:plasma ratio of 0.18. In three of the mothers, breast milk concentrations of mefenamic acid plus metabolites ranged from 0.62 to 1.99 mcg/mL. The mean infant blood

concentration of mefenamic acid was 0.08 mcg/mL, whereas the mean urine concentration of mefenamic acid plus metabolites was 9.8 mcg/mL (14).

One reviewer concluded that because of the potential toxicity of mefenamic acid, other agents (diclofenac, fenoprofen, flurbiprofen, ibuprofen, ketoprofen, ketorolac, and tolmetin) were safer alternatives if a NSAID was required during nursing (15). However, the American Academy of Pediatrics classifies mefenamic acid as usually compatible with breastfeeding (16).

MEFLOQUINE

Antimalarial

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Mefloquine is a quinoline-methanol antimalarial agent used in the prevention and treatment of malaria caused by *Plasmodium falciparum*, including chloroquine-resistant strains, or by *Plasmodium vivax*. If indicated, mefloquine should not be withheld in pregnancy because the maternal and embryo–fetal risk from malaria far outweighs the unknown potential of developmental toxicity.

FETAL RISK SUMMARY

At high doses (80–160 mg/kg/day), mefloquine is teratogenic in mice, rats, and rabbits, and, at one dose (160 mg/kg/day), it is embryotoxic in rabbits (1). Smaller doses (20–50 mg/kg/day) impaired fertility in rats, but no adverse effect was observed on spermatozoa in humans taking 250 mg/week for 22 weeks (1).

A study published in 1990 examined the pharmacokinetics of mefloquine during the 3rd trimester of pregnancy (2). Twenty women were treated with either 250 mg of mefloquine base (N = 10) or 125 mg of base (N = 10) weekly until delivery at term. Peak and trough concentrations of mefloquine were lower than those measured in nonpregnant adults, and the terminal elimination half-life was 11.6 days. The half-life reported in nonpregnant adults is 15–33 days (1). No obstetric complications were observed at either dosage level, including during labor, and no toxicity was observed in the exposed infants. Normal infant development was observed during a 2-year follow-up.

The risks of complications from malarial infection occurring during pregnancy are increased, especially in women not living in endemic areas (i.e., nonimmune women) (3–6). Infection is associated with a number of severe maternal and fetal outcomes: maternal death, anemia, abortion, stillbirth, prematurity, low

birth weight, fetal distress, and congenital malaria (3–7). However, one of these outcomes, low birth weight with the resulting increased risk of infant mortality, may have other causes inasmuch as it has not been established that antimalarial chemoprophylaxis can prevent this complication (4). Increased maternal morbidity and mortality includes adult respiratory distress syndrome, pulmonary edema, massive hemolysis, disseminated intravascular coagulation, acute renal failure, and hypoglycemia (5–7). Severe *P. falciparum* malaria in pregnant nonimmune women has a poor prognosis and may be associated with asymptomatic uterine contractions, intrauterine growth restriction, fetal tachycardia, fetal distress, placental insufficiency because of intense parasitization, and hypoglycemia (4,7). The exacerbation of this latter adverse effect has not been reported with mefloquine (7), but it occurs frequently with quinine (7–9). Because of the severity of this disease in pregnancy, chemoprophylaxis is recommended for women of childbearing age traveling in areas where malaria is present (3–5). However, some authors state that mefloquine should not be used for prophylaxis during pregnancy, especially during the 1st trimester, because of the potential for fetotoxicity (3–5,7,10–14), except in areas where chloroquine-resistant *P. falciparum* is present (11). An editorial comment to one reference stated that recent data indicated the use of mefloquine during early pregnancy could result in congenital defects, but no other information was provided (15).

Two reports have described the therapeutic use of mefloquine during pregnancy without causing adverse fetal effects (4,16). A 24-year-old woman presented at 33 weeks' gestation with fever, scleral icterus, and tender splenomegaly secondary to *P. falciparum* infection involving 3% of her erythrocytes (16). After two attempts to administer doses of mefloquine (750 and 500 mg), both of which were vomited, predosing with IV metoclopramide allowed the woman to tolerate three 250-mg doses spaced 4 hours apart and two 250-mg doses the following day (total dose 1250 mg). Maternal fever resolved the day after therapy and, at 5 days, no parasites were observed in the mother's blood. Two months later, a 3405-g infant (sex not specified) was delivered by cesarean section for pelvic disproportion and poor beat-to-beat fetal heart rate variability. Apgar scores at 1 and 5 minutes were 6 and 9, respectively. The child was developing normally at 2 months.

An unpublished double-blind, randomized controlled study from Thailand conducted between 1983 and 1989 was briefly described in a World Health Organization (WHO) publication (4) and a 1993 review (13). A total of 178 pregnant women were randomized to two groups; one group received

mefloquine 500 mg every 8 hours for two doses (N = 87), and the other group received quinine 600 mg every 8 hours for 7 days (N = 91). Although the exact stages of pregnancy at the time of treatment were not specified, a small number of the women in the mefloquine group were in the 1st trimester (4,13). All of the women were followed to term. The incidence of uterine contractions, premature labor, and fetal distress in the mefloquine and quinine groups were 18% vs. 25%, 1% vs. 5%, and 2% vs. 4%, respectively (4). None of the differences was statistically significant. No stillbirths occurred, but one spontaneous abortion was observed in each group, 21 days after mefloquine and 37 days after quinine; neither was thought to be related to drug treatment (4). The 21-day cure rate was 97% among those treated with mefloquine compared with 86% of those treated with quinine. Three newborns had congenital malformations, but these were believed to be unrelated to the drug therapy (13). The study investigators concluded that the therapeutic use of mefloquine during pregnancy was safe and effective. The WHO Scientific Group concluded, however, that because of the small number of patients, treatment with mefloquine should be undertaken cautiously during the first 12–14 weeks of gestation (4).

Two trials of mefloquine prophylaxis in pregnancy were reviewed in a 1993 reference (13). An unpublished study compared weekly prophylaxis with either mefloquine (N = 468) or chloroquine (N = 1312) in asymptomatic pregnant women (13). Mefloquine was more effective than chloroquine in preventing fetal growth restriction and was also effective in reducing placental *P. falciparum* infections. In another double-blind, placebo-controlled trial, prophylaxis during the second half of pregnancy with 250 mg/week for 1 month followed by 125 mg/week until delivery in 360 Karen women (living on the Thailand–Burma border) was 95% effective in preventing malaria (13). The incidence of stillbirths was similar between mefloquine (N = 4) and placebo (N = 5).

A presentation made at a 1991 conference described the follow-up of 98 prospectively recorded pregnancy exposures to mefloquine (17). Five diverse congenital malformations were observed, an incidence that does not support mefloquine-induced teratogenicity.

BREASTFEEDING SUMMARY

Mefloquine is excreted into human milk (1,18). Two women, who were not breastfeeding, were given a single 250-mg dose, 2–3 days after delivery (18). Milk samples were collected from both women during the first 4 days after dosing, and from one woman at various intervals up to 56 days. The

milk:plasma ratios in the two women during the first 4 days were 0.13 and 0.16, respectively. In one woman, the ratio was 0.27 calculated over 56 days. The investigators estimated that a 4-kg infant consuming 1000 mL of milk daily would ingest 0.08 mg/day of the mother's dose (18), or approximately 4% of the dose would be recovered from the milk (1,18). Although these amounts are not thought to be harmful to the nursing infant, they are insufficient to provide adequate protection against malaria (3).

Long-term effects of mefloquine exposure via breast milk have not been studied. Because the antimalarial agent has a long plasma half-life, averaging nearly 12 days during pregnancy (2) and 14.4–18.0 days during and after lactation (18), weekly prophylactic doses of mefloquine will result in continuous exposure of a nursing infant. Moreover, higher milk concentrations of mefloquine than those reported should be expected after therapeutic or weekly prophylactic doses (18).

MELATONIN

Hormone (Pineal Gland)/Nutritional Supplement

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible (Low Doses) No Human Data—Potential Toxicity (High Doses)

PREGNANCY SUMMARY

No reports of human pregnancy exposure to exogenous melatonin have been located. Moreover, there have been no long-term studies of the safety of melatonin in nonpregnant humans. This neurohormone is available as an OTC nutritional supplement, as well as a drug. Thus, the use in human pregnancy has most likely occurred but apparently has not been reported. The lack of noticeable toxicity and structural defects in rat fetuses and newborn pups exposed in utero to maternal doses higher than those used in humans is reassuring, but the dose comparison is based on body weight, not BSA or AUC. Moreover, melatonin doses very near the human dose (again based on body weight) did adversely affect the development of the neuroendocrine reproductive axis in female rat fetuses, a toxicity that would not be immediately apparent. There is probably no relationship of this toxicity in pregnant humans consuming occasional low (≤ 10 mg) doses, but high doses or frequent use during gestation should be avoided. One source recommends avoiding the agent in pregnancy (1). High daily doses have been shown to inhibit ovulation. In addition, maternal consumption of melatonin may affect the fetal suprachiasmatic nucleus with resulting adverse effects for the prenatal and postnatal expression and entrainment of circadian rhythms (2). If melatonin is used, synthetic preparations should be chosen. Animal-derived products should be avoided because of the risk of contamination and/or the transmission of infectious agents.

FETAL RISK SUMMARY

Melatonin is a neurohormone produced by the pineal gland (pineal body) under

the control of the suprachiasmatic nucleus located in the anterior hypothalamus (3,4). Secretion of melatonin from the pineal body occurs in a diurnal pattern (during periods of darkness) and affects sleep pattern (3–5). The endogenous hormone is thought to have a wide range of effects. These include increased concentrations of serotonin and aminobutyric acid in the brain; enhanced activity of an enzyme (pyridoxal-kinase) that is involved in the synthesis of serotonin, aminobutyric acid, and dopamine; inhibition of gonadal development; and a role in the control of estrus (5).

Melatonin is commercially available as a nutritional supplement, either as a synthetic or animal-derived product (6). Two sources recommend avoiding the product produced from animal pineal tissue (beef cattle) because of the theoretical risk of contamination or viral transmission (1,6).

A 1981 study evaluated the effect on female offspring of maternal administration of melatonin to rats (7). Pregnant rats were given daily SC doses of 250 mcg/100 g (2.5 mg/kg); about 2–10 times the usual recommended human dose of 10–100 mg in a 70-kg person (RHD) throughout gestation and compared with two control groups (nonmedicated and pinealectomized pregnant rats). Female offspring of melatonin-treated rats showed significantly later vaginal opening compared with the control groups. In addition, they also had significantly lower luteinizing hormones blood levels. The concentrations of melatonin in the three offspring groups did not differ. The investigators concluded that the exogenous melatonin crossed the placenta and demonstrated an inhibitory influence on the development of the neuroendocrine reproductive axis in the fetus (7).

In another animal study, pregnant rats were administered up to 200 mg/kg/day (about 143–1430 times the RHD) from gestational day 6 to day 19 (8,9). No maternal or fetal toxicity was observed. The developmental toxicity NOAEL (no-observed-adverse-effect level) was ≥ 200 mg/kg/day (8,9).

A 2000 study suggested that melatonin might be useful in protecting the fetal brain from neurodegenerative conditions, such as fetal hypoxia and preeclampsia (10). These conditions may involve free radical production, and melatonin is known to be scavenger of oxygen free radicals. The investigators gave melatonin intraperitoneal injections to rats on gestational day 20 and then measured the concentrations of the substance in fetal brains over the next 3 hours. Melatonin rapidly crossed the rat placenta, with peak levels in maternal serum and fetal brain occurring 1 hour after the dose. Moreover, over the 3-hour period, the fetal brain had significant increases in the activities of two free radical scavenging enzymes, superoxide dismutase and glutathione peroxidase.

The investigators concluded that the changes in melatonin concentrations and enzyme activity might protect the fetal brain from oxidation of cerebral lipids and DNA, thereby preventing central nervous system injury (10).

Because of its enhancement of circadian rhythm, melatonin has been used for treating jet lag and other sleep disorders (1,4–6). In the United States, melatonin has orphan drug status for circadian rhythm sleep disorders in blind persons without light perception (6,11). Other possible indications that have been studied, without establishing efficacy, are an anticancer action, chemotherapy-induced thrombocytopenia, cluster headaches, tinnitus, and as an antiaging hormone with antioxidant and immune system–boosting properties to extend life (6,12).

High doses of melatonin also have been studied as a human contraceptive. A 1992 study compared the contraceptive effect of melatonin (75 or 300 mg/day) either alone or in combination with the synthetic progestin, norethisterone (0.3 or 0.75 mg/day) (13). Both melatonin groups, compared with controls, inhibited ovarian function with significant decreases in blood levels of luteinizing hormone, estradiol, and progesterone.

Two publications, one in 1997 (2) and the other in 2000 (3), reviewed the role of melatonin in animal and human development. The human embryo and fetus have multiple binding melatonin sites in the pituitary and hypothalamus, actually more than in adults (2,3). As early as the 18th week of gestation, melatonin receptors can be found in the fetal suprachiasmatic nucleus. However, the effects of the neurohormone during this period are thought primarily to involve melatonin of maternal origin (2). Melatonin is a lipophilic hormone that easily crosses the placenta and is present in human fetal blood and amniotic fluid (2,3). The two main functions of melatonin during human prenatal development are thought to be: (a) establishment of periodicity by communicating information about photoperiod; and (b) entrainment of the developing circadian pacemaker (2). However, circadian rhythms (such as sleep and the secretion of cortisol and melatonin) are not expressed until several months after birth (2,4).

One author critically reviewed the literature on the consequences of abnormal melatonin rhythmicity development in infancy as a result of either prenatal or postnatal events (3). These consequences included sudden infant death syndrome, fetal onset of adult disease (e.g., cardiovascular disease), and scoliosis. In none of these conditions, however, has a causative association with abnormal melatonin rhythmicity been established (3).

BREASTFEEDING SUMMARY

Although no reports describing the use of exogenous melatonin during lactation have been located, endogenous melatonin is excreted into human breast milk (14). In 10 mothers, 3–4 days after delivery, blood and milk samples were collected between 1400 and 1700 (day samples) and between 0200 and 0400 (night samples). No melatonin was detected in the day samples (<43 pmol/L for blood and milk), but the mean levels in the blood and milk of the night samples were 280 and 99 pmol/L, respectively. Milk samples were collected after each feeding from another group of six women within 3 months after delivery. A marked daily rhythm of melatonin excretion was detected; undetectable levels during the day and high levels at night. The investigators speculated that the circadian rhythm of melatonin in milk might be involved in postnatal development by communicating the time of day to the nursing infant (14). The effects of potentially higher milk concentrations when the mother is taking melatonin are unknown, but the best course is to avoid the hormone during lactation. One source recommends avoiding the agent because of the lack of information (1).

MELOXICAM

Nonsteroidal Anti-inflammatory

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 1st and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Constriction of the ductus arteriosus in utero is a pharmacologic consequence arising from the use of prostaglandin synthesis inhibitors during pregnancy (see also Indomethacin) (1). Persistent pulmonary hypertension of the newborn may occur if these agents are used in the 3rd trimester close to delivery (1,2). These drugs have also been shown to inhibit labor and prolong gestation, both in humans (3) (see also Indomethacin) and in animals (4,5). Women attempting to conceive should not use any prostaglandin synthesis inhibitor, including meloxicam, because of the findings in a variety of animal models that indicate these agents block blastocyst implantation (6,7). Moreover, as noted, nonsteroidal anti-inflammatory drugs (NSAIDs) have been associated with spontaneous abortions (SABs) and congenital malformations. The risk for these defects, however, appears to be small.

FETAL RISK SUMMARY

The NSAID meloxicam shares the same mechanism of action and uses as other agents in this class. It is an oxicam derivative in the same subclass as piroxicam. No published reports linking meloxicam to human congenital malformations have been located.

Reproduction studies have been conducted in the rat and rabbit. In rabbits, oral doses 64.5 times the human dose at 15 mg/day for a 50-kg adult based on BSA (HD) given throughout organogenesis resulted in an increased incidence of cardiac septal defects. Embryo lethality was observed at ≥ 5.4 times the HD. In pregnant rats, no teratogenicity was noted at doses up to 2.2 times the HD. An increase in stillbirths, however, occurred at oral doses about ≥ 0.5 times the HD

and a decrease in pup survival at 2.1 times the HD, when these doses were administered throughout organogenesis. At ≥ 0.5 times the HD in late gestation, meloxicam was associated with stillbirths, an increased length of delivery time, and delayed parturition. At doses ≥ 0.07 times the HD during late gestation and lactation, reductions in birth index, live births, and neonatal survival were seen in rats (4).

It is not known if meloxicam crosses the human placenta. The molecular weight (about 351) is low enough that transfer to the fetus should be expected. Meloxicam does cross the rat placenta (1).

A combined 2001 population-based observational cohort study and a case–control study estimated the risk of adverse pregnancy outcome from the use of NSAIDs (8). The use of NSAIDs during pregnancy was not associated with congenital malformations, preterm delivery, or low birth weight, but a positive association was discovered with SABs. A similar study, also published in 2001, failed to find a relationship, in general, between NSAIDs and congenital malformations, but did find a significant association with cardiac defects and orofacial clefts (9). In addition, a 2003 study found a significant association between exposure to NSAIDs in early pregnancy and SABs (10). (See Ibuprofen for details on these three studies.)

A brief 2003 editorial on the potential for NSAID-induced developmental toxicity concluded that NSAIDs, and specifically those with greater COX-2 affinity, had a lower risk of this toxicity in humans than aspirin (11).

BREASTFEEDING SUMMARY

No reports describing the use of meloxicam during lactation have been located. The molecular weight (about 351) is low enough that excretion into breast milk should be expected. The effects of this exposure on a nursing infant are unknown, but a similar agent, piroxicam, is classified as compatible with breastfeeding by the American Academy of Pediatrics (see Piroxicam).

MELPHALAN

Antineoplastic

PREGNANCY RECOMMENDATION: Contraindicated—1st Trimester

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Melphalan, a phenylalanine derivative of nitrogen mustard, is a bifunctional alkylating antineoplastic agent. Other agents in this class (e.g., see also Busulfan, Chlorambucil, and Cyclophosphamide) are known to be human teratogens and, combined with the animal data, strongly suggest that melphalan should not be given in the 1st trimester.

FETAL RISK SUMMARY

No reports linking the use of melphalan with congenital defects have been located. The drug is mutagenic as well as carcinogenic (1–8). These effects have not been described in infants following in utero exposure.

Reproduction studies in rats with oral doses of 6–18 mg/m²/day for 10 days, or with a single intraperitoneal dose of 18 mg/m² revealed embryoletal and teratogenic effects (9). Congenital anomalies included those of the brain (underdevelopment, deformation, meningocele, and encephalocele), eye (anophthalmia and microphthalmos), reduction of the mandible and tail, and hepatocele.

Studies examining the placental transfer of melphalan have not been found. The molecular weight (about 305) is low enough that exposure of the embryo and/or fetus should be expected.

Data from one review indicated that 40% of the infants exposed to anticancer drugs were of low birth weight (10). Long-term studies of growth and mental development in offspring exposed to melphalan and other antineoplastic drugs during the 2nd trimester, the period of neuroblast multiplication, have not been conducted (11).

Melphalan has caused suppression of ovarian function resulting in amenorrhea (11–14). These effects should be considered before administering the drug to patients in their reproductive years. However, of 436 long-term

survivors treated with chemotherapy between 1958 and 1978 for gestational trophoblastic tumors, 15 received melphalan as part of their treatment regimens (15). Three of these women had at least one live birth (mean melphalan dose 18 mg; maximum dose 24 mg), and the remaining 12 did not attempt to conceive. Complete details of this study are discussed in the monograph for methotrexate (see Methotrexate).

Occupational exposure of the mother to antineoplastic agents during pregnancy may present a risk to the fetus. A position statement from the National Study Commission on Cytotoxic Exposure and a research article on some antineoplastic agents are presented in the monograph for cyclophosphamide (see Cyclophosphamide).

BREASTFEEDING SUMMARY

No reports describing the use of melphalan during lactation have been located. The molecular weight (about 305) is low enough that excretion into breast milk should be expected. Because of the potential for severe toxicity in the nursing infant, women receiving this antineoplastic agent should not nurse.

MENADIONE

[Withdrawn from the market. See 9th edition.]

MEPENZOLATE

Parasympatholytic (Anticholinergic)

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The very limited pregnancy experience showing a possible association with minor malformations requires confirmation. In general, however, anticholinergics appear to be low risk in pregnancy (see Atropine).

FETAL RISK SUMMARY

Mepenzolate is an anticholinergic quaternary ammonium bromide. In a large prospective study, 2323 patients were exposed to this class of drugs during the 1st trimester, 1 of whom took mepenzolate (1). A possible association was found between the total group and minor malformations.

BREASTFEEDING SUMMARY

No reports describing the use of mepenzolate during human lactation have been located (see Atropine).

MEPERIDINE

Narcotic Agonist Analgesic

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

The National Birth Defects Prevention Study discussed below found evidence that opioid use during organogenesis is associated with a low absolute risk of congenital birth defects. As with all opioids, maternal and neonatal addiction is possible from inappropriate use. Neonatal depression, at times fatal, has historically been the primary concern following obstetric meperidine analgesia. Controversy has arisen over the potential long-term adverse effects resulting from this use.

FETAL RISK SUMMARY

The placental transfer of meperidine is very rapid, appearing in cord blood within 2 minutes following IV administration (1). It is detectable in amniotic fluid 30 minutes after IM injection (2). Cord blood concentrations average 70%–77% (range 45%–106%) of maternal plasma levels (3,4). The drug has been detected in the saliva of newborns for 48 hours following maternal administration during labor (5). Concentrations in pharyngeal aspirates were higher than in either arterial or venous cord blood.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 62 newborns had been exposed to meperidine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Three (4.8%) major birth defects were observed (three expected), including (observed/expected) 1/0 polydactyly and 1/0 hypospadias. No malformations were observed in four other defect categories (cardiovascular defects, oral clefts, spina bifida, and limb reduction defects) for which specific data were available.

Respiratory depression in the newborn following use of the drug in labor is time- and dose-dependent. The incidence of depression increases markedly if delivery occurs 60 minutes or longer after injection, reaching a peak around 2–3

hours after injection (6,7). Whether this depression is caused by metabolites of meperidine (e.g., normeperidine) or the drug itself is not known (2,8–10). However, recent work suggests that these effects are related to unmetabolized meperidine and not to normeperidine (7).

Impaired behavioral response and electroencephalographic changes persisting for several days have been observed (11,12). These persistent effects may be partially explained by the slow elimination of meperidine and normeperidine from the neonate over several days (13,14). One group of investigators related depressed attention and social responsiveness during the first 6 weeks of life to high cord blood levels of meperidine (15). An earlier study reported long-term follow-up of 70 healthy neonates born to mothers who had received meperidine within 2 hours of birth (16,17). Psychologic and physical parameters at 5 years of age were similar in both exposed and control groups. Academic progress and behavior during the 3rd and 4th years in school were also similar.

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 268 of whom had 1st trimester exposure to meperidine (18, pp. 287–295). For use anytime during pregnancy, 1100 exposures were recorded (18, p. 434). No evidence was found to suggest a relationship to large categories of major or minor malformations. A possible association between the use of meperidine in the 1st trimester and inguinal hernia was found based on six cases (18, p. 471). The statistical significance of this association is unknown and independent confirmation is required.

Results of a National Birth Defects Prevention Study (1997–2005) were published in 2011 (19). This population-based case–control study examined the association between maternal use of opioid analgesics and >30 types of major structural birth defects. In 17,449 case mothers, therapeutic opioid use was reported by 454 (2.6%) compared with 134 (2.0%) of 6701 control mothers. Indications for use of opioid analgesics were surgical procedures (41%), infections (34%), chronic diseases (20%), and injuries (18%). Dose, duration, or frequency were not evaluated. The exposure period evaluated was from 1 month before to 3 months after conception. Limiting the exposure period to the first 2 months after conception produced similar results. Infants with >1 defect were included in multiple birth defect categories. The following opioids were included (number of cases for each agent not specified): codeine, hydrocodone, hydromorphone, fentanyl, meperidine, methadone, morphine, oxycodone, pentazocine, propoxyphene, and tramadol. The birth defect, total number, number exposed, and the adjusted odds ratio (aOR) with 95%

confidence interval (CI) were as follows:

| Birth Defect | Total | Cases | aOR (95% CI) |
|--|-------|-------|---------------|
| Spina bifida | 718 | 26 | 2.0 (1.3–3.2) |
| <i>Any heart defect (20 types)</i> | 7724 | 211 | 1.4 (1.1–1.7) |
| Atrioventricular septal defect | 175 | 9 | 2.4 (1.2–4.8) |
| Teratology of Fallot | 672 | 21 | 1.7 (1.1–2.8) |
| Conotruncal defect | 1481 | 41 | 1.5 (1.0–2.1) |
| Conoventricular septal defect | 110 | 6 | 2.7 (1.1–6.3) |
| Left ventricular outflow tract obstruction defect | 1195 | 36 | 1.5 (1.0–2.2) |
| Hypoplastic left heart syndrome | 357 | 17 | 2.4 (1.4–4.1) |
| Right ventricular outflow tract obstruction defect | 1175 | 40 | 1.6 (1.1–2.3) |
| Pulmonary valve stenosis | 867 | 34 | 1.7 (1.2–2.6) |
| Atrial septal defect (ASD) | 511 | 17 | 2.0 (1.2–3.6) |
| Ventricular septal defect + ASD | 528 | 17 | 1.7 (1.0–2.9) |
| Hydrocephaly | 301 | 11 | 2.0 (1.0–3.7) |
| Glaucoma/anterior chamber defects | 103 | 5 | 2.6 (1.0–6.6) |
| Gastroschisis | 726 | 26 | 1.8 (1.1–2.9) |

The authors speculated that the activity of opioids and their receptors as growth regulators during development of the embryo might be a mechanism to explain the above findings. The exposure data were obtained by retrospective maternal self-report; the authors acknowledged that recall bias and misclassification might have affected their results. They concluded that the absolute risk was a modest absolute increase above the baseline risk for birth defects (19).

BREASTFEEDING SUMMARY

Meperidine is excreted into breast milk (20,21). In a group of mothers who had received meperidine during labor, the breastfed infants had higher saliva levels of the drug for up to 48 hours after birth than a similar group that was bottle-

fed (5). In nine nursing mothers, a single 50-mg IM dose produced peak levels of 0.13 mcg/mL at 2 hours (21). After 24 hours, the concentrations decreased to 0.02 mcg/mL. Average milk:plasma ratios for the nine patients were greater than 1.0. No adverse effects in nursing infants were reported in any of the above studies.

The American Academy of Pediatrics classifies meperidine as compatible with breastfeeding (22).

MEPROBAMATE

Sedative

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Few indications exist for meprobamate in the pregnant woman. If therapy is required, avoiding the 1st trimester is the safest course, but inadvertent exposure does not appear to represent a major risk. Two large surveillance studies did not support the associations with defects reported in earlier studies. In those studies, the defects may have occurred by chance or have been caused by unidentified factors. Moreover, meprobamate is the active metabolite of the central acting muscle relaxant, carisoprodol. That agent has been used in pregnancy without causing birth defects (see Carisoprodol). Nevertheless, until additional data are available, avoiding meprobamate in the 1st trimester is best.

FETAL RISK SUMMARY

Meprobamate is used in the treatment of anxiety disorders or for the short-term treatment of the symptoms of anxiety. It has hypnotic, sedative, and sedative-related muscle-relaxant properties (1). It is partially metabolized to inactive metabolites before excretion in the urine. Meprobamate also is the active metabolite of carisoprodol (see Carisoprodol). The elimination half-life is in the range of 6–17 hours, but may be prolonged after chronic administration (1).

Schardein (2) reviewed seven reproduction studies in mice, rats, and rabbits. Meprobamate caused digital defects in mice and neurobehavior toxicity in rats. However, because most of the studies involved parenteral administration, the findings cannot be used to assess the degree of human risk (2).

Meprobamate crosses the placenta to the fetus and has been measured in umbilical cord blood at or near maternal plasma levels (3). The low molecular weight (about 218) and long elimination half-life are in agreement with that finding.

Four reports have associated the use of meprobamate in pregnancy with an increased risk of congenital anomalies (4–7). In a study of 395 patients (402 live births) who took meprobamate during pregnancy, 115 infants had been exposed during the 1st trimester (4). Ten of the 115 infants had birth defects, but only 5 of the defects, all involving different defects of the heart, could be potentially related to drugs or other unidentified factors. The other non-meprobamate-related defects were Down's syndrome, partial deafness (a toxicity not known to be associated with meprobamate), deformed elbows and joints (a probable deformation), and two unspecified defects. A second report described multiple anomalies, including congenital heart defects, in a newborn exposed to meprobamate (5). The mother of this patient was treated very early in the 1st trimester with meprobamate and propoxyphene. Malformations observed were omphalocele, defective anterior abdominal wall, defect in diaphragm, congenital heart disease with partial ectopic cordis secondary to sternal cleft, and dysplastic hips. Multiple defects of the eye and central nervous system were observed in a newborn exposed to multiple drugs, including meprobamate and lysergic acid diethylamide (LSD) (6). A brief 1975 report summarized the findings of a combined England–France study on the fetal effects of tranquilizers (7). Of the 84 women that took meprobamate during the 1st trimester, 4 delivered infants with congenital malformations. None of the defects were cardiac malformations. In addition, three of the four mothers had experienced a previous pregnancy with a poor outcome (abortion, stillbirth, or malformation) (7).

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 356 of whom were exposed in the 1st trimester to meprobamate (8). No association of meprobamate with large classes of malformations or to individual defects was found. In a follow-up to this study, there was no evidence that exposure to meprobamate in the 1st trimester was related to congenital malformations (20 of 356 infants; expected 17.4; ns), deaths (stillbirth to the fourth birthday), adverse effects on mental and motor scores at the age of 8 months, or intelligence quotient scores at 4 years of age (9). Others also have failed to find a relationship between the use of meprobamate and congenital malformations (10).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 75 newborns had been exposed to meprobamate during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Three (4.0%) major birth defects were observed (three expected), including (observed/expected) 1/0 oral cleft and 2/0

polydactyly. No anomalies were observed in four other defect categories (cardiovascular defects, spina bifida, limb reduction defects, and hypospadias) for which specific data were available. Only with the cases of polydactyly is there a suggestion of a possible association, but other factors, such as the mother's disease, concurrent drug use, and chance, may be involved.

A 1997 report described the pregnancy outcomes of 12 women who had taken large doses of various medications during the first postconception month and who had delivered live infants (11). Four of the cases involved the ingestion of meprobamate either alone or with other drugs. No birth defects were observed in three cases (dose and other drugs in parentheses): meprobamate (1400 mg), meprobamate (5000 mg), and meprobamate (2000 mg, plus chlordiazepoxide 25 mg). A nondrug-induced defect (bilateral undescended testis) was observed in one case in which the mother took meprobamate 1000 mg, promethazine 250 mg, diazepam 120 mg, and metoprolol 1000 mg (11).

BREASTFEEDING SUMMARY

Meprobamate is excreted into breast milk with concentrations 2–4 times that of maternal plasma (1,12). Two case reports described mothers who took carisoprodol throughout gestation and during breastfeeding. Both carisoprodol and meprobamate, the active metabolites, were found in milk. Meprobamate had the highest concentration (see Carisoprodol). The lack of detectable adverse effects in both infants suggested that the risk of toxicity is low, at least in infants that also were exposed during pregnancy. Starting meprobamate during breastfeeding may have different results in a nursing infant. Women taking meprobamate and who elect to nurse should closely monitor their infants for sedation and other changes in behavior or functions.

MERCAPTOPURINE

Antineoplastic

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 3rd Trimester

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Mercaptopurine (6-MP) is an antimetabolite antineoplastic agent. It is the active metabolite of azathioprine (see also Azathioprine). 6-MP is in the same subclass of purine analogs and related agents as cladribine, clofarabine, fludarabine, pentostatin, and thioguanine. Although the data are limited, 6-MP does not appear to be a major human teratogen, but the agent has been associated with newborn toxicity when used near delivery.

FETAL RISK SUMMARY

References citing the use of mercaptopurine in 79 human pregnancies have been located, including 34 cases in which the drug was used in the 1st trimester (1–21). Excluding those pregnancies that ended in abortion or stillbirths, congenital abnormalities were observed in only one infant (10). Defects noted in the infant were cleft palate, microphthalmia, hypoplasia of the ovaries and thyroid gland, corneal opacity, cytomegaly, and intrauterine growth restriction. The anomalies were attributed to busulfan.

Neonatal toxicity as a result of combination chemotherapy has been observed in three infants: pancytopenia (6), microangiopathic hemolytic anemia (9), and transient severe bone marrow hypoplasia (12). In the latter case, administration of mercaptopurine was stopped 3.5 weeks before delivery because of severe maternal myelosuppression. No chemotherapy was given during this period and the patient's peripheral blood counts were normal during the final 2 weeks of her pregnancy (12).

In another case, a 34-year-old woman with acute lymphoblastic leukemia was treated with multiple antineoplastic agents from 22 weeks' gestation until delivery of a healthy female infant 18 weeks later (14). Mercaptopurine was

administered throughout the 3rd trimester. Chromosomal analysis of the newborn revealed a normal karyotype (46,XX) but with gaps and a ring chromosome. The clinical significance of these findings is unknown, but because these abnormalities may persist for several years, the potential existed for an increased risk of both cancer and genetic damage in the next generation (14).

Data from one review indicated that 40% of the infants exposed to anticancer drugs were of low birth weight (2). This finding was not related to the timing of exposure. In addition, except in a few cases, long-term studies of growth and mental development in infants exposed to mercaptopurine during the 2nd trimester, the period of neuroblast multiplication, have not been conducted (22). However, growth and development were normal in 13 infants (one set of twins) examined for 6 months to 10 years (12,15,16,18–21).

Severe oligospermia has been described in a 22-year-old male receiving sequential chemotherapy of cyclophosphamide, methotrexate, and mercaptopurine for leukemia (23). After treatment was stopped, the sperm count returned to normal and the patient fathered a healthy female child. Others have also observed reversible testicular dysfunction (24).

Ovarian function in women exposed to mercaptopurine does not seem to be affected adversely (25–29). An investigator noted in 1980 that long-term analysis of human reproduction following mercaptopurine therapy had not been reported (30). However, a brief 1979 correspondence described the reproductive performance of 314 women after treatment of gestational trophoblastic tumors, 159 of whom had conceived with a total of 218 pregnancies (28). Excluding the 17 women still pregnant at the time of the report, 38 (79%) of 48 women, exposed to mercaptopurine as part of their therapy, delivered live, term infants. A more detailed report of these and additional patients was published in 1984 (31). This latter study and another published in 1988 (32), both involving women treated for gestational trophoblastic neoplasms, are discussed below.

In 436 long-term survivors treated with chemotherapy between 1958 and 1978, 95 (22%) received mercaptopurine as part of their treatment regimens (31). Of the 95 women, 33 (35%) had at least one live birth (numbers given in parentheses refer to mean/maximum mercaptopurine dose in grams) (5.9/30.0), 3 (3%) conceived but had no live births (5.3/14.0), 3 (3%) failed to conceive (1.3/2.0), and 56 (59%) did not try to conceive (5.4/30.0). Additional details, including congenital anomalies observed, are described in the monograph for methotrexate (see Methotrexate).

A 1988 report described the reproductive results of 265 women who had been treated from 1959 to 1980 for gestational trophoblastic disease (32). Single-agent chemotherapy was administered to 91 women, including 26 cases in which mercaptopurine was the only agent used, whereas sequential (single agent) and combination therapy was administered to 67 and 107 women, respectively. Of the total group, 241 were exposed to pregnancy and 205 (85%) of these women conceived, with a total of 355 pregnancies. The time interval between recovery and pregnancy was 1 year or less (8.5%), 1–2 years (32.1%), 2–4 years (32.4%), 4–6 years (15.5%), 6–8 years (7.3%), 8–10 years (1.4%), and >10 years (2.8%). A total of 303 (4 sets of twins) liveborn infants resulted from the 355 pregnancies, 3 of whom had congenital malformations: anencephaly, hydrocephalus, and congenital heart disease (1 in each case). No gross developmental abnormalities were observed in the dead fetuses. Cytogenetic studies were conducted on the peripheral lymphocytes of 94 children and no significant chromosomal abnormalities were noted. Moreover, follow-up of the children, with >80% of the group >5 years of age (the oldest was 25 years), revealed normal development. The reproductive histories and pregnancy outcomes of the treated women were comparable to those of the normal population (32).

A 2012 case described a 27-year-old woman with ulcerative colitis who was treated throughout pregnancy with allopurinol 100 mg/day, mercaptopurine 25 mg/day, and mesalazine 4 g/day (33). Pregnancy was complicated by diarrhea and blood loss in the 2nd trimester. An elective cesarean section was performed at 39 weeks to give birth to a healthy 3550-g infant (sex not specified) with Apgar score of 9, 10, and 10 at 1, 5, and 10 minutes, respectively. No anomalies were observed in the infant (33).

Occupational exposure of the mother to antineoplastic agents during pregnancy may present a risk to the fetus. A position statement from the National Study Commission on Cytotoxic Exposure and a research article involving some antineoplastic agents are presented in the monograph for cyclophosphamide (see Cyclophosphamide).

BREASTFEEDING SUMMARY

No reports describing the use of mercaptopurine during lactation have been located. The molecular weight (about 170) suggests that the drug will be excreted into milk. Because of the potential for severe toxicity in the nursing infant, women receiving this antineoplastic agent should not nurse. However, if the mother chooses to breastfeed, the infant's complete blood count and liver

function tests should be monitored.

MEROPENEM

Antibiotic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Two reports have described the use of meropenem in human pregnancy. Although the limited human pregnancy experience does not allow a full assessment of the embryo–fetal risk, another carbapenem antibiotic is considered safe to use during the perinatal period (i.e., 28 weeks' gestation or later), and, most likely, meropenem can be classified similarly. The fetal risk of use before this period is unknown.

FETAL RISK SUMMARY

Meropenem is a broad-spectrum, carbapenem antibiotic given IV. The drug belongs to the same class of antibiotics as imipenem. Meropenem is indicated as single-agent therapy for the treatment of complicated skin and skin structure infections (adult patients and pediatric patients ≥ 3 months only), complicated intra-abdominal infections (adult patients and pediatric patients ≥ 3 months only), and bacterial meningitis (pediatric patients ≥ 3 months only). The drug is metabolized to an inactive metabolite. Plasma protein binding is minimal (about 2%) and the elimination half-life is about 1 hour (1).

Reproduction studies in rats and cynomolgus monkeys at doses up to 1.8 and 3.7 times, respectively, the usual human dose (1 g every 8 hours), found no evidence of impaired fertility or fetal harm, except for slight changes in fetal weight in rats at doses of 0.4 times the usual human dose or greater (1).

Placental passage in humans has apparently not been studied, but the molecular weight (about 384) suggests that the drug will cross to the embryo–fetus. Moreover, the drug is distributed into many human tissues, including the endometrium, fallopian tubes, and ovaries (1).

Vancomycin-resistant *Enterococcus faecium* pyelonephritis occurred in a

woman at 27 weeks' gestation (2). She also had positive cultures for *Ralstonia pickettii*, methicillin-resistant *Staphylococcus epidermidis*, and *Enterobacter gergoviae* from blood drawn through a peripherally inserted central catheter (PICC) line. The woman was successfully treated with a 14-day course of IV daptomycin (4 mg/kg/day) and meropenem 1 g every 8 hours. The woman went into premature labor 1 month after completion of the therapy and delivered a baby without evidence of infection or abnormalities (no other details were provided) (2).

In a 2013 case report, a 24-year-old woman at 22 weeks' gestation was treated with 6 weeks of meropenem (3 g/day) and cefotaxime (2 g/day) for a brain abscess (3). Glycerin (20 g/day) was given to reduce intracranial pressure. She responded well to the therapy and was then given amoxicillin (750 mg/day) for 4 weeks. At term, she gave birth to a normal 2890-g female infant (3).

BREASTFEEDING SUMMARY

Consistent with the molecular weight (about 384), meropenem is excreted into breast milk. A 2012 case report described the use of meropenem (3 g/day) for 7 days starting on postpartum day 6 by a mother exclusively breastfeeding her infant (4). Five hindmilk samples were collected over a 48-hour period. The average and maximum meropenem concentrations were 0.48 and 0.644 mcg/mL, respectively. The theoretical maximum infant dose was 97 mcg/kg/day which was 0.18% of the maternal weight-adjusted dose. No dermatologic or gastrointestinal adverse effects were noted in the infant (4).

In another case, a mother breastfed her infant until the 4th postpartum month (5). At 2 months, the mother was treated with a 2-week course of meropenem and tobramycin (doses not specified) for a cystic fibrosis exacerbation. There was no change in the infant's stool pattern and it had normal renal function at 6 months of age (5).

In the above cases, the absence of toxic effects in the nursing infants, even with prolonged therapy, suggests that use of meropenem during breastfeeding is probably compatible. However, additional data are warranted and, until such data are available, infants should be monitored for the most common ($\geq 2\%$) adverse effects observed in adult patients (headache, nausea, constipation, diarrhea, anemia, vomiting, and rash (1)).

MESALAMINE

Anti-inflammatory Bowel Disease Agent

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

The maternal benefits of therapy with mesalamine appear to outweigh the potential risks to the fetus. No teratogenic effects due to mesalamine have been described and, although toxicity in the fetus has been reported in one case, a causal relationship between the drug and the outcome is controversial.

FETAL RISK SUMMARY

Mesalamine (5-aminosalicylic acid, 5-ASA) is administered by either rectal suspension or suppository for the treatment of distal ulcerative colitis, proctosigmoiditis, and proctitis. It also results from metabolism in the large intestine of the oral preparation sulfasalazine, which is split to mesalamine and sulfapyridine, and from balsalazide and olsalazine, oral formulations that are metabolized in the colon to mesalamine. The history, pharmacology, and pharmacokinetics of mesalamine and olsalazine were extensively reviewed in a 1992 reference (1).

Reproduction studies in rats and rabbits at oral doses of 480 mg/kg/day observed no fetal toxicity or teratogenicity (2).

Sulfasalazine and one of the metabolites, sulfapyridine, readily cross the placenta and could displace bilirubin from albumin if the concentrations were great enough. Mesalamine is bound to different sites on albumin than bilirubin and, thus, has no bilirubin-displacing ability (3). Moreover, only small amounts of mesalamine are absorbed from the cecum and colon into the systemic circulation, and most of this is rapidly excreted in the urine (4).

A 1987 reference reported the concentrations of mesalamine and its metabolite, acetyl-5-aminosalicylic acid, in amniotic fluid at 16 weeks' gestation and in maternal and cord plasma at term in women treated prophylactically with

sulfasalazine 3 g/day (5). The drug and metabolite levels (all in mcg/mL) and the number of patients were as follows: amniotic fluid (N = 4), 0.02–0.08 and 0.07–0.77, respectively; maternal plasma (N = 5), 0.08–0.29 and 0.31–1.27, respectively; and cord plasma (N = 5), <0.02–0.10 and 0.29–1.80, respectively. No effects on the fetus or newborn from the maternal drug therapy were mentioned. At delivery in a woman taking 1 g of mesalamine 3 times daily, the concentrations of the drug and its metabolite, 3.3 hours after the last dose, in the mother's serum were 1.2 and 2.8 mcg/mL, respectively, and in the umbilical cord serum 0.4 and 5.7 mcg/mL, respectively (6). The cord:maternal serum ratios were 0.33 and 2.0, respectively.

A review of drug therapy for ulcerative colitis recommended that women taking mesalamine to maintain remission of the disease should continue the drug when trying to conceive or when pregnant (7). A study published in 1993 described the course of 19 pregnancies in 17 women (ulcerative colitis N = 10; Crohn's disease N = 7) who received mesalamine (mean dose 1.7 g/day; range 0.8–2.4 g/day) throughout gestation (8). Full-term deliveries occurred in 18, and 1 patient, with a history of 4 previous miscarriages, suffered a spontaneous abortion. No congenital malformations were observed.

Only one report has described possible in utero mesalamine-induced toxicity that may have occurred during 2nd trimester exposure to the drug (9). The 24-year-old mother was treated, between the 13th and 24th week of gestation, for Crohn's disease with 4 g/day of mesalamine for 5 weeks, then tapered to 2 g/day for 6 weeks, then stopped. A fetal ultrasound at 17 weeks' gestation was normal, but a second examination at 21 weeks' showed bilateral renal hyperechogenicity (9). The term male infant had a serum creatinine at birth of 115 $\mu\text{mol/L}$ (normal 18–35 $\mu\text{mol/L}$). Renal hyperechogenicity was confirmed at various times up to 6 months of age. At this age, the serum creatinine was 62 $\mu\text{mol/L}$ with a creatinine clearance of 52 mL/min (normal 80–90 mL/min). A renal biopsy at 6 months of age showed focal tubulointerstitial lesions with interstitial fibrosis and tubular atrophy in the absence of cell infiltration (9). Because no other cause of the renal lesions could be found and there was some resemblance to lesions induced by the prostaglandin synthesis inhibitor, indomethacin, the authors attributed the defect to mesalamine (9). A letter published in response to this study, however, questioned the association between the drug and observed renal defect because of the lack of toxicity in an unpublished series of 60 exposed pregnancies and the lack of evidence that mesalamine causes renal prostaglandin synthesis inhibition in utero (10).

A 1997 report described the successful outcomes of 19 pregnancies

followed prospectively in 16 women with proven distal colitis (11). The women received either 4-g mesalamine enemas 3 times weekly or a 500-mg mesalamine suppository every night throughout gestation. No fetal abnormalities were observed during pregnancy and all of the full-term offspring were normal at birth and at a median follow-up of 2 years (range 2 months to 5 years) (11).

A 1998 prospective study reported the pregnancy outcomes of 165 women exposed to mesalamine (146 during the 1st trimester) who had contacted a teratogen information service (TIS) (12). The study patients were compared with 165 matched controls who had called the TIS concerning nonteratogenic exposures. There were no significant differences between the two groups in spontaneous abortions (6.7% vs. 8.5%), ectopic pregnancies (0.6% vs. 0%), or elective abortions (none were associated with malformed fetuses) (4.2% vs. 1.8%). There was one major defect (an extra right thumb) in the study group compared with five major anomalies in controls (ns). Eight subjects had minor malformations compared with five controls (ns). However, compared with controls, significantly more preterm deliveries occurred in subjects (13.0% vs. 4.7%), the mean birth weight was lower (3253 vs. 3461 g), and the mean maternal weight gain was lower (13.1 vs. 15.6 kg) (12).

A 2004 report described the pregnancy outcomes of 113 women who were being treated for inflammatory bowel disease (39 ulcerative colitis; 73 Crohn's disease; and 1 indeterminate colitis) (13). In the group, there were 207 pregnancies, 100 during treatment with a 5-ASA agent (mesalamine, sulfasalazine, balsalazide, or olsalazine) at sometime during pregnancy. Other agents used included 49 cases with prednisone, 101 with azathioprine or mercaptopurine, 27 with metronidazole, 18 with ciprofloxacin, and 2 with cyclosporine. The pregnancy outcomes of the first eligible pregnancy in the 113 women were 2 ectopic pregnancies, 2 elective abortions, 16 spontaneous abortions, 6 premature infants, 85 full-term infants (1 set of twins), and 3 major defects (2.7%). However, one of the "defects" was a case of immature lungs, which is not considered a congenital defect. The other two defects were imperforate anus and an unspecified heart defect. In addition, the two elective abortions were for unspecified fetal defects. The study concluded that there was no evidence that any of the drugs used either alone or in combination was associated with poor pregnancy outcomes (13).

A 2012 case described a 27-year-old woman with ulcerative colitis who was treated throughout pregnancy with allopurinol 100 mg/day, mercaptopurine 25 mg/day, and mesalazine 4 g/day (14). Pregnancy was complicated by diarrhea

and blood loss in the 2nd trimester. An elective cesarean section was performed at 39 weeks to give birth to a healthy 3550-g infant (sex not specified) with Apgar score of 9, 10, and 10 at 1, 5, and 10 minutes, respectively. No anomalies were observed in the infant (14).

In contrast to sulfasalazine, mesalamine apparently has no adverse effect on spermatogenesis. Treatment of males with sulfasalazine may adversely affect spermatogenesis (15–19), but either stopping therapy or changing to mesalamine allows recovery of sperm production, usually within 3 months (16–19).

BREASTFEEDING SUMMARY

Small amounts of mesalamine are excreted into human milk. A 1990 report described the excretion of mesalamine and its metabolite, acetyl-5-aminosalicylic acid, into breast milk (20). The woman was receiving 500 mg 3 times daily for ulcerative colitis. In a single plasma and milk sample obtained 5.25 hours after a dose, milk and plasma levels of mesalamine were 0.11 and 0.41 mcg/mL, respectively, a milk:plasma ratio of 0.27. Milk and plasma levels of acetyl-5-aminosalicylic acid were 12.4 and 2.44 mcg/mL, respectively, a ratio of 5.1. In another study, women treated prophylactically with 3 g/day of sulfasalazine had milk levels of mesalamine and acetyl-5-aminosalicylic acid of 0.02 and 1.13–3.44 mcg/mL, respectively (5). No adverse effects on the nursing infants were mentioned.

Low concentrations of mesalamine and its metabolite were also found in a woman taking 1 g 3 times daily (6). Maternal serum levels of the drug and metabolite, determined at 7 and 11 days postpartum, were 0.6 and 1.1 mcg/mL (day 7) and 1.1 and 1.8 mcg/mL (day 11), respectively. Milk concentrations of the drug and metabolite at these times were 0.1 and 18.1 mcg/mL (day 7) and 0.1 and 12.3 mcg/mL (day 11), respectively, representing milk:plasma ratios for mesalamine of 0.17 and 0.09 (day 7 and 11), respectively, and for the metabolite of 16.5 and 6.8 (day 7 and 11), respectively. The estimated daily intake by the infant of mesalamine and metabolite was 0.065 mg (0.015 mg/kg) and 10 mg (2.3 mg/kg), respectively, considered to be negligible amounts (6).

A study published in 1993 described the excretion of olsalazine, a prodrug that is partially (2.4%) absorbed into the systemic circulation before conversion of the remainder by colonic bacteria into two molecules of mesalamine (see Olsalazine), in the breast milk of a woman 4 months postpartum (21). Following a 500-mg oral dose, olsalazine, olsalazine sulfate, and mesalamine were

undetectable in breast milk up to 48 hours (detection limits 0.5, 0.2, and 1.0 $\mu\text{mol/L}$, respectively). Acetyl-5-aminosalicylic concentrations at 10, 14, and 24 hours, were 0.8, 0.86, and 1.24 $\mu\text{mol/L}$, respectively, but undetectable (detection limit 1.0 $\mu\text{mol/L}$) during the first 6 hours and after 24 hours. The quantities detected were considered clinically insignificant (21).

Diarrhea in a nursing infant, apparently because of the rectal administration of mesalamine to the mother, has been reported (22). The mother had relapsing ulcerative proctitis. Six weeks after childbirth, treatment was begun with 500-mg mesalamine suppositories twice daily. Her exclusively breastfed infant developed watery diarrhea 12 hours after the mother's first dose. After 2 days of therapy, the mother stopped the suppositories and the infant's diarrhea stopped 10 hours later. Therapy was reinstated on four occasions with diarrhea developing each time in the infant 8–12 hours after the mother's first dose and stopping 8–12 hours after therapy was halted. Because of the severity of the mother's disease, breastfeeding was discontinued and no further episodes of diarrhea were observed in the infant (22).

Because of the adverse effect described above, a possible allergic reaction, nursing infants of women being treated with mesalamine or olsalazine should be closely observed for changes in stool consistency. The American Academy of Pediatrics classifies 5-aminosalicylic acid (i.e., mesalamine) as a drug that has produced adverse effects in a nursing infant and should be used with caution during breastfeeding (23).

MESNA

Cytoprotective Agent (Antineoplastic)

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

The limited animal and human data and the pharmacokinetic properties of mesna suggest that the drug poses little, if any, risk to a human fetus. There is no experience, however, in the 1st trimester. Moreover, mesna is probably not protective against ifosfamide- or cyclophosphamide-induced birth defects if these chemotherapy agents are used in the 1st trimester. However, the maternal benefits from use of the agent with ifosfamide or cyclophosphamide to lessen or prevent hemorrhagic cystitis appear to outweigh the unknown fetal risks.

FETAL RISK SUMMARY

Mesna (sodium 2-mercaptoethane sulfonate) is a cytoprotective agent that is used to prevent hemorrhagic cystitis caused by ifosfamide (approved indication) and cyclophosphamide (off label indication). Upon administration, the agent is rapidly oxidized to its only metabolite, mesna disulfide (dimesna). Dimesna remains in the intravascular compartment and is rapidly eliminated by the kidneys where it is changed back to mesna. The elimination half-lives of mesna and dimesna in the blood are 0.36 and 1.17 hours, respectively (1).

Reproduction studies have been conducted in rats and rabbits. Both species were given doses up to 1000 mg/kg during pregnancy without evidence of fetal harm (1). Two studies investigated the reproductive effects of mesna in pregnant rats and rabbits (2,3). In rats, IV doses up to 800 mg/kg on days 7–17 were associated with lumbar ribs at 400 mg/kg and decreased fetal weight at 800 mg/kg (2). Increased open field activity was observed in rat pups exposed in utero to doses of 400 mg/kg or higher. In pregnant rabbits treated similarly, decreased fetal weights and lumbar ribs were observed with doses of 600 mg/kg or higher (3).

In a 1986 study with rats, two doses of mesna were evaluated to determine if they were protective against cyclophosphamide-induced teratogenicity (4). The low dose (5 mg/kg) offered no protection, but the high dose (30 mg/kg) significantly decreased the number of fetuses with external and skeletal malformations. However, the protection was not extensive enough to be considered effective in protecting pregnant women exposed to cyclophosphamide (4).

In a 2003 study, mesna was combined with ifosfamide to determine if the cytoprotective agent could decrease the toxic effects of ifosfamide on the testes and semen characteristics of rabbits (5). Three groups of male rabbits were given different doses of the combination (ifosfamide 30, 45, or 60 mg/kg plus mesna 6, 9, or 12 mg/kg, followed by a second equal dose of mesna 4 hours later, respectively). Each group received 10 weekly treatments. Controls were given either mesna alone (three groups) or saline (one group). Dose-related ifosfamide-mesna suppression of spermatogenesis and epididymal sperm maturation was observed. In addition, the investigators noted incomplete recovery of the germinal epithelium (5).

It is not known if mesna crosses the human placenta. The molecular weight (about 164) is low enough to cross the placenta, but the short elimination half-life of the parent compound and its rapid metabolism to a metabolite that is restricted to the intravascular compartment suggest that little, if any, exposure of embryo or fetus occurs.

Two reports have described the use of mesna in human pregnancy. In both cases, mesna was combined with ifosfamide in the 2nd and/or 3rd trimesters (see Ifosfamide).

BREASTFEEDING SUMMARY

No reports describing the use of mesna during lactation have been located. The molecular weight (about 164) is low enough for excretion into breast milk, but the short elimination half-life of the parent compound (0.36 hours) and its rapid metabolism to a metabolite that is restricted to the intravascular compartment suggest that little, if any, of the drug will appear in milk. However, mesna is always combined with ifosfamide or cyclophosphamide and women receiving these antineoplastic agents should not breastfeed.

MESORIDAZINE

[Withdrawn from the market. See 9th edition.]

MESTRANOL

Estrogenic Hormone

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Mestranol is the 3-methyl ester of ethinyl estradiol. Mestranol is used frequently in combination with progestins for oral contraception (see Oral Contraceptives). Congenital malformations attributed to the use of mestranol alone have not been reported.

FETAL RISK SUMMARY

The Collaborative Perinatal Project monitored 614 mother–child pairs with 1st trimester exposure to estrogenic agents (including 179 with exposure to mestranol) (1, pp. 389, 391). An increase in the expected frequency of cardiovascular defects, eye and ear anomalies, and Down's syndrome was found for estrogens as a group but not for mestranol (1, pp. 389, 391, 395). Reevaluation of these data in terms of timing of exposure, vaginal bleeding in early pregnancy, and previous maternal obstetric history, however, failed to support an association between estrogens and cardiac malformations (2). An earlier study also failed to find any relationship with nongenital malformations (3). The use of estrogenic hormones during pregnancy is contraindicated.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 190 newborns had been exposed to mestranol during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 13 (6.8%) major birth defects were observed (8 expected). Specific data were available for six defect categories, including (observed/expected) 1/2 cardiovascular defects, 1/0.5 oral clefts, 0/0 spina bifida, 0/0.5 polydactyly, 1/0.5 limb reduction defects, and 0/0.5 hypospadias.

BREASTFEEDING SUMMARY

Estrogens are frequently used for suppression of postpartum lactation (4). Doses of 100–150 mcg of ethinyl estradiol (equivalent to 160–240 mcg of mestranol) for 5–7 days are used (4). Mestranol, when used in oral contraceptives with doses of 30–80 mcg, has been associated with decreased milk production, lower infant weight gain, and decreased composition of nitrogen and protein content of human milk (5–7). The magnitude of these changes is low. However, the changes in milk production and composition may be of nutritional importance in malnourished mothers. If breastfeeding is desired, the lowest dose of oral contraceptives should be chosen. Monitoring of infant weight gain and the possible need for nutritional supplementation should be considered (see Oral Contraceptives).

METAPROTERENOL

Respiratory Drug (Bronchodilator)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No published reports linking the use of metaproterenol with congenital defects have been located. Selective β_2 -agonists, including metaproterenol, are commonly used during gestation for the treatment of asthma (1). Fetal tachycardia may occur, but because there is no evidence of fetal injury, there is no contraindication to their use in pregnancy (1). If metaproterenol is used in pregnancy for the treatment of asthma, health care professionals are encouraged to call the toll-free number (877-311-8972) for information about patient enrollment in an Organization of Teratology Information Specialists (OTIS) study.

FETAL RISK SUMMARY

Metaproterenol, a selective β_2 -adrenergic agonist, is used as a bronchodilator for bronchial asthma and for reversible bronchospasm occurring in bronchitis and emphysema.

Reproduction studies in mice, rats, and rabbits have been conducted. No embryotoxic or fetotoxic effects, or teratogenicity was observed in rats at a dose that was about 25 times the maximum recommended human oral dose (MRHOD), but embryo toxicity was observed in mice at 31 times the MRHOD. In rabbits, oral doses 620 times the human inhalation dose and 62 times the MRHOD caused both embryotoxic and teratogenic (skeletal anomalies, hydrocephalus, and skull bone separation) effects (2).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 361 newborns had been exposed to metaproterenol during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 17 (4.7%) major birth defects were observed (15 expected). Specific data were available for six defect categories,

including (observed/expected) 3/4 cardiovascular defects, 1/1 oral clefts, 0/0 spina bifida, 1/1 limb reduction defects, 0/1 hypospadias, and 3/1 polydactyly. Only with the latter defect is there a suggestion of a possible association, but other factors, including the mother's disease, concurrent drug use, and chance, may be involved.

Metaproterenol has been used to prevent premature labor (3–5). Its use for this purpose has been largely assumed by ritodrine, albuterol, or terbutaline. As with all β -mimetics, metaproterenol causes maternal and, to a lesser degree, fetal tachycardia. Maternal hypotension and hyperglycemia and neonatal hypoglycemia should be expected (see also Ritodrine, Albuterol, and Terbutaline). Long-term evaluation of infants exposed in utero to β -mimetics has been reported, but not specifically for metaproterenol (6). No harmful effects in the infants were observed.

BREASTFEEDING SUMMARY

No reports describing the use of metaproterenol during lactation have been located. However, agents in this class, including metaproterenol, are commonly used in the treatment of asthma and there is no contraindication to their use during breastfeeding (1). Neonatal tachycardia, hypoglycemia, or tremor are potential adverse effects (1).

METARAMINOL

[Withdrawn from the market. See 9th edition.]

METAXALONE

Skeletal Muscle Relaxant

PREGNANCY RECOMMENDATION: No Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of metaxalone in human pregnancy have been located. The manufacturer states that postmarketing experience has not revealed evidence of fetal harm (1), but additional details are not provided. The very limited, incomplete animal data and absence of reported human pregnancy experience prevents an assessment of human embryo–fetal risk. Therefore, avoid in the 1st trimester, if possible, if metaxalone is required in pregnancy.

FETAL RISK SUMMARY

Metaxalone is a skeletal muscle relaxant that is indicated as an adjunct to rest and physical therapy and other measures for the relief of discomforts associated with acute, painful musculoskeletal conditions. The agent has no direct effect on muscles. It is thought to act centrally as a sedative. Metaxalone is metabolized by the liver and the unidentified metabolites are excreted in the urine. The mean terminal elimination half-life is approximately 2.4 hours (1).

Reproduction studies in rats revealed no evidence of impaired fertility or fetal harm (1). Further details of these studies have apparently not been published.

It is not known if metaxalone crosses the human placenta. The molecular weight (about 221) suggests that transfer to the fetal compartment should be expected.

BREASTFEEDING SUMMARY

No reports describing the use of metaxalone during lactation have been located. The molecular weight (about 221) suggests the drug will be excreted into breast milk. The effects of this exposure on a nursing infant are unknown.

Because the drug is to be a centrally acting sedative, nursing infants should be closely observed for sedation.

METFORMIN

Antidiabetic Agent

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Both the animal and human data suggest that metformin is low risk in pregnancy. There also appears to be benefit for the use of metformin in women with polycystic ovary syndrome (PCOS). However, for the treatment of diabetes, although metformin may be beneficial for decreasing the incidence of fetal and/or newborn morbidity and mortality in developing countries where the proper use of insulin is problematic, insulin is still the treatment of choice. Moreover, insulin, unlike metformin, does not cross the placenta and, thus, eliminates the additional concern that the drug therapy itself is adversely affecting the fetus. Carefully prescribed insulin therapy will provide better control of the mother's blood glucose, thereby preventing the fetal and neonatal complications that occur with this disease. High maternal glucose levels, as may occur in diabetes mellitus, are associated with a number of maternal and fetal adverse effects, including fetal structural anomalies if the hyperglycemia occurs early in gestation. To prevent this toxicity, the American College of Obstetricians and Gynecologists recommends that insulin be used for types 1 and 2 diabetes occurring during pregnancy and, if diet therapy alone is not successful, for gestational diabetes (1,2).

FETAL RISK SUMMARY

Metformin is an oral, biguanide, antihyperglycemic agent that is chemically and pharmacologically unrelated to the sulfonylureas. Its mechanism of action is thought to include decreased hepatic glucose production, decreased intestinal absorption of glucose, and increased peripheral uptake and utilization of glucose. The latter two mechanisms result in improved insulin sensitivity (i.e., decreased insulin requirements) (3,4).

Reproduction studies found no evidence of impaired fertility in male and

female rats and no evidence of teratogenicity in rats and rabbits at doses up to 600 mg/kg/day, approximately 2 times the maximum recommended human dose based on BSA. A partial placental barrier to metformin was observed, however, based on fetal concentrations (3).

Shepard (5) and Schardein (6) cited a study in rats that observed teratogenesis (neural tube closure defects and edema) in rat fetuses exposed to metformin. The drug did not appear to be a major teratogen because less than 0.5% of the rat fetuses in mothers fed 500–1000 mg/kg developed anophthalmia and anencephaly (5). Higher doses in this study were embryotoxic (7).

A 1994 abstract described the teratogenic effects of high metformin concentrations on early somite mouse embryos exposed in vitro (8). At levels much higher than those obtained clinically, metformin produced neural tube defects and malformations of the heart and eye. In contrast, a study that also appeared in 1994 observed no major malformations in mouse embryos exposed in culture to similar concentrations of metformin (9). About 10% of the embryos, however, demonstrated a transient delay in closure of cranial neuropores.

Several studies have documented that metformin crosses the placenta to the embryo and fetus. In an experiment using the human single-cotyledon model with placentas obtained from diabetic patients and normal controls, researchers measured the effect of metformin on the uptake and transport of glucose in both the maternal-to-fetal and fetal-to-maternal directions (10). A second publication described only the results of the experiments studying the effect of metformin on the maternal-to-fetal direction of glucose (11). Compared with controls, metformin had no effect on the movement of glucose in either direction (10,11). In a third study, a dually perfused human placental lobule was used (12). Metformin was rapidly transferred to the fetal side and was the same in placentas obtained from uncomplicated pregnancies and pregnancies with gestational diabetes. A fourth study measured metformin in women and cord blood at delivery (13). All 15 women had PCOS and were taking 850 mg twice daily. The median maternal, umbilical vein, and umbilical artery serum concentrations were 1.50, 2.81, and 3.16 $\mu\text{mol/L}$, respectively. Metformin had no effect on the pH of umbilical artery blood. No teratogenic effects were observed in the offspring (13).

Among 26 women undergoing treatment for PCOS with metformin, 1.5 g/day for 8 weeks, 3 became pregnant during treatment (14). The women were involved in a study to determine whether metformin was effective in normalizing

the condition that is characterized by insulin resistance and hyperandrogenism. One of the pregnancies aborted after 2 months, but the outcomes of the other two were not mentioned. In three reports from the same center, women who had successfully conceived while taking metformin for PCOS were continued on the agent during pregnancy (15–17). Metformin reduced the incidences of 1st trimester spontaneous abortion and gestational diabetes without causing birth defects or neonatal or maternal complications. The therapy had no adverse effect on birth weight or height, or growth and development at 3 and 6 months of age (16).

A number of references have described the use of metformin during all stages of gestation for the control of maternal diabetes (18–26). A 1979 reference described the therapy of gestational diabetes that included the use of metformin alone (N = 15), glyburide alone (N = 9), or metformin plus glyburide (N = 6) in women who were not controlled on diet alone and did not require insulin (20). None of the newborns developed symptomatic hypoglycemia, and only one infant had a congenital defect (ventricular septal defect). Although the treatment group was not specified, ventricular septal defects are commonly associated with poorly controlled diabetes occurring early in gestation (26).

A 1979 reference described the pregnancy outcomes of 60 obese women who received metformin in the 2nd and the 3rd trimester for diabetes (preexisting [N = 39] or gestational [N = 21]) that was not controlled by diet alone (21). The drug was not effective in 21 (54%) and 6 (29%) of the patients, respectively. The pregnancy outcomes, in terms of hyperbilirubinemia, polycythemia, necrotizing enterocolitis, and major congenital abnormalities, were not better than those observed in another group of insulin-dependent and non-insulin-dependent diabetic women treated by the investigators, except for perinatal mortality. None of the newborns had symptoms of hypoglycemia. The three infants with congenital malformations had defects (two heart defects and one sacral agenesis) that were most likely caused by poorly controlled diabetes occurring early in gestation (21).

Metformin in combination with diet (N = 22) and glyburide (N = 45) was used during pregnancy for the treatment of preexisting diabetes (22). No cases of lactic acidosis or neonatal hypoglycemia were observed with metformin and diet alone, but the latter complication did occur when glyburide was added. Although neonatal hypoglycemia is a well-known complication of sulfonylurea agents ingested close to delivery (e.g., see Chlorpropamide), this effect is unusual with glyburide (see Glyburide). In an earlier reference, 56 patients received metformin up to 24 hours of delivery without adverse effects in the

newborns (19).

Metformin was used during the 1st trimester in 21 pregnancies in a 1984 report (23). A minor abnormality (polydactyly) was observed in a newborn whose mother had taken metformin and glyburide (23). Based on this and previous experience, a treatment regimen was proposed for the management of women with non-insulin-dependent diabetes mellitus (NIDDM) (i.e., type 2 diabetes mellitus) who become pregnant consisting of diet and treatment with metformin and glyburide as necessary (24). If this regimen did not provide control of the blood glucose, a change to insulin therapy was recommended. It was concluded that the drug therapy was not teratogenic, did not cause ketosis, and that neonatal hypoglycemia was preventable if the therapy was changed to insulin before delivery (24).

A 1990 reference addressed the problem of treating diabetes in tropical countries where the availability of medical support and facilities is poor (25). It was recommended that gestational diabetes, not responding to diet alone, could be treated with sulfonylurea agents or metformin or both because of the difficulty in initiating insulin therapy in developing countries (25).

The fetal effects of oral hypoglycemic agents on the fetuses of women attending a diabetes and pregnancy clinic were reported in 1991 (26). All of the women (N = 21) had NIDDM and were treated during organogenesis with oral agents (1 with metformin, 2 with phenformin, 17 with sulfonylureas, and 1 with an unknown agent), with a duration of exposure of 3–28 weeks. A control group (N = 40) of similar women with NIDDM who were also attending the clinic, matched for age, race, parity, and glycemic control, was used for comparison. Both groups of patients were changed to insulin therapy at the first prenatal visit. From the study group, 11 infants (52%) had congenital malformations, compared with 6 (15%) from the controls ($p < 0.002$). Moreover, six of the newborns from the study group (none in the control group) had ear defects, a malformation that is observed, albeit uncommonly, in diabetic embryopathy. No defects were seen in the one infant exposed to metformin. Sixteen live births occurred in the exposed group, compared with 36 in controls. The groups did not differ in the incidence of hypoglycemia at birth (53% vs. 53%), but three of the exposed newborns had severe hypoglycemia lasting 2, 4, and 7 days, respectively, even though the mothers had not used the oral agents close to delivery. In one of these cases, the mother had been taking metformin 1500 mg daily for 28 weeks. Hyperbilirubinemia was noted in 10 (67%) of 15 exposed liveborn infants, compared with 13 (36%) of the controls, and polycythemia and hyperviscosity requiring partial exchange transfusions were observed in 4

(27%) of 15 exposed vs. 1 (3.0%) control (one exposed infant was not included in these data because the child presented after completion of the study) (26).

A 2004 report described the outcomes of 90 women with PCOS who conceived on metformin (27). Metformin was not associated with preeclampsia. Of the 100 live births, there were no major birth defects (27).

In a second 2004 study, the growth and motor-social development during the first 18 months of 126 live births to 109 women (122 pregnancies) with PCOS was assessed (28). All of the women had conceived while on metformin (1.5–2.55 g/day) and 104 (85%) continued the drug throughout pregnancy. There were two (1.6%) birth defects: a sacrococcygeal teratoma and a tethered spinal cord. Gestational diabetes was significantly lower in the PCOS group than in controls, 7/6% vs. 15.9%. In the 52 male neonates, the birth weight and length did not differ from controls, whereas the 74 female neonates weighed less (3.09 vs. 3.29 kg) and were shorter (48.9 vs. 50.6 cm) than controls. However, there were no systematic differences in growth between the PCOS group and controls over 18 months. At 3, 6, 9, 12, and 18 months, motor-social development scores were >94% and no metformin-exposed infant had motor-social development delays (28).

BREASTFEEDING SUMMARY

Consistent with its molecular weight (about 166), metformin is excreted into breast milk. In seven women taking metformin (500 mg 3 times daily), the mean milk:plasma ratio was 0.35 and the average metformin concentration over the dosing interval was 0.27 mcg/mL (29). The average infant dose received from the milk was about 0.28% of the mother's weight-adjusted dose. A second study involving eight women (three at steady state and five after a single 500-mg dose) estimated that nursing infants would ingest about 0.11%–0.21% of the mother's weight-adjusted dose (30). For the women at steady state, the milk:plasma ratios (based on AUC) were 0.37–0.71. The concentration–time profile of the drug was relatively flat in all subjects (30).

A 2005 study measured metformin in the milk of five women and the effects of this exposure in three of their infants (31). The women were started on metformin (500 mg twice daily) on the first day after cesarean delivery. Peak and trough serum and milk samples were drawn at steady state. The mean serum peak and trough levels in four women (one woman was excluded because her trough level was below the level of detection) were 1.06 and 0.42 mcg/mL, respectively, whereas similar samples from milk yielded mean concentrations of 0.42 and 0.39 mcg/mL, respectively. The mean milk:serum

ratio was 0.63. The mean estimated dose as a percentage of the mother's weight-adjusted dose was 0.65% (range 0.43%–1.08%). In three infants, the blood glucose concentrations 4 hours after a feeding were normal (47–77 mg/dL) (31).

METHACYCLINE

[Withdrawn from the market. See 9th edition.]

METHADONE

Narcotic Agonist Analgesic

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

The reported use in pregnancy of methadone is almost exclusively related to the treatment of heroin addiction, but the drug also is used in patients addicted to other opioid agonists. The National Birth Defects Prevention Study discussed below found evidence that opioid use during organogenesis is associated with a low absolute risk of congenital birth defects. A second study also found a similar association. Because patients taking methadone usually consume a wide variety of drugs, it is not always possible to separate completely the effects of methadone from the effects of other agents. Neonatal narcotic withdrawal and low birth weight appear to be major problems.

FETAL RISK SUMMARY

Withdrawal symptoms occur in approximately 60%–90% of the infants exposed in utero to methadone (1–6). One study concluded that the intensity of withdrawal was increased if the daily maternal dosage exceeded 20 mg (5). When withdrawal symptoms do occur, they normally start within 48 hours after delivery, but a small percentage may be delayed up to 7–14 days (1). One report observed initial withdrawal symptoms appearing up to 28 days after birth, but the authors do not mention if mothers of these infants were breastfeeding (6). Methadone concentrations in breast milk are reported to be sufficient to prevent withdrawal in addicted infants (see Breastfeeding Summary below). Some authors believe methadone withdrawal is more intense than that occurring with heroin (1). Less than one-third of symptomatic infants, require therapy (1–5). A lower incidence of hyaline membrane disease is seen in infants exposed in utero to chronic methadone and may be due to elevated blood levels of prolactin (7).

Infants of drug-addicted mothers are often small for gestational age (SGA). In some series, one-third or more of the infants weigh less than 2500 g (1,2,4). The newborns of methadone addicts may have a higher birth weight than comparable offspring of heroin addicts for reasons that remain unclear (4).

Other problems occurring in the offspring of methadone addicts are increased mortality, sudden infant death syndrome (SIDS), jaundice, and thrombocytosis. A correlation between drug addiction and SIDS has been suggested with 20 cases (2.8%) in a group of 702 infants, but the data could not attribute the increase to a single drug (8,9). Another study of 313 infants of methadone-addicted mothers reported 2 cases (0.6%) of SIDS, an incidence similar to the overall experience of that location (4). In one study, a positive correlation was found between severity of neonatal withdrawal and the incidence of SIDS (9). Maternal withdrawal during pregnancy has been observed to produce a marked response of the fetal adrenal glands and sympathetic nervous system (10). An increased stillborn and neonatal mortality rate has also been reported (11). Both reports recommend against detoxification of the mother during gestation. Jaundice is comparatively infrequent in both heroin- and methadone-exposed newborns. However, a higher rate of severe hyperbilirubinemia in methadone-exposed infants than in a comparable group of heroin-exposed infants has been observed (1). Thrombocytosis developing in the 2nd week of life, with some platelet counts exceeding $1,000,000/\text{mm}^3$ and persisting for more than 16 weeks has been reported (12). The condition was not related to withdrawal symptoms or neonatal treatment. Some of these infants also had increased circulating platelet aggregates.

Respiratory depression is not a significant problem, and Apgar scores are comparable to those of a nonaddicted population (1–5). Long-term effects on the behavior and gross motor development skills are not known.

Results of a National Birth Defects Prevention Study (1997–2005) were published in 2011 (13). This population-based case–control study examined the association between maternal use of opioid analgesics and >30 types of major structural birth defects. In 17,449 case mothers, therapeutic opioid use was reported by 454 (2.6%) compared with 134 (2.0%) of 6701 control mothers. Indications for use of opioid analgesics were surgical procedures (41%), infections (34%), chronic diseases (20%), and injuries (18%). Dose, duration, or frequency were not evaluated. The exposure period evaluated was from 1 month before to 3 months after conception. Limiting the exposure period to the first 2 months after conception produced similar results. Infants with >1 defect

were included in multiple birth defect categories. The following opioids were included (number of cases for each agent not specified): codeine, hydrocodone, hydromorphone, fentanyl, meperidine, methadone, morphine, oxycodone, pentazocine, propoxyphene, and tramadol. The birth defect, total number, number exposed, and the adjusted odds ratio (aOR) with 95% confidence interval (CI) were as follows:

| Birth Defect | Total | Cases | aOR (95% CI) |
|--|-------|-------|---------------|
| Spina bifida | 718 | 26 | 2.0 (1.3–3.2) |
| <i>Any heart defect (20 types)</i> | 7724 | 211 | 1.4 (1.1–1.7) |
| Atrioventricular septal defect | 175 | 9 | 2.4 (1.2–4.8) |
| Teratology of Fallot | 672 | 21 | 1.7 (1.1–2.8) |
| Conotruncal defect | 1481 | 41 | 1.5 (1.0–2.1) |
| Conoventricular septal defect | 110 | 6 | 2.7 (1.1–6.3) |
| Left ventricular outflow tract obstruction defect | 1195 | 36 | 1.5 (1.0–2.2) |
| Hypoplastic left heart syndrome | 357 | 17 | 2.4 (1.4–4.1) |
| Right ventricular outflow tract obstruction defect | 1175 | 40 | 1.6 (1.1–2.3) |
| Pulmonary valve stenosis | 867 | 34 | 1.7 (1.2–2.6) |
| Atrial septal defect (ASD) | 511 | 17 | 2.0 (1.2–3.6) |
| Ventricular septal defect + ASD | 528 | 17 | 1.7 (1.0–2.9) |
| Hydrocephaly | 301 | 11 | 2.0 (1.0–3.7) |
| Glaucoma/anterior chamber defects | 103 | 5 | 2.6 (1.0–6.6) |
| Gastroschisis | 726 | 26 | 1.8 (1.1–2.9) |

The authors speculated that the activity of opioids and their receptors as growth regulators during development of the embryo might be a mechanism to explain the above findings. The exposure data were obtained by retrospective maternal self-report; the authors acknowledged that recall bias and misclassification might have affected their results. They concluded that the absolute risk was a modest absolute increase above the baseline risk for birth defects (13).

In a 2011 retrospective cohort study from Ireland, there were 61,030

singleton births from one hospital in 2000–2007 (14). Among these births, there were 618 (1%) on methadone at delivery who were more likely to be younger and smokers. Exposure to methadone was associated with increased risk of preterm birth <32 weeks' gestation (aOR 2.47, 95% CI 1.40–4.34), SGA (<10th percentile) (aOR 3.27, 95% CI 2.49–4.28), admission to the neonatal unit (aOR 9.14, 95% CI 7.21–11.57), and a major birth anomaly (aOR 1.94, 95% CI 1.10–3.43). There was a dose–response relationship between methadone and neonatal abstinence syndrome (14).

A 1980 case report described a female infant born at 34 weeks' to a mother enrolled in a methadone program for heroin addiction and who also used LSD (15). Both drugs were used throughout gestation. The infant had left anophthalmia but no other defects. The authors thought that LSD was the most likely cause of the defect (15).

Two reports described the occurrence of strabismus in infants exposed in utero to methadone (primarily) and other opioids (16,17). The incidence of the eye defect was 8–10 times the occurrence in a nonexposed population.

BREASTFEEDING SUMMARY

Methadone is excreted into breast milk and claims have been made that it could prevent withdrawal in addicted infants. One study reported an average milk concentration in 10 patients of 0.27 mcg/mL, representing an average milk:plasma ratio of 0.83 (18). The same investigators earlier reported levels ranging from 0.17 to 5.6 mcg/mL in the milk of mothers on methadone maintenance (2). At least one infant death has been attributed to methadone obtained through breast milk (19). However, a recent report claimed that methadone enters breast milk in very low quantities that are clinically insignificant (20).

A 1997 report described two cases where the mothers were taking high maintenance doses of methadone (73 and 60 mg/day) (21). Both mothers breastfed their infants. The average milk:plasma ratios were 0.66 and 1.22, respectively. The amounts of methadone in milk were considered to be negligible (21). A 2000 study evaluated eight lactating women who were taking methadone (25–180 mg/day) (22). The mean amount of methadone in milk was 95 ng/mL (range 27–260 ng/mL). Based on an estimated newborn milk intake of 475 mL/day, the estimated mean daily methadone dose was 0.05 mg/day. No adverse effects of the exposure were observed during the duration of breastfeeding (2.5–21 months) or during weaning (22).

In another 1997 study, 12 breastfeeding women were taking methadone in

single daily doses of 20–80 mg (23). The mean milk:plasma ratio was 0.44 (95% CI 0.24–0.64). The mean infant dose as a percentage of the mother's dose was 2.79% (2.07%–3.51%). In blood samples obtained from eight infants, seven had methadone concentrations below the limit of detection. The plasma concentration in the eighth infant was 6.5 mcg/L. Milk methadone was insufficient to prevent the development of neonatal abstinence syndrome in seven infants. No drug-induced adverse effects were observed in the 12 infants (23).

The American Academy of Pediatrics classifies methadone as compatible with breastfeeding (24).

METHAZOLAMIDE

Diuretic (Carbonic Anhydrase Inhibitor)

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Methazolamide is a carbonic anhydrase inhibitor used in glaucoma to lower intraocular pressure. No reports describing the use of methazolamide in human pregnancy have been located. The drug is teratogenic in some animal species (1). (See also Acetazolamide.)

BREASTFEEDING SUMMARY

No reports describing the use of methazolamide during human lactation have been located.

METHDILAZINE

[Withdrawn from the market. See 9th edition.]

METHENAMINE

Urinary Germicide

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Methenamine, in either the mandelate or the hippurate salt forms, is used for chronic suppressive treatment of bacteriuria. The limited human data do not suggest risk.

FETAL RISK SUMMARY

In two studies, the mandelate form was given to 120 patients and the hippurate to 70 patients (1,2). No increases in congenital defects or other problems as compared with controls were observed.

The Collaborative Perinatal Project reported 49 1st trimester exposures to methenamine (3, pp. 299, 302). For use anytime in pregnancy, 299 exposures were recorded (3, p. 435). Only in the latter group was a possible association with malformations found. Independent confirmation is required.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 209 newborns had been exposed to methenamine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Eight (3.8%) major birth defects were observed (nine expected). Specific data were available for six defect categories, including (observed/expected) 1/2 cardiovascular defects, 1/0.5 oral clefts, 0/0 spina bifida, 1/1 polydactyly, 1/0.5 limb reduction defects, and 0/0.5 hypospadias. These data do not support an association between the drug and congenital defects.

Methenamine interferes with the determination of urinary estrogen (4). Urinary estrogen was formerly used to assess the condition of the fetoplacental unit, depressed levels being associated with fetal distress. This assessment is now made by measuring unconjugated estriol, which is not affected by methenamine.

BREASTFEEDING SUMMARY

Methenamine is excreted into breast milk. Peak levels occur at 1 hour (5). No adverse effects on the nursing infant have been reported.

METHICILLIN

[Withdrawn from the market. See 9th edition.]

METHIMAZOLE

Antithyroid

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Structural anomalies that have been observed after exposure during organogenesis have suggested a phenotype for methimazole embryopathy (1,2), but the complete spectrum of anomalies may need further definition (3). Carbimazole is converted in vivo to methimazole. Some of the anomalies have also been seen in untreated hyperthyroidism. If methimazole or carbimazole is used, the lowest possible dose to control the maternal disease should be given. One review recommended that the dosage should be adjusted to maintain the maternal free thyroxine levels in a mildly thyrotoxic range (4).

FETAL RISK SUMMARY

Methimazole, a thiourea antithyroid agent, is used for the treatment of hyperthyroidism. It readily crosses the placenta to the fetus. Two patients undergoing 2nd trimester therapeutic abortions were given a single 10-mg ³⁵S-labeled oral dose 2 hours before pregnancy termination (5). Fetal:maternal serum ratios were 0.72 and 0.81, representing 0.22% and 0.24% of the administered dose. In the same study, three patients at 14, 14, and 20 weeks' gestation were given an equimolar dose of carbimazole (16.6 mg). Fetal:maternal serum ratios were 0.80–1.09 with 0.17%–0.87% of the total radioactivity in the fetus. The highest serum and tissue levels were found in the 20-week-old fetus (5).

A comparison of the placental transfer of methimazole and propylthiouracil (PTU) in the perfused human term placental lobule was reported in 1997 (6). Because there were no significant differences between the drugs, the investigators concluded that the drugs have similar placental transfer kinetics.

Early references reported 11 cases of scalp defects (aplasia cutis congenita) in newborns exposed in utero to methimazole or carbimazole (converted in vivo

to methimazole) (7–11). In 2 of the 11 infants, umbilical defects (patent urachus in one; patent vitelline duct in another) were also observed, suggesting to one investigator, because of the rarity of these defects, that the combination of anomalies represented a possible malformation syndrome (9). In one of the above cases, α -fetoprotein was elevated in both the maternal serum (3–18 standard deviations [SD] above normal) and the amniotic fluid (2.4–4 SD above normal) (11). The 6-cm scalp defect was the only defect found in the newborn who had been exposed during the 1st trimester to methimazole (10 mg/day).

In contrast, a 1987 study examined the records of 49,091 live births for cases of congenital skin defects (12). Of such cases 25 (0.05%) were identified, 13 (0.03%) of which were confined to the scalp. In the sample of 48,057 women, 24 were treated with methimazole or carbimazole during the 1st trimester, but none of these mothers produced children with the skin defects. The authors concluded that they could not exclude an association between the therapy and scalp defects, but if it existed, it was a weak association (12).

Defects observed in two infants exposed to the antithyroid agents in two other reports were imperforate anus (8) and transposition of the great arteries (died at 3 days of age) (13). In a large prospective study, 25 patients were exposed to one or more noniodide thyroid suppressants during the 1st trimester, 9 of whom took methimazole (14). From the total group, 4 children with nonspecified malformations were found, suggesting that the drugs may be teratogenic. However, since 16 of the group took other antithyroid drugs, the relationship between methimazole and the anomalies cannot be determined. In a study of 25 infants exposed to carbimazole, 2 were found to have defects: bilateral congenital cataracts and partial adactyly of the right foot (15). Because no pattern of malformations has emerged from these reports, it appears that these malformations were not associated with the drug therapy. In addition, other reports have described the use of methimazole and carbimazole during pregnancy without fetal anomalies (16–30).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 5 newborns had been exposed to methimazole during the 1st trimester (F. Rosa, personal communication, FDA, 1993). One (20.0%) major birth defect was observed (none expected), a hypospadias.

A 1984 report described the relationship between maternal Graves' disease and major structural malformations of external organs, including the oral cavity, in 643 newborns (31). Of 167 newborns delivered from mothers who were

hyperthyroid during gestation, 117 were exposed in utero to methimazole. In 50 newborns, the mothers received no treatment, other than subtotal thyroidectomy before or during pregnancy. The incidences of anomalies in these two groups were 1.7% (2 of 117) and 6.0% (3 of 50), respectively. For 476 neonates the mothers were euthyroid during gestation, with 126 receiving treatment with methimazole and 350 receiving no treatment (other than surgery). No malformations were observed in the methimazole-exposed infants and only 1 (0.3%) occurred in the patients not receiving drug therapy. The difference in malformation rates between the nonexposed neonates in the hyperthyroid and euthyroid groups was significant (6% vs. 0.3%, $p < 0.01$). Similarly, the difference between the two groups in total malformations, 3% (5 of 167) vs. 0.2% (1 of 476) was also significant ($p < 0.01$). The defects observed were malformation of the earlobe (methimazole-exposed, hyperthyroid), omphalocele (methimazole-exposed, hyperthyroid), imperforate anus (hyperthyroid), anencephaly (hyperthyroid), harelip (hyperthyroid), and polydactyly (euthyroid). The authors concluded that the disease itself causes congenital malformations and that the use of methimazole lessened the risk for adverse outcome (31).

A 1987 case report described a female infant (46,XX) who had been exposed throughout gestation to methimazole and propranolol given for maternal hyperthyroidism (32). Choanal atresia was noted at birth and treated surgically. At 6 months of age, she was noted to be developmentally delayed, especially in gross motor development, and had mild neurosensory hearing loss bilaterally and recurrent dacryocystitis. By 3.5 years, her development continued to be markedly delayed. Her height and weight were below the 3rd percentile and a small area of alopecia was noted in the parietal region close to the midline on the otherwise normal scalp. Although the chest was symmetrical, both nipples were absent (athelia). Other abnormalities noted at this time were upper slanting palpebral fissures and epicanthal folds, a broad nasal bridge with slightly anteverted nostrils, and a tented upper lip with a short philtrum (32).

Two cases of esophageal atresia and tracheoesophageal fistula in newborn infants exposed throughout gestation to methimazole (30 mg/day) were reported in 1992 (33). The mothers were euthyroid during pregnancy. Both newborns were small for gestational age and had palpable goiters with laboratory evidence of hypothyroidism. Surgical correction of the defects was attempted but the infants died from postoperative sepsis and renal failure. At autopsy, in addition to the defects noted above, one infant had a ventricular

septal defect and a Meckel's diverticulum, and both had diffuse goiters. Because of the relatively low frequency of esophageal atresia and tracheoesophageal fistula (1:3000–1:4500), the authors attributed the defects to methimazole (33).

A 1992 study reported no difference in the intellectual capacity of offspring of 31 mothers with Graves' disease who were treated during gestation with either methimazole (N = 15) or PTU (N = 16) when compared with nonexposed controls (34). The ages of the subjects ranged from 4 to 23 years. None was hypothyroid or had goiter at birth. There were no differences between the antithyroid drugs, and there was no correlation between dosage used and intelligence (34).

Two reports, one in 1994 and the other in 1995, described aplasia cutis in two newborns exposed during pregnancy to methimazole (35,36). In reviewing their case and previously published cases, the authors of the 1994 publication were uncertain of a causal association between the drug and the scalp defect (35). The other group of authors concluded that the evidence indicated a strong association between the drug and aplasia cutis (36). Both groups concluded, because no such cases had been reported with PTU, that this drug was preferred for the treatment of hyperthyroidism during pregnancy (35,36).

A female infant exposed in utero to methimazole during the first 2 months of pregnancy and then to PTU until term was described in a 1997 abstract (37). Birth weight and length were normal as was the chromosomal analysis (46,XX). Malformations observed in the infant were choanal atresia, right iris/retinal coloboma, right renal pelvis ectasia, and minor facial anomalies (37).

A brief 1996 report described multiple malformations in a newborn of a woman who was treated with methimazole (38). Metoprolol (150 mg/day) and methimazole (30 mg/day) were taken throughout most of the 1st trimester. Levothyroxine was also administered during most of the pregnancy. Metoprolol was discontinued at about 9 weeks' gestation and the methimazole dose was gradually tapered until a subtotal thyroidectomy was performed at 18 weeks'. Premature labor could not be arrested and a 750-g male infant was delivered at 27 weeks' with Apgar scores of 1, 0, and 3 at 1, 5, and 10 minutes, respectively. Major malformations evident were choanal atresia, esophageal atresia with tracheoesophageal fistula, omphaloenteric connection, and multiple ventricular septal defects. The infant died at 6 weeks of age secondary to complications arising from corrective surgery (38).

A 1998 case report described a 3-year-old boy with choanal atresia (surgically corrected shortly after birth), hypoplastic nipples (hypothelia; see

also reference 32 for a case of athelia), and developmental delay (1). He had been exposed throughout a 34 weeks' gestation to carbimazole, but was euthyroid at birth. He was hypotonic at birth and remained so at 3 years of age. He had mild global but predominantly motor developmental delay. His height and weight were at the 10th percentile or less. Other features noted were short upslanting palpebral fissures (length <3rd percentile), small nose and mouth, and a short philtrum. The nipples were hypoplastic and inverted. The mother had a normal, healthy child before and after the subject case. The authors suggested that the combination of malformations represented a rare but distinct syndrome of methimazole teratogenicity (1).

A case of multiple defects in a newborn infant exposed in utero to methimazole (20 mg/day) was reported in 1999 (2). The mother, who was euthyroid on therapy, had taken methimazole for 9 years prior to conception and was continued on the drug during the first 7 gestational weeks (i.e., 9 weeks after the first day of the last menstrual period). At that time, she was changed to PTU for the remainder of her pregnancy. A 1475-g (25th–50th percentile) male preterm infant was delivered at 31 gestational weeks because of premature rupture of the membranes. The Apgar scores, length, and head circumference were not recorded, but severe respiratory distress required assisted ventilation. Anomalies observed in the infant were bilateral choanal atresia, esophageal atresia and tracheoesophageal fistula, patent ductus arteriosus (closed spontaneously at 2 months), and periventricular leukomalacia with bilateral parieto-occipital cavitations. The latter defect was confirmed by magnetic resonance imaging (MRI) at age 2 years and was thought to be of possible hypoxic-ischemic origin and related to prematurity. At 7 months of age, abdominal sonography, chromosomal analysis, and brain-stem auditory evoked responses were normal. An eye examination revealed bilateral convergent strabismus, mildly pale papillae, and diffuse depigmentation of the fundi. Severe psychomotor retardation with mixed tetraparesis was evident. At 4.25 years, the weight and height were both below the 3rd percentile for age, he was unable to walk or sit without support, and language was absent. Physical examination noted dolichocephaly, bilateral ptosis of the eyelid with inner epicanthal fold, convergent squint, mild malar hypoplasia, small nose with moderately anteverted nostrils, long and flat philtrum, a highly arched palate, bilateral bridged palmar creases, axial hypotonia and limb hypertonia, poor head control, Moro-like reflexes, and bilateral talipes varus. A localized (6 × 6 cm) patchy defect consisting of short, sparse, kinky, and hypopigmented hair in the occipital region was also noted. Based on previously reported cases, the

defects suggested to the authors that they represented a specific teratogenic malformation syndrome (2).

A 2000 report described various congenital abnormalities observed in a term, female infant of a woman who was kept euthyroid throughout pregnancy with methimazole 30 mg/day (3). Aplasia cutis congenita was noted at birth. Seizures were noted at 18 months of age. At 3 years of age, the child's height, weight, and head circumference were normal (75th–80th percentile) as was her psychomotor development. Minor facial abnormalities consisted of hypertrichosis of the eyelashes and synophrys. There were areas of hyperpigmented skin on the back; two supernumerary nipples' bilateral syndactylies between the third and fourth fingers and between the second and third toes; dystrophic, small and shortened fingernails; and longitudinal ridges on a finger of each hand. Brain MRI, electroencephalogram, and karyotyping findings were normal. The authors considered this case to represent a new combination of signs, including abnormalities of various tissues of ectodermal origin (fingernails and skin anomalies) and epilepsy that were associated with in utero exposure to methimazole (3).

Several reports have studied pregnancies complicated by hyperthyroidism and the effects of methimazole and carbimazole on maternal and fetal thyroid indexes (4,27,39–41). In separate pregnancies in a mother with Graves' disease, fetal thyrotoxicosis was treated with 20–40 mg/day of carbimazole with successful resolution of fetal tachycardia in both cases and disappearance of fetal goiter in the first infant (27). A woman with hyperthyroidism was treated with a partial thyroidectomy before pregnancy (40). She subsequently had four pregnancies, all of which were complicated by fetal hyperthyroidism. No antithyroid therapy was administered during her first two pregnancies. The first ended in a late stillbirth, and the second resulted in a child with skull deformities. Both adverse outcomes were compatible with fetal hyperthyroidism. Carbimazole was administered in the next two pregnancies and both resulted in normal infants (40).

A 1992 abstract and a later full report described a retrospective evaluation of hyperthyroid pregnancy outcomes treated with either methimazole (N = 36) or PTU (N = 99) (42,43). One newborn (2.8%) in the methimazole group had a birth defect (inguinal hernia) whereas 3 (3.0%) defects were observed in those exposed to PTU (ventricular septal defect, pulmonary stenosis, patent ductus arteriosus in a term infant). No scalp defects were observed.

A 2001 report described the pregnancy outcomes of 241 women counseled by Teratology Information Services (TIS) associated with the European

Network of Teratology Information Services because of exposure to carbimazole (20–40 mg/day) or methimazole (8–50 mg/day) during the 1st trimester (44). The control group consisted of 1089 pregnant women who had contacted the TIS concerning exposures to nonteratogenic agents. There was no increase in the rate of major birth defects in the exposed pregnancies compared with controls. However, two newborns had defects (choanal atresia; esophageal atresia) that were consistent with the anomalies postulated for methimazole embryopathy (44).

A 2003 case report described the outcomes of two pregnancies with hyperthyroidism (45). Diagnosis of the disease was made in the 2nd trimester and methimazole was started at 14 and 16 weeks' gestation, respectively. In the first case, discordant female twins (2000 and 1200 g) were delivered at 33.5 weeks'. Twin A was normal but twin B had esophageal atresia and tracheoesophageal fistula. After corrective surgery, she was growing adequately at 9 months of age. In the second case, intrauterine growth restriction occurred and a 1400-g female infant was delivered at 33 weeks'. Apgar scores were 6 and 10 at 1 and 5 minutes, respectively. The infant developed jaundice and examination revealed a complete absence of the biliary ducts and tree. The infant is now 18 months old and is waiting for a liver transplantation. Both affected infants were euthyroid at birth. Because the observed defects were associated with 1st trimester methimazole exposure, the authors raised the question of whether the actual teratogen was untreated hyperthyroidism (45).

Two cases of major congenital defects were described in another 2003 report (46). Both pregnancies (one with twins) were treated with methimazole in the 1st trimester. In one case, methimazole (10 mg/day) was replaced with propylthiouracil at 8 weeks'. A 2550-g, euthyroid female infant was delivered at 36 weeks' with Apgar scores of 5, 7, and 7 at 1, 5, and 10 minutes, respectively. Defects recognized in the infant included choanal atresia, aplasia cutis, umbilical hernia, sacral pilonidal sinus, limb hypertonia, and downslanting palpebral fissures. Additional follow-up could not be obtained. In the second case (twins), the mother received methimazole 40 mg/day until the 18th week when the dose was decreased to 20 mg/day. The male twins were euthyroid with birth weights of 1850 and 1900 g with Apgar scores of 9 and 9 at 1 and 5 minutes, respectively. No malformations were detected in the larger twin. However, the smaller twin had a full-thickness defect of the parietal scalp and a small omphalocele. At 12 months of age, the small twin had mild global (mostly motor) developmental delay, whereas development in the larger twin was

normal (46).

Treatment of maternal hyperthyroidism may result in mild fetal hypothyroidism because of increased levels of fetal pituitary thyrotropin (21,24,41,47). This usually resolves within a few days without treatment (20). An exception to this occurred in one newborn exposed to 30 mg of carbimazole daily to term who appeared normal at birth but who developed hypothyroidism evident at 2 months of age with subsequent mental retardation (16).

A brief 1992 report from Spain examined the relationship between the illicit and uncontrolled use of methimazole in cattle feed as a weight enhancer and the appearance of congenital scalp aplasia cutis in humans (48). Seven cases of the rare malformation were observed in 1990–1991 in regions thought to have used methimazole in cattle food. The investigators speculated that pregnant women eating the meat of methimazole-exposed cattle would expose their fetuses to the drug (48).

Small, usually nonobstructing goiters in the newborn have been reported frequently with PTU (see Propylthiouracil). Only two goiters have been reported in carbimazole-exposed newborns and none with methimazole (13). Long-term follow-up of 25 children exposed in utero to carbimazole showed normal growth and development (15).

Combination therapy with thyroid–antithyroid drugs was advocated at one time but is now considered inappropriate (see also Propylthiouracil) (22,25,47,49,50). Two reasons contributed to this change: (a) use of thyroid hormones may require higher doses of the antithyroid drug to be used, and (b) placental transfer of levothyroxine and liothyronine is minimal and not sufficient to reverse fetal hypothyroidism (see also Levothyroxine and Liothyronine) (24).

A 2002 review of the fetal effects of antithyroid drugs concluded that the evidence for a specific methimazole syndrome is inadequate (51). However, the cluster of case reports of aplasia cutis congenita cases suggests a weak association but additional studies are required.

A 2007 case report described a male child whose mother had taken methimazole throughout most of pregnancy; 50 mg/day from conception to 5.5 weeks', no medication until 9 weeks', then 30 mg/day until delivery (52). At 40 weeks', a 2.270-kg (3rd percentile) male was delivered with Apgar scores of 9 and 10 at 1 and 5 minutes, respectively. Examination at 19 months of age revealed the following: height 75 cm (3rd percentile), weight 8.9 kg (<3rd percentile), and head circumference 44 cm (<3rd percentile). Relevant features included upward slanted palpebral fissures, arched flared eyebrows, small nose with broad nasal bridge, restriction of supination–rotation in both arms,

and bilateral radioulnar synostosis. No choanal stenosis was found. Developmental delay was documented at 4 years 5 months of age (52).

Because of the possible association with aplasia cutis and other malformations, and the passage of methimazole into breast milk, many investigators, including two in 1984 (53), consider PTU to be the drug of choice for the medical treatment of hyperthyroidism during pregnancy. However, this opinion is not universal (50).

BREASTFEEDING SUMMARY

Methimazole is excreted into breast milk (54–57). In a patient given 10 mg of radiolabeled carbimazole (converted in vivo to methimazole), the milk:plasma ratio was a fairly constant 1.05 over 24 hours (54). This represented about 0.47% of the given radioactive dose. In a second study, a patient was administered 2.5 mg of methimazole every 12 hours (55). The mean milk:plasma ratio was 1.16, representing 16–39 mcg of methimazole in the daily milk supply. Extrapolation of these results to a daily dose of 20 mg indicated that approximately 3 mg/day would be excreted into the milk (55). Five lactating women were given 40 mg of carbimazole, producing a mean milk:plasma ratio at 1 hour of 0.72 (56). For the 8-hour period after dosing, the milk:plasma ratio was 0.98. A new radioimmunoassay was used to measure methimazole milk levels after a single 40-mg oral dose in four lactating women. The mean milk:plasma ratio during the first 8 hours was 0.97, with 70 mcg excreted in the milk (56).

A 1987 publication described the results of carbimazole therapy in a woman breastfeeding twins (57). Two months after delivery, the mother was started on carbimazole, 30 mg/day. The dose was decreased as she became euthyroid. Three paired milk:plasma levels revealed ratios of 0.30–0.70. The mean free methimazole concentration in milk, determined between 2 and 16 weeks of therapy, was 43 ng/mL (range 0–92 ng/mL). Peak milk levels occurred 2–4 hours after a dose. Mean plasma levels in the twins were 45 ng/mL (range 0–105 ng/mL) and 52 ng/mL (range 0–156 ng/mL), with the highest concentrations occurring while the mother was taking 30 mg/day. No evidence of thyroid suppression was found clinically or after thyroid function tests in the nursing twins (57).

Two other studies also found no effect on clinical status or thyroid function in nursing infants of mothers taking carbimazole or methimazole (58,59). In one report, no adverse effects were observed during a 3-week study of 11 infants whose mothers were taking carbimazole 5–15 mg/day (58). In the other study,

normal thyroid function in 35 nursing infants, whose mothers were taking methimazole, was documented over periods ranging from 1 to 6 months (59). Most mothers were taking 5–10 mg/day, but six received 20 mg/day for 1 month and then tapered to 5 mg/day.

Because the amounts found in some studies may cause thyroid dysfunction in the nursing infant, methimazole and carbimazole have, in the past, been considered contraindicated during lactation. If antithyroid drug therapy was required, PTU was considered the treatment of choice, partially because PTU is ionized at physiologic pH and because 80% of the drug is protein bound (60). Methimazole is neither ionized nor protein bound, but small doses of methimazole (e.g., 10–20 mg/day or less) do not appear to pose a major risk to the nursing infant if thyroid function is monitored at frequent (e.g., weekly or biweekly) intervals (58–60).

In 2000, a long-term study confirmed the lack of toxicity in infants of mothers being treated with methimazole (61). A total of 139 thyrotoxic lactating mothers and their nursing infants were studied, 51 of the mothers were treated with methimazole during pregnancy and continued their treatment during lactation. The other 88 women started methimazole therapy during lactation with 10–20 mg/day for 1 month, 10 mg/day during the second month, then 5–10 mg/day thereafter. Methimazole serum levels in six infants whose mothers were taking 20 mg/day were <0.03 mcg/mL, 2 hours after breastfeeding. No effects on infant thyroid function were detected at various times up to 12 months. In a blinded assessment, the total IQ scores, including verbal and performance IQ, of 14 children (age 48–74 months) exposed to methimazole in milk did not differ from 17 nonexposed controls (61).

The American Academy of Pediatrics classifies methimazole and carbimazole as compatible with breastfeeding (62).

METHIXENE

[Withdrawn from the market. See 9th edition.]

METHOCARBAMOL

Muscle Relaxant

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No evidence of human developmental toxicity attributable to methocarbamol has been located.

FETAL RISK SUMMARY

The centrally acting muscle relaxant, methocarbamol, is not teratogenic in animals (A.H. Robins Company, personal communication, 1987). It is not known if the drug crosses the human placenta. The agent crosses the placenta of dogs (1).

One manufacturer has an unpublished case on file relating to a mother who consumed methocarbamol, 1 g 4 times/day, throughout gestation (A.H. Robins Company, personal communication, 1987). The mother also used marijuana, and possibly other illicit substances, during her pregnancy. No physical or developmental abnormalities were noted at birth, but the infant did exhibit withdrawal symptoms consisting of prolonged crying, restlessness, easy irritability, and seizures. The infant was hospitalized for 2 months following birth to treat these symptoms. No further withdrawal symptoms or seizures were observed following discharge from the hospital. Follow-up neurologic examination indicated that developmental patterns were normal.

The above manufacturer also has informal data on file obtained from the Boston Collaborative Drug Surveillance Program (A.H. Robins Company, personal communication, 1987). These data, compiled between 1977 and 1981, relate to the use of methocarbamol by pregnant patients of the Puget Sound Group Health Cooperative in Seattle, Washington. During the data collection interval, 27 1st trimester exposures to the muscle relaxant were documented. None of the exposed infants had a congenital malformation.

The Collaborative Perinatal Project monitored 50,282 mother-child pairs, 22

of whom were exposed to methocarbamol during the 1st trimester (2, pp. 358, 360). One of these infants had an inguinal hernia. For use anytime during pregnancy, 119 exposures were recorded (2, p. 493). In this latter group, six infants had an inguinal hernia. An association between the drug and the defect cannot be determined from these data.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 340 newborns had been exposed to methocarbamol during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 13 (3.8%) major birth defects were observed (14 expected), including (observed/expected) 1/1 polydactyly and 1/1 limb reduction defect. No anomalies were observed in four other defect categories (cardiovascular defects, oral clefts, spina bifida, and hypospadias) for which specific data were available. These data do not support an association between the drug and congenital defects.

The authors of a 1982 study of 350 patients with congenital contractures of the joints (arthrogryposis) concluded that only 15 had been exposed to a possible teratogen (3). One of the 15 cases involved a 24-year-old woman who at 2 months of gestation had consumed methocarbamol and propoxyphene, 750 and 65 mg, respectively, 2–3 times/day for 3 days to treat severe back pain. The term female infant was noted at birth to have multiple joint contractures involving the thumbs, wrists, elbows, knees, and feet. The latter was described as a bilateral equinovarus deformity. There were practically no foot creases. Other abnormalities present were frontal bosselation, a midline hemangioma, and weak abdominal musculature. Development was normal at 3 years of age except for the joint contractures, which had improved with time and a grade I/VI systolic murmur.

The authors of the above study attributed the multiple joint contractures in the infant to methocarbamol because of its muscle relaxant properties. However, their review of the literature and of the records of the Centers for Disease Control and Prevention failed to find any other cases of arthrogryposis with maternal methocarbamol ingestion. Moreover, no reports have appeared since then relating the defect to maternal use of the drug. A case of arthrogryposis, however, had been previously described with propoxyphene ingestion (see Propoxyphene for details) (4). Thus, based on the present information, it is unlikely that a relationship exists between maternal use of methocarbamol and congenital contractures in the newborn.

BREASTFEEDING SUMMARY

No reports describing the use of methocarbamol during human lactation have been located. Because newborns have been directly treated for tetanus with methocarbamol, any amount excreted in milk is probably clinically insignificant.

METHOHEXITAL SODIUM

General Anesthetic

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Methohexital sodium is commonly used for induction of general anesthesia for cesarean sections and for electroconvulsive therapy (ECT). The drug can cause dose-related fetal heart rate slowing and respiratory depression and sedation in the newborn. Moreover, reported experience in the 1st trimester is lacking. The animal reproduction studies found no fetal harm.

FETAL RISK SUMMARY

Methohexital sodium is a rapid, ultra short-acting barbiturate anesthetic. It is indicated for IV induction of anesthesia before the use of other general anesthetic agents. In pediatric patients older than 1 month it is given either rectally or as an IM injection (1).

Reproduction studies have been conducted in pregnant rats and rabbits. Doses that were 4 and 7 times the human dose revealed no fetal harm. Studies for carcinogenic or mutagenic potential have not been conducted. There was no evidence of impaired fertility in animals (1).

Consistent with the molecular weight (about 284), methohexital sodium crosses the human placenta (2,3). Women undergoing a cesarean section were given a 1 mg/kg IV dose (2). The mean umbilical vein serum concentration in newborns 5 minutes after injection was 0.02 mcg/mL. No adverse effects in the newborns were observed (2). In a 2000 report, perfused human term placentas were used to study the bidirectional (mother to fetus and fetus to mother) transfer of methohexital sodium (3). Although protein binding significantly affected the degree of transfer, the drug readily crossed the placenta in both directions.

A study reported in 1974 evaluated two doses of methohexital sodium, 1.0 and 1.4 mg/kg, in 26 women undergoing an elective cesarean section (4). In

the group that received the lower dose, fewer infants required assisted ventilation, took less time to establish regular respiration, and had higher Apgar scores. A letter to the editor commented on this study and thought that the data suggested a greater degree of acidemia in the infants exposed to the higher maternal dose (5).

A 2009 review of ECT in pregnancy noted that the most frequently used anesthetic agent for ECT was methohexital sodium (6). Although not teratogenic, the agent does cause dose-related fetal heart rate slowing and newborn sedation. These effects can be minimized, however, by using low doses (0.5–1.0 mg/kg).

BREASTFEEDING SUMMARY

Methohexital sodium is excreted into breast milk. Nine women undergoing tubal sterilization 32–341 days after giving birth received 120 or 150 mg IV methohexital sodium for induction of general anesthesia (7). Milk and maternal blood samples were drawn 1–2 hours after induction in five women and 2–4 hours in four. Subsequent samples were drawn at 8–10 hours and 24–28 hours. The highest milk concentration (407 ng/mL) was drawn 63 minutes after induction. The mean milk: blood ratio was 1.1 at 1–2 hours. The drug was undetectable in milk in four women at 8–10 hours and undetectable in milk or blood at 24 hours. The maximum dose to a nursing infant in a 100-mL feeding 1 hour after induction was estimated to be 0.04 mg. This amount did not warrant interruption of breastfeeding (7).

METHOTREXATE

Antineoplastic/Immunologic Agent (Antirheumatic)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

The use of methotrexate during organogenesis is associated with a spectrum of congenital defects collectively called methotrexate embryopathy or the fetal aminopterin-methotrexate syndrome. The critical period of exposure is 6–8 weeks postconception (8–10 weeks after the first day of the last menstrual period) and the critical dose is thought to be ≥ 10 mg/week. Typical characteristics of the syndrome are intrauterine growth restriction (IUGR); a marked decrease in ossification of the calvarium; hypoplastic supraorbital ridges; small, low-set ears; micrognathia; limb abnormalities; and occasional mental retardation (1). Exposure in the 2nd and 3rd trimesters may be associated with fetal toxicity and mortality. Although methotrexate may persist in tissues for long periods, pregnancies occurring after treatment with methotrexate do not appear to be at a risk any different from that of an unexposed population. If methotrexate is used in pregnancy for the treatment of rheumatoid arthritis, health care professionals are encouraged to call the toll-free number 877-311-8972 for information about patient enrollment in the Organization of Teratology Information Specialists (OTIS) Rheumatoid Arthritis study.

FETAL RISK SUMMARY

Methotrexate is a folic acid antagonist. It is in the same antineoplastic subclass as aminopterin, pemetrexed, and pralatrexate.

A number of references describing the use of this antineoplastic agent in pregnancy have been located (1–28). Methotrexate-induced congenital defects (also known as the aminopterin-methotrexate syndrome) are similar to those produced by another folic acid antagonist, aminopterin (see also Aminopterin) (7). Anomalies in two infants were absence of lambdoid and coronal sutures, oxycephaly, absence of frontal bone, low-set ears, hypertelorism,

dextroposition of heart, absence of digits on feet, growth restriction, very wide posterior fontanelle, hypoplastic mandible, multiple anomalous ribs (3); and oxycephaly caused by absent coronal sutures, large anterior fontanelle, depressed and wide nasal bridge, low-set ears, long webbed fingers, wide-set eyes (4).

A 1990 report described the pregnancy outcomes of eight women who were treated with low-dose oral methotrexate for rheumatic disease during 10 pregnancies (18). The outcomes included two elective abortions (EABs) (no details given for these cases), three spontaneous abortions (SABs), and five normal full-term live births. In the eight pregnancies (six women) with details, the methotrexate weekly dose (usually given as a single dose) was 7.5 mg in seven and 10 mg in one. In the live birth group, the mean methotrexate exposure was 6.8 weeks postconception (range 2–15 weeks), whereas in the SAB group the mean exposure was 7 weeks (range 4–9 weeks). The mean cumulative methotrexate dose prior to conception was 1384 mg (range 165–3545 mg) (live births) and 333 mg (range 45–775 mg) (SAB). Other drugs taken by the women included aspirin, nonsteroidal anti-inflammatory agents, prednisone (<10 mg/day), and hydroxychloroquine. Folate supplements had been taken in three of the five pregnancies ending in live births and in all three of the SAB cases. No obvious differences were apparent between the live birth and SAB groups in terms of smoking, use of alcohol, or the use of other drugs. Information on the long-term development of the five live births was obtained by telephone interview at a mean age of 11.5 years (range 3.7–16.7 years). All of the children were healthy and had experienced normal physical and mental development (one child had a minor speech impediment that had resolved with speech therapy) (18).

A 1993 case report and review described the pregnancy outcome of a 39-year-old woman with severe rheumatoid arthritis who was exposed to methotrexate and other drugs shortly after conception (19). For about 6 months before conception she had been taking methotrexate (7.5 mg once weekly), ibuprofen (6.4 g/day), misoprostol (0.4 mg/day), and cimetidine (600 mg) or sucralfate (3 g) per day. All medications were stopped within 10 days of the last menstrual period (as determined by ultrasound at 5–6 weeks' gestation). A healthy full-term, 3962-g male infant was delivered by cesarean section (breech presentation) with Apgar scores of 8 and 9 at 1 and 5 minutes, respectively. Examination by a dysmorphologist at 12 weeks of age revealed a healthy, normal infant with no evidence of embryopathy (19).

A 25-year-old woman at 30 weeks' gestation was diagnosed with metastatic

choriocarcinoma of the vagina and lungs (20). The woman was treated with IV methotrexate 20 mg/day for 5 days. Five days later, she delivered a preterm male infant with an Apgar of 10 (no other details given). The mother and infant were alive and well at 12 months' follow-up (20).

In a 1994 reference, data relating to methotrexate use before or during pregnancy were gathered from programs participating in the Organization of Teratology Information Services (OTIS) and the European Network of Teratology Information Services (ENTIS) (21). The survey resulted in data for 21 prospectively ascertained cases. Seven exposures occurred more than 1 year before conception and they were excluded from the analysis. In the remaining 14 cases, 9 were exposed within 1 year of conception and 5 were exposed during pregnancy. Four of the five pregnancy exposures occurred within the first 6 weeks of gestation with a duration of exposure of 1–3 weeks and one single dose exposure occurred at 37–38 weeks' gestation. Doses ranged from 7.5 mg/week (one woman had been taking this dose for 3 years) to a single 42 mg IV dose. All of these outcomes resulted in healthy infants without birth defects (one delivered at 36 weeks'). In the women exposed within 1 year of pregnancy, the duration of exposures ranged from a few weeks to 6 years. The doses were known in four cases (7.5 mg/week in three, 12.5 mg/week in one). The outcomes of these nine cases were four SABs, four healthy infants, and one infant born at term with a cavernous hemangioma. The authors concluded that the limited data confirmed that the critical time for methotrexate-induced defects was 6–8 weeks postconception and the critical dose was ≥ 10 mg/week (21).

A 1997 case report described an adverse pregnancy outcome in a 20-year-old woman with polyarticular rheumatoid arthritis who had been treated with oral doses of methotrexate (10–12.5 mg/week) for about 5–6 years (22). Folic acid (1 mg/day) was also prescribed but her compliance was unclear. The woman discontinued treatment at about 8 weeks' gestation (estimated dose during gestation about 100 mg). At 35 weeks' she gave birth to a 1.79-kg female (normal 46,XX karyotype) infant with IUGR and multiple congenital anomalies. The defects included brachycephaly, 0.5-cm anterior fontanelle, coronal ridging, shallow orbits with hypertelorism, retrognathia, malformed ears, palate with a posterior groove and a bifid uvula, umbilical hernia, spinal defects (dorsal kyphosis with L5 and S1 hemivertebrae), deformed thumb, bilateral simian creases, hypoplastic nails, reduction of radial ray on right side, syndactyly of fourth and fifth toes, absent fifth metatarsal bone, and cardiovascular defects (double-outlet right ventricle, doubly committed

ventricular septal defect, transposed great vessels, restrictive atrial septal defect, pulmonary stenosis, and an aberrant right subclavian artery). The infant died at 6 months of age. The authors concluded that the anomalies were consistent with methotrexate-induced embryopathy (22).

A 26-year-old man with fetal methotrexate syndrome and two children with mild manifestations of the syndrome were described in 1998 (23). In the adult's case, his mother (who gave him up for adoption) had attempted to terminate the pregnancy at 6–8 weeks' gestation with an unknown amount of methotrexate. His malformations included hypertelorism, ptosis of the eyelids, short palpebral fissures, sparse eyebrows, prominent nose, low-set ears, a widow's peak at the frontal hairline, flexion contractures of the metacarpophalangeal joints of both thumbs and syndactyly of all fingers (all repaired surgically), four metacarpals, and a single fused hypoplastic nub of tissue at the forefoot (corrected surgically with reconstruction of all toes). His physical growth was restricted, but his psychomotor development was normal, as is his intelligence. The first child, a 9-year-old male, was exposed to 80 mg/week of methotrexate for 6 doses at 7.5–28.5 weeks' gestation. His mother, with an undetected pregnancy, had been treated for breast cancer with methotrexate, fluorouracil (1200 mg/week × 10 doses), and radiation (total dose estimated to be 14 rads). He was born at 29 weeks with a birth weight of 820 g (small for gestational age) and he remains growth restricted. Malformations included hypertelorism, a frontal hair whorl, upsweep of the frontal hairline, microcephaly, low-set ears, micrognathia, right palmar simian crease, and borderline mental retardation (composite IQ of 70). The second child is a 3.5-year-old male infant who was born at 29 weeks' gestation with a normal weight (1160 g; 50th percentile). His mother had undergone a failed EAB (dilatation, suction, and curettage; 11 weeks after the last menstrual period [LMP]) and then, because of large uterine myomas, had chosen to have a medical abortion with methotrexate. She received 100 mg bi-weekly from about 13 to 19 weeks' and 200 mg bi-weekly from 19 to 25 weeks', but this abortion attempt also failed. Birth defects noted were a bulging forehead, bitemporal narrowing, upward slanting palpebral fissures, sparse hair on the temporal areas, low-set ears, broad nasal tip, and a high arched palate. He has had chronic diarrhea since 9 months of age. An intestinal biopsy revealed villous atrophy. His psychomotor development has been normal. At 34 months, his weight and length were restricted, but his head circumference was normal (75th percentile) (23).

A 1999 report described the outcomes of pregnancies in 20 women with

breast cancer who were treated with antineoplastic agents (24). (See also Fluorouracil.) Methotrexate (25 mg/m²), in combination with epirubicin and vincristine, was administered to one woman at 6 weeks' gestation. The pregnancy ended in an SAB (24).

Another 1999 reference reported the outcome of a male infant (normal karyotype 46,XY) whose mother had been treated for chronic severe psoriasis with 12.5 mg methotrexate 3 times weekly during the first 8 weeks postconception (1). He was delivered at 40 weeks' gestation with Apgar scores of 2, 5, and 6 at 1, 5, and 10 minutes, respectively. Birth weight, length, and head circumference were severely restricted (<3rd percentile). Malformations included widely separated sutures and large fontanel; bilateral epicanthal folds and sparse eyebrows laterally with hypoplastic supraorbital ridges; broad nasal bridge; anteverted nares; smooth long philtrum; hypoplastic nipples; small umbilical hernia; diastasis recti; a shawl scrotum; decreased extension of the elbows; short bilateral proximal phalanges of the third, fourth, and fifth fingers; and mildly hypoplastic fingernails. The only neurologic abnormality noted was mild hypotonia. At 20 months, he was still growth restricted. He had a triangular face (trigonocephaly) with a prominent metopic suture and the open anterior fontanel finally closed at age 30 months. Generalized tonic-clonic seizures associated with fever were noted at 1 and 2 years (both of his older sisters had a similar episode during the first 2 years of life). Developmental testing revealed mental retardation with significant early motor and cognitive delays (1).

A 23-year-old woman underwent an attempted EAB at 8 weeks' gestation with IM methotrexate 100 mg followed by misoprostol 800 mcg 4 days later (25). Four weeks later she still had a viable pregnancy but could not afford hospitalization for surgical termination. She eventually delivered a 2050-g female infant at term with Apgar scores of 4 and 8 at 1 and 5 minutes, respectively. The infant was hypotonic. All growth parameters (weight, height, and head circumference) were severely growth restricted. Multiple malformations were noted including a disproportionately long head (dolichocephaly), a prominent broad nose, hypertelorism, short palpebral fissure, small mouth, micrognathia, fifth-finger clinodactyly, extra flexion creases on the thumbs, mild syndactyly of the second and third toes with fourth and fifth toe clinodactyly, and hypoplastic toenails. Severe growth restriction was evident at the 12- and 18-month examinations. The mother declined developmental testing of the child, but stated that the usual developmental milestones were normal (25).

A 2002 case report described the pregnancy outcome of a woman who was treated for psoriasis with two doses of methotrexate 7.5 mg/day at 3.5 weeks postconception (26). She also was taking sertraline and smoked cigarettes. An ultrasound examination at 18 weeks' gestation revealed multiple anomalies and the pregnancy was terminated 2 weeks later. The male fetus (normal 46,XY karyotype) had a wide anterior fontanelle, sloping forehead, under mineralization of the skull, low-set and poorly formed ears, absent auditory canals, flat nose, micrognathia, multiple skeletal abnormalities (absent and slender ribs, a hemivertebrae, and fusion of the third through fifth lumbar vertebral bodies), limb defects (absent left radius, hypoplastic right radius, bilaterally short forearms, hypoplastic left thumb, and clinodactyly of the fifth digit bilaterally), tracheal atresia, markedly hypoplastic lungs, cardiovascular defects (left ventricle mildly hypoplastic, ventricular septal defect, persistent right subclavian artery with an arterial ring, and absent left and right pulmonary arteries), malrotated intestines, duodenal atresia, a Meckel's diverticulum, multiple accessory spleens, enlarged left liver lobe, and a two-vessel umbilical cord (26).

A 2003 case reported a failed pregnancy termination attempt at 6 weeks' gestation with IM methotrexate 75 mg and oral misoprostol 400 mcg (27). The pregnancy was terminated at 27 weeks' secondary to ultrasound diagnosis of methotrexate embryopathy. Autopsy revealed a 918-g female (normal karyotype) fetus with upper extremities that were asymmetric in length, bilateral shortening of the radii and ulnae, asymmetric in length lower extremities with bilateral absent fibulae, polydactyly of the right foot, small head, prominent eyes, low-set ears, micrognathia, and a two-vessel umbilical cord (27).

A survey of 600 members of the American College of Rheumatology, partially conducted to determine the outcomes of pregnancies exposed to disease-modifying antirheumatic drugs (etanercept, infliximab, leflunomide, and methotrexate), was published in 2003 (28). From the 175 responders, the outcomes of 39 pregnancies exposed to methotrexate were 21 full-term healthy infants, 7 spontaneous abortions (1 with a congenital malformation), 8 elective abortions, 1 woman still pregnant, and 2 liveborn infants with birth defects. No information was available on the three cases with malformations or if they were thought to have resulted from methotrexate exposure (28).

Possible retention of methotrexate in maternal tissues before conception was suggested as the cause of a rare pulmonary disorder in a newborn, desquamating fibrosing alveolitis (29). The infant's mother had conceived within 6 months of completing treatment with the antineoplastic. (Note: A later

publication from these investigators, which included this case, noted that the newborn was conceived within 2 months of treatment termination [41]). In addition, a sister of the infant born 3 years later developed the same disorder, although a third child born from the mother 1 year later developed normally.) Previous studies have shown that methotrexate may persist for prolonged periods in human tissues (30). However, conception occurred 3 months after discontinuance of therapy in one case (31), after 6 months in a second (14), and after 7 months in a third (32). Four (one set of twins) normal infants resulted from these latter pregnancies. Thus, the association between methotrexate and the pulmonary disorder is unknown.

Two cases of severe newborn myelosuppression have been reported after methotrexate use in pregnancy. In one case, pancytopenia was discovered in a 1000-g male newborn after exposure to six different antineoplastic agents, including methotrexate, in the 3rd trimester (5). The second infant, delivered at 31 weeks' gestation, was exposed to methotrexate only during the 12th week of pregnancy (10). The severe bone marrow hypoplasia was most likely caused by the use of mercaptopurine near delivery.

Data from one review indicated that 40% of the infants exposed to cytotoxic drugs were of low birth weight (2). This finding was not related to the timing of the exposure. Long-term studies of growth and mental development in offspring exposed to antineoplastic agents during the 2nd trimester, the period of neuroblast multiplication, have not been conducted (32–34). Several studies, however, have followed individual infants for periods ranging from 2 to 84 months and have not discovered any problems (10–14,16,17).

Methotrexate crosses the placenta to the fetus (15). A 34-year-old mother was treated with multiple antineoplastic agents for acute lymphoblastic leukemia beginning in her 22nd week of pregnancy. Weekly intrathecal methotrexate (10 mg/m^2) was administered from approximately 26–29 weeks' gestation; the dose was then increased to 20 mg/m^2 weekly until delivery at 40 weeks' gestation. Methotrexate levels in cord serum and red cells were $1.86 \times 10^{-9} \text{ mol/L}$, and $2.6 \times 10^{-9} \text{ mol/g}$ of hemoglobin, respectively, with 29% as the polyglutamate metabolite (15).

In the case described above, chromosomal analysis of the newborn revealed a normal karyotype (46,XX), but with gaps and a ring chromosome (15). The clinical significance of these findings is unknown, but because these abnormalities may persist for several years, the potential existed for an increased risk of cancer as well as for a risk of genetic damage in the next generation (15).

Successful pregnancies have followed the use of methotrexate before conception (14,29,31,32,35–41). Apparently, ovarian and testicular dysfunction are reversible (34,42–45). Two studies, one in 1984 and one in 1988, both involving women treated for gestational trophoblastic neoplasms, have analyzed reproductive function after methotrexate therapy and are described below (41,46).

In 438 long-term survivors treated with chemotherapy between 1958 and 1978, 436 received methotrexate either alone or in combination with other antineoplastic agents (41). This report was a continuation of a brief 1979 correspondence that discussed some of the same patients (29). The mean duration of chemotherapy was 4 months with a mean interval from completion of therapy to the first pregnancy of 2.7 years. Conception occurred within 1 year of therapy completion in 45 women, resulting in 31 live births, 1 anencephalic stillbirth, 7 SABs, and 6 EABs. Of the 436 women, 187 (43%) had at least one live birth (numbers given in parentheses refer to mean/maximum methotrexate dose in grams when used alone; mean/maximum dose in grams when used in combination) (1.26/6.0; 1.22/6.8), 23 (5%) had no live births (1.56/2.6; 1.33/6.5), 7 (2%) failed to conceive (1.30/1.6; 1.95/4.5), and 219 (50%) did not try to conceive (1.10/2.0; 2.20/34.5). The average ages at the end of treatment in the four groups were 24.9, 24.4, 24.4, and 31.5 years, respectively. Congenital abnormalities noted were anencephaly (2), spina bifida (1), tetralogy of Fallot (1), talipes equinovarus (1), collapsed lung (1), umbilical hernia (1), desquamative fibrosing alveolitis (1; same case as described above), asymptomatic heart murmur (1), and mental retardation (1). An 11th child had tachycardia but developed normally after treatment. One case of sudden infant death syndrome occurred in a female infant at 4 weeks of age. None of these outcomes differed statistically from that expected in a normal population (41).

The 1988 report described the reproductive results of 265 women who had been treated from 1959 to 1980 for gestational trophoblastic disease (46). Single-agent chemotherapy was administered to 91 women, only 2 of whom received methotrexate. Sequential (single agent) and combination therapy were administered to 67 and 107 women, respectively, but the individual agents used were not specified. Further details of this study are provided in the monograph for mercaptopurine (see Mercaptopurine).

The long-term effects of combination chemotherapy on menstrual and reproductive function have also been described in women treated for malignant ovarian germ cell tumors (47). Only 2 of the 40 women treated received

methotrexate. The results of this study are discussed in the monograph for cyclophosphamide (see Cyclophosphamide).

A 34-year-old man, being treated with oral methotrexate for Reiter's syndrome, fathered a normal full-term female infant (48). The man had been receiving treatment with the drug intermittently for approximately 5 years and continuously for 5 months before conception.

Occupational exposure of the mother to antineoplastic agents during pregnancy may present a risk to the fetus. A position statement from the National Study Commission on Cytotoxic Exposure and a research article involving some antineoplastic agents are presented in the monograph for cyclophosphamide (see Cyclophosphamide).

BREASTFEEDING SUMMARY

Methotrexate is excreted into breast milk in low concentrations (49). After a dose of 22.5 mg/day, milk concentrations of 0.26 mcg/dL have been measured with a milk:plasma ratio of 0.08. The significance of this small amount is not known. However, because the drug may accumulate in neonatal tissues, breastfeeding is contraindicated. The American Academy of Pediatrics classifies methotrexate as a cytotoxic drug that may interfere with cellular metabolism of the nursing infant (50).

METHOTRIMEPRAZINE

[Withdrawn from the market. See 9th edition.]

METHOXAMINE

[Withdrawn from the market. See 9th edition.]

METHOXSALEN

Dermatologic Agent

PREGNANCY RECOMMENDATION: Compatible (Oral and Topical Lotion)
Contraindicated (Extracorporeal Solution)

BREASTFEEDING RECOMMENDATION: Hold Breastfeeding

PREGNANCY SUMMARY

Although methoxsalen combined with ultraviolet A (UV-A) is mutagenic, clastogenic, carcinogenic, and cataractogenic in humans, it does not appear to be a significant human teratogen. However, the long-term effects of in utero exposure to methoxsalen, such as cancer, have not been studied but warrant investigation.

FETAL RISK SUMMARY

Methoxsalen (8-methoxypsoralen; 8-MOP), available in oral capsules and as a topical lotion, is used as a photosensitizer in conjunction with long-wave UV-A radiation (PUVA) for the symptomatic control of severe psoriasis (1). The drug also is available as a sterile solution that is indicated for extracorporeal photopheresis in the palliative treatment of the skin manifestations of cutaneous T-cell lymphoma that is unresponsive to other forms of treatment (2).

Reproductive toxicity testing of the oral agent in animals has not been conducted (1). However, the extracorporeal product was studied in pregnant rats (2). Doses given during organogenesis that were ≥ 4000 times the single human dose based on BSA were maternal (weight loss, anorexia, and increased relative liver weight) and fetal toxic. Fetal toxicity included increased fetal death and resorptions, late fetal death, fewer fetuses per litter, and decreased fetal weight. An increase in skeletal malformations and variations also was observed (2).

Shepard (3) reviewed a closely related compound, 5-methoxypsoralen (5-MOP), that was not teratogenic in mice given up to 500 mg/kg/day, but was teratogenic in rabbits (type of malformations not specified) fed 70 or 560 mg/kg/day. A 2003 reference cited evidence suggesting that the developmental toxicity of 8-MOP and 5-MOP given in the diet of female rats was due to

enhanced metabolism of estrogens (4).

Because PUVA treatments are mutagenic, a 1991 report described the pregnancy outcomes among 1380 patients (892 men and 488 women) who had received the therapy (5). Of the men, 99 (11.1%) reported 167 pregnancies in their partners, whereas 94 (19.3%) of the women reported 159 pregnancies. Among the men, 34% (55 of 163; data missing for 4 pregnancies) received PUVA therapy near the time of conception. In the women, 20% (31 of 158; data missing for 1 pregnancy) received treatment at the time of conception or during pregnancy. The difference in the incidence of spontaneous abortions among those exposed (men 3.6% vs. women 12.9%) was thought to be related to reporting bias, but the total rate of abortions is no different from that expected in a nonexposed population. No congenital malformations were reported in the offspring of the exposed patients (5).

A 1993 publication described the outcome of 689 infants born before maternal PUVA treatment, 502 infants conceived and born after treatment, and 14 infants whose mothers had received the therapy during pregnancy (6). No difference among the three groups was noted in sex ratio, twinning, and mortality rate after birth. A significant increase in low-birth-weight infants was observed in those conceived and born after maternal treatment, an effect, the authors concluded, that may have resulted from the mother's disease. No congenital abnormalities were observed in the 14 infants exposed in utero to PUVA therapy. In the other two groups, 3.6% (25 of 689) and 3.2% (16 of 502) of the infants had congenital defects (6).

Treatment with PUVA occurred around the time of conception or during the 1st trimester of pregnancy (none treated after the 1st trimester) in 41 women identified by the European Network of Teratology Information Services (7). Of these cases, 32 were treated before conception and during the 1st trimester, 8 were treated only during the 1st trimester, and 1 stopped treatment 2 weeks before conception. The number of treatments was described as normal (two to three per week) in 27 cases, less than normal in 6 cases, greater than normal in 2 cases, and unknown in 6 women. The maximum daily dose of methoxsalen was 40 mg. Four (10%) of the pregnancies terminated with a spontaneous abortion (a normal incidence), 6 were voluntarily terminated, 1 woman was lost to follow-up, and 31 infants (1 set of twins) were liveborn. Two of the infants had low birth weights (2120 and 2460 g), but neither was attributable to the mother's therapy or to psoriasis. No malformations were observed at birth or in the neonatal period. The sample size in this study allowed the authors to exclude a sixfold increase in the risk for all malformations (7).

BREASTFEEDING SUMMARY

No reports describing the use of methoxsalen during breastfeeding have been located, nor is it known whether the drug is excreted into breast milk. Because the drug acts as a photosensitizer, breastfeeding should be stopped and the milk discarded, probably for at least 24 hours (approximately 95% of a dose is excreted in the urine as metabolites within 24 hours (1,2)), if the drug is administered.

METHSCOPOLAMINE

Parasympatholytic (Anticholinergic)

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The very limited pregnancy experience showing a possible association with minor malformations requires confirmation. In general, however, anticholinergics appear to be low risk in pregnancy (see Atropine).

FETAL RISK SUMMARY

Methscopolamine is an anticholinergic quaternary ammonium bromide derivative of scopolamine (see also Scopolamine). In a large prospective study, 2323 patients were exposed to this class of drugs during the 1st trimester, 2 of whom took methscopolamine (1). A possible association was found in the total group between this class of drugs and minor malformations.

BREASTFEEDING SUMMARY

No reports describing the use of methscopolamine during human lactation have been located (see also Atropine).

METHSUXIMIDE

Anticonvulsant

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Methsuximide is a succinimide anticonvulsant used in the treatment of petit mal epilepsy. The use of methsuximide during the 1st trimester has been reported in only five pregnancies (1,2). No evidence of adverse fetal effects was found. Methsuximide has a much lower teratogenic potential than the oxazolidinedione class of anticonvulsants (see Trimethadione) (3,4). The succinimide anticonvulsants have been considered the anticonvulsants of choice for the treatment of petit mal epilepsy during the 1st trimester (see Ethosuximide).

BREASTFEEDING SUMMARY

No reports describing the use of methsuximide during human lactation have been located. Other agents in this class have been classified as compatible with breastfeeding (see Ethosuximide).

METHYCLOTHIAZIDE

Diuretic

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

There is no evidence that thiazide diuretics are teratogenic. However, diuretics are not recommended for the treatment of gestational hypertension–preeclampsia because of the maternal hypovolemia characteristic of this disease.

FETAL RISK SUMMARY

Methyclothiazide is a member of the thiazide class of diuretics (see Chlorothiazide). Reproduction studies in rats and rabbits at doses up to about 20 times the maximum recommended human dose did not observe any evidence of impaired fertility or fetal harm (1).

BREASTFEEDING SUMMARY

See Chlorothiazide.

Reference

METHYLDOPA

Antihypertensive

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Methyldopa is a centrally acting, antiadrenergic agent used in the treatment of hypertension. It has been used frequently in pregnancy for this indication. There is no confirmed evidence that use of this agent presents a risk to the embryo or fetus.

FETAL RISK SUMMARY

Reproduction studies in mice, rats, and rabbits at doses 1.4, 0.2, and 1.1 times, respectively, the maximum recommended human dose based on BSA (MRHD), revealed no fetal harm (1). No impairment of fertility was noted in male or female rats at 0.2 times the MRHD. At higher doses (0.5 and 1 times the MRHD) in male rats, however, methyldopa decreased sperm count, sperm motility, the number of late spermatids, and the male fertility index (1).

Methyldopa crosses the placenta and achieves fetal concentrations similar to the maternal serum concentration (2–4). The Collaborative Perinatal Project monitored only one mother–child pair in which 1st trimester exposure to methyldopa was recorded (5). No abnormalities were found.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 242 newborns had been exposed to methyldopa during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 11 (4.5%) major birth defects were observed (10 expected). Specific data were available for six defect categories, including (observed/expected) 1/2 cardiovascular defects, 1/0 oral clefts, 0/0 spina bifida, 1/1 polydactyly, 0/0 limb reduction defects, and 0/1 hypospadias. These data do not support an association between the drug and congenital defects.

A decrease in intracranial volume has been reported after 1st trimester

exposure to methyldopa (6,7). Children evaluated at 4 years of age showed no association between small head size and slow mental development (8). Review of 1157 hypertensive pregnancies demonstrated no adverse effects from methyldopa administration (9–21). A reduced systolic blood pressure of 4–5 mmHg in 24 infants for the first 2 days after delivery has been reported (22). This mild reduction in blood pressure was not considered significant. An infant born with esophageal atresia with fistula, congenital heart disease, absent left kidney, and hypospadias was exposed to methyldopa throughout gestation (23). The mother also took clomiphene early in the 1st trimester.

BREASTFEEDING SUMMARY

Methyldopa is excreted into breast milk in small amounts. In four lactating women taking 750–2000 mg/day, milk levels of free and conjugated methyldopa ranged from 0.1 to 0.9 mcg/mL (2). A milk:plasma ratio could not be determined because simultaneous plasma levels were not obtained. The American Academy of Pediatrics classifies methyldopa as compatible with breastfeeding (24).

METHYLENE BLUE

Urinary Germicide/Diagnostic Dye

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The intraamniotic injection of methylene blue to detect ruptured membranes should be discouraged. If indicated, other dyes, such as indigo carmine or Evans blue appear to be safer alternatives, although both have limited pregnancy data (see Indigo Carmine and Evans Blue) (1).

FETAL RISK SUMMARY

Methylene blue has been administered orally for its weak urinary germicide properties or injected into the amniotic fluid to diagnose premature rupture of the membranes. For oral dosing, nine exposures in the 1st trimester have been reported (2, p. 299). No congenital abnormalities were observed. For use anytime during pregnancy, 46 exposures were reported (2, pp. 434–435). Based on three malformed infants, a possible association with malformations (type not specified) was found.

Diagnostic intraamniotic injection of methylene blue has resulted in hemolytic anemia, hyperbilirubinemia, and methemoglobinemia in the newborn (3–12). Doses of the dye in most reports ranged from 10 to 70 mg, but in one case, 200 mg was injected into the amniotic cavity (9). Deep blue staining of the newborn may occur after injection of the agent into the amniotic fluid (8–10,12). One author suggested that smaller doses, such as 1.6 mg, would be adequate to confirm the presence of ruptured membranes without causing hemolysis (3).

In a 1989 report, 1 mL of a 1% solution (10 mg) was used to diagnose suspected membrane rupture in a woman with premature labor at 26 weeks of gestation (13). A 920-g girl was born 18 hours later who was stained a deep blue. The clinical assessment of hypoxia was impaired by the skin color as was pulse oximetry. A transcutaneous oxygen monitor was eventually used to

measure arterial blood gas so that ventilator therapy could be regulated. No evidence of hemolysis was observed. The bluish tinge persisted for more than 2 weeks despite frequent baths (13).

Inadvertent intrauterine injection in the 1st trimester has been reported (14). No adverse effects were reported in the full-term neonate.

Multiple ileal occlusions were found in seven newborns born to mothers with twin pregnancies, at three different medical centers, who had received diagnostic intraamniotic methylene blue into one of the amniotic sacs at 15–17 weeks' gestation (15). The doses in these cases ranged from 10 to 30 mg. Four of the infants required surgery for intestinal obstruction, but no information was given on the other three. The authors speculated that the mechanism of the adverse effect was related either to hemolysis or to acute intestinal hypoxia secondary to methylene blue–induced release of norepinephrine and subsequent vasoconstriction (15).

In an abstract published in 1992, data on jejunal and ileal atresia in twins were reported from Australia (16). Higher risks of atresia were found in twins, compared with singletons, and in twins delivered from older mothers. When undiluted 1% methylene blue was used in one group, 1 of 9 twins of 40 (22.5%) twin pregnancies had atresia, compared with 3 cases among 53 (5.7%) in those exposed to a 0.25% solution (16).

A third report of the above complication appeared in 1992 (17). Intraamniotic methylene blue, 10–20 mg, was used in 86 of 89 consecutive twin pregnancies for prenatal diagnosis. No dye was used in three pregnancies for technical reasons. Jejunal atresia occurred in 17 (19%) of the pregnancies; in 15 of the affected cases, it was possible to determine that the affected fetus had been the one exposed to the dye. All of the infants required surgery to relieve the intestinal obstruction. A portion of this report also described 67 newborns that were treated for jejunal atresia, 20 of whom were one of a set of twins. Of the 20 newborns from twins, 18 had been exposed to methylene blue during 2nd trimester amniocentesis. Because the incidence of jejunal atresia was much higher than expected and because the dye appears to cause the defect, the authors of the study (17) and an accompanying commentary (18) recommended avoidance of methylene blue for this purpose. The commentary also alluded to the vasoconstrictor properties of methylene blue as a possible mechanism (18).

A brief 1993 report described the use of methylene blue dye in women with twins who underwent amniocentesis in the Atlanta, Georgia, area between 1977 and 1991 (19). A total of 195 women were included, 4 (2%) of whom

were administered methylene blue during the procedure. Of the eight fetuses, one had anencephaly (no association with the dye), but no cases of small intestinal atresia were observed.

A 1993 article reviewed the teratogenicity and newborn adverse effects resulting from intraamniotic injection of methylene blue (1). The most frequent adverse effects in newborns were hyperbilirubinemia, hemolytic anemia with or without Heinz body formation, blue staining of the skin, and occasionally methemoglobinemia and fetal death. Respiratory distress was also frequently observed but may have been related to other causes. The structural defects observed were jejunal-ileal atresias, but the mechanism of the bowel injury is unknown. Based on the pharmacologic properties of the dye, the most likely mechanism was thought to be vascular disruption caused by methylene blue–induced arterial constriction. However, methemoglobinemia- and hemolytic anemia–induced hypoxia causing a shunting of blood away from the intestine with resulting ischemia and atresia, or a direct toxic effect from the dye when swallowed with amniotic fluid were other possible mechanisms (1).

BREASTFEEDING SUMMARY

No reports describing the use of methylene blue during human lactation have been located. However, the dye does not appear to present a risk to a nursing infant.

METHYLERGONOVINE MALEATE

Oxytocic

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Methylergonovine does not appear to be a major teratogen in either animals or humans, but the data are too limited for any conclusion. The drug is contraindicated during pregnancy because of its propensity to cause sustained, tetanic uterine contractions that result in fetal hypoxia. Because of this, it is used as an alternate drug to oxytocin for management of the third stage of labor (i.e., from delivery of the infant to delivery of the placenta) and for the treatment of postpartum or postabortion hemorrhage. Care must be taken before administering this agent to confirm that the intended recipient has delivered her fetus.

FETAL RISK SUMMARY

Methylergonovine maleate (methylergometrine maleate; methylergobasine maleate) is an ergot alkaloid derivative used in the treatment of postpartum and postabortion hemorrhage. It is contraindicated during pregnancy because it may cause sustained, tetanic uterine contractions and resulting fetal compromise.

Only one animal reproductive study has been located that investigated the effect of methylergonovine on the fetus (1). Thirteen albino rats were administered 0.5 mg/kg intraperitoneally twice daily from the 12th day through the 21st day (second half of gestation) after sperm were found in the vaginal smears of the animals (1). Three other groups received different ergot alkaloids and another group acted as controls. Three (23%) of the methylergonovine group failed to conceive or resorbed their conception compared with an average of 17% (10 of 58) in the other three treated groups and 17% (2 of 12) in the controls. The surviving pups were not examined for congenital malformations (drug-induced anomalies not expected) but their birth weights were similar to those of pups in the control group.

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 32 of whom were exposed to ergot derivatives other than ergotamine during the 1st trimester (2). Five of this group were exposed to methylergonovine maleate, 18 to ergonovine, 5 to ergot, 3 to dihydroergotamine, and 1 to methysergide. Three children with any malformation were observed in the total group, but only 1 had a malformation considered easily recognizable among the 12 medical centers participating in the study. The authors concluded that, although the numbers were small, there was no evidence that these agents were teratogenic (2).

A 1979 report described the effects of methylergonovine on a woman in the first stage of labor (i.e., from onset of labor to full dilation of the cervix) at 43 weeks' gestation (3). The woman was accidentally given 0.2 mg methylergonovine IM that had been ordered for a postpartum patient. Within 20 minutes, uterine hypertonus was evident, and the fetal heart rate (FHR) decreased to 80–90 beats/minute (bpm) with increased variability. IV epinephrine (0.5 mL of 1:1000) was administered with a rapid decline in excessive uterine activity but the FHR fell to 40–50 bpm (most likely because of epinephrine-induced vasoconstriction) before slowly returning to baseline. When uterine tetany returned, a second dose of epinephrine (1/6 mL) was required, producing similar effects on uterine activity and the FHR, but of shorter duration. An approximate 2731-g male infant was delivered 6 hours later with Apgar scores of 5 and 7 at 1 and 5 minutes, respectively. Examinations of the infant over the next 9 months were normal.

A similar case of accidental (i.e., a dose intended for another patient) methylergonovine administration resulting in uterine hypertonus was reported in 1988 (4). The 18-year-old woman at 37 weeks' gestation in the first stage of labor with uterine contractions every 2–3 minutes and a partially dilated and effaced cervix received 0.2 mg methylergonovine IM. Six minutes later, the FHR fell from 150 to 70 bpm and uterine hypertonus was detected on palpation. Terbutaline, 0.25 mg IV reversed the fetal bradycardia but did not relax the uterus. Magnesium sulfate, 4-g IV loading dose followed by 2 g/hr, also failed to reverse the hypertonus. Adverse changes in the fetus, including loss of FHR beat-to-beat variability, late decelerations, development of tachycardia (170 bpm), and acidosis (scalp pH 7.12), impelled the authors to perform a cesarean section, under general anesthesia, to deliver the approximate 3604-g male infant. Apgar scores were 8 and 9 at 1 and 5 minutes, respectively. At delivery, the umbilical artery blood had a pH of 7.13, confirming the diagnosis of metabolic acidosis (4). The infant did well after delivery and was discharged

home at 4 days of age.

BREASTFEEDING SUMMARY

Methylergonovine is excreted into breast milk in very small quantities. No accumulation of the drug in breast milk has been measured. This ergot derivative appears to inhibit release of prolactin, including that induced by suckling, resulting in a decreased milk production, but not to the same degree as the structurally related drug bromocriptine. The clinical significance of the lactation suppression and the exposure of the nursing infant to the drug, however, is most likely nil. This may be a result of its usual short-term use after delivery and its lower potency (on a milligram-to-milligram basis) as a prolactin-release inhibitor. No adverse effects attributable to methylergonovine in a nursing infant have been reported. Moreover, methylergonovine is one of the most commonly prescribed drugs during the first postpartum week.

Small amounts of methylergonovine are excreted into breast milk. During the first 4 days postpartum, eight lactating women (not stated whether the women were nursing) were treated with the drug, 0.125 mg orally 3 times daily, because of incomplete uterine involution (5). On the 5th postpartum day, a 0.25-mg oral dose was administered, and milk and plasma samples were collected 1 and 8 hours later. Methylergonovine concentrations in the milk were determined by radioimmunoassay. Measurable (test sensitivity 0.5 ng/mL) amounts were found in four of the eight milk samples at 1 hour (average 0.8 ng/mL; range 0.6–1.3 ng/mL) and in one sample at 8 hours (1.2 ng/mL). Seven other milk samples had detectable amounts of the drug, but the concentrations were <0.5 ng/mL. In contrast, all eight of the plasma samples had measurable drug (average 2.5 ng/mL; range 0.6–4.4 ng/mL). At 8 hours after the dose, two plasma samples had measurable drug (0.5 and 0.6 ng/mL), and one had detectable drug (<0.5 ng/mL). In the four cases at 1 hour that had measurable drug in both the plasma and milk, the milk:plasma ratio was about 0.3. Based on the lack of accumulation of methylergonovine in the plasma or milk, the authors concluded that the use of the drug during breastfeeding would not affect the infant (5).

Higher plasma and, presumably, milk drug levels may have occurred at 3 hours after a dose based on other research conducted by these investigators (6). In this study, conducted in the same manner as the study described above but with drug levels determined on the 3rd and 6th postpartum days, maternal plasma levels of methylergonovine at 1 and 3 hours after a 0.25-mg oral dose were about 1.7 and 2 ng/mL, respectively (5,6). The authors, however, did not

believe that measurement of the higher drug levels would have changed their conclusion (5).

The effect of methylergonovine, which is structurally related to bromocriptine, a known inhibitor of prolactin secretion and human lactation, on suckling-induced release of prolactin and subsequent milk production is controversial. In a study published in 1975, 14 women received a 0.2-mg IM dose of the drug after delivery of the placenta and 15 other women acted as controls (7). Serum prolactin levels before drug administration in the two groups were 90.1 and 93.6 ng/mL, respectively. At 80–90 minutes after delivery, the mean serum prolactin concentration in the treated group was 141 ng/mL (difference not significant from baseline). In contrast, the level in the controls was 266 ng/mL, significantly higher than baseline and the methylergonovine group.

Similar effects of methylergonovine on prolactin release were published in a 1975 reference (8). A 0.2-mg IM dose administered on the 3rd postpartum day produced a statistically significant decrease in serum prolactin between 45 and 60 minutes after injection. At 180 minutes after the dose, the prolactin levels began to rise, but they still had not returned to baseline by 240 minutes.

In another 1975 report, 10 breastfeeding mothers in the immediate postpartum period were treated with methylergonovine, 0.2 mg orally 3 times daily for 7 days (9). A similar group of 10 breastfeeding women received no medication. Plasma prolactin concentrations in both groups were measured each morning. No significant difference between the groups in prolactin concentrations was measured with plasma levels of prolactin decreasing from a mean of 144 ng/mL (both groups) to 41 ng/mL (methylergonovine) and 37 ng/mL (controls) at 7 days. Milk let-down occurred between the 2nd and 4th postpartum day in both groups. Moreover, the mean milk volume production (estimated by infant weight gain and residual milk obtained by electric breast pump) on the 7th postpartum day was 386 mL in the treated group and 367 mL in the controls.

Contrary to the above study, two reports, one in 1976 (10) and one in 1979 (11), described the inhibitory effects of ergot derivatives on prolactin secretion and lactation. In the 1976 paper, ergonovine, an agent closely related to methylergonovine, was given to 10 women in a dose of 0.2 mg orally 3 times daily from the 1st through the 7th postpartum day (10). None of the women nursed their infants. Six other women who were not breastfeeding acted as controls. Blood samples for serum prolactin measurement were drawn each morning in both groups. Before-treatment mean serum prolactin concentrations in the ergonovine and control groups were 537 and 562 ng/mL, respectively,

and on postpartum day 7 they were 89.7 and 218.0 ng/mL, respectively. Moreover, the serum prolactin concentrations were significantly lower each day than the levels in the ergonovine group. Three of the ergonovine-treated women showed progressive lactation inhibition, whereas the other seven women had painful breast engorgement and spontaneous milk let-down.

Two other women in the above study received ergonovine 0.2 mg IV before nursing on the 5th postpartum day (10). One of these women also received ergonovine, 0.2 mg orally 3 times daily, before and after the IV dose. In the woman who received both IV and oral doses, the normal rise in serum prolactin induced by suckling was abolished.

The 1979 report described the effects of methylergonovine, 0.2 mg orally 3 times daily, in 30 breastfeeding women compared with 30 nonmedicated, breastfeeding control women (11). Plasma prolactin concentrations were determined in both groups on postpartum days 1, 3, and 7. Milk yields, estimated by weighing the nursing baby before and after suckling, were determined on postpartum days 3 and 7. In the control group, mean plasma prolactin levels on days 1, 3, and 7 were 374.1, 226.2, and 166.3 ng/mL, respectively. Mean plasma prolactin levels in the treated group on these days were 352.9, 219.6, and 88.7 ng/mL, respectively. Only the levels on day 7 were statistically different (11). Milk production (in g/day) was significantly less in the treated group compared with the controls on days 3 and 7 (specific weights of milk not stated).

METHYLNALTREXONE

Narcotic Antagonist

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Published human pregnancy experience with methylnaltrexone has not been located. The animal reproduction data suggest low risk, but the absence of human data prevents a complete assessment of the embryo–fetal risk. Orthostatic hypotension, an effect that could decrease placental perfusion, is a potential risk if the drug is inadvertently given IV. Close attention to the dose and SC administration technique is warranted.

FETAL RISK SUMMARY

Methylnaltrexone, a selective antagonist of opioid binding at the mu-opioid receptor, is given by SC injection. It is a quaternary amine that because of its restricted ability to cross the blood–brain barrier acts peripherally without affecting opioid-mediated analgesic effects in the central nervous system. Methylnaltrexone is indicated for the treatment of opioid-induced constipation in patients with advanced illness who are receiving palliative care, when response to laxative therapy has not been sufficient. The drug undergoes partial metabolism before elimination. Plasma protein binding is about 15% or less and the elimination half-life is about 8 hours (1).

Reproduction studies have been conducted in pregnant rats and rabbits. In these species, IV doses up to about 14 and 17 times, respectively, the maximum recommended human SC dose of 0.3 mg/kg based on BSA (MRHD) revealed no evidence of impaired fertility or fetal harm. There were no effects on the mother, labor, delivery, offspring survival, or growth in rats (1).

Carcinogenicity studies have not been conducted, but the drug was not mutagenic in multiple assays. SC doses up to 81 times the MRHD had no adverse effect on fertility or reproductive performance in male or female rats

(1).

It is not known if methylnaltrexone crosses the human placenta. The molecular weight (about 436), minimal plasma protein binding, and long elimination half-life suggest that the drug will cross. However, quaternary amines cross biological membranes poorly; this should limit the exposure of the embryo or fetus.

Orthostatic hypotension, an effect that could decrease placental perfusion if it occurred in pregnancy, has been noted in healthy volunteers given an IV bolus of 0.64 mg/kg. However, this dose is twice the recommended maximum SC dose. Moreover, a 0.5 mg SC dose was well tolerated by healthy volunteers (1).

BREASTFEEDING SUMMARY

No reports describing the use of methylnaltrexone, a quaternary amine, during human lactation have been located. The molecular weight (about 436), minimal plasma protein binding (<15%), and long elimination half-life (about 8 hours) suggest that the drug will be excreted into breast milk. The effects of this exposure on a nursing infant are unknown, but are probably clinically insignificant.

METHYLPHENIDATE

Central Stimulant

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although the animal data suggest moderate risk, the limited human data prevent a more complete assessment of embryo–fetal risk. Neither the isolated cases of structural defects nor the outcomes observed with methylphenidate abuse are suggestive of methylphenidate-induced developmental toxicity.

FETAL RISK SUMMARY

Methylphenidate is a mild central nervous system stimulant used in the treatment of attention-deficit disorders and in narcolepsy.

Reproductive testing with methylphenidate in mice found no teratogenicity (1). In rabbits, doses about 40 times the maximum recommended human dose based on BSA (MRHD) were teratogenic (increased incidence of spina bifida) (2). The no-effect dose for embryo–fetal development was about 11 times the MRHD. No teratogenic effects were observed in rats, but a dose 7 times the MRHD caused maternal toxicity and fetal skeletal variations. The no-effect dose in rats was 2 times the MRHD. Dosing in rats throughout gestation and lactation at 4 times the MRHD resulted in decreased body weight gain in the offspring. In this case, the no-effect dose was equal to the MRHD (2).

The Collaborative Perinatal Project monitored 3082 mother–child pairs with exposure to sympathomimetic drugs, 11 of which were exposed to methylphenidate (3). No evidence for an increased malformation rate was found.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 13 newborns had been exposed to methylphenidate during the 1st trimester (F. Rosa, personal

communication, FDA, 1993). One (7.7%) major birth defect was observed (one expected), a cardiovascular defect (none expected).

A report of an infant with microtia following in utero exposure to methylphenidate from the 3rd to the 6th week of pregnancy appeared in a 1962 publication (4). No other details of the case were provided, other than the fact that the mother did not take antiemetic medication and had no virus infection during gestation.

A 1975 report described a male infant, delivered at 30 weeks' gestation, with multiple congenital limb malformations. The infant had been exposed during the first 7 weeks of pregnancy to haloperidol (15 mg/day), methylphenidate (30 mg/day), and phenytoin (300 mg/day) (5). The mother had also taken tetracycline and a decongestant for a cold during the 1st trimester. The infant died at 2 hours of age of a subdural hemorrhage. Limb malformations included a thumb and two fingers on each hand, syndactyly of the two fingers on the right hand, deformed radius and missing ulna in the left forearm, four toes on the right foot, shortened right tibia, and incomplete development of the right midfoot ossification centers. A defect of the aortic valve (bicuspid with a notch in one of the valve leaflets) was also found. The chromosomal analysis was normal and the mother had no family history of limb malformations (5).

A study published in 1993 examined the effects on the fetus and newborn of IV pentazocine and methylphenidate abuse during pregnancy (6). During a 2-year (1987–1988) period, 39 infants (38 pregnancies, 1 set of twins) were identified in the study population as being subjected to the drug abuse during gestation, a minimum incidence of 5 cases per 1000 live births. Many of the mothers had used cigarettes (34%), alcohol (71%), or abused other drugs (26%). The median duration of IV pentazocine and methylphenidate abuse was 3 years (range 1–9 years), with a median frequency of 14 injections/week (range 1–70 injections/week). Among the infants, 8 were delivered prematurely, 12 were growth restricted, and 11 had withdrawal symptoms after birth. Four of the infants had birth defects including twins with fetal alcohol syndrome, one with a ventricular septal defect, and one case of polydactyly. Of the 21 infants that had formal developmental testing, 17 had normal development and 4 had low–normal developmental quotients (6).

BREASTFEEDING SUMMARY

Methylphenidate is excreted into breast milk (7). A 26-year-old mother was taking methylphenidate 80 mg/day (40 mg 4 hours apart in the morning) for 5 days each week for attention-deficit disorder. At the time of the study, she had

been taking the drug for 5.5 weeks and for 7 consecutive days. The mother's male infant was 6.4 months old and was obtaining his primary sustenance from breast milk. His weight was at the 50th percentile and he had been feeding and sleeping well. Using an electric pump, breast milk samples were collected immediately before the first morning dose and at each of the 7 times the infant breastfed over the next 24 hours. Over the 24-hour interval, the average milk and maternal plasma concentrations were 15.4 and 5.8 mcg/L, respectively, a milk:plasma ratio of 2.7. The absolute infant dose of 2.3 mcg/kg/day was 0.2% of the weight-adjusted maternal dose. Methylphenidate was not detected in the infant's plasma 5.3 hours after the first morning dose. The mother had not observed any adverse effects in her infant (7).

The excretion of methylphenidate into milk is consistent with its molecular weight (about 270). The absolute infant dose was very low in comparison to the maternal dose and no adverse effects were observed in the infant. However, toxicity from exposure to drugs in breast milk is infrequent in nursing infants who are >6 months of age, accounting only for 4% of 100 reported cases involving adverse effects (8). If a mother chooses to breastfeed while taking methylphenidate, the greatest risk of toxicity probably will occur in the first month after birth. However, regardless of the infant's age, the mother should be counseled to observe her nursing for signs and symptoms of central nervous system stimulation, such as decreased appetite, insomnia, and irritability.

METHYLTESTOSTERONE

Androgenic Hormone

See Testosterone.

METOCLOPRAMIDE

Antiemetic/Gastrointestinal Stimulant

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Metoclopramide has been used during all stages of pregnancy. No evidence of embryo, fetal, or newborn harm has been found in human and animal studies.

FETAL RISK SUMMARY

Metoclopramide has been used during pregnancy as an antiemetic and to decrease gastric emptying time (1–24). Reproductive studies in mice, rats, and rabbits at doses up to 250 times the human dose have revealed no evidence of impaired fertility or fetal harm as a result of the drug (25). Metoclopramide (10 mg) given IV to pregnant sheep increased maternal heart rate, but had no effect on maternal blood pressure, uterine blood flow, or fetal hemodynamic variables (26).

No congenital malformations or other fetal or newborn adverse effects attributable to the drug have been observed. Except for the one study noted below (7), long-term evaluation of infants exposed in utero to metoclopramide has not been reported.

Metoclopramide crosses the placenta at term (1–3). Cord:maternal plasma ratios were 0.57–0.84 after IV doses just before cesarean section. Placental transfer during other stages of pregnancy has not been studied.

Nine reports described the use of metoclopramide for the treatment of nausea and vomiting occurring in early pregnancy (4–7, 20–24). Administration of the drug was begun at 7–8 weeks' gestation in two of these studies (4,5) and at 6 weeks in another (6). The exact timing of pregnancy was not specified in one report (7). Daily doses ranged between 10 and 60 mg. Metoclopramide was as effective as other antiemetics for this indication and superior to placebo (8,9). Normal infant development for up to 4 years was mentioned in one study,

but no details were provided (7).

In another case of metoclopramide use for nausea and vomiting, the drug was started at 10 weeks' gestation (20). Dose was not specified. At 18 weeks, after 8 weeks of therapy, the patient developed a neuropsychiatric syndrome with acute asymmetrical axonal motor-sensory polyneuropathy and marked anxiety, depression, irritability, and memory and concentration difficulties (20). Acute porphyria was diagnosed based on the presence of increased porphyrin precursors in the patient's urine. Metoclopramide was discontinued and the patient was treated with a high-carbohydrate diet. Eventually, a normal, 3500-g infant was delivered at term. The woman recovered except for slight residual weakness in the lower extremities. The investigators speculated that the pregnancy itself, the starvation, the drug, or a combination of these may have precipitated the acute attack (20).

A 1996 report described the use of metoclopramide, droperidol, diphenhydramine, and hydroxyzine in 80 women with hyperemesis gravidarum (21). The mean gestational age at the start of treatment was 10.9. All of the women received metoclopramide 40 mg/day orally for approximately 7 days, and 12 (15%) required a second course because of the recurrence of their symptoms of nausea and vomiting. Three of the mothers (all treated in the 2nd trimester) delivered offspring with congenital defects: Poland's syndrome, fetal alcohol syndrome, and hydrocephalus and hypoplasia of the right cerebral hemisphere. Only the latter anomaly is a potential drug effect, but the most likely cause was thought to be the result of an in utero fetal vascular accident or infection (21).

A 2001 study, using a treatment method similar to the above study, described the use of droperidol and diphenhydramine in 28 women hospitalized for hyperemesis gravidarum (22). Pregnancy outcomes in the study group were compared with a historical control of 54 women who had received conventional antiemetic therapy. Oral metoclopramide and hydroxyzine were used after discharge from the hospital. Therapy was started in the study and control groups at mean gestational ages of 9.9 and 11.1 weeks, respectively. The study group appeared to have more severe disease than controls as suggested by a greater mean loss from the prepregnancy weight, 2.07 vs. 0.81 kg (ns), and a slightly lower serum potassium level, 3.4 vs. 3.5 mmol/L (ns). Compared with controls, the droperidol group had a shorter duration of hospitalization (3.53 vs. 2.82 days, $p = 0.023$), fewer readmissions (38.9% vs. 14.3%, $p = 0.025$), and lower average daily nausea and vomiting scores (both $p < 0.001$). There were no statistical differences ($p > 0.05$) in outcomes (study vs. controls)

in terms of spontaneous abortions (N = 0 vs. N = 2 [4.3%]), elective abortions (N = 3 [12.0%] vs. N = 3 [6.5%]), Apgar scores at 1, 5, and 10 minutes, age at birth (37.3 vs. 37.9 weeks'), and birth weight (3114 vs. 3347 g) (22). In controls, there was one (2.4%) major malformation of unknown cause, an acardiac fetus in a set of triplets, and one newborn with a genetic defect (Turner syndrome). There was also one unexplained major birth defect (4.4%) in the droperidol group (bilateral hydronephrosis), and two genetic defects (translocation of chromosomes 3 and 7; tyrosinemia) (22).

The Pharmaco-Epidemiological Prescription Database of North Jutland County (Denmark) identified 309 women with singleton pregnancies who filled prescriptions for metoclopramide during a 6-year period (1991–1996) (23). The pregnancy outcomes of this group were compared with 13,327 women who did not receive prescriptions of any kind during pregnancy. The mean birth weights of the metoclopramide and control groups were nearly identical, 3480 vs. 3470 g, respectively. No significant differences were found between the groups in terms of congenital malformations (odds ratio [OR] 1.11, 95% confidence interval [CI] 0.6–2.1), low birth weight (OR 1.79, 95% CI 0.8–3.9), or preterm delivery (OR 1.02, 95% CI 0.6–1.7) (23).

A brief 2000 communication examined the outcome of 126 women who had received metoclopramide for nausea and vomiting of pregnancy during the 1st trimester (24). The pregnancy outcomes of these women, who had called one of five teratogen information centers (one each in Italy and Brazil and three in Israel), were compared with a control group of 126 women who had contacted the centers for information on nonteratogenic and nonembryotoxic drug exposures, matched for age, smoking status, and alcohol use. The pregnancy outcomes were similar between the groups in terms of live births, spontaneous abortions, gestational age at delivery, rate of prematurity, birth weight, fetal distress, and major malformations. Both groups had five infants with major birth defects. In the metoclopramide group, two infants had patent ductus arteriosus, two had ventricular septal defects (VSD), and one had hypospadias. The birth defects in the infants born to the control group were two cases of VSD and one each of bilateral syndactyly of the foot, hypospadias, and an inguinal hernia. The gross motor development (as measured by the Denver Development Scale) of the infants in the two groups at ages 4–15 months was also similar (24).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 192 newborns had been exposed to metoclopramide during the 1st trimester (F. Rosa, personal

communication, FDA, 1993). Ten (5.2%) major birth defects were observed (8 expected), including (observed/expected) 1/2 cardiovascular defects and 1/1 polydactyly. No anomalies were observed in four other defect categories (oral clefts, spina bifida, limb reduction defects, and hypospadias) for which specific data were available. These data do not support an association between the drug and congenital defects.

A 1997 case report described the signs and symptoms of acute intermittent porphyria in a 29-year-old woman at 13 weeks' gestation (27). The patient presented with abdominal pain, constipation, and vomiting and was treated with IV metoclopramide. Her symptoms worsened with treatment and included weakness of the lower extremities and a severe neuropsychiatric syndrome consisting of both autonomic and neurologic functions. Metoclopramide was stopped and she was treated with high-dose IV glucose and a high-carbohydrate diet. Evaluation of urine and stool porphyrin precursors confirmed the diagnosis. She eventually delivered a normal 2760-g infant at term. The authors concluded that the severe maternal symptoms were brought on by metoclopramide, a porphyrinogenic agent, and starvation resulting from hyperemesis (27).

Several studies have examined the effect of metoclopramide on gastric emptying time during labor for the prevention of Mendelson's syndrome (i.e., pulmonary aspiration of acid gastric contents and resulting chemical pneumonitis and pulmonary edema) (1,3,10–16,28,29). Gastroesophageal reflux was decreased as was the gastric emptying time. The drug was effective in preventing vomiting during anesthesia. No effects were noted on the course of labor or the fetus. Apgar scores and results of neurobehavioral tests did not differ from those of controls (1,3,10,16) nor did newborn heart rates or blood pressures (1).

The effect of metoclopramide on maternal and fetal prolactin secretion during pregnancy and labor has been studied (2,17,18). The drug is a potent stimulator of prolactin release from the anterior pituitary by antagonism of hypothalamic dopaminergic receptors. However, transplacentally acquired metoclopramide did not cause an increased prolactin release from the fetal pituitary nor did maternal prolactin cross the placenta to the fetus (2,17). In two other studies, 10 mg of intravenous metoclopramide administered during labor did not affect the levels of maternal or fetal thyroid-stimulating hormone or thyroid hormones (19), or maternal growth hormone concentrations (30).

BREASTFEEDING SUMMARY

Metoclopramide is excreted into breast milk. Because of ion trapping of the drug in the more acidic (as compared with plasma) milk, accumulation occurs with milk:plasma ratios of 1.8–1.9 after steady state conditions are reached (31–33).

Several studies have examined the effect of metoclopramide as a lactation stimulant in women with inadequate or decreased milk production (31–43). One study involved 23 women who had delivered prematurely (mean gestational length, 30.4 weeks) (41). The drug, by stimulating the release of prolactin from the anterior pituitary, was effective in increasing milk production with doses of 20–45 mg/day (9,32–42). Doses of 15 mg/day were not effective (37). In one study, metoclopramide caused a shift in the amino acid composition of milk, suggesting an enhanced rate of transition from colostrum to mature milk (38). No effect on the serum levels of prolactin, thyroid-stimulating hormone, or free thyroxin was observed in nursing infants in a 1985 study of 11 women with lactational insufficiency (39). A 1994 investigation found a positive response in 78% (25 of 32) of treated women, but the increase in daily milk production was inversely correlated with maternal age (43).

The total daily dose that would be consumed by a nursing infant during the maternal use of 30 mg/day has been estimated to be 1–45 mcg/kg (31–33). This is much less than the maximum daily dose of 500 mcg/kg recommended in infants (9) or the 100 mcg/kg/day dosage that has been given to premature infants (44). Metoclopramide was detected in the plasma of one of five infants whose mothers were taking 10 mg 3 times daily (32,33). Adverse effects have been observed in only two infants—both with mild intestinal discomfort (36,37). In one case, the mother was consuming 30 mg/day (36) and in the other, 45 mg/day (37).

Metoclopramide apparently represents a small risk to the nursing infant with maternal doses of 45 mg/day or less. Mild adverse effects only have been reported in two nursing infants. One review stated that the drug should not be used during breastfeeding because of the potential risks to the neonate (45), but there are no published studies to substantiate this caution. The American Academy of Pediatrics classifies metoclopramide as a drug for which the effect on a nursing infant is unknown but may be of concern because it is a dopaminergic blocking agent (46).

METOLAZONE

Diuretic

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Metolazone is structurally related to the thiazide diuretics. (See also Chlorothiazide.) There is no evidence that thiazide diuretics are teratogenic. However, diuretics are not recommended for the treatment of gestational hypertension–preeclampsia because of the maternal hypovolemia characteristic of this disease.

FETAL RISK SUMMARY

Reproduction studies in mice, rats, and rabbits at doses up to 50 mg/kg/day revealed no evidence of fetal harm (1).

BREASTFEEDING SUMMARY

See Chlorothiazide.

METOPROLOL

Sympatholytic (Antihypertensive)

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although the use of metoprolol for maternal disease does not seem to pose a major risk to the fetus, the long-term effects of in utero exposure to β -blockers have not been studied. Persistent β -blockade has been observed in newborns exposed near delivery to other members of this class (see Acebutolol, Atenolol, and Nadolol). Therefore, newborns exposed in utero to metoprolol should be closely observed during the first 24–48 hours after birth for bradycardia and other symptoms. Some β -blockers may cause intrauterine growth restriction (IUGR) (as may have occurred in some of the cases) and reduced placental weight, especially those lacking intrinsic sympathomimetic activity (ISA) (i.e., partial agonist). Metoprolol does not possess ISA. Treatment beginning early in the 2nd trimester results in the greatest weight reductions, whereas treatment restricted to the 3rd trimester primarily affects only placental weight. Although growth restriction is a serious concern, the benefits of maternal therapy, in some cases, might outweigh the risks to the fetus and must be judged on a case-by-case basis.

FETAL RISK SUMMARY

Metoprolol, a cardioselective β_1 -adrenergic blocking agent, has been used during pregnancy for the treatment of maternal hypertension and tachycardia (1–10). Reproductive studies in mice and rats have found no evidence of impaired fertility or teratogenicity (11). In rats, however, increases in fetal loss and decreases in neonatal survival were observed at doses up to 55.5 times the maximum daily human dose (11).

The drug readily crosses the placenta, producing approximately equal

concentrations of metoprolol in maternal and fetal serum at delivery (1–3). The serum half-lives of metoprolol determined in five women during the 3rd trimester and repeated 3–5 months after delivery were similar (1.3 vs. 1.7 hours, respectively), but peak levels during pregnancy were only 20%–40% of those measured later (4). Neonatal serum levels of metoprolol increase up to fourfold in the first 2–5 hours after birth, then decline rapidly during the next 15 hours (2,3).

No fetal malformations attributable to metoprolol have been reported, but experience during the 1st trimester is limited. Twins, exposed throughout gestation to metoprolol 200 mg/day plus other antihypertensive agents for severe maternal hypertension, were reported to be doing well at 10 months of age (7).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 52 newborns had been exposed to metoprolol during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Three (5.8%) major birth defects were observed (two expected). No anomalies were observed in six defect categories (cardiovascular defects, oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available.

A 1978 study described 101 hypertensive pregnant patients treated with metoprolol alone (57 patients) or combined with hydralazine (44 patients) compared with 97 patients treated with hydralazine alone (1). The duration of pregnancy at the start of antihypertensive treatment was 34.1 weeks (range 13–41 weeks) for the metoprolol group and 32.5 weeks (range 12–40 weeks) for the hydralazine group. The metoprolol group experienced a lower rate of perinatal mortality (2% vs. 8%) and a lower incidence of IUGR (11.7% vs. 16.3%). No signs or symptoms of β -blockade were noted in the fetuses or newborns in this or other studies (1,2,5).

The use of metoprolol in a pregnant patient with pheochromocytoma has been reported (5). High blood pressure had been controlled with prazosin, an α -adrenergic blocking agent, but the onset of maternal tachycardia required the addition of metoprolol during the last few weeks of pregnancy. No adverse effects were observed in the newborn.

The acute effects of metoprolol on maternal hemodynamics have been studied (12). Nine women at a mean gestational age of 36.7 weeks with a diagnosis of gestational hypertension were given a single oral dose of 100 mg of metoprolol. Statistically significant ($p < 0.01$) decreases were observed in maternal heart rate, systolic and diastolic blood pressure, and cardiac output.

No significant change was noted in mean blood volume or intervillous blood flow. An improvement was observed in four women for the latter parameter, but a reduction occurred in another four. The intervillous blood flow did not change in the ninth patient.

Cardiac palpitations, accompanied by lightheadedness and dyspnea but without syncope, developed in a previously healthy 33-year-old woman at 10 weeks' gestation (13). A diagnosis of ventricular tachycardia and mitral valve prolapse with mild mitral regurgitation was diagnosed at 22 weeks, and treatment with metoprolol, 50 mg twice daily, was begun. Four weeks later, quinidine was added to the regimen because of recurrent palpitations. Growth restriction was noted during her obstetric care and she eventually gave birth at term to a healthy newborn weighing about 2242 g. Follow-up of the infant was not mentioned (13).

New-onset ventricular tachycardia was diagnosed in seven pregnant women among whom four were treated with metoprolol (250–450 mg/day) throughout the remainder of their pregnancy (14). Metoprolol therapy in a fifth patient did not resolve the arrhythmia and it was discontinued. Treatment was started in the 1st trimester in one, during the 2nd trimester in one, and in the 3rd trimester in two. All four were delivered at term of healthy newborns with birth weights (in grams) (daily metoprolol dose shown in parentheses) of 3380 (250 mg), 3462 (350 mg), 3560 (250 mg), and 2535 (450 mg), respectively (14).

A retrospective study published in 1992 reported the follow-up of 35 very low birth weight (≤ 1500 g) infants who had been exposed in utero to maternal antihypertensive therapy (15). Nineteen of the infants (mean birth weight 1113 g) had been exposed to β -blockers (metoprolol N = 15, propranolol N = 4; combination with hydralazine or clonidine in 17 cases) whereas in 16 cases (mean birth weight 1102 g), other antihypertensives (hydralazine alone N = 11, hydralazine plus clonidine N = 3, hydralazine plus methyldopa N = 1, and diuretics N = 1) had been used. The metoprolol dose ranged from 100 to 200 mg/day while that of hydralazine varied from 30 to 150 mg/day. The mean duration of therapy was similar in both groups (12 vs. 11 days). Among the 19 infants exposed to β -blockers, 7 died, 4 within 15 days of birth, compared with no deaths in the other group ($p = 0.006$). The authors speculated that the β -blockade might have impaired the infant's adaptation to the postnatal environment by inhibition of the sympathoadrenal system (15).

BREASTFEEDING SUMMARY

Metoprolol is concentrated in breast milk (1,3,16–18). Milk concentrations are

approximately 3 times (range 2.0–3.7) those found simultaneously in the maternal serum. No adverse effects have been observed in nursing infants exposed to metoprolol in milk. Based on calculations from a 1984 study, a mother ingesting 200 mg/day of metoprolol would provide only about 225 mcg in 1000 mL of her milk (3). To minimize this exposure even further, one reference suggested waiting 3–4 hours after a dose to breastfeed (18). Although these levels are probably clinically insignificant, nursing infants should be closely observed for signs or symptoms of β -blockade. The long-term effects of exposure to β -blockers from milk have not been studied but warrant evaluation. The American Academy of Pediatrics classifies metoprolol as compatible with breastfeeding (19).

METRIZOATE

[Withdrawn from the market. See 9th edition.]

METRONIDAZOLE

Anti-infective/Amebicide/Trichomonacide

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Hold Breastfeeding (Single Dose)
Limited Human Data—Potential Toxicity (Divided Dose)

PREGNANCY SUMMARY

Although some of the available reports have arrived at conflicting conclusions as to the safety of metronidazole in pregnancy, most of the published evidence suggests that the anti-infective does not represent a significant risk of structural defects to the fetus. At present, it is not possible to assess the risk to the fetus from the carcinogenic potential of metronidazole. The answer to the question of transplacental carcinogenic potential of metronidazole has major public health implications, but may never be answered because of the rarity of childhood cancers and the inability to identify potentially confounding environmental factors in older children and adults. The manufacturer considers metronidazole to be contraindicated during the 1st trimester in patients with trichomoniasis or bacterial vaginosis (1). The use of metronidazole for trichomoniasis or vaginosis during the 2nd and 3rd trimesters is acceptable. For other indications, metronidazole can be used during pregnancy if there are no other alternatives with established safety profiles.

FETAL RISK SUMMARY

Metronidazole possesses trichomonacidal and amebicidal activity as well as effectiveness against certain bacteria. The drug crosses the placenta to the fetus throughout gestation with a cord:maternal plasma ratio at term of approximately 1.0 (2–4). The pharmacokinetics of metronidazole in pregnant women has been reported (5,6).

Reproduction studies conducted in mice (at oral doses about 0.1 times the human dose) and in rats (at doses up to 5 times the human dose) revealed no fetal harm. After intraperitoneal administration in mice, however, some fetal deaths were noted (1).

The use of metronidazole in pregnancy is controversial. The drug is mutagenic in bacteria and carcinogenic in rodents, and although these properties have never been shown in humans, concern for these toxicities have led some to advise against the use of metronidazole in pregnancy (7,8). However, no association with human cancer has been proven (8,9).

A 1995 case report described a 32-year-old woman who was treated with metronidazole during the 12th and 13th weeks of pregnancy with 500 mg/day orally plus 500 mg/day intravaginally for 10 days (10). She eventually delivered an apparently normal, 3640-g male infant at term. Fifteen days later, the infant was diagnosed with adrenal neuroblastoma with hepatic metastasis (eventual outcome not mentioned). The authors acknowledged that neuroblastoma was the second most common malignant solid tumor in childhood and that a causal relationship between the tumor and metronidazole in this case could not be established (10).

A retrospective cohort study of childhood cancer and in utero exposure to metronidazole was reported in 1998 (11). The cohort included 328,846 children under 5 years of age who had been born to women (ages 15–44 years) enrolled from 1975 through 1992 in Tennessee Medicaid at any time between the last menstrual period and the date of delivery. Exposure to metronidazole was based on Medicaid pharmacy prescription records. A statewide childhood cancer database was developed to identify study cases. In the cohort, 8.1% were exposed in utero to metronidazole and 91.9% were not exposed. From 952 children younger than 5 years of age in the cancer database, 175 met the criteria for the study (first primary cancer before age 5 years, a Tennessee resident, and seen at a Tennessee hospital at the time of diagnosis). The study was limited to children under the age of 5 years to minimize the loss to out-of-state migration (expected to be no more than 6% (12)). None of the study cases had a history of therapeutic radiation or exposure to chemotherapy before their cancer diagnosis. The cancer type, number of cases, adjusted relative risk (RR), and 95% confidence interval (CI) were, for all cancers: N = 175, RR 0.81, 95% CI 0.41–1.59; for leukemia: N = 42, no exposed cases; for central nervous system tumors: N = 30, RR 1.23, 95% CI 0.29–5.21; for neuroblastoma: N = 28, RR 2.60, 95% CI 0.89–7.59; and other cancers: N = 75, RR 0.57, 95% CI 0.18–1.82. Although none of the observed relative risks were statistically significant, the authors stated that the increased risk for neuroblastoma needed further evaluation (11).

In a brief comment, other investigators agreed with the conclusions of the above study but expressed concern that the frequent use of medications during

pregnancy combined with the rarity of childhood cancer made it difficult to establish a carcinogenic effect (12). In addition, limiting the study to children less than 5 years of age prevented the identification of potential effects on later developing cancers such as Hodgkin's disease, Ewing's sarcomas, and osteosarcoma.

Several studies, individual case reports, and reviews have described the safe use of metronidazole during pregnancy (13–27). Included among these is a 1972 review summarizing 20 years of experience with the drug and involving 1469 pregnant women, 206 of whom were treated during the 1st trimester (27). No association with congenital malformations, abortions, or stillbirths was found. Some investigations, however, found an increased risk when the agent was used early in pregnancy (9,28–30).

In a 1979 report, metronidazole was used in 57 pregnancies including 23 during the 1st trimester (9). Three of the 1st trimester exposures ended in spontaneous abortion (a normal incidence), and in the remaining 20 births, there were 5 congenital anomalies: hydrocele (two), congenital dislocated hip (female twin), metatarsus varus, and mental retardation (both parents mentally slow). Analysis of the data is not possible because of the small numbers and possible involvement of genetic factors (9).

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 31 of whom had 1st trimester exposure to metronidazole (28). A possible association with malformations was found (RR 2.02) based on defects in four children, but independent confirmation is required.

Two mothers, treated with metronidazole during the 5th–7th weeks of gestation for amebiasis, gave birth to infants with midline facial defects (29). Diiodohydroxyquinoline was also used in one of the pregnancies. One of the infants had holotelencephaly and one had unilateral cleft lip and palate.

A mother treated for trichomoniasis between the 6th and 7th weeks of gestation gave birth to a male infant with a cleft of the hard and soft palate, optic atrophy, a hypoplastic, short philtrum, and a Sydney crease on the left hand (30). The mother was also taking an antiemetic medication (Bendectin) on an “as needed” basis. Chromosomal analysis of the infant was normal. The relationship between metronidazole and the defects is unknown.

As of May 1987, the FDA had received reports of 26 adverse outcomes with metronidazole: spontaneous abortions (N = 3), brain defects (N = 6), limb defects (N = 5), genital defects (N = 3), unspecified defects (N = 3), and 1 each of craniostenosis, peripheral neuropathy, ventricular septal defect, retinoblastoma, obstructive uropathy, and a chromosomal defect (31). In this

same report, the authors, from data obtained from the Michigan Medicaid program between 1980 and 1983, cited 1020 other cases in which metronidazole use in the 1st trimester for treatment of vaginitis was not linked with birth defects. In an additional 63 cases, use of the agent for this indication was linked to a birth defect diagnosis. Based on these data, the estimated RR of a birth defect was 0.92 (95% CI 0.7–1.2). Of the 122 infants with oral clefts, none was exposed to metronidazole. An estimated RR for spontaneous abortion of 1.67 (95% CI 1.4–2.0) was determined from 135 exposures among 4264 spontaneous abortions compared to 1020 exposures among 55,736 deliveries (31).

In a continuation of the study cited immediately above, 229,101 completed pregnancies of Michigan Medicaid recipients were evaluated between 1985 and 1992 (F. Rosa, personal communication, FDA, 1993). Of this group, 2445 newborns had been exposed to metronidazole during the 1st trimester. A total of 100 (4.1%) major birth defects were observed (97 expected). Specific data were available for six defect categories, including (observed/expected) 23/24 cardiovascular defects, 1/1 spina bifida, 4/7 polydactyly, 2/4 limb reduction defects, 7/6 hypospadias, and 8/4 oral clefts. Only with oral clefts is there a suggestion of a possible association, but in view of the outcomes observed between 1980 and 1983, other factors, such as the mother's disease, concurrent drug use, and chance, are probably involved.

Using data from the Tennessee Medicaid program, pregnancy outcomes of women (N = 1307) who had filled a prescription for metronidazole between 30 days before and 120 days after the onset of their last normal menstrual period were compared with those of women who had not filled such a prescription (32). The groups were matched for age, race, year of delivery, and hospital. Data were available for 1322 exposed (1318 live births; 4 stillbirths) and 1328 nonexposed (1320 live births; 8 stillbirths) infants. The occurrence of birth defects was similar in the two groups; 96 in the exposed group and 80 in the nonexposed group (adjusted odds ratio [OR] 1.2; 95% CI 0.9–1.6). Similar results were obtained when congenital malformations were analyzed by specific types, including those of the central nervous system, heart, gastrointestinal tract, musculoskeletal system, urogenital system, respiratory tract, chromosomal, and by multiple organ systems. The investigators concluded that the use of metronidazole was not associated with an increased risk for birth defects (32).

A study published in 1995 conducted a meta-analysis of seven studies (from a total of 32 references identified in their search) that met their criteria for

assessing the safety of metronidazole use in human pregnancy (33). The criteria required exposure during the 1st trimester and comparison of these outcomes with the outcomes of pregnancies that were not exposed or only exposed during the 3rd trimester. Six of the studies were prospective and one was retrospective. The OR (exposure vs. no exposure during the 1st trimester) for the seven studies was 0.93 (95% CI 0.73–1.18) and for the six prospective studies was 1.02 (95% CI 0.48–2.18). Based on these findings, the investigators concluded that the use of metronidazole during the 1st trimester was not associated with an increased risk of congenital defects (33).

A second meta-analysis, similar in design to the study above, evaluated the risk for birth defects after the use of metronidazole early in pregnancy (34). A total of five studies, one unpublished case–control study and four published cohort studies, met the inclusion criteria. As in the study immediately above, the OR 1.08 (95% CI 0.90–1.29) indicated that exposure to metronidazole during the 1st trimester was not associated with birth defects (34).

A large ethnically homogeneous population-based dataset (Hungarian Case–Control Surveillance of Congenital Abnormalities, 1980–1991) was used in a study published in 1998 to evaluate whether the use of metronidazole in the 1st trimester was associated with congenital anomalies (35). The background rate of congenital malformations in the dataset was 4.0%–4.7% (liveborn, stillborn, and selectively terminated fetuses). Minor abnormalities and congenital abnormality syndromes of known origin were excluded. Among 17,300 cases with birth defects, 665 (3.8%) were treated with metronidazole (oral and IV) in the 2nd to 3rd months of gestation (dating from last menstrual period). In comparison, among 30,663 matched controls, 1041 (3.4%) were treated with metronidazole (oral and IV) during this period of gestation. Using the McNemar analysis of case–control pairs, the only defect with a positive association was cleft lip ± palate (nine cases) (adjusted OR 8.54, 95% CI 1.06–68.86). The investigators concluded that the most likely reasons for the association were recall bias or chance alone, but that a true association could not be ruled out. However, based on the prevalence of isolated cleft lip (with or without cleft palate) in their population and the prevalence of exposure to metronidazole during the 2nd and 3rd months of pregnancy, their analysis suggested that even a true association would only increase the prevalence of the defect from 100 cases/100,000 births to 103 cases/100,000 births. Moreover, the finding was not confirmed when the comparison was made with the total control group (35).

In a second study from the above group, the teratogenic potential of vaginal

metronidazole plus miconazole treatment during the 2nd and 3rd months of pregnancy was evaluated using the 1980–1996 dataset of the Hungarian Case–Control Surveillance of Congenital Abnormalities (36). Their analysis included 21 groups of congenital anomalies. They compared 22,843 women who had newborn infants or fetuses with congenital anomalies (cases) with 38,151 pregnant women who had newborns without defects (controls). Vaginal treatment with the drug combination occurred in 2.5% (576) cases and 2.2% (846) controls. The analysis of cases and their matched controls found an association between the drug combination and polysyndactyly (21 cases) with an adjusted prevalence OR 6.0, 95% CI 2.4–15.2. The authors thought that recall bias was unlikely and considered their findings to be a signal of the defect, although they had no plausible biological mechanism (36).

A population-based cohort study on the use of metronidazole during pregnancy from 1991 to 1996 was conducted in Denmark and reported in 1999 (37). An estimated 35,000 pregnancies were used in the risk analysis for the specific outcomes of congenital abnormalities, low birth weight (<2500 g), and preterm birth (<37 weeks). Data on the use of metronidazole were determined from a prescription database and classified as either exposure from 30 days before conception to the end of the 1st trimester (group 1) or during the 2nd and 3rd trimesters (group 2). A total of 138 prescriptions to the agent were obtained by 124 women during the study period. A control group of 13,327 pregnancies was used for comparison. Outcome data were determined independently from exposure information. Based on prevalence rates of congenital anomalies in the exposed (group 1) and control groups of 2.4% and 5.2%, respectively, no increased risk for malformations was found (OR 0.44, 95% CI 0.11–1.81). The two birth defects in group 1 were transposition vasorum with ventricular septum defect and hypertelorism. Preterm birth occurred in 6 of the 124 exposed women (4.8%) and in 793 of 13,327 controls (6.0%) (adjusted OR 0.80, 95% CI 0.35–1.83). After adjustment for maternal age, birth order, gestational age, and smoking, there was no difference in mean birth weight between those exposed and the controls. The investigators acknowledged the major limitations of their study: low statistical power due to the small number of exposed subjects; the inability to control for potentially confounding factors; and the lack of information on spontaneous abortions and fetuses aborted for prenatal diagnosis of malformations. They concluded, however, that their results showed no evidence of major teratogenicity and no indication for the termination of pregnancies because of exposure to metronidazole (37).

Metronidazole has been shown to markedly potentiate the fetotoxicity and teratogenicity of alcohol in mice (38). Human studies of this possibly clinically significant interaction have not been reported.

A 2001 prospective, controlled cohort study evaluated the pregnancy outcomes of 217 women exposed to metronidazole (86.2% exposed in 1st trimester) (39). The women had consulted a Teratogen Information Service concerning their exposure to the drug. A matched control group consisted of 612 women who had called about nonteratogenic exposures. There were no statistical differences between the groups in terms of spontaneous abortions (7.8% vs. 7.2%), stillbirths (0.0% vs. 0.2%), preterm delivery (6.8% vs. 5.7%), or rate of major birth defects (2.6% vs. 2.1%). However, exposed cases had a lower birth weight than controls (3253 vs. 3375 g, $p = 0.004$) (39).

A number of reports have described the use of metronidazole in pregnant women with bacterial vaginosis in attempts to reduce the incidence of preterm births (40–50). A 1994 randomized, double-blind, placebo-controlled study found that two courses of oral metronidazole (400 mg twice daily for 2 days) administered at 24 and 29 weeks' gestation, respectively, were effective in suppressing *Gardnerella vaginalis* for 2–3 months in the majority of women with bacterial vaginosis (40).

A prospective, randomized, double-blind, placebo-controlled study first published in abstract form in 1993 (41) and then in full in 1994 (42) compared a 7-day course of oral metronidazole (750 mg/day) to a 7-day course of placebo in women with bacterial vaginosis and a history of preterm birth (<37 weeks' gestation) in the preceding pregnancy from either idiopathic preterm labor or premature rupture of membranes. The women were enrolled between 13 and 20 weeks' gestation. Compared to the placebo group ($N = 36$), the pregnancy outcomes of the active drug group ($N = 44$) included significantly fewer admissions for preterm labor (27% vs. 78%, $p < 0.05$), fewer preterm births (18% vs. 39%, $p < 0.05$), fewer newborns with birth weight <2500 g (14% vs. 33%, $p < 0.05$), and fewer cases of premature rupture of membranes (5% vs. 33%, $p < 0.05$) (42).

Another prospective randomized, double-blind, placebo-controlled study first published in abstract form in 1993 (43) and then in full in 1995 (44) described the effect of a 7-day course of oral metronidazole (750 mg/day) combined with a 14-day course of oral erythromycin base (999 mg/day) in pregnant women at increased risk for preterm delivery (based on a history of spontaneous preterm delivery or prepregnancy body weight less than 50 kg). At enrollment (at a mean 23 weeks' gestation for both groups), 41% of the 433 women in the

active drug group had bacterial vaginosis compared with 46% of the 191 women receiving placebo. If a second examination (at a mean 27.6 weeks' gestation for both groups) revealed bacterial vaginosis, a second course of active drugs or placebo was administered. Eight women were lost to follow-up. A total of 110 women (26%) in the active group delivered preterm (<37 weeks) compared with 68 women (36%) in the placebo group ($p = 0.01$). However, the rates of preterm delivery in those without bacterial vaginosis were nearly identical (22% in the active drug group vs. 25% in the placebo group, $p = 0.55$). In contrast, in those with bacterial vaginosis, the rates of preterm delivery were 31% for the active drug group compared with 49% in those receiving placebo, $p = 0.006$. The positive association with anti-infective treatment existed both for women with a history of preterm birth (39% vs. 57%, $p = 0.02$) and prepregnancy body weight less than 50 kg (14% vs. 33%, $p = 0.04$) (44).

A 1997 randomized, placebo-controlled study also found that the beneficial effect of a 2-day course of oral metronidazole (400 mg twice daily) on prolonging pregnancy was restricted to those women with bacterial vaginosis and a previous history of spontaneous preterm birth (45). Metronidazole therapy was started at 24 weeks' gestation and repeated at 29 weeks' if *G. vaginalis* was still present.

Another 1997 randomized, double blind, placebo-controlled study administered a combination of metronidazole and ampicillin to 59 women and placebo to 51 women (46). The subjects in both groups had threatened idiopathic preterm labor and intact membranes. The anti-infective regimen was an 8-day course of metronidazole (500 mg IV every 8 hours for 24 hours, then 400 mg orally every 8 hours for 7 days) and ampicillin (2 g IV every 6 hours for 24 hours, then pivampicillin 500 mg orally every 8 hours for 7 days). The women were enrolled in the study at 26–34 weeks' gestation from six clinics in the Copenhagen area. Treatment with the anti-infectives was associated with prolongation of gestation (47.5 vs. 27 days, $p < 0.05$), higher gestational age at birth (37 vs. 34 weeks, $p < 0.05$), reduced preterm birth rate (40% vs. 63%, $p < 0.05$), and a lower rate of admission to neonatal intensive care unit (40% vs. 63%, $p < 0.05$). The incidences of maternal (5% vs. 0%, $p = 0.30$) and neonatal (10% vs. 22%, $p = 0.18$) infectious morbidity, however, were statistically similar between the groups (46). In four other reports, all from the same source, gestational metronidazole treatment of women with asymptomatic bacterial vaginosis, but without a history of previous preterm birth, either did not reduce the risk of preterm birth (47–49) or increased the risk for that outcome (50).

Metronidazole was not effective in preventing preterm delivery among pregnant women with asymptomatic *Trichomonas vaginalis* infection in a 2001 report (51). Women were screened for the infection at 16–23 weeks' gestation and then randomized to either metronidazole (N = 320) or placebo (N = 297). The metronidazole group received two 2-g doses 48 hours apart at randomization and then again at 24–29 weeks'. Preterm delivery (<37 weeks') occurred in 19% of the treated group and about 11% of the controls (51).

BREASTFEEDING SUMMARY

Metronidazole is excreted into breast milk. Following a single 2-g oral dose in three patients, peak milk concentrations in the 50–60 mcg/mL range were measured at 2–4 hours (52). With normal breastfeeding, infants would have received about 25 mg of metronidazole during the next 48 hours. By interrupting feedings for 12 hours, infant exposure to the drug would have been reduced to 9.8 mg, or 3.5 mg if feeding had been stopped for 24 hours (52).

In women treated with divided oral doses of either 600 or 1200 mg/day, the mean milk levels were 5.7 and 14.4 mcg/mL, respectively (53). The milk:plasma ratios in both groups were approximately 1.0. The mean plasma concentrations in the exposed infants were about 20% of the maternal plasma drug level. Eight women treated with metronidazole rectal suppositories, 1 g every 8 hours, produced a mean milk drug level of 10 mcg/mL with maximum concentrations of 25 mcg/mL (54).

One report described diarrhea and secondary lactose intolerance in a breastfed infant whose mother was receiving metronidazole (55). The relationship between the drug and the events is unknown. Except for this one case, no reports of adverse effects in metronidazole-exposed nursing infants have been located. However, because the drug is mutagenic and carcinogenic in some test species (see Fetal Risk Summary), unnecessary exposure to metronidazole should be avoided. However, topical or vaginal use of metronidazole during breastfeeding does not appear to represent a risk to a nursing infant.

A 1988 report analyzed the milk and plasma concentrations of metronidazole and its metabolite (hydroxymetronidazole) in 12 breastfeeding women who had been taking 400 mg 3 times daily for 4 days (56). The mean milk:plasma ratios for the parent drug and metabolite were 0.9 and 0.76, respectively. In seven of the nursing infants, the plasma concentrations for the parent drug and metabolite ranged from 1.27 to 2.41 mcg/mL and 1.1 to 2.4 mcg/mL, respectively. The investigators also monitored 35 other women under treatment

with metronidazole while nursing. There were no significant increases in adverse effects in their infants that could be attributed to the drug therapy (56).

If a single, 2-g oral dose of metronidazole is used for trichomoniasis, the American Academy of Pediatrics recommends discontinuing breastfeeding for 12–24 hours to allow excretion of the drug (57).

METYROSINE

Antihypertensive

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Metyrosine, an enzyme inhibitor, is used for preoperative preparation in patients with pheochromocytoma management when surgery is contraindicated, or as chronic treatment of malignant pheochromocytoma. Because these indications are relatively rare in pregnancy, the human pregnancy experience is very limited and there are no animal reproduction data. However, if required, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Metyrosine inhibits tyrosine hydroxylase, the enzyme that catalyzes the conversion of tyrosine to dihydroxyphenylalanine, the first transformation in catecholamine biosynthesis (1).

No reproduction studies in animals have been located. The molecular weight of the compound (195) is low enough that transfer to the fetus should be expected.

A case report published in 1986 described the pregnancy of a 24-year-old woman at 30 weeks' gestation who was treated for recurrent pheochromocytoma with a combination of metyrosine, prazosin (α_1 -adrenergic blocker), and timolol (β -adrenergic blocker) (2). Hypertension had been noted at her first prenatal visit at 12 weeks' gestation. Because of declines in fetal breathing, body movements, and amniotic fluid volume that began 2 weeks after the start of therapy, a cesarean section was conducted at 33 weeks'. The 1450-g female infant had Apgar scores of 3 and 5 at 1 and 5 minutes, respectively. Mild metabolic acidosis was found on analysis of umbilical cord blood gases. Multiple infarcts were noted in the placenta but no evidence of

metastatic tumor. The growth-restricted infant did well and was discharged home on day 53 of life (2).

BREASTFEEDING SUMMARY

No reports describing the use of metyrosine during human lactation have been located. The molecular weight (195) is low enough that excretion into breast milk probably occurs. The effects of this exposure on a nursing infant are unknown.

MEXILETINE

Antiarrhythmic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Based on the very limited published information in humans, mexiletine does not appear to present a significant risk to the fetus. However, three reviews on the use of cardiovascular drugs during pregnancy caution that too few data are available to assess the safety of this agent during pregnancy (1–3).

FETAL RISK SUMMARY

Mexiletine is a local anesthetic, orally active, antiarrhythmic agent structurally similar to lidocaine. It is indicated for the treatment of documented ventricular arrhythmias, such as sustained ventricular tachycardia. The drug is metabolized to inactive metabolites. Depending on hepatic or renal function, the elimination half-life is in the range of about 13–25 hours (6).

The drug is not teratogenic in pregnant mice, rats, and rabbits given doses up to and including maternal toxicity (4–6). Human pregnancy experience with mexiletine is limited to three women, one treated throughout gestation, one starting during the 14th week, and one at 32 weeks (7–9). No adverse effects attributable to mexiletine were mentioned in these reports.

A healthy 2600-g male infant was delivered at 39 weeks' gestation (Apgar scores 9 and 10 at 1 and 5 minutes, respectively) to a 26-year-old primigravida woman who had been treated throughout her pregnancy with mexiletine (200 mg 3 times daily) and atenolol (50 mg/day) for ventricular tachycardia with multifocal ectopic beats (7). A serum mexiletine level obtained from the infant 9 hours after birth was 0.4 mcg/mL (normal therapeutic range 0.75–2.0 mcg/mL). Heart rates during a normal newborn course were 120–160 beats/minute (bpm). Postpartum, the mother continued both mexiletine and atenolol. The

infant was fed breast milk only, and by 17 days of age, his weight had decreased to 2155 g. The weight loss was attributed to failure to feed and was corrected with maternal education and formula supplementation. Breastfeeding was halted at 3 months of age. Gastroesophageal reflux, presenting with seizure-like episodes but with a normal neurologic examination and electroencephalogram, was diagnosed at 8 months of age. The condition responded to corrective measures, and growth and development were appropriate at 10 months of age (7).

A 1981 report described the treatment of a 30-year-old woman with cardiac palpitations with mexiletine (600 mg/day) and propranolol (60 mg/day) starting at approximately 14 weeks' gestation (8). A healthy infant (birth weight and sex not specified) was delivered 5 months later.

A 34-year-old woman was treated at 32 weeks' gestation with a combination of mexiletine 200 mg 3 times daily and propranolol 40 mg 3 times daily for paroxysmal ventricular tachycardia (9). A normal male infant (birth weight not given) was delivered by spontaneous vaginal birth at 39 weeks' gestation. Bradycardia, most likely as a result of propranolol, was noted in the infant during the first 6 hours after birth. The heart rate was 90 bpm, before increasing to a normal rate of 120 bpm. An electrocardiogram was normal. The cord blood and maternal serum mexiletine concentrations at birth were both 0.3 mcg/mL.

A 27-year-old woman was treated with mexiletine during pregnancy (10). Her initial dose was 100 mg 3 times daily but her symptoms required higher doses as her pregnancy progressed, eventually requiring 200 mg every 4 hours. At about 38 weeks', a repeat cesarean section was performed to deliver a 3750-g male infant with Apgar scores of 4 and 9 at 1 and 5 minutes, respectively. After 5 minutes, the infant's extremities were still blue. The low 1-minute Apgar was explained by the 9-minute general anesthesia induction to delivery time. The infant was large for gestational age and had hypoglycemia. The mother had no history of diabetes and there was no glucosuria noted during pregnancy. At delivery, maternal and fetal cord blood mexiletine concentrations were 0.6 and 0.4 mcg/mL (therapeutic concentrations are 0.7–2.0 mcg/mL), respectively. At 2 years of life, the child was developing normally (10).

A 1990 case report described the postoperative use of mexiletine (200 mg 3 times a day) in a 27-year-old woman who had undergone an aortic valve replacement under general anesthesia at 29 weeks' gestation (11). A normal 2510-g female infant was born by cesarean section at 28 weeks' with Apgar scores of 8 and 9 at 1 and 5 minutes, respectively. The postoperative course

after delivery was uneventful (11).

BREASTFEEDING SUMMARY

Mexiletine is excreted into breast milk in concentrations exceeding those in the maternal serum (8,9). Three cases have been reported in which a nursing infant was exposed to the drug via the milk with drug levels determined in two of these cases. All three infants had been exposed to mexiletine in utero, and no adverse effects attributable to the drug were noted.

Milk and serum mexiletine concentrations in a woman described above, who was taking 600 mg/day in divided doses, were 0.6 and 0.3 mcg/mL, respectively, 2 days postpartum, and 0.8 and 0.7 mcg/mL, respectively, 6 weeks after delivery (9). These levels represented milk:plasma ratios of 2.0 and 1.1, respectively. Mexiletine was not detected in serum samples from the breastfed infant at either sampling time, nor were adverse effects observed in the infant. A second report, appearing 1 year later, described the excretion of the antiarrhythmic agent into breast milk of a woman also taking 600 mg/day in divided doses (8). Again, no adverse effects were noted in the breastfed infant. Twelve paired milk and serum levels, collected from the mother between the 2nd and 5th postpartum days, yielded peak concentrations of 0.959 mcg/mL in the milk compared with 0.724 mcg/mL in the serum, a ratio of 1.32 (mean ratio 1.45, range 0.78–1.89) (8).

Failure to feed was observed in a wholly breastfed infant whose mother was taking mexiletine (600 mg/day) and atenolol (50 mg/day) (7). The infant's weight dropped from 2600 g at birth to 2155 g at 17 days of age. An acceptable growth curve was obtained with maternal education and formula supplementation for the next 2.5 months, after which breastfeeding was stopped (7).

The American Academy of Pediatrics classifies mexiletine as compatible with breastfeeding (12).

MICAFUNGIN

Antifungal

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of micafungin in human pregnancy have been located. The single animal species studied for developmental toxicity suggests moderate risk. However, the absence of pregnancy experience prevents an assessment of the risk in human embryos and fetuses. Although animal data do not always predict human risk, the safest course is to avoid micafungin in the 1st trimester.

FETAL RISK SUMMARY

Micafungin is a semisynthetic lipopeptide (echinocandin) hydrophilic antifungal agent derived from *Coleophoma empetri* F-11899 that is administered by IV infusion. It is in the same antifungal class as caspofungin. Micafungin is indicated for the treatment of patients with esophageal candidiasis and for the prophylaxis of *Candida* infections in patients undergoing hematopoietic stem cell transplantation. The mean elimination half-life ranges from 14 to 17 hours. Micafungin is highly bound to plasma proteins (>99%), mainly to albumin. At therapeutic concentrations, it does not competitively displace bilirubin binding from albumin. The antifungal agent undergoes partial metabolism before excretion in the feces (primary route) and urine (1).

Reproduction studies have been conducted in rabbits. During organogenesis, an IV dose equivalent to about 4 times the recommended human dose based on BSA (RHD) resulted in visceral abnormalities and abortions. The visceral abnormalities observed included abnormal lobation of the lung, levocardia, retrocaval ureter, anomalous right subclavian artery, and dilatation of the ureter (1).

Micafungin was not mutagenic or clastogenic in a number of assays. In male

rats, IV dosing at 0.6 times the RHD over 9 weeks resulted in vacuolation of the epididymal ductal epithelial cells. Doses about twice the RHD resulted in higher epididymis weights and reduced numbers of sperm cells. In a 39-week study in dogs, doses about 2 and 7 times the RHD resulted in seminiferous tubular atrophy and decreased sperm in the epididymis, respectively. However, fertility was not impaired in these species (1).

It is not known if micafungin crosses the human placenta. The high molecular weight (about 1292 for the sodium salt), low lipid solubility, and very high protein binding should limit transfer to the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use of micafungin during human lactation have been located. The high molecular weight (about 1292 for the sodium salt), low lipid solubility, and very high protein binding suggest that excretion into breast milk will be limited. The antifungal agent is given as an IV infusion and this may imply that the oral bioavailability is low. Although the effect of exposure to micafungin in breast milk on a nursing infant is unknown, the risk appears to be low, if it exists at all.

MICONAZOLE

Antifungal

PREGNANCY RECOMMENDATION: Compatible (Topical)

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Miconazole is normally used as a topical antifungal agent. Small amounts are absorbed from the vagina (1). Use in pregnant patients with vulvovaginal candidiasis (moniliasis) has not been associated with an increase in congenital malformations (1–7). Effects following IV use are unknown. However, one study did find a significant increase in the risk of spontaneous abortions (SABs) with 1st trimester vaginitis treatment (8). A later study speculated that this effect might have been due to inhibition of the critical enzyme aromatase (9). Until there are data on this potential association, the best course is to avoid the use of miconazole for vaginitis treatment in the 1st trimester or the application of the antifungal to large areas of skin at any time in pregnancy.

FETAL RISK SUMMARY

Miconazole is in the same antifungal class of imidazole derivatives as butoconazole, clotrimazole, econazole, ketoconazole, oxiconazole, sertaconazole, sulconazole, and tioconazole.

In data obtained from the Michigan Medicaid program between 1980 and 1983, a total of 2092 women were exposed to miconazole during the 1st trimester from a total sample of 97,775 deliveries not linked to a birth defect diagnosis (8). Of 6564 deliveries linked to such a diagnosis, miconazole was used in 144 cases. The estimated relative risk for birth defects from these data was 1.02 (95% confidence interval [CI] 0.9–1.2). An estimated relative risk for SABs of 1.38 (95% CI 1.2–1.5) was calculated based on 250 miconazole exposures among 4264 abortions compared with 2236 1st trimester exposures among 55,736 deliveries. No association was found between miconazole use and oral clefts, spina bifida, or cardiovascular defects. Although the relative

risks for total birth defects or the three specific defects were not increased, the authors could not exclude the possibility of an association with other specific defects (8).

In an extension of the above investigation, data were obtained for 229,101 completed pregnancies between 1985 and 1992, in which 7266 newborns had been exposed to miconazole administered vaginally during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 304 (4.2%) major birth defects were observed (273 expected). Specific data were available for six defect categories, including (observed/expected) 77/73 cardiovascular defects, 14/12 oral clefts, 3/4 spina bifida, 22/21 polydactyly, 12/12 limb reduction defects, and 20/17 hypospadias. These data do not support an association between the drug and congenital defects.

A 2002 study evaluated azole antifungals commonly used in pregnancy for their potential to inhibit placental aromatase, an enzyme that is critical for the production of estrogen and for the maintenance of pregnancy (9). The authors speculated that the embryotoxicity observed in animals and humans (see also Clotrimazole and Sulconazole) might be explained by inhibition of placental aromatase. They found that the most potent inhibitors of aromatase were (shown in order of decreasing potency) econazole, bifonazole (not available in the United States), sulconazole, clotrimazole, and miconazole. However, an earlier study reported a pregnancy that was maintained even when there was severe fetal and placental aromatase deficiency (<0.3% of that of controls) caused by a rare genetic defect (10). In this case, both the fetus and mother were virilized because of diminished conversion of androgens to estrogen. Because the pregnancy was maintained and because of the virilization, the case suggested that the main function of placental aromatase was to protect the mother and fetus from exposure to adrenal androgens (10).

A 2005 report evaluated the teratogenic potential of vaginal metronidazole + miconazole treatment during the 2nd and 3rd months of pregnancy using the population-based dataset of the Hungarian Case–Control Surveillance of Congenital Abnormalities, 1980–1996 (11). Their analysis included 21 groups of congenital anomalies. They compared 22,843 women who had newborn infants or fetuses with congenital anomalies (cases) with 38,151 pregnant women who had newborns without defects (controls). Vaginal treatment with the drug combination occurred in 2.5% (576) cases and 2.2% (846) controls. The analysis of cases and their matched controls found an association between the drug combination and poly/syndactyly (21 cases) with an adjusted prevalence odds ratio of 6.0, 95% CI 2.4–15.2. The authors thought that recall bias was

unlikely and considered their findings to be a signal, although they had no plausible biological mechanism (11).

BREASTFEEDING SUMMARY

No reports describing the use of miconazole during human lactation have been located. No risk for a nursing infant is expected if the mother is applying the agent topically.

MIDAZOLAM

Sedative

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Compatible*

*Potential Toxicity If Combined with Other CNS Depressants

PREGNANCY SUMMARY

Midazolam is a short-acting benzodiazepine used for anesthetic induction. No reports have been located that describe the use of midazolam in humans during the 1st or 2nd trimesters. Use immediately near birth has resulted in adverse neonatal neurobehavior.

FETAL RISK SUMMARY

Reproduction studies in rats and rabbits at 10 and 5 times the human dose, respectively, found no evidence of teratogenicity in either species or impairment of fertility in rats (1).

Midazolam crosses the human placenta, but this transfer, at least after oral and IM use, appears to be slower than that experienced with other benzodiazepines, such as diazepam, oxazepam, or lorazepam (2). In 13 patients given 15 mg of midazolam orally a mean of 11.4 hours (range 10.5–12.4 hours) before cesarean section, only 1 had measurable levels of the drug at the time of surgery. Maternal venous level was 12 ng/mL and cord venous level was 7 ng/mL. No patient had detectable levels of the drug in the amniotic fluid. A second group of patients (N = 11) was administered 15 mg of midazolam orally a mean of 34.3 minutes (15–60 minutes) before cesarean section. The mean serum concentrations in maternal venous, umbilical venous, and umbilical arterial blood were 12.7, 8.4, and 5.7 ng/mL, respectively. The cord venous:maternal venous and cord arterial:maternal venous ratios were 0.74 and 0.45, respectively. Six patients in a third group were administered midazolam, 0.05 mg/kg IM, 18–45 minutes (mean 30.5 minutes) before cesarean section. Drug levels from the same sampling sites and ratios obtained in the second group were measured in this group, with results of 40.0, 21.7,

and 12.8 ng/mL, respectively, and 0.56 and 0.32, respectively. None of the 1- and 5-minute Apgar scores of the 30 infants was less than 7, and no adverse effects attributable to midazolam were observed in the newborns (2).

The placental transfer of midazolam and its metabolite, α -hydroxymidazolam, was described in a 1989 reference (3). (See reference 7 for the clinical and physiologic condition of the newborns.) Twenty women were given 0.03 mg/kg of midazolam IV for anesthesia induction before cesarean section. The mean concentrations of midazolam in the mothers' serum and cord blood were 339 and 318 ng/mL (ratio 0.66), respectively. Similar measurements of the metabolite produced values of 22 and 5 (ratio 0.28), respectively. The elimination half-life of midazolam in the newborn infants was 6.3 hours (3).

Plasma levels of midazolam were measured at frequent intervals up to 2 hours after a 5-mg IV dose administered to two groups of pregnant patients in a study published in 1985 (4). Levels were significantly higher in 12 patients in early labor than in 8 women undergoing elective cesarean section. No reason was given for the significant difference. Data on the exposed newborns were not given.

Midazolam, 0.2 mg/kg (N = 26), or thiopental, 3.5 mg/kg (N = 26), was combined with succinylcholine for rapid-sequence IV induction before cesarean section in a study examining the effects of these agents on the newborn (5). Five of the newborns exposed to midazolam required tracheal intubation compared with one in the thiopental group, a significant difference ($p < 0.05$). The authors concluded that thiopental was superior to midazolam for this procedure.

A 1989 study compared the effects of midazolam 0.3 mg/kg (N = 20) with thiopental 4 mg/kg (N = 20) in mothers undergoing induction of anesthesia before cesarean section (6). The only difference found between the groups was a significantly higher (mean 7.9 mmHg) diastolic blood pressure in the midazolam group during, but not after, induction. Characteristics of the newborns from the midazolam and thiopental groups (both N = 19) were compared in the second part of this study (7). Oxygen via face mask was required in five midazolam-exposed newborns compared with three in the thiopental group. Respiratory depression on day 1 and hypoglycemia and jaundice on day 3 were also observed in the midazolam group. Moreover, three statistically significant ($p < 0.05$) neurobehavioral adverse effects, from the 19 tested, consisting of body temperature, general body tone, and arm recoil, were noted after midazolam exposure during the first 2 hours after birth. Other parameters that were inferior in the midazolam group, but that did not reach

statistical significance, were palmar grasp, resistance against pull, and startle reaction (7). Although these differences do not meet all of the criteria for “floppy infant syndrome” (see Diazepam), they do indicate that the use of midazolam before cesarean section has a depressant effect on the newborn that is greater than that observed with thiopental.

BREASTFEEDING SUMMARY

Midazolam is excreted into breast milk. In a study published in 1990, 12 women in the immediate postpartum period took 15 mg midazolam orally at night for 5 nights (8). No measurable concentrations of midazolam or the metabolite, hydroxy-midazolam, were detected (<10 nmol/L) in milk samples collected a mean 7 hours (range 6–8 hours) after drug intake during the 5-day period. One mother, however, who was accidentally given a second dose (total dose 30 mg) did have a milk concentration of 30 nmol/L (milk:plasma ratio 0.20) at 7 hours. The authors estimated that the exposure of the infant would be nil in early breast milk if nursing was held for 4 hours after a 15-mg dose. Two women also were studied at 2–3 months postpartum. In six paired milk and serum samples collected up to 6 hours after a 15-mg dose, the mean milk:plasma ratio was 0.15. Based on an average milk concentration of 10 nmol/L, a nursing infant would ingest an estimated 0.33 mcg of midazolam and 0.34 mcg of metabolite per 100 mL of milk if nursed within 4–6 hours of the maternal dose (8).

The effects of exposure to benzodiazepines during breastfeeding were reported in a 2012 study (9). In a 15-month period, spanning 2010–2011, 296 women called the Motherisk Program in Toronto, Ontario, seeking advice on the use of these drugs during lactation and 124 consented to the study. The most commonly used benzodiazepines were lorazepam (52%), clonazepam (18%), and midazolam (15%). Neonatal sedation was reported in only two infants. Midazolam was not used by either mother. There was no significant difference between the characteristics of these 2 and the 122 that reported no sedation in terms of maternal age, gestational age at birth, daily amount of time nursing, amount of time infant slept each day, and the benzodiazepine dose (mg/kg/day). The only difference was in the number of CNS depressants that the mothers were taking: 3.5 vs. 1.7 ($p = 0.0056$). The investigators concluded that their results supported the recommendation that the use of benzodiazepines was not a reason to avoid breastfeeding (9).

The American Academy of Pediatrics classifies midazolam as a drug for which the effect on a nursing infant is unknown but may be of concern if

exposure is prolonged (10).

MIDODRINE

Sympathomimetic (Adrenergic)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

One report has described the use of midodrine during human pregnancy. The active metabolite, desglymidrodrine, is an α_1 -adrenergic receptor agonist that increases the vascular tone to raise blood pressure. It is indicated for the treatment of symptomatic orthostatic hypotension. Marked increases in systolic blood pressure greater than 200 mmHg may occur, which in itself could jeopardize the fetus. (Withdrawn from the market in September 2010).

FETAL RISK SUMMARY

Reproduction studies have been conducted in pregnant rats and rabbits (1). At doses 13 and 7 times, respectively, the maximum human dose based on BSA, embryo toxicity (resorptions) and reduced fetal weights occurred in both species, and decreased fetal survival was noted in rabbits. No teratogenicity was observed in either species.

It is not known if midodrine or its metabolite cross the human placenta. The molecular weight (about 255 for the free base) is low enough that transfer to the fetus should be expected.

A 26-year-old woman with postural orthostatic tachycardia syndrome (POTS) became pregnant while taking midodrine 10 mg 5 times daily (2). Because her disease was partially controlled, she continued the midodrine throughout pregnancy. She had hyperemesis gravidarum that was treated with ondansetron. A scheduled cesarean section at 37 weeks' gave birth to a healthy, about 3.5-kg, male infant (2).

BREASTFEEDING SUMMARY

No reports describing the use of midodrine in human lactation have been located. The molecular weight (about 255 for the free base) suggests that the drug will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown. Because severe systolic hypertension is a potential effect in an infant, women who are taking midodrine should probably not breastfeed.

MIFEPRISTONE

Antiprogestogen

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Mifepristone (RU 486) is a potent antiprogestogen compound that is mainly used for the termination of pregnancy, usually in combination with a prostaglandin agent. It has also been used for cervical ripening before abortion and is currently being studied as an aid in the induction of labor at term. It is teratogenic in one animal species, but not in two others, one of which is a primate species. Data are too limited to determine whether the drug is a human teratogen. Because the incidence of successful abortion after mifepristone is high, but not total, women should be informed of the risk for embryotoxicity if their pregnancy continues after use of this drug.

FETAL RISK SUMMARY

Mifepristone (RU 38486; RU 486) is an orally active, synthetic antiprogestogen that has been used primarily to terminate pregnancy. At higher doses, the drug also has antiglucocorticoid effects. The mechanism of action of mifepristone, which exerts its antiprogestogen effect at the level of the receptor, and the physiologic effects it produces in both animals and humans have been studied and reviewed in a number of references (1–16). A 1993 review summarized the drug's antiprogesterin and other pharmacologic effects in humans (17).

Mifepristone rapidly crosses the placenta to the fetus in both monkeys (18) and humans (19,20). The fetal:maternal ratio decreased from 0.31 to 0.18 in monkeys between the 2nd and 3rd trimesters (18). In 13 women undergoing 2nd trimester abortions, a single 100-mg oral dose produced fetal cord blood concentrations of mifepristone ranging from 20 ng/mL (30 minutes) to 400 ng/mL (18 hours) (19). The peak maternal concentration (1500 ng/mL) was attained in 1–2 hours, and the average fetal:maternal ratio was approximately 0.33. In contrast to a simple diffusion process observed in monkeys (18), an active transport mechanism was suggested because the fetal concentration

increased exponentially (19). In the second human study, a lower mean fetal:maternal ratio (0.11) was measured at 17.2 hours in six women treated with 600 mg of mifepristone for 2nd trimester abortion (20). Maternal plasma concentrations of aldosterone, progesterone, estradiol, or cortisol did not change significantly 4 hours after mifepristone, but a significant increase in fetal aldosterone occurred at this time, rising from 999 to 1699 pmol/L. Mean changes in the fetal levels of the other three steroids were not significant.

A large number of studies have investigated the use of mifepristone as an abortive agent, either when given alone (21–36), or when combined with a prostaglandin analog (24,30,37–51). The drug has also been studied for labor induction after 2nd trimester intrauterine death (52,53), and as a cervical ripening agent in the 1st trimester (54–59), in the 2nd trimester (60), and at term (61–63). Although mifepristone, especially when combined with a prostaglandin analog, is an effective abortive agent, it has not been effective when used for the termination of ectopic pregnancies (64,65). The use of mifepristone as a postcoital contraceptive or for routine administration during the mid- to late luteal phase to prevent a potential early pregnancy by induction of menses (i.e., contragestation) has also been frequently investigated (22,66–79).

Mifepristone is teratogenic in rabbits and the effect is both dose and duration dependent (80). Abnormalities observed included growth restriction, nonfused eyelids and large fontanelle, opened cranial vault with exposure of the meninges and hemorrhagic or necrotic nervous tissue, necrotic destruction of the upper part of the head and brain, and absence of closure of the vertebral canal (80). At doses approximating those used in clinical practice, no evidence of teratogenicity was observed in postimplantation rat embryos exposed to mifepristone in culture (81). Similarly, no teratogenicity was observed after in vitro exposure of monkey embryos to mifepristone (82,83).

In humans, only six cases have been reported of exposure to mifepristone that was not followed by subsequent abortion. Although specific details were not provided, in the United Kingdom Multicenter Trial (gestational age <36–69 days from last menstrual period), one woman changed her mind after taking mifepristone and her pregnancy continued until a normal infant was delivered at term (41). In 1989, brief mention was made of fetal malformations discovered after pregnancy termination at 18 weeks' gestation (84). Additional information on this and one other case was published in 1991 (85–87). A 25-year-old primigravida was treated with 600 mg of mifepristone at 5 weeks' gestation, but then decided not to proceed with termination (85,86). Severe malformations

were observed by ultrasound examination at 17 weeks' gestation, consisting of an absence of amniotic sac, stomach, gallbladder, and urinary tract, and the pregnancy was stopped with prostaglandin at 18 weeks' (85). The 190-g fetus had typical features of the sirenomelia sequence (sympodia; caudal regression syndrome): fused lower limbs with a single flexed foot containing seven toes; no external genitalia or anal or urethral openings; and absence of internal reproductive organs, lower urinary tract, and kidneys. Other anomalies were hypoplastic lungs, a cleft palate, and a cleft lip. Sirenomelia is thought to date back to the primitive streak stage during the 3rd week of gestation, and, thus, in this case, before exposure to mifepristone (85). However, induction of cleft palate and cleft lip occurs at approximately 36 days of gestation (85) and may have been a consequence of drug exposure.

A normal outcome was achieved in the second case in which a 30-year-old woman was treated with 400 mg of mifepristone 6 weeks after her last menstrual period, but then decided to continue her pregnancy (85). She eventually delivered a healthy, 3030-g male baby at 41 weeks' gestation. Three other normal infants have been described after in utero exposure to mifepristone (59,88). All three were participants in clinical trials who decided to continue their pregnancies after treatment with mifepristone at 8, 8, and 9 weeks' gestation (88). The latter patient vomited 1.5 hours after taking the drug and reported seeing at least one partially digested tablet in the vomit. Delivery occurred at 40 weeks (4150-g male), 39 weeks (3930-g male), and 41 weeks (3585 g, female), respectively. Follow-ups of the infants at 15, 9, and 6 months, respectively, were completely normal.

BREASTFEEDING SUMMARY

No data have been located on the excretion of mifepristone in breast milk. Because the drug is well absorbed after oral administration, it should not be used during breastfeeding because of its potent antihormonal effects. However, as a result of the limited indications for this agent, the opportunities for its use during lactation should be infrequent.

MIGLITOL

Antidiabetic Agent

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of miglitol during human pregnancy have been located. Miglitol is normally used either alone or in combination with oral hypoglycemic agents, and these hypoglycemic drugs are not indicated for the pregnant diabetic as they may not provide good control in patients who cannot be controlled by diet alone. Carefully prescribed insulin therapy provides better control of the mother's glucose, thereby preventing the fetal and neonatal complications that occur with this disease. Moreover, insulin, unlike most oral agents, does not cross the placenta to the fetus, thus eliminating the additional concern that the drug therapy itself will adversely affect the fetus. High maternal glucose levels, as may occur in diabetes mellitus, are closely associated with a number of maternal and fetal adverse effects, including fetal structural anomalies if the hyperglycemia occurs early in gestation. To prevent this toxicity, the American College of Obstetricians and Gynecologists recommends that insulin be used for types 1 and 2 diabetes in pregnancy and, if diet therapy alone is not successful, for gestational diabetes (1,2).

FETAL RISK SUMMARY

Miglitol is an oral α -glucosidase inhibitor, in the same class as acarbose (see Acarbose), that delays the digestion of ingested carbohydrates within the gastrointestinal tract, thereby reducing the rise in blood glucose following meals. It is used either alone or in combination with a sulfonylurea as an adjunct to diet in the management of type 2 diabetes (non-insulin-dependent diabetes mellitus). In contrast to acarbose, miglitol is readily absorbed into the systemic circulation, but the absorption is saturable at high doses. In addition, miglitol is

not metabolized and is excreted unchanged in the urine with an elimination half-life of approximately 2 hours (3).

Reproduction studies have been conducted in animals with miglitol. In rats and rabbits at doses up to 12 and 10 times, respectively, the maximum recommended human exposure based on BSA (MRHE), no evidence of teratogenicity was observed. In addition, no evidence of impaired fertility or fetal harm was noted at doses up to 4 and 3 times the MRHE, respectively, in these species. At 12 and 10 times the MRHE in rats and rabbits, respectively, maternal and/or fetal toxicity were noted. In rats, fetotoxicity was characterized by a slight but significant reduction in fetal weight. In rabbits, a slight reduction in fetal weight, an increased number of nonviable fetuses, and delayed ossification of the fetal skeleton were evident. In the rat peri-postnatal study, an increase in stillborns occurred at 4 times the MRHE (3).

It is not known if miglitol crosses the human placenta. The molecular weight (about 207) is low enough that exposure of the embryo and/or fetus should be expected.

BREASTFEEDING SUMMARY

Miglitol is excreted into breast milk. This is consistent with its relatively low molecular weight (about 207). The total amount excreted, however, is very small, accounting only for 0.02% of a 100-mg dose (only 50%–70% of a 100-mg dose is bioavailable). The estimated exposure of a nursing infant was about 0.4% of the mother's dose (3).

The effects of this exposure on a nursing infant are unknown, but the manufacturer recommends that miglitol should not be used during lactation (3). A 2000 review also stated that miglitol should not be used during breastfeeding (4). Nevertheless, based on the single study above, the exposure of a nursing infant appears to be clinically insignificant.

MIGLUSTAT

Endocrine/Metabolic Agent (Gaucher Disease)

PREGNANCY RECOMMENDATION: No Human Data—Contraindicated

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of miglustat in human pregnancy have been located. The animal data suggest risk for embryotoxicity and decreased fetal weight at exposure levels comparable to human systemic exposure.

FETAL RISK SUMMARY

Miglustat is an oral medication that inhibits the enzyme glucosylceramide synthase and is used for the treatment of type I Gaucher disease in individuals for whom enzyme replacement therapy is not an option. Miglustat does not bind to plasma proteins. The effective elimination half-life is 6–7 hours (1).

Reproduction studies have been conducted in rats and rabbits. In rats, miglustat was given by oral gavage at doses up to ≥ 2 times the human therapeutic systemic exposure based on BSA (HTSE) beginning 14 days before mating and continuing through day 17 (organogenesis). At the mid-to-high doses that were ≥ 2 times the HTSE, decreased fetal survival, including complete litter loss, and decreased fetal weights were observed. Delayed parturition and dystocia were observed in another rat study that used the same mid-to-high doses and route of administration from gestation day 6 through lactation. In addition, decreased survival and reduced fetal weights were seen at doses comparable to or below the HTSE. In rabbits, doses that were less than the HTSE during gestation days 6–18 resulted in maternal toxicity and death (1).

In 2-year carcinogenicity studies conducted in mice, mucinous adenocarcinomas of the large intestine were observed in male and female mice given oral doses that were 3 and 6 times the recommended human dose (RHD), respectively. In rats, an increased incidence of interstitial cell adenomas of the testis was observed in males at doses equivalent to the RHD. Miglustat

was not mutagenic or clastogenic in multiple in vitro and in vivo assays. Fertility studies in rats demonstrated decreased spermatogenesis in males who were treated 14 days prior to mating and at doses below the HTSE. In females, decreased corpora lutea were noted, as well as increased postimplantation loss at the lowest dose (1). However, in a study conducted in seven normal human males who were administered 100 mg of miglustat twice a day for 6 weeks, no effects on sperm concentration, motility, and morphology were seen (2).

It is not known if miglustat crosses the human placenta. The molecular weight (about 200), lack of plasma protein binding, and prolonged elimination half-life suggest that the drug will cross the placenta throughout gestation.

No reports of human pregnancy exposure to miglustat have been located. Because the drug is contraindicated in pregnancy, pregnancy exposures should be rare. One pharmacovigilance study in Europe followed 122 type I Gaucher disease patients for 5 years and identified 1 woman who discontinued the drug for a planned pregnancy (3).

BREASTFEEDING SUMMARY

No reports describing the use miglustat during human lactation have been located. The molecular weight (about 200), lack of plasma protein binding, and relatively long elimination half-life (6–7 hours) suggest that the drug will be excreted into breast milk.

MILNACIPRAN

Antidepressant

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 3rd Trimester

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of milnacipran in human pregnancy have been located. Neither the animal reproduction data nor the human data from other selective norepinephrine and serotonin reuptake inhibitors (SNRIs) suggest that this class of drugs is a risk for structural anomalies. However, other SNRIs (e.g., see Venlafaxine) as well as selective serotonin reuptake inhibitors (SSRIs) have been associated with developmental toxicity, including spontaneous abortions, low birth weight, prematurity, neonatal serotonin syndrome, neonatal behavioral syndrome (withdrawal including seizures), possibly sustained abnormal neurobehavior beyond the neonatal period, and respiratory distress. Persistent pulmonary hypertension of the newborn (PPHN) is an additional potential risk, but confirmation is needed.

FETAL RISK SUMMARY

Milnacipran is an SNRI that is indicated for the management of fibromyalgia. Although not indicated for depression, it is in the same class of SNRI antidepressants as desvenlafaxine, duloxetine, and venlafaxine. The drug partially undergoes metabolism before urinary excretion. Plasma protein binding is low (13%). Milnacipran is racemic mixture with an elimination half-life of about 6–8 hours. However, the half-life of the active enantiomer, d-milnacipran, is 8–10 hours, whereas it is 4–6 hours for the l-enantiomer (1).

Reproduction studies have been conducted in rats, mice, and rabbits. In rats, doses that were 0.25 times the maximum recommended human dose based on BSA (MRHD) increased the incidence of dead fetuses in utero. In mice and rabbits during organogenesis, doses up to 3 and 6 times, respectively, the

MRHD did not cause embryotoxicity or teratogenicity. However, a dose one-fourth of the above dose in rabbits increased the incidence of an extra single rib, a skeletal variation (1).

In a 2-year carcinogenicity study in rats, a dose twice the MRHD caused a statistically significant increase in the incidence of thyroid C-cell adenomas and combined adenomas and carcinomas in males. A 6-month study in mice did not induce tumors at any dose tested. Milnacipran was not mutagenic or clastogenic in various assays. No significant effects on mating or fertility were observed in males and females given doses up to 4 times the MRHD. However, there was an apparent dose-related decrease in the fertility index at clinically relevant doses based on BSA (1).

It is not known if milnacipran crosses the human placenta. The molecular weight (about 247 for the free base), the terminal elimination half-life of 6–8 hours (both enantiomers), and the very low plasma protein binding suggest that the drug will cross to the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use milnacipran during human lactation have been located. The molecular weight (about 247 for the free base), the terminal elimination half-life of 6–8 hours (both enantiomers), and the very low plasma protein binding suggest that the drug will be excreted into breast milk. The effects of this exposure on a nursing infant are unknown. However, the long-term effects on neurobehavior and cognitive development from exposure to SNRIs during a period of rapid central nervous system development have not been adequately studied. The American Academy of Pediatrics classifies other antidepressants as drugs for which the effect on nursing infants is unknown but may be of concern (2).

MILRINONE

Cardiac Agent

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Milrinone is used IV in the treatment of congestive heart disease. No reports describing the use of this drug in human pregnancy have been located.

FETAL RISK SUMMARY

Reproductive studies in rats (doses up to 40 mg/kg/day) and rabbits (doses up to 12 mg/kg/day) have revealed an increased resorption rate, but no teratogenic effects (1).

In an experiment with four pregnant baboons at 155–165 days' gestation (term 175 days), milrinone was given as an IV bolus of 75 mcg/kg followed by a continuous infusion of 1 mcg/kg/minute for 180 minutes (loading and maintenance doses considered maximal in humans) (2). Placental transfer was demonstrated as early as 5 minutes after beginning. At steady state (60 minutes), the maternal:fetal concentration ratio was 4:1. Although a significant increase in maternal heart rate was measured during the experiment, no significant changes were observed in the maternal mean arterial pressure or in the fetal heart rate and arterial blood gasses or pH values. All four fetuses appeared normal at birth.

BREASTFEEDING SUMMARY

No reports describing the use of milrinone during human lactation have been located.

MINERAL OIL

Laxative

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Mineral oil is an emollient laxative. The drug is generally considered nonabsorbable. Chronic use may lead to decreased absorption of fat-soluble vitamins.

BREASTFEEDING SUMMARY

No reports describing the use of mineral oil during lactation have been located. The product probably is harmless, but chronic use may cause deficiencies of fat-soluble vitamins in the mother.

MINOCYCLINE

Antibiotic (Tetracycline)

See Tetracycline.

MINOXIDIL

Antihypertensive

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Minoxidil is not teratogenic in rats and rabbits, but some fetotoxicity was observed in rabbits. The human pregnancy experience is too limited, after both oral dosing and topical application, to determine the risk of teratogenicity. A possible exception involves the two infants exposed in utero to oral minoxidil who had hypertrichosis. This is a known adverse effect in adults and, indeed, one of the mothers had hypertrichosis. However, the causes of the multiple congenital malformations observed in one of these infants and the heart defects in the other are unknown. Similarly, the causes of the multiple anomalies observed in two fetuses after minoxidil topical application also are unknown. Although the doses applied in these two cases were not specified, only small amounts of topically applied minoxidil are absorbed into the systemic circulation. Of interest, both mothers had a flu-like illness in the 1st trimester. Even if these malformations are not related to drug exposure, the potential toxicity of oral minoxidil is severe enough to preclude its use in pregnancy. One of these toxicities includes large orthostatic decreases in blood pressure that could severely jeopardize placental perfusion. Although the possibility of a causal relationship to malformations after topical application appears to be remote, the safest course is to avoid applying the agent during the 1st trimester.

FETAL RISK SUMMARY

Minoxidil is a potent antihypertensive peripheral vasodilator. It is indicated for the treatment of hypertension that is symptomatic or associated with target organ damage. Minoxidil is considered a second-line antihypertensive therapy

because of the potential for severe adverse effects. After oral dosing, minoxidil is nearly completely (90%) metabolized to metabolites that have much less antihypertensive effects. The average plasma elimination half-life of the parent compound is 4.2 hours (1).

Minoxidil is also used topically for the treatment of androgenetic alopecia (male baldness) and alopecia areata. After topical application, it is poorly absorbed from normal intact skin, with an average of 1.4% (range 0.3%–4.5%) entering the systemic circulation. Steady state concentrations in the plasma are reached at the end of the third dosing interval (36 hours) (2).

Reproduction studies have been conducted in rats and rabbits (1–3). In rats, no evidence of teratogenicity or fetotoxicity was observed after an oral dose that was 5 times the human dose (1,2). Similarly, no teratogenicity was observed with an SC dose (80 mg/kg/day) that produced maternal toxicity (1). The oral dose, however, reduced the conception rate (2). There also was no teratogenicity in the offspring of pregnant rabbits given an oral dose that was 5 times the human dose, but an increased incidence of fetal resorptions was noted (1,2).

Pregnant rats were administered minoxidil at doses of 3 and 10 mg/kg/day on gestational days 6–15 (3). No evidence of teratogenicity or acute toxicity was observed. However, in the 10 mg/kg/day group, there was a higher than expected incidence of retinal folds in the eyes of offspring. Additional studies did not confirm this finding. In pregnant rabbits, similar doses administered on gestational days 6–18 resulted in fewer live pups per litter. At the highest dose, there was a higher incidence of resorptions (3).

It is not known if minoxidil crosses the human placenta. The molecular weight (about 209) is low enough that fetal exposure should be expected. Moreover, the moderately long elimination half-life (4.2 hours) should increase the opportunity for the drug to cross to the fetal compartment. In addition, the two cases of hypertrichosis described below suggest that minoxidil crosses the placenta.

Information on the use of oral minoxidil in human pregnancy is very limited, and only four cases of fetal exposure have been located (4–6). In one report, minoxidil was used throughout gestation with no effect seen in the healthy newborn (4). A second report involved a mother with a history of renal artery stenosis and malignant hypertension who was treated throughout gestation with minoxidil, captopril, and propranolol (5). Three of her four previous pregnancies had ended in midgestation stillbirths. The most recent stillbirth, her fourth pregnancy, involved a 500-g male infant with low-set ears but no gross

anomalies. The mother had been treated with the above regimen plus furosemide. In her second pregnancy, she was treated only with hydrochlorothiazide, and delivered a normal term infant. No information was available on the first and third pregnancies, both of which ended in stillbirths.

In her current pregnancy, daily doses of the three drugs were 10, 50, and 160 mg, respectively. The infant, delivered by cesarean section at 38 weeks' gestation, had multiple abnormalities, including an omphalocele (repaired on the 2nd day), pronounced hypertrichosis of the back and extremities, depressed nasal bridge, low-set ears, micrognathia, bilateral fifth finger clinodactyly, undescended testes, a circumferential midphallic constriction, a large ventriculoseptal defect, and a brain defect consisting of slightly prominent sulci, especially the basal cisterns and interhemispheric fissure. Growth restriction was not evident, but the weight (3170 g, 60th percentile), length (46 cm, 15th percentile), and head circumference (32.5 cm, 25th percentile) were disproportionate. Neurologic, skeletal, and kidney examinations were normal. Marked hypotension (30–50 mmHg systolic) was present, which resolved after 24 hours. Heart rate, blood glucose, and renal function were normal.

The infant's hospital course was marked by failure to thrive, congestive heart failure, prolonged physiologic jaundice, and eight episodes of hyperthermia ($>38.5^{\circ}\text{C}$ without apparent cause) at 2–6 weeks of age. The hypertrichosis, which was much less prominent at 2 months of age, is a known side effect of minoxidil therapy in both children and adults, and the condition in this infant was thought to be caused by that drug. The cause of the other defects could not be determined, but a chromosomal abnormality was excluded based on a normal male karyotype (46,XY) determined after a midgestation amniocentesis (5).

It is interesting that captopril (see Captopril) is known to cause structural defects (hypocalvaria or acalvaria) and severe renal toxicity (anuria), but none of the anomalies observed in the above infant have been reported with captopril. The relatively low dose of 50 mg/day (recommended dose 50–150 mg/day) may have protected the fetus from the characteristic renal toxicity observed with angiotensin 1-converting enzyme inhibitors.

Two additional cases of in utero exposure to oral minoxidil were reported to the FDA and published in 1987 (6). The first infant was the product of a 32 weeks' gestation in a 22-year-old woman with severe uncontrolled renal hypertension who was treated during pregnancy with minoxidil, methyldopa, hydralazine, furosemide, and phenobarbital. The 1770-g infant died of congenital heart disease the day after delivery. Defects noted at autopsy were transposition of the great vessels and pulmonic bicuspid valvular stenosis.

Hypertrichosis was not observed. No conclusions can be drawn on the cause of the cardiac defects. The second infant, delivered near term and weighing 3220 g, was exposed throughout gestation to minoxidil (5 mg/day) plus metoprolol (100 mg/day) and prazosin (20 mg/day). The mother had severe hypertension secondary to chronic nephritis. Hypertrichosis was evident in both the mother and the newborn, but no other abnormalities were noted in the infant. The excessive hair growth, which was longest in the sacral area, gradually disappeared during the following 2–3 months. Normal development was noted at 2 years of age (6).

Two reports have described the outcomes of pregnancies exposed to topical minoxidil (7,8). A 14 weeks' gestation was diagnosed in a nondiabetic 28-year-old, primigravid, woman who had used minoxidil 2% topical solution to treat hair loss during the 1st trimester (7). Her pregnancy was terminated at 17 weeks' gestation because an ultrasound examination had revealed oligohydramnios, a single umbilical artery, and multiple, severe anomalies. The woman also had experienced a flu-like upper respiratory disease during the 7th to 9th weeks of gestation which had been treated with trimethoprim-sulfamethoxazole (2 tablets twice daily for 2 weeks) and erythromycin (500 mg 4 times daily for 1 week). At termination, no evidence of infection was found, with a negative TORCH (toxoplasmosis, other infections, rubella, cytomegalovirus, and herpes simplex) test. Malformations in the male fetus included a transverse reduction deformity of the lower limbs and pelvis, agenesis of the cloacal membrane, imperforate anus, absence of external genitalia and bladder, renal agenesis, esophageal atresia, tracheoesophageal fistula, hypoplastic left thumb and thenar eminence, 11 ribs and absence of L5, sacrum and pelvis (7). There was no evidence of an amniotic band, and the cause of the malformations remained unknown. Trimethoprim is a folate antagonist and is believed to cause congenital anomalies but not of the type observed in this infant. (See Trimethoprim.) The constellation of defects was thought to represent a severe form of caudal regression syndrome, although the most severe form of this syndrome, the sirenomelia complex, could not be completely excluded (7).

A 28-year-old woman applied a 2% solution of minoxidil on her whole scalp to treat a diffuse bristly hair condition for at least 1 year and throughout her current pregnancy (8). She experienced a brief flu-like syndrome at the 9th week of gestation (maximum temperature 38.5°C). The woman elected to terminate her pregnancy at about 22 weeks' gestation after an ultrasound examination had revealed a fetus with multiple anomalies. The 450-g female fetus had extradural occipital hematomas, funnel-like posterior cranial base,

hypoplastic middle cranial base, underdeveloped cerebellar lobes, fourth ventricle dilation, and diffuse intracerebral hemorrhages. Other defects included a globose heart, partial subaortic stenosis, mesentery commune, and a significantly increased length of the sigmoid colon. Histologic examination of the brain revealed multiple areas of necrosis, diffuse areas of white matter demyelination with reactive gliosis, with capillary agglomerates. There also was dilation and congestion of cerebral small vessels and capillaries. The woman stopped the minoxidil and gave birth to a normal infant 2 years later. The cause of the malformations could not be determined, but the authors thought they were secondary to minoxidil (8).

BREASTFEEDING SUMMARY

Minoxidil is excreted into breast milk (4). Levels in the milk ranged from 41.7 ng/mL (1 hour) to 0.3 ng/mL (12 hours), with milk:plasma ratios during this interval varying from 0.67 to 1.0. No adverse effects were observed in the infant. The American Academy of Pediatrics classifies minoxidil as compatible with breastfeeding (9).

MIRABEGRON

Urinary Tract Agent (Antispasmodic)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of mirabegron in human pregnancy have been located. The animal data suggest low risk, but the absence of human pregnancy experience prevents a more complete assessment of the embryo–fetal risk.

FETAL RISK SUMMARY

Mirabegron is an oral agonist of the human β_3 -adrenergic receptor but, at higher doses, also stimulates the β_1 -adrenergic receptor. The primary action increases bladder capacity. It is indicated for the treatment of overactive bladder with symptoms of urge urinary incontinence.

The drug is metabolized to inactive metabolites. Plasma protein binding to albumin and α -1 acid glycoprotein is about 71% and the terminal elimination half-life is about 50 hours (1).

Reproduction studies have been conducted in rats and rabbits. No embryo or fetal toxicity was observed in rats given daily oral doses from implantation to closure of the fetal hard palate (gestational days 7–17) that resulted in maternal exposures that were 1–6 times the systemic exposure in women treated with the maximum recommended human dose of 50 mg based on AUC (MRHD). At systemic exposures 22 times the MRHD, an increased incidence of delayed ossification and wavy ribs were observed. These findings were reversible. When the drug was given daily from day 7 of gestation until 20 days after birth, maternal exposures up to 6 times the MRHD had no discernable adverse effects on the offspring. At exposures 22 times the MRHD, a slight but statistically significant decrease in pup survival, as well as a decrease in pup body weight gain were noted. In utero or lactational exposure at exposures 22

times the MRHD had no effect on behavior or fertility of offspring (1).

No embryo or fetal toxicity was noted in rabbits given daily oral doses from implantation to closure of the fetal hard palate (gestational days 6–20) that resulted in maternal exposures similar to those in women at the MRHD. Reduced fetal body weight was observed at exposures that were 14 times exposures at the MRHD. At exposures that were 36 times the systemic exposures at the MRHD, maternal toxicity (reduced maternal body weight gain and food consumption, and 1 of 17 pregnant rabbits died), an increased incidence of fetal death, and fetal findings of dilated aorta and cardiomegaly were reported (1).

In long-term studies in mice and rats, mirabegron showed no carcinogenic potential. Assays for mutagenic and clastogenic effects also were negative. No impairment of fertility was observed in male and female rats given high but nonlethal doses (1).

It is not known if mirabegron crosses the human placenta. The molecular weight (about 397), long terminal elimination half-life, and moderate plasma protein binding suggest that the drug will cross to the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use of mirabegron during human lactation have been located. The molecular weight (about 397), long terminal elimination half-life (50 hours), and moderate plasma protein binding (about 71%) suggest that the drug will be excreted into breast milk. Moreover, the drug is concentrated in the milk of rats (twice the maternal plasma level) (1) and may be in humans. The effect of this exposure on a nursing infant is unknown. The most common (>2%) adverse reactions in adults were hypertension, nasopharyngitis, urinary tract infections, and headache. If the mother receiving this drug is nursing, her infant should be monitored for these effects.

MIRTAZAPINE

Antidepressant

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although the limited human pregnancy experience suggests that the embryo–fetal risk is low, at least for the more common major defects, additional data are needed to make a better assessment of the overall risk of developmental toxicity.

FETAL RISK SUMMARY

Mirtazapine is a tetracyclic antidepressant in the same subclass as maprotiline. It is chemically unrelated to selective serotonin reuptake inhibitors, tricyclic antidepressants, and monoamine oxidase inhibitors. Mirtazapine is also a potent inhibitor of histamine (H₁) receptors, a property that probably explains the marked sedation often seen with this agent (1).

Mirtazapine has an active metabolite, desmethylmirtazapine. Plasma protein binding is 85% and the mean plasma elimination half-life is 20–40 hours (2).

No teratogenic effects were observed in rats and rabbits given doses up to 20 and 17 times, respectively, the maximum recommended human dose based on BSA (MRHD). However, toxicity was observed in rats at the maximum dose that included an increase in postimplantation losses, increased pup deaths during the first 3 days of lactation, and lower pup birth weights. This developmental toxicity was not observed with a dose that was 15% of the maximum dose (about 3 times the MRHD) (1).

It is not known whether mirtazapine crosses the placenta to the fetus. Because of its low molecular weight (about 265) and prolonged elimination half-life, transfer to the embryo and/or fetus should be anticipated.

A brief 2002 report described the use of mirtazapine in two women very early in gestation (3). The first patient took mirtazapine 60 mg/day and

trifluoperazine 8 mg/day in gestational weeks 1–5. The second woman took mirtazapine 30 mg/day for three consecutive days and trifluoperazine 4 mg/day for two consecutive days in the 4th gestational week. In both cases, healthy infants were delivered at term (one female and one male). The infants were followed for 6 months and were developing normally (3).

A 2003 study reported the use mirtazapine in the 1st trimester of 41 pregnancies (4). The pregnancy outcomes were 8 spontaneous abortions (SABs), 8 elective abortions (EABs), 1 unknown outcome, and 24 live births. Four of the live births were premature, one of whom had patent ductus arteriosus. No birth defects were observed (4).

A woman at 15 weeks' gestation with treatment-resistant hyperemesis gravidarum requested termination of her pregnancy because of the severe symptoms (5). Treatment with IV mirtazapine 6 mg/day stopped the nausea/vomiting and she no longer desired termination. After 3 days of IV therapy, she was changed to oral 30 mg/day. The oral dose was weaned over 4 weeks and then stopped. A second course was required at 27 weeks' gestation. Healthy male twins were delivered at 36 weeks' with normal Apgar scores. At 6 months of age, the twins were normal (5). A second report involving three women with intractable hyperemesis treated with mirtazapine resulted in similar outcomes (6).

A 2004 report described the pregnancy outcomes of nine women who had taken mirtazapine (doses 30 mg/day in eight, 60 mg/day in one) during the 1st trimester (7). None of the exposures went beyond 12 weeks' gestation. In five cases, mirtazapine was combined with other psychotropic agents and one patient took illicit drugs. The outcomes included one EAB, two SABs, and seven healthy infants that were normal at 12 months of age (7).

An international prospective study compared pregnancy outcomes in mirtazapine-exposed women with two control groups (disease-matched pregnant women with depression taking other antidepressants and nonteratogen exposed) (8). There were 104 pregnancy outcomes in each of the three groups. Mirtazapine was taken in the 1st trimester by 95% of the women with 25% taking it throughout gestation. The outcomes in subjects were 20 SABs, 6 EABs, 1 stillbirth, and 77 live births. Two major malformations were observed (no details provided), but the prevalence was similar to the two control groups. There were significantly fewer live births in subjects compared with nonteratogen-exposed controls and the number of SABs were higher, but not significantly so, in both antidepressant groups. Compared with nonteratogen-exposed controls, the mirtazapine group had significantly more

preterm births. There were no significant differences between the groups in terms of EABs, stillbirths, gestational age at birth, or birth weight (8).

A prospective cohort study evaluated a large group of pregnancies exposed to antidepressants in the 1st trimester to determine if there was an association with major malformations (9). The patient population came from the Motherisk database and involved 928 cases that met their criteria. The 928 matched (for age, smoking, and alcohol use) controls were pregnancies not exposed to antidepressants or known teratogens. In addition to the 68 mirtazapine cases, the other cases were 113 bupropion, 184 citalopram, 21 escitalopram, 61 fluoxetine, 52 fluvoxamine, 39 nefazodone, 148 paroxetine, 61 sertraline, 17 trazodone, and 154 venlafaxine. In the antidepressant group, there were 24 (2.5%) major defects compared with 25 (2.6%) in controls (odds ratio 0.9, 95% CI 0.5–1.61). There were two major anomalies in the mirtazapine group: tracheomalacia and vesicoureteral reflux. There were no major defects in the pregnancies exposed to bupropion, escitalopram, or trazodone (9).

BREASTFEEDING SUMMARY

Mirtazapine is excreted into breast milk (9,10). A 27-year-old woman, 3 weeks postpartum, suffered a severe depressive episode with suicidal thoughts and was admitted to a psychiatric hospital (10). She was treated with mirtazapine 30 mg/day while breastfeeding her infant 6 times a day. Maternal blood and milk samples were drawn at steady state 22 and 15 hours postdose. At 22 hours, the maternal plasma level was 7 ng/mL (therapeutic range 5–100 ng/mL) and fore- and hind-milk levels were 7 and 18 ng/mL, respectively. At 15 hours, the three levels were 25, 28, and 34 ng/mL, respectively, and the infant's plasma level was 0.2 ng/mL. No adverse effects in the nursing infant were observed over a 6-week interval while the woman was hospitalized (10).

A 2007 study investigated the excretion of mirtazapine into milk of eight breastfeeding women (11). The median dose was 38 mg/day. The mean milk:plasma ratio based on AUC was 1.1 for mirtazapine and 0.6 for the active metabolite, desmethylmirtazapine. The mean relative infant dose for mirtazapine and the active metabolite were 1.5% and 0.4%, respectively, of the maternal weight-adjusted dose. Only one of the four infants tested had a detectable mirtazapine plasma level (1.5 mcg/L). No toxicity was observed in the nursing infants (11).

Although no adverse effects have been reported, the long-term effects on neurobehavior and development from exposure to this class of agents during a period of rapid central nervous system development have not been studied. The

American Academy of Pediatrics classifies other antidepressants as drugs for which the effect on nursing infants is unknown but may be of concern (12).

MISOPROSTOL

Gastrointestinal Agent (Antisecretory)

PREGNANCY RECOMMENDATION: Contraindicated (Oral) Human Data Suggest Low Risk (Term Cervical Ripening)

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Misoprostol is a potent uterine stimulant that induces abortion after either oral or vaginal administration early in pregnancy. The drug has been used as an illicit abortifacient and most cases of birth defects have been associated with abortion attempts. However, congenital malformations have also been associated with the therapeutic use of the drug. The teratogenic mechanism appears to be related to the induction of uterine contractions that deform the embryo, resulting in vascular disruption, hemorrhage, and cell death. Investigational and clinical use during the 2nd and 3rd trimesters has demonstrated the utility of misoprostol for labor induction and cervical ripening. Misoprostol appears to be superior, in terms of maternal morbidity and cost, to prostaglandin E₂ (PGE₂) when used for 2nd trimester pregnancy terminations and for cervical ripening.

FETAL RISK SUMMARY

Misoprostol, a synthetic prostaglandin E₁ analog, is used to prevent gastric ulcers induced by nonsteroidal anti-inflammatory agents. It is contraindicated in pregnancy because of the risk of uterine bleeding and contractions that may result in abortion. Although not indicated for such, misoprostol is routinely used for cervical ripening in term pregnancies and for 2nd trimester pregnancy termination.

In reproduction studies reported by the manufacturer, misoprostol was not teratogenic in rats and rabbits at doses 625 and 63 times the maximum recommended human dose (MRHD), respectively (1). At 6.25–625 times the MRHD, dose-related pre- and postimplantation losses and a significant decrease in the number of live pups were seen in rats (1). In another study,

teratogenicity observed in pregnant rabbits given doses of 300–1500 mcg/kg on days 7–19 included spinal bifida, caudal vertebral defects, umbilical hernia, and gastroschisis (2).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 5 newborns had been exposed to misoprostol during the 1st trimester (F. Rosa, personal communication, FDA, 1993). One (20.0%) major birth defect was observed (none expected)—a cardiovascular defect.

During the initial clinical trials, menstrual complaints were higher among nonpregnant women treated with misoprostol (3.7%) than with placebo (1.7%) (3). In a clinical study designed to assess the effect of misoprostol on the pregnant uterus, 111 women, who had consented to an elective 1st trimester abortion, were treated with either placebo or one or two 400-mcg doses of the prostaglandin. All six of the women who aborted spontaneously the day following treatment had received misoprostol. Uterine bleeding occurred in 45% (25 of 56) of the women treated with misoprostol compared with 4% (2 of 55) of the placebo-treated women (3).

Misoprostol has been combined with the antiprogesterone mifepristone (RU 486) to induce legal abortion (see also Mifepristone) (4–7). Some of the advantages of this prostaglandin analog over similar agents are that it is effective, active by the oral route, inexpensive, and stable at room temperature (4,5). In one study, 40 women were treated with 400 mcg of the drug 7 days before surgical termination of pregnancy (6). Only two of the women from this group had a complete abortion. In a second part of the study, 21 women were given 200–1000 mcg of misoprostol 48 hours after a 200-mg dose of mifepristone, resulting in a complete abortion in 18 women (6). Similar effectiveness was found in a large study published in 1993 involving 895 women who received misoprostol either 4 or 48 hours after a dose of mifepristone (7).

A 1991 reference cited the use of misoprostol as an illegal abortifacient in Brazil (8). The drug is freely available as an over-the-counter product in the country, where abortions are illegal. At one university hospital maternity unit, 20 women sought emergency treatment for uterine bleeding in 1988 after an unsuccessful attempt to induce abortion with misoprostol. In 1990, the number rose to 525. The usual dose consumed was 800 mcg (two 200-mcg tablets orally plus two tablets vaginally), but some women may have taken as much as 9200 mcg (46 tablets) (8).

Five infants with congenital malformations who had been exposed during the 1st trimester to misoprostol in unsuccessful attempts at abortion were

described in a 1991 case report (9). The total dose was 1200 mcg in two of the mothers and 400–600 mcg in the other three cases. The five infants had an unusual defect of the frontotemporal region of the skull consisting of an asymmetric, well-circumscribed anomaly of the cranium and overlying scalp, exposing the dura mater and underlying cerebrum. Surgical correction of the defect was attempted within 4 days of birth in each of the cases, but one infant died of severe infection. Although the authors conceded that a later-acting agent was suggested by the nature of the defect, three of the mothers denied any further attempts to terminate their pregnancies after the use of misoprostol (9). In a later publication, two of the authors described more fully the defects of the scalp and cranium in three of the newborns (10).

Two additional reports describing the use of misoprostol as an abortifacient by Brazilian women appeared in 1993 (11,12). In Rio de Janeiro during a 9-month period of 1991, of 803 women admitted to hospitals with abortion complications, 458 (57%) had self-administered misoprostol to induce abortion (11). Most (80%) of these women had used the drug alone. The median dose used was 800 mcg (range 200–16,800 mcg) with 65% taking it orally, 29% orally and vaginally, and 6% vaginally only. The most frequently cited reasons by the women for seeking medical care were vaginal bleeding (80%) and uterine cramps (78%). Only 8% of the women reported vomiting and diarrhea. Morbidity among the 458 women included heavy bleeding (19%) (1% required blood transfusion), infection (17%), curettage required (85%), uterine perforation after curettage (1%), and systemic collapse (1%). In Fortaleza, Brazil, misoprostol use accounted for 444 (75%) of 593 incomplete abortions treated in a hospital by uterine evacuation during 1991 (12). Complications observed in the 444 women included 144 (32%) with infection, 1 with septic shock, 3 with hypovolemic shock, and 1 with uterine perforation.

A 1992 report from Brazil questioned the teratogenicity of misoprostol (13). Since 1990, 29 women had contacted a teratogen information counseling service after unsuccessful attempts at inducing abortion with misoprostol during the 1st trimester. The mean dose used by these women was 4000 mcg (20 tablets), with a range of 200 mcg (one tablet) to 11,200 mcg (56 tablets). The women were monitored with ultrasonography during the remainder of their pregnancies. The results of the pregnancies were: spontaneous abortions (2nd trimester)—3; still pregnant—3; lost to follow-up—6; normal infants—17 (one with preauricular tag). Of the 17 normal infants, 8 were examined by the authors, 4 were examined by pediatricians not associated with the authors, and in 5 cases verbal information was received from the mothers (13). The absence

of data for the 9 (31%) cases, however, lessens the ability to interpret this report.

Seven cases of limb defects involving the hands and feet following 1st trimester use of misoprostol (dose range 600–1800 mcg) as an unsuccessful abortifacient were described in a 1993 report (14). Four of the infants demonstrated bilateral palsy of cranial nerves, leading to a diagnosis of Möbius sequence (6th and 7th nerve palsies). An additional five cases (one with limb deficiency, one with limb deficiency and Möbius sequence, and three with Möbius sequence) following failed abortion attempts with misoprostol were appended to the report, but specific details were not given. In the seven pregnancies with sufficient detail, misoprostol exposure was thought to have occurred between 30 and 60 days following conception. The investigators attributed the anomalies to misoprostol-induced vascular disruption (14). In a 1993 invited editorial on the strengths and weaknesses of case reports, the publication of the above research was thought to be valid because the association with birth defects was biologically plausible and there were other reports supporting a causal association (15).

A brief report (16) and abstract (17) suggested that a possible mechanism for Möbius syndrome was flexion of the embryo in the area of cranial nuclei 6 and 7 that resulted in vascular disruption of the region bent. The cranial nuclei 6 and 7 are located in a region of the embryo that would be bent if there was pressure in a cephalocaudal direction. The hypothesis proposed that flexing of the region would result in decreased blood flow and hemorrhage and/or cell death of the cranial nuclei. It was hypothesized that misoprostol-induced uterine contractions early in gestation, before there was sufficient amniotic fluid to cushion the embryo, would cause the flexing if the embryo was correctly positioned. Experiments in rat embryos confirmed that hemorrhage would occur in this region after mechanical flexion in the proposed direction. Although limb reduction defects are often associated with Möbius syndrome and may also be due to mechanical factors, the author's hypothesis could not reasonably explain these defects (16,17).

A 1998 study (18) and earlier abstract (19) compared the frequency of 1st trimester misoprostol use in 96 infants with Möbius syndrome with 96 infants with neural tube defects (NTD). In the 96 infants with Möbius syndrome, there were no differences in the clinical appearance between those exposed to misoprostol (N = 47; 46 for attempted abortion) and those not exposed (N = 49): bilateral facial-nerve (cranial nerve VII) paralysis, 34 vs. 36; unilateral facial-nerve paralysis, 13 vs. 13; abducens-nerve (cranial nerve VI) paralysis,

39 vs. 37; other cranial nerve palsy, 10 vs. 8; all limb defects, 31 vs. 28; club feet only, 25 vs. 18; limb reduction, 6 vs. 10; orofacial anomalies, 18 vs. 11; mental retardation, 26 vs. 26; other defects, 15 vs. 14 (all ns). Misoprostol was used in 47 cases of Möbius syndrome and 3 cases of NTD (odds ratio 29.7, 95% confidence interval [CI] 11.6–76.0). Among the 47 cases of misoprostol use, 20 took the drug orally, 20 took it both orally and vaginally, 3 took it vaginally only, and 4 could not recall how they took the drug. The authors concluded that attempted abortion with misoprostol was associated with an increased risk of Möbius syndrome (18,19).

A 1994 abstract reported a case of a woman who took misoprostol 600 mcg/day for 2 days at 7 weeks' gestation in an unsuccessful attempt to induce abortion (20). An elective abortion at 17 weeks' gestation revealed a male fetus with an omphalocele, left leg below-the-knee amputation, absence of the middle and distal phalanges of four fingers of the right hand with distal fusion by amniotic band, and evidence of early amniotic rupture. Although the mother had had chicken pox at 12 weeks, there was no evidence in the placenta or fetus of viral infection.

The Latin-America Collaborative Study of Congenital Malformations found 12 misoprostol-exposed newborns among 5708 malformed and 5708 nonmalformed matched controls (21). Each of the exposures involved unsuccessful attempts by the women to induce abortion. Four of the infants were in the control group, but the maternal dose (1000 mcg) was known in only one case. Of the eight exposed infants, two had Down's syndrome (doses 1400 and 4000 mcg) and two had minor anomalies (café-au-lait spot on right leg, dose 600 mcg; extranumerary nipple on left, dose 400 mcg). These cases do not appear to be related to misoprostol. In the remaining four infants, the authors characterized the defects as suggestive of misoprostol-induced in utero vascular disruption (maternal dose shown in parentheses) (21):

Missing metacarpals and phalanges; hypoplasia of thumbs and two fingers; partial syndactyly of two fingers; peculiar face with prominent nasal bridge and ocular hypertelorism; weak cry (400 mcg)

Complete bilateral cleft lip and palate; ocular hypertelorism; short limbs; absence of thumbs and 5th fingers; skin tags on one finger; stiff knees; bilateral talipes equinovarus (dose unknown)

Skin scar over T2–T3; no evidence of spina bifida by x-ray (dose unknown)
Gastroschisis (1400 mcg)

In a second report from the above group, they found 57 newborn infants

exposed to misoprostol among 9653 newborns: 34 in 4673 malformed infants and 23 in 4980 control infants (ns) (22). In comparing exposed vs. nonexposed malformed infants, significant differences were measured for four vascular disruption malformations that had been reported by others: arthrogryposis (5.88% vs. 0.73%), hydrocephalus (11.76% vs. 3.04%), terminal transverse limb reduction (8.82% vs. 0.67%), and limb constriction ring or skin scars (8.82% vs. 0.24%). No cases of cranial nerve palsies (e.g., Möbius sequence) were in the registry because these types of defects would not be obvious at birth. Significant associations with two other malformations that had not been reported previously were holoprosencephaly (5.88% vs. 0.34%) and bladder exstrophy (2.94% vs. 0.06%). However, the authors recommended caution in interpreting these latter defects as causal associations. They concluded that there was a causal association between the four vascular disruption defects and the use of misoprostol as an abortifacient (22).

Of note, a 1996 report provided detailed descriptions of three cases of arthrogryposis (i.e., arthrogryposis multiplex congenita; the use of the shorter term, arthrogryposis, implies multiple, nonprogressive congenital joint contractures) after failed mechanical attempts at pregnancy termination (23). The cause of the defect was thought to be vascular disruption resulting in nerve damage that led to fetal akinesia and subsequent contractures (23).

A relative risk of >7.0 for congenital malformations, particularly Möbius sequence, was found among 732 children born after 1990 who were attending 5 outpatient genetic clinics in Brazil (24). About 10% of the children had been exposed in utero to misoprostol. There were 25 cases of Möbius syndrome, 24 cases of reduction of phalanges, and 227 cases with isolated malformations. Associations with misoprostol occurred in 17 (68%), 7 (29%), and 15 (6.6%), respectively, of the cases (24).

A below-the-knee amputation was observed in a female newborn delivered at 29 weeks' gestation because of fetal distress (25). An abortion had been attempted at about 13 weeks' under medical supervision. A single misoprostol tablet (strength not specified) had been inserted vaginally for 4 days, but only some vaginal bleeding had occurred on day 4. Spontaneous rupture of the membranes was documented at about 26 weeks' gestation (25).

A 1998 study proposed that the abnormalities observed in children exposed in utero during the 1st trimester to misoprostol were induced by uterine contractions that caused vascular disruption in the fetuses, including ischemia of the brain-stem (26). Of the 42 infants with congenital malformations, 17 had equinovarus with cranial nerve defects (usually of nerves V, VI, and VII), 10 had

equinovarus as part of a more extensive arthrogryposis, and 9 had terminal transverse limb defects. Five children had a distinctive arthrogryposis, without cranial nerve injury, that was confined to the legs. Severe amyoplasia of the legs was confirmed in five children by electromyography, and two of the cases had deficient anterior horn cell activity. Eight had hydrocephalus associated with increased pressure that required shunt placement to relieve. One child had an omphalocele, but no evidence of cranial nerve defects of arthrogryposis (26).

A 1997 abstract and 1999 full report described a prospective, observational cohort study of 86 misoprostol-exposed pregnancies compared with 86 pair-matched controls (27,28). All of the women had called a teratogen information service regarding pregnancy exposure to either misoprostol or nonteratogenic agents. There were no statistical differences between the groups in the rates of major (2/67 vs. 2/81) or minor (7/67 vs. 3/81) malformations, gestational age at birth, prematurity, birth weight, low birth weight, sex ratio, or rates of cesarean section. However, there were more abortions in the exposed group, 17.1% vs. 5.8%, relative risk 2.97, 95% CI 1.12–7.88. The sample size had limited power as it was only able to detect an eightfold increase in the risk of major malformations (28).

A study published in 2000 reported the clinical evaluations of 15 children (8 males, 7 females; average age 2 years) from Salvador and Brazil with misoprostol-induced arthrogryposis (29). Their mothers had taken 400–4800 mcg of misoprostol, orally or vaginally, from 8 to 12 weeks' gestation for attempted abortions. Common pathologic features in the children were growth restriction, underdeveloped bones, short feet with equinovarus, rigidity of joints with skin dimples and webs, neurologic impaired leg movement, bilateral symmetrical hypoplasia or atrophy of limb muscles, and absent tendon reflexes. Twelve had normal intelligence (information not available for the other three). Other abnormalities included neurogenic bladder/bowel (N = 9), hip dislocation (N = 6), upper and lower limb deformity (N = 5), cryptorchidism (N = 2), inguinal hernia (N = 2), and single cases of medullar stenosis/syringomyelia, spina bifida, abdominal muscle hypoplasia, and nail hypoplasia. Neurogenic patterns suggestive of anterior horn cell defects were observed on electromyogram in five children (29).

In another 2000 report, a multicenter, case–control study compared the frequency of misoprostol exposure in 93 children with vascular disruption anomalies (subjects) and 279 children with other types of defects (controls) (30). All of the children were born after 1992. Congenital malformations

classified as vascular disruptions in the subject cases were Möbius syndrome (N = 29), transverse limb reduction (N = 27), hemifacial microsomia (N = 16), arthrogyrosis (N = 9), microtia (N = 9), porencephalic cyst (N = 2), and hypoglossia hypodactyly (N = 1). Misoprostol exposure (all for attempted abortion) occurred in 32 subject cases (34.4%) compared with 12 controls (4.3%), $p < 0.0000001$. In 16 subjects, misoprostol was used between the 5th and 8th week after the last menstrual period, and in two the exposure occurred after the 1st trimester. There was no difference between the two groups in the misoprostol dose taken. Based on their data, the investigators concluded that misoprostol was associated with vascular disruption defects (30).

A case of maternal misoprostol overdose resulting in fetal death was reported in 1994 (31). In a suicide attempt, a 19-year-old woman at 31 weeks' gestation ingested 6000 mcg (thirty 200-mcg tablets) and 8 mg of trifluoperazine. She was seen 2 hours later at a hospital complaining of feeling hot, chills, shortness of breath, restlessness, and discomfort. A tetanic uterus was observed, and physical examination revealed her cervix to be dilated to 5 cm with 80% effacement. Fetal movements and heart motion (by sonogram) were absent 1 hour after admission (3 hours after ingestion), and 1 hour later she delivered a stillborn 1800-g fetus that was diffusely ecchymotic. Postmortem examination was remarkable only for diffuse head and upper body bruising (31).

A 2006 meta-analysis reviewed the risk of specific birth defects when misoprostol was used in the 1st trimester (32). The data source consisted of case-control studies through June 2005. The analysis of 4899 cases of congenital malformations and 5742 controls revealed the following odds ratios (OR): any congenital defect OR 3.56, 95% CI 0.98–12.98; Möbius sequence OR 25.31, 95% CI 11.11–57.66; and terminal transverse limb defects OR 11.86, 95% CI 4.86–28.90 (32).

Misoprostol has been used for the induction of labor in cases involving intrauterine fetal death (IUFD) or when medical or genetic reasons existed for pregnancy termination (33–35). In 20 cases of IUFD, pregnancy termination was conducted a mean 9.2 hours after the start of oral misoprostol, 400 mcg every 4 hours (mean total dose 1000 mcg) (33). Maternal adverse effects were common. A second study, involving 72 women with IUFD at 18–40 weeks' gestation, used a lower dose (100 mcg) introduced into the vaginal posterior fornix every 12 hours (up to 48 hours) until effective contractions and cervical dilatation were obtained (34). Only 6 women (8%) required treatment between 24 and 48 hours and all had delivered within 48 hours (mean 12.6 hours; range

2–48 hours). None of the women required surgical intervention. Other than one case of abruptio placentae, no complications were observed. A dose of 200 mcg, also administered vaginally, was used in a third study with a comparison group receiving a 20-mg PGE₂ vaginal suppository every 3 hours (35). Successful abortions were obtained within 24 hours in 89% (25 of 28) of women treated with misoprostol and in 81% (22 of 27) of women administered PGE₂ (ns). The remaining three misoprostol-treated women had successful abortions within 38 hours (similar data for PGE₂ were not given). Complete abortions (passage of the fetus and the placenta simultaneously) occurred in 43% and 32% of the misoprostol- and PGE₂-treated groups, respectively. Significantly more women experienced adverse effects (pyrexia, uterine pain, vomiting, and diarrhea) with PGE₂ than with misoprostol, and the difference in average cost between the treatments was large (\$315.30 for PGE₂ vs. \$0.97 for misoprostol). Two other studies have described the use of intravaginal misoprostol (200–800 mcg) to successfully induce legal abortion at gestational ages ranging from 11 to 23 weeks (36,37).

Several reports and communications have described the use of misoprostol for cervical ripening and labor induction in the 3rd trimester (38–44). The doses used were 50–100 mcg administered either as a single dose or at 4-hour intervals, but one group of investigators was studying a 25-mcg dose (43). Tachysystole was observed in some cases, but the uterine hyperstimulation was not associated with an increased incidence of fetal distress or a higher rate of operative deliveries. The American College of Obstetricians and Gynecologists considers low-dose (e.g., 25 mcg) intravaginal misoprostol to be effective for inducing labor in pregnant women who have unfavorable cervixes (45,46).

Some authors consider the potential teratogenicity of misoprostol following an unsuccessful abortion attempt a reason to proceed cautiously with the use of the drug for this purpose, particularly in countries with limited medical services (47).

BREASTFEEDING SUMMARY

No studies describing the use of misoprostol during human lactation have been located. The manufacturer considers the drug to be contraindicated during nursing because of the potential for severe, drug-induced diarrhea in the nursing infant (1). Naturally occurring PGE₁, however, is excreted into milk in concentrations similar to that in maternal plasma and may have an important

function (e.g., cytoprotection) in the gastrointestinal tract of the nursing infant (48).

MITOMYCIN

Antineoplastic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest High Risk

BREASTFEEDING RECOMMENDATION: Hold Breastfeeding

PREGNANCY SUMMARY

No reports describing the use of mitomycin in human pregnancy have been located. Although the doses were not compared with the human dose in terms of BSA or AUC, the drug was teratogenic or embryo-lethal in three animal species. If the drug is indicated in a pregnant woman, avoidance of the 1st trimester should be considered.

FETAL RISK SUMMARY

Mitomycin (mitomycin-C) is an antibiotic with antitumor activity isolated from *Streptomyces caespitosus*. It is in the same antineoplastic subclass of antibiotics as bleomycin and dactinomycin. Mitomycin is indicated in the therapy of disseminated adenocarcinoma of the stomach and pancreas in proven combinations with other approved chemotherapeutic agents and as palliative treatment when other modalities have failed. It is given as a single IV dose at 6–8-week intervals. The drug is primarily metabolized in the liver, but metabolism occurs in other tissues as well. However, metabolic pathways are saturated at relatively low doses. After a 30-mg IV bolus injection, the serum half-life was 17 minutes (1).

A number of reproduction studies in mice, rats, and dogs have been cited by Shepard and Lemire (2) and Schardein (3). Mitomycin caused either congenital malformations or embryo-lethality in these species when given during pregnancy (2,3). The studies specified doses based on weight, but apparently did compare them with the human dose based on BSA or AUC.

Mitomycin was carcinogenic in male rats and female mice. At doses approximating the recommended human clinical dose (assumed to be based on body weight), the tumor incidence in these species was increased by >100% and >50%, respectively. Assays for mutagenicity and tests for impaired fertility

have not been conducted (1).

It is not known if mitomycin crosses the human placenta. The molecular weight (about 334) and the high lipid solubility suggest that it will, but the short serum half-life will limit the embryo–fetal exposure.

A 28-year-old nulliparous woman with squamous cell carcinoma of the uterine cervix was treated with four courses of low-dose mitomycin, cisplatin, bleomycin, and vincristine (4). The therapy produced a complete response. Two years later, she became pregnant and gave birth to a healthy infant.

BREASTFEEDING SUMMARY

No reports describing the use of mitomycin during human lactation have been located. The molecular weight (about 334) and the high lipid solubility suggest that it will be excreted into breast milk, but the short serum half-life (17 minutes) will limit the amount in milk. Because the drug is given as a single IV dose at 6–8-week intervals, pumping and dumping for a few hours after a dose should prevent exposure of a nursing infant.

MITOXANTRONE

Antineoplastic

PREGNANCY RECOMMENDATION: Contraindicated—1st Trimester

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

This synthetic anthracenedione, structurally related to doxorubicin, is an antineoplastic antibiotic used in the treatment of acute nonlymphocytic leukemia, refractory lymphomas, and cancers of the breast, ovary, and liver. Reports describing the use of this agent in five pregnancies, all in the 2nd trimester, have been located. Mitoxantrone is toxic to DNA and has a cytocidal effect on both proliferating and nonproliferating human cells (1).

FETAL RISK SUMMARY

The mean half-life of mitoxantrone is 5.8 days (range 2.3–13.0 days) and may be longer in tissue. Moreover, the drug accumulates after multiple dosing in plasma and tissue (1).

Mitoxantrone administration to pregnant rats at a dose 0.05 times the recommended human dose based on BSA (RHD) caused decreased fetal weight and retarded development of the fetal kidney (1). Although not teratogenic in rabbits, a dose 0.01 times the RHD was associated with an increased incidence of premature delivery (1).

Two case reports, both during the 2nd trimester, have described the use of mitoxantrone in human pregnancy (2,3). A 26-year-old woman at 20 weeks' gestation presented with acute myeloblastic leukemia and was treated with an induction course of cytarabine and daunorubicin that failed to halt the disease progression (2). At approximately 23 weeks' gestation, a second induction course was started with mitoxantrone (12 mg/m², days 1–3) and cytarabine (days 1–4). Complete remission was achieved 60 days from the start of therapy. Weekly ultrasound examinations documented normal fetal growth. Because of the long interval required for remission, treatment was changed to idarubicin and cytarabine for the consolidation phase. Shortly after the start of this therapy, the woman delivered a 2200-g stillborn infant (gestational age not

specified). No apparent congenital malformations were observed but permission for an autopsy was refused. The authors speculated that the fetal death was secondary to the use of idarubicin (2).

In the second case, a 28-year-old woman at 24 week's gestation with acute promyelocytic leukemia was treated with an induction course of behenoyl-cytosine arabinoside (enocitabine; converted in vivo to cytarabine), daunorubicin, and 6-mercaptopurine (3). Following a rapid, complete remission and her first consolidation therapy with cytarabine and mitoxantrone (dose not specified), a cesarean section was performed at 34 weeks' gestation to deliver a healthy 2960-g female infant who was alive and well at 16 months of age (3).

A 1999 report from France described the outcomes of pregnancies in 20 women with breast cancer who were treated with antineoplastic agents (4). The first cycle of chemotherapy occurred at a mean gestational age of 26 weeks with delivery occurring at a mean 34.7 weeks. A total of 38 cycles were administered during pregnancy with a median of two cycles per woman. None of the women received radiation therapy during pregnancy. The pregnancy outcomes included two spontaneous abortions (both exposed in the 1st trimester), one intrauterine death (exposed in the 2nd trimester), and 17 live births, one of whom died at 8 days of age without apparent cause. The 16 surviving children were developing normally at a mean follow-up of 42.3 months (4). Mitoxantrone, in combination with cyclophosphamide and fluorouracil, was administered to two of the women at a mean dose of 12 mg/m². The outcomes were two surviving liveborn infants, both exposed in the 2nd trimester. One of the infants was growth restricted (1460 g, born at 33 weeks' gestation after two cycles of chemotherapy) (4).

In a 2009 case report, a woman with relapse of acute myeloid leukemia at 22 weeks' gestation was treated with mitoxantrone, fludarabine, cytarabine, idarubicin, and gemtuzumab ozogamicin (5). The fetus developed signs of idarubicin-induced cardiomyopathy, transient cerebral ventriculomegaly, anemia, and intrauterine growth restriction. The newborn, delivered at 33 weeks' by cesarean section, showed no congenital malformations (5).

Occupational exposure of the mother to antineoplastic agents during pregnancy may present a risk to the fetus. A position statement from the National Study Commission on Cytotoxic Exposure and a research article involving some antineoplastic agents are presented in the monograph for cyclophosphamide (see Cyclophosphamide).

BREASTFEEDING SUMMARY

Mitoxantrone is excreted in breast milk (3). After delivery at 34 weeks' gestation, a 28-year-old woman with acute promyelocytic leukemia in remission (case described above) was treated with a second consolidation therapy course of cytarabine and mitoxantrone. She maintained milk secretion by pumping her breasts during this and a third consolidation course consisting of mitoxantrone (6 mg/m², days 1–3), etoposide, and behenoyl-cytosine arabinoside (enocitabine; converted in vivo to cytarabine). The milk concentration of mitoxantrone on the 3rd day of this last course of therapy was 120 ng/mL and was still high (18 ng/mL) 28 days later. Although data on the drug concentration in milk were not yet available, and against the authors' advisement, the patient voluntarily began to breastfeed her infant 21 days after drug administration. Her infant, exposed to mitoxantrone in utero and during nursing was doing well at 16 months of age (3).

Although no adverse effects were observed in the above infant, the long-term consequences of such exposure are unknown. Mitoxantrone accumulates in the plasma and tissue after multiple doses and is slowly eliminated from the body (1). Because of its long elimination time and the uncertainty over the potential toxicity, women who have been treated with this agent should not breastfeed. The American Academy of Pediatrics classifies doxorubicin, an antineoplastic agent structurally related to mitoxantrone, as contraindicated during breastfeeding (see Doxorubicin).

MODAFINIL

Central Stimulant

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Only one report, in addition to the nine cases mentioned by the manufacturer, describing the use of modafinil in human pregnancy has been located. The animal data suggest moderate risk, but the limited human pregnancy experience prevents a full assessment of the embryo–fetal risk. Avoiding modafinil during pregnancy is the best course, but inadvertent exposure does not appear to represent a major risk of embryo–fetal harm.

FETAL RISK SUMMARY

Modafinil is a mixture of R- and S-enantiomers and the R-enantiomer, armodafinil, also is available (see Armodafinil). Modafinil is indicated to improve wakefulness in patients with excessive daytime sleepiness associated with narcolepsy. Its pharmacologic profile is not identical to that of sympathomimetic agents. Plasma protein binding, primarily to albumin, is moderate (about 60%). Modafinil is extensively (>90%) metabolized by the liver. After chronic dosing, the elimination half-life is about 15 hours (1).

Reproduction studies have been conducted in rats and rabbits. In rats, doses 10 times the maximum recommended human daily dose of 200 mg based on BSA (MRHDD) given throughout organogenesis were associated with increased resorptions, hydronephrosis, and skeletal variations. No maternal toxicity was observed at this dose. The no-effect dose for these effects was 5 times the MRHDD. Doses up to 4.8 times the MRHDD given to male and female rats before and during gestation had no effect on fertility. In rabbits, no embryotoxicity was observed at doses up to 10 times the MRHDD during organogenesis. However, the sample sizes and doses were inadequate to assess the toxic effects on fertility or reproduction (1). (See Armodafinil for

additional animal data.)

It is not known if modafinil crosses the human placenta. The molecular weight (about 273), moderate plasma protein binding, and long elimination half-life suggest that the drug will cross to the embryo–fetus.

The manufacturer cited the outcomes of nine pregnancies that were exposed to modafinil, but few details were given. There were seven normal births, one healthy male infant delivered 3 weeks before the expected range of delivery dates (based on ultrasound), and one spontaneous abortion (woman had history of previous spontaneous abortions) (1).

A 16-year-old primigravid woman with narcolepsy, cataplexy, and glutaric aciduria type II, an autosomal recessive disorder, was treated throughout pregnancy with modafinil 200 mg/day, fluoxetine 20 mg/day, L-carnitine, and riboflavin (2). Because the episodes of narcolepsy and cataplexy increased in frequency, a cesarean section was conducted at 38 weeks' to deliver 2.360-kg infant (sex not specified) with Apgar scores of 7, 8, and 9. No signs of withdrawal or abnormalities in vital signs or behaviour were noted in the infant. The infant was discharged home with the mother after 3 days (2).

BREASTFEEDING SUMMARY

No reports describing the use of modafinil during human lactation have been located. The relatively low molecular weight (about 273), moderate plasma protein binding (about 60%), and long elimination half-life (about 15 hours) suggest that the drug will be excreted in breast milk. The effects of this exposure on a nursing infant are unknown. However, if a lactating woman uses modafinil, her infant should be closely observed for adverse effects that are commonly seen in adults (i.e., headache, nausea, nervousness, anxiety, and insomnia).

MOEXIPRIL

Antihypertensive

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The fetal toxicity of moexipril in the 2nd and 3rd trimesters is similar to other angiotensin-converting enzyme (ACE) inhibitors. The use of this drug during the 2nd and 3rd trimesters may cause teratogenicity and severe fetal and neonatal toxicity. Fetal toxic effects may include anuria, oligohydramnios, fetal hypocalvaria, intrauterine growth restriction (IUGR), prematurity, and patent ductus arteriosus. Stillbirth or neonatal death may occur. Anuria-associated oligohydramnios may produce fetal limb contractures, craniofacial deformation, and pulmonary hypoplasia. Severe anuria and hypotension, which is resistant to both pressor agents and volume expansion, may occur in the newborn following in utero exposure. Newborn renal function and blood pressure should be closely monitored.

FETAL RISK SUMMARY

The prodrug, moexipril, is rapidly metabolized to the active drug, moexiprilat. It is indicated in the management of hypertension either alone, or in combination with thiazide diuretics. The active metabolite, moexiprilat, is an ACE inhibitor, thus preventing the conversion of angiotensin I to angiotensin II.

Reproduction studies have been conducted in pregnant rats and rabbits (1). Doses up to 90.9 and 0.7 times, respectively, the maximum recommended human dose based on BSA revealed no embryotoxic, fetotoxic, or teratogenic effects.

It is not known if moexipril or moexiprilat crosses the human placenta. The molecular weight (about 535 for the hydrochloride salt forms) is low enough that transfer to the fetus should be expected.

A retrospective study using pharmacy-based data from the Tennessee

Medicaid program identified 209 infants, born between 1985 and 2000, that had 1st trimester exposure to ACE inhibitors (2). Infants of mothers with evidence of diabetes, either before or during pregnancy, were excluded, as were those exposed to angiotensin-receptor antagonists (ARBs), ACE inhibitors or other antihypertensives beyond the 1st trimester, and exposure to known teratogens. Two comparison groups, other antihypertensives (N = 202) and no antihypertensives (N = 29,096), were formed. The number of major birth defects in each of the three groups was 18 (8.6%), 4 (2%), and 834 (2.9%), respectively. Compared with the no-antihypertensives group, exposure to ACE inhibitors was associated with a significantly increased risk of major defects (relative risk [RR] 2.71, 95% confidence interval [CI] 1.72–4.27). When the analysis was conducted by the type of defect, the highest rates were with cardiovascular defects, 9, 2, and 294, respectively, RR 3.72, 95% CI 1.89–7.30, and with CNS defects, 3, 0, and 80, respectively, RR 4.39, 95% CI 1.37–14.02. The major defects observed in the subject group were atrial septal defect (N = 6) (includes three with pulmonic stenosis and/or three with patent ductus arteriosus [PDA]), renal dysplasia (N = 2), PDA alone (N = 2), and one each of ventricular septal defect, spina bifida, microcephaly with eye anomaly, coloboma, hypospadias, intestinal and choanal atresia, Hirschsprung disease, and diaphragmatic hernia (2).

In an accompanying editorial, it was noted that neither previous reports of 1st trimester exposure to ACE inhibitors nor the animal studies had observed an increased risk of birth defects (3). It also was noted that no mechanism for ACE inhibitor-induced teratogenicity was known. A subsequent communication raising concerns about the validity of the study in terms of adequate exclusion of diabetes, charting and coding errors in busy medical practices, and the effects of maternal obesity (4) was addressed by the investigators (5).

Moexipril and other ACE inhibitors are human teratogens when used in the 2nd and 3rd trimesters, producing fetal hypocalvaria and renal defects. The cause of the defects and other toxicity is probably related to fetal hypotension and decreased renal blood flow. The compromise of the fetal renal system may result in severe, and at times fatal, anuria, both in the fetus and in the newborn. Anuria-associated oligohydramnios may produce pulmonary hypoplasia, limb contractures, persistent patent ductus arteriosus, craniofacial deformation, and neonatal death (6,7). IUGR, prematurity, and severe neonatal hypotension may also be observed. Two reviews of fetal and newborn renal function indicated that both renal perfusion and glomerular plasma flow are low during gestation and that high levels of angiotensin II may be physiologically necessary to

maintain glomerular filtration at low perfusion pressures (8,9). Moexipril prevents the conversion of angiotensin I to angiotensin II and, thus, may lead to in utero renal failure. Because the primary means of removal of the drug is renal, impairment of this system in the newborn prevents elimination of the drug resulting in prolonged hypotension. Newborn renal function and blood pressure should be closely monitored. If oligohydramnios occurs, stopping moexipril may resolve the problem but may not improve infant outcome because of irreversible fetal damage (6). In those cases in which moexipril must be used to treat the mother's disease, the lowest possible dose should be used combined with close monitoring of amniotic fluid levels and fetal well-being. Guidelines for counseling exposed pregnant patients have been published and should be of benefit to health professionals faced with this task (6,10).

The observation in Tennessee Medicaid data of an increased risk of major congenital defects after 1st trimester exposure to ACE inhibitors raises concerns about teratogenicity that have not been seen in other studies (3). Medicaid data are a valuable tool for identifying early signals of teratogenicity, but are subject to a number of shortcomings and their findings must be considered hypotheses until confirmed by independent studies.

A 2012 review of the use of ACE inhibitors and ARBs in the 1st trimester concluded that there may be an elevated teratogenic risk, but the risk appeared to be related to other factors (11). The factors, that typically coexist with hypertension in pregnancy, included diabetes, advanced maternal age, and obesity.

BREASTFEEDING SUMMARY

No reports describing the use of moexipril in human lactation have been located. The molecular weight (about 535 for the salt forms of the parent drug and metabolite) suggests that excretion into breast milk should be expected. The effects of this exposure on a nursing infant are unknown. However, other ACE inhibitors are excreted into breast milk and are considered compatible with breastfeeding by the American Academy of Pediatrics (see Captopril and Enalapril).

MOLINDONE

[Withdrawn from the market. See 9th edition.]

MOMETASONE

Corticosteroid

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of mometasone in human pregnancy have been located. The animal data suggest risk, but the observed developmental toxicity is similar to that observed after systemic exposure to other corticosteroids (e.g., see Hydrocortisone). In addition, the animal reproduction studies were not conducted with the inhaled or nasal spray formulation of mometasone. These products are known to have very low systemic bioavailability. Moreover, several large studies involving asthma patients have found no association between inhaled corticosteroids and adverse pregnancy outcomes, such as congenital anomalies (1), intrauterine growth restriction (2), or preterm delivery, low birth weight, small size for gestational age, and major malformations (3). Although mometasone was not included in any of these studies, and allergic rhinitis was not a condition studied, there is no reason to believe that the use of this corticosteroid or the additional diagnosis would have resulted in different outcomes. Because asthma is known to cause maternal and fetal harm, the use of mometasone should not be withheld because of pregnancy. However, beclomethasone or budesonide have been considered the inhaled corticosteroids of choice for use during pregnancy (4).

FETAL RISK SUMMARY

Mometasone is a corticosteroid in inhaled and nasal spray formulations. The inhaled product is indicated for the maintenance treatment of asthma as prophylactic therapy. It also is used to reduce or eliminate the need for oral corticosteroids (5). The nasal spray is indicated for the treatment of the nasal

symptoms of seasonal allergic and perennial allergic rhinitis and for prophylaxis in patients with a known seasonal allergen that precipitates nasal symptoms of seasonal allergic rhinitis (6).

The mean absolute systemic bioavailability of a single inhaled 400-mcg dose, compared with a similar IV dose, is less than 1% (5). Plasma concentrations in most subjects were near or below the lower limit of quantitation (50 pg/mL). After administration of the recommended highest inhaled dose (400 mcg twice daily) for 28 days, the mean peak plasma concentrations were 94–114 pg/mL (5). Systemic bioavailability after use of the nasal spray also is low, with concentrations virtually undetectable at the quantitation limit (6). Moreover, any of the drug that is swallowed and absorbed undergoes extensive metabolism in the liver.

Reproduction studies have been conducted in mice, rats, and rabbits but not with the inhaled or nasal spray formulations (5,6). In mice, SC doses less than the maximum recommended daily inhaled dose in humans based on BSA (MRDID-BSA) caused cleft palate. Fetal survival was reduced at doses about equal to the MRDID-BSA. The no-toxicity dose was one-third the dose causing cleft palate. In rats, a topical dermal dose about 6 times more than the MRDID-BSA or higher resulted in umbilical hernia. A dose about 3 times the MRDID-BSA produced delays in ossification, but no malformations. An SC dose about 6 times the maximum recommended daily inhalation dose based on AUC (MRDID-AUC) or less than the MRDID-BSA, given throughout pregnancy or during the later stages of pregnancy, caused prolonged and difficult labor. In addition, this dose reduced the number of live births, birth weight, and early pup survival. These effects were not observed when the dose was halved. In rabbits, topical dermal doses about 3 times the MRDID-BSA caused multiple anomalies including flexed front paws, gallbladder agenesis, umbilical hernia, and hydrocephaly. When given orally in a dose less than the MRDID-AUC, mometasone increased resorptions and caused cleft palate and/or head defects (hydrocephaly and domed head). When the dose was increased to about twice the MRDID-AUC, most litters were aborted or resorbed. The no-toxicity dose was 20% of the dose causing cleft palate and/or head defects (5,6).

It is not known if mometasone crosses the animal or human placenta. The molecular weight (about 513) is low enough for passage, but the very low systemic bioavailability suggests that little, if any, drug will reach the embryo or fetus.

BREASTFEEDING SUMMARY

No reports describing the use of mometasone during human lactation have been located. Other corticosteroids are excreted into breast milk in low concentrations. (See Prednisone.) The molecular weight (about 513) suggests that the drug, if it reached the plasma, would be excreted into breast milk. However, the very low systemic concentrations obtained after use of the inhaled or nasal spray formulations suggest that any excretion into milk will be clinically insignificant.

MONTELUKAST

Respiratory (Leukotriene Receptor Antagonist)

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Montelukast is not teratogenic in animals, and the few adverse outcomes in humans do not demonstrate a pattern that suggests a common etiology. One source states that montelukast may be safe to use during pregnancy, but this conclusion was based solely on animal studies (1). A 2000 position statement of the American College of Obstetricians and Gynecologists and the American College of Allergy, Asthma and Immunology recommended that montelukast could be considered in patients with recalcitrant asthma who had shown a uniquely favorable response to the drug prior to becoming pregnant (2). The available data support this assessment. The manufacturer maintains a pregnancy registry for women exposed to montelukast. Health care professionals are encouraged to report pregnancy exposures to the registry by calling the toll-free number 800-986-8999.

FETAL RISK SUMMARY

Montelukast, an oral inhibitor of the cysteinyl leukotriene CysLT₁ receptor, is indicated for the prophylaxis and chronic treatment of asthma. It is extensively metabolized and plasma protein binding is >99%. Excretion of montelukast and its metabolites is almost exclusively via the bile with a mean plasma elimination half-life of 2.7–5.5 hours (3).

Reproduction studies in rats and rabbits at doses up to about 100 and 110 times the maximum recommended human daily oral dose based on AUC (MRHD), respectively, found no evidence of teratogenicity (1). The drug impaired the fertility and fecundity of female rats at about 70 times, but not at about 20 times, the MRHD. Fertility in male rats was not affected by oral doses

up to 160 times the MRHD. No evidence of carcinogenicity was found in long-term animal studies, and assays for mutagenic and clastogenic effects were negative (3).

It is not known if montelukast crosses the human placenta. The drug crosses the placenta in rats and rabbits (3). The molecular weight (about 608) and elimination half-life suggest that transfer to the embryo and fetus should be expected. However, the extensive metabolism and high plasma protein binding should limit the exposure.

The manufacturer maintains a pregnancy registry for montelukast (4). As of July 2009, there were 391 prospective (reported before outcome of pregnancy known) reports of exposure during gestation. The outcomes of these pregnancies were: 3 pending, 140 lost to follow-up, 3 spontaneous abortions (SABs), 2 elective abortions (EABs), and 245 live births (2 sets of twins). Of the live births, 193 were known to have been exposed in the 1st trimester. Congenital anomalies were observed in eight cases, seven in live births, exposed in the 1st trimester: absent left hand (amniotic band deformity); two cases of hypospadias; slight valgus foot deviation; mild chordee; polydactyly (a tiny pedicle [skin] on the small finger of the left hand); multicystic dysplasia of right kidney with compensatory left kidney hypertrophy and hydronephrosis, small congenital hydroceles, and a cleft tongue; and triploidy 69XXY (EAB). There were 11 congenital defects in retrospective reports (reported after the outcome of pregnancy known), 5 of which involved 1st trimester exposures: bilateral sensorineural hearing loss; partial right hand (thumb, three-fourths of the palm and finger nubbins); large hole in heart (exposed in 2nd trimester; no other details); 2 cases of polydactyly; cleft palate; 2 cases of hypospadias (1 required corrective surgery); 3 chromosomal abnormalities (trisomy 18 [SAB], Down's syndrome and fetal alcohol syndrome, and unspecified chromosomal abnormalities [SAB]). When national and international studies were combined, there were six reports of potential limb reduction defects after 1st trimester exposure, two of which are described above. The other four (all from retrospective reports) were: no left hand, left radius and cubitus were incomplete; hypoplasia of distal phalanx of the thumb; missing or hypoplastic fingers, camptodactyly, and syndactyly; and reduction defect of left arm. No additional reports of limb reduction defects were received by the registry from August 2006 through July 2009. A health insurance claims database study with medical record review identified 1535 women dispensed montelukast during pregnancy; none of their infants had a limb reduction defect. The report noted that there was no plausible mechanism by which montelukast could have

caused limb reduction defects (4).

A 2007 report described the pregnancy outcomes of 96 women exposed to leukotriene receptor antagonists (montelukast and zafirlukast) (5). The women were enrolled in the Organization of Teratology Information Specialists (OTIS) Asthma Medications in Pregnancy study. Two comparison groups were formed consisting of 122 pregnant women who exclusively took short-acting β_2 -sympathomimetics or 346 pregnant women without asthma (control group). Among the 96 subjects, 72 took montelukast, 22 took zafirlukast, and 2 took both drugs. Most subjects (89.6%) were exposed in the 1st trimester and 50% were exposed throughout gestation. There were no differences between the three groups in terms of preterm delivery, Apgar scores at 1 and 5 minutes, birth weight and height ≤ 10 th percentile, or ponderal index < 2.2 . The adjusted mean birth weight in subject infants was significantly lower than that in infants from controls without asthma, 3384 vs. 3529 g ($p < 0.05$). There were also no significant differences in pregnancy loss (SABs, ectopic pregnancies, and stillbirths), gestational diabetes, preeclampsia, and maternal weight gain. There was significantly ($p < 0.05$) more birth defects in subjects (5.95%) compared with the control group (0.3%), but the prevalence in the control group was abnormally low. There was no significant difference in the prevalence of defects between subjects and those treated with β_2 -agonists (3.9%). No birth defects were reported in stillbirths, SABs, or EABs. Birth defects in liveborn infants of subjects (specific exposure not given) were: Sturge-Weber sequence, congenital hip dislocation, bilateral club foot, neurofibromatosis type 1 (an autosomal-dominant inheritance pattern), and imperforate anus. The causes of the other four defects are either unknown or multifactorial, but no specific pattern of defects is evident (5).

A 2009 study enrolled 180 asthmatic pregnant women using montelukast (usually in combination with other drugs such as short- and long-acting β -agonists and inhaled corticosteroids) from six teratogen information services in Canada, Israel, Italy, and the United States (6). The outcomes of these pregnancies were compared with the outcomes from two controls: 180 disease-matched using inhalers and 180 healthy not exposed to any known teratogens. In the montelukast group, 166 (92%) used the drug in the 1st trimester and 56 (31%) continued to use it throughout pregnancy. There were 160 live births (3 sets of twins), 20 (11%) SABs, and 3 (1.7%) EABs (1 for a trisomy 21). The only major birth defect among live births exposed in utero to montelukast was a twin with patent ductus arteriosus, atrial septal defect, and congestive heart failure. There were no statistical differences between the

three groups in the number of live births, SABs, and major birth defects, but the number of birth defects in the montelukast and healthy control groups (1 vs. 0) were unusually low. Compared with healthy controls, the montelukast group had lower mean gestational age (37.8 vs. 39.3 weeks) and birth weight (3214 vs. 3425 g) among singleton outcomes. There were also significantly more cases of fetal distress at birth compared with both control groups (25.6% vs. 13.6% vs. 8.7%). However, in a sub-analysis of women who continued to use montelukast until the end of pregnancy, only birth weight remained significantly lower than the healthy controls and that was thought to be due to disease severity (6).

BREASTFEEDING SUMMARY

No reports describing the use of montelukast during human lactation have been located. The molecular weight (about 608) and elimination half-life (2.7–5.5 hours) suggest that the drug will be excreted into breast milk. However, the extensive metabolism and high plasma protein binding (>99%) should limit the exposure. The effect on this potential exposure on a nursing infant is unknown.

MORICIZINE

Antiarrhythmic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports of the use of moricizine in human pregnancy have been located. It is an orally active agent used in the treatment of ventricular tachycardia. The drug is neither teratogenic nor fetotoxic in rats and rabbits at doses up to 6.7 and 4.7 times the maximum recommended human dose, respectively (1).

BREASTFEEDING SUMMARY

The excretion of moricizine in human milk has been documented in one patient (data on file, Roberts Pharmaceutical Corporation, 1993), but no details on the amount in milk or its relationship to maternal levels are available. The clinical significance to the nursing infant is unknown.

Reference

MORPHINE

Narcotic Agonist Analgesic

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

The National Birth Defects Prevention Study discussed below found evidence that opioid use during organogenesis is associated with a low absolute risk of congenital birth defects. Similar to other opioid analgesics, the use of morphine late in pregnancy has the potential to cause respiratory depression and withdrawal in the newborn.

FETAL RISK SUMMARY

Morphine is not teratogenic in rats at a dose 35 times the usual human dose (1).

Bilateral horizontal nystagmus persisting for 1 year was reported in one addicted newborn (2). Like all narcotics, placental transfer of morphine is very rapid (3,4). Maternal addiction with subsequent neonatal withdrawal is well known following illicit use (see also Heroin) (2,5,6). Morphine was widely used in labor until the 1940s, when it was largely displaced by meperidine. Clinical impressions that meperidine caused less respiratory depression in the newborn were apparently confirmed (7,8). Other clinicians reported no difference between narcotics in the degree of neonatal depression when equianalgesic IV doses were used (4). Epidural use of morphine has been reported in women in labor but with unsatisfactory analgesic effects (9). The intrathecal route, however, has provided safe and effective analgesia without fetal or newborn toxicity (10–12).

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 70 of whom had 1st trimester exposure to morphine (13, pp. 287–295). For use anytime during pregnancy, 448 exposures were recorded (13, p. 434). No evidence was found to suggest a relationship to large categories of major or minor malformations. A possible association with inguinal hernia (10 cases)

after anytime use was observed (13, p. 484). The statistical significance of this association is unknown and independent confirmation is required.

Results of a National Birth Defects Prevention Study (1997–2005) were published in 2011 (14). This population-based case–control study examined the association between maternal use of opioid analgesics and >30 types of major structural birth defects. In 17,449 case mothers, therapeutic opioid use was reported by 454 (2.6%) compared with 134 (2.0%) of 6701 control mothers. Indications for use of opioid analgesics were surgical procedures (41%), infections (34%), chronic diseases (20%), and injuries (18%). Dose, duration, or frequency were not evaluated. The exposure period evaluated was from 1 month before to 3 months after conception. Limiting the exposure period to the first 2 months after conception produced similar results. Infants with >1 defect were included in multiple birth defect categories. The following opioids were included (number of cases for each agent not specified): codeine, hydrocodone, hydromorphone, fentanyl, meperidine, methadone, morphine, oxycodone, pentazocine, propoxyphene, and tramadol. The birth defect, total number, number exposed, and the adjusted odds ratio (aOR) with 95% confidence interval (CI) were as follows:

| Birth Defect | Total | Cases | aOR (95% CI) |
|--|-------|-------|---------------|
| Spina bifida | 718 | 26 | 2.0 (1.3–3.2) |
| <i>Any heart defect (20 types)</i> | 7724 | 211 | 1.4 (1.1–1.7) |
| Atrioventricular septal defect | 175 | 9 | 2.4 (1.2–4.8) |
| Teratology of Fallot | 672 | 21 | 1.7 (1.1–2.8) |
| Conotruncal defect | 1481 | 41 | 1.5 (1.0–2.1) |
| Conoventricular septal defect | 110 | 6 | 2.7 (1.1–6.3) |
| Left ventricular outflow tract obstruction defect | 1195 | 36 | 1.5 (1.0–2.2) |
| Hypoplastic left heart syndrome | 357 | 17 | 2.4 (1.4–4.1) |
| Right ventricular outflow tract obstruction defect | 1175 | 40 | 1.6 (1.1–2.3) |
| Pulmonary valve stenosis | 867 | 34 | 1.7 (1.2–2.6) |
| Atrial septal defect (ASD) | 511 | 17 | 2.0 (1.2–3.6) |
| Ventricular septal defect + ASD | 528 | 17 | 1.7 (1.0–2.9) |
| Hydrocephaly | 301 | 11 | 2.0 (1.0–3.7) |
| Glaucoma/anterior chamber defects | 103 | 5 | 2.6 (1.0–6.6) |
| Gastroschisis | 726 | 26 | 1.8 (1.1–2.9) |

The authors speculated that the activity of opioids and their receptors as growth regulators during development of the embryo might be a mechanism to explain the above findings. The exposure data were obtained by retrospective maternal self-report; the authors acknowledged that recall bias and misclassification might have affected their results. They concluded that the absolute risk was a modest absolute increase above the baseline risk for birth defects (14).

BREASTFEEDING SUMMARY

Although earlier reports had indicated that only trace amounts of morphine enter breast milk and that the clinical significance of this was unknown (15–17), in a 1990 report, much higher concentrations of morphine were measured in the breast milk of one woman and in her infant's serum (18). A 30-year-old, 75-kg woman with systemic lupus erythematosus and severe arthritic back pain was treated with morphine, 50 mg every 6 hours, during the 3rd trimester and then

with tapering doses during breastfeeding. At the time of the study, the normal, healthy 3.5-kg infant was 21 days of age. One day before the study, the dose was 10 mg every 6 hours and then was tapered to 5 mg every 6 hours on the study day. Milk sampling times and morphine concentrations were: 4.5 hours after a dose (before feeding), 100 ng/mL; 4.75 hours after a dose (at end of feeding), 10 ng/mL; and 0.5 hours after a dose, 12 ng/mL (reported as 12 ng/L). A blood sample drawn from the infant 1 hour after a feeding (4 hours after a dose) had a morphine concentration of 4 ng/mL, a close approximation to the estimated therapeutic level. It was presumed that the infant had been exposed to much higher morphine concentrations from the milk before dose tapering and, thus, had higher therapeutic serum concentrations. Using pharmacokinetic calculations, the authors estimated that the infant was receiving between 0.8% and 12% of the maternal dose. No adverse effects of the exposure were observed in the infant (18).

The American Academy of Pediatrics classifies morphine as compatible with breastfeeding (19). However, the long-term effects on neurobehavior and development are unknown but warrant study.

MOXALACTAM

[Withdrawn from the market. See 9th edition.]

MOXIFLOXACIN

Anti-infective (Quinolone)

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

There is limited human pregnancy experience with moxifloxacin. Only two reports have been located and both involved single doses, one report in the 2nd trimester and the other just before delivery, to measure amniotic concentrations and placental passage, respectively. There is no evidence that fluoroquinolones are a major risk of developmental toxicity. Some reviewers, however, have concluded that all fluoroquinolones should be considered contraindicated in pregnancy (e.g., see Ciprofloxacin and Norfloxacin), because safer alternatives are usually available. A 2013 review stated that fluoroquinolones are usually avoided in pregnancy because of concerns for fetal cartilage damage, but there were no human studies to validate this concern (1).

FETAL RISK SUMMARY

Moxifloxacin is a synthetic, broad-spectrum, fluoroquinolone anti-infective agent that is available in oral and IV formulations. It is in the same anti-infective class as ciprofloxacin, enoxacin, gatifloxacin, lomefloxacin, levofloxacin, norfloxacin, ofloxacin, sparfloxacin, and trovafloxacin. About 52% of a dose is metabolized and the plasma protein binding is moderate (30%–50%). Depending on the number of doses and route, the elimination half-life varies between about 8 and 15 hours (2).

In reproduction studies with pregnant rats, oral doses up to 0.24 times the maximum recommended human dose (MRHD) based on AUC (MRHD-AUC) were not teratogenic. At this dose, fetal toxicity was observed, as indicated by decreased fetal body weight and slightly delayed fetal skeletal development. Moreover, in a pre- and postnatal development study, the highest dose (0.24 times the MRHD-AUC) was associated with increases in pregnancy duration

and prenatal loss, reduced pup birth weight, decreased neonatal survival, and treatment-related maternal death during gestation. In rats, IV doses that were about 2 times the MRHD based on BSA resulted in maternal toxicity and a marginal effect on fetal and placental weights but no evidence of teratogenicity. In pregnant rabbits given an IV dose during organogenesis that was about equal to the MRHD-AUC (a maternal toxic dose), decreased fetal body weights and delayed fetal skeletal ossification were observed. In addition, there was an increased fetal and litter incidence of rib and vertebral malformations when these effects were combined. No evidence of teratogenicity was seen when cynomolgus monkeys were given oral doses up to 2.5 times the MRHD-AUC, but fetal growth restriction was observed (2).

Consistent with the molecular weight (about 401 for the free base), moxifloxacin crosses the human placenta. In a 2010 study, 10 women scheduled for a cesarean section were given IV moxifloxacin 400 mg over 60 minutes (3). The transplacental passage rate calculated as a percentage of fetal venous concentration to maternal blood concentration was about 75%, whereas the transfetal passage rate calculated as a percentage of fetal arterial drug concentration to fetal venous concentration was about 91% (3).

A second study, by the same group as above, measured moxifloxacin amniotic fluid concentrations in 10 women given a 400 mg oral dose about 2 hours before amniocentesis (4). The study was conducted between the 16th and 20th gestational weeks. The mean concentrations of moxifloxacin in maternal blood and amniotic fluid were 3.53 mcg/mL and 0.27 mcg/mL, respectively; a amniotic fluid passage rate of about 8% (4).

BREASTFEEDING SUMMARY

No reports describing the use of moxifloxacin in human lactation have been located. The molecular weight (about 401 for the free base), moderate metabolism (52%) and plasma protein binding (30%–50%), and long elimination half-life (about 8–15 hours) suggest that the agent will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown. However, two other fluoroquinolones are classified as compatible with breastfeeding by the American Academy of Pediatrics (see Ciprofloxacin and Ofloxacin).

MUPIROCIN

Antibiotic

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of any of the three mupirocin formulations in human pregnancy have been located. The animal data and the minimal systemic concentrations in humans suggest that the embryo–fetal risk, if it exists at all, is probably nil.

FETAL RISK SUMMARY

Mupirocin is an antibacterial agent produced by fermentation from *Pseudomonas fluorescens*. It is active against many gram-positive bacteria, including methicillin-resistant *Staphylococcus aureus* (MRSA), and some gram-negative bacteria. Mupirocin is bactericidal at concentrations achieved by topical application. Mupirocin cream is indicated for the treatment of secondarily infected traumatic skin lesions (up to 10 cm in length or 100 cm² in area) due to susceptible strains of *S. aureus* and *Streptococcus pyogenes*. The ointment formulation is indicated for the topical treatment of impetigo due to *S. aureus* and *S. pyogenes*, whereas the nasal spray is indicated for the eradication of nasal colonization with MRSA in adult patients and health care workers (1).

Minimal amounts of mupirocin are absorbed into the systemic circulation after use of cream, but not after use of the ointment. For the nasal spray, the extrapolated systemic exposure, based on the concentration of the inactive metabolite monic acid in urine, was 3.3% of the dose. Any antibiotic reaching the circulation is rapidly metabolized to monic acid that is excreted in the urine. The elimination half-lives of mupirocin and monic acid after IV administration in healthy adults were 20–40 and 30–80 minutes, respectively (1).

Reproduction studies have been conducted in rats and rabbits. During

pregnancy in these species, SC doses up to 78 and 154 times, respectively, the daily human topical dose of the cream based on BSA revealed no evidence of fetal harm. For the ointment, the dose comparisons were 22 and 43 times, respectively, the daily human topical dose based on BSA and, for the nasal spray, 65 and 130 times, respectively, the daily human intranasal dose based on BSA (1).

Studies for carcinogenicity have not been conducted with mupirocin. Multiple assays for mutagenicity were negative. SC doses in male and female rats revealed no evidence of impaired fertility or reproductive performance (1).

It is not known if mupirocin crosses the human placenta. The molecular weight of the free acid (about 501) is low enough for passage, but the minimal plasma concentrations and rapid metabolism and elimination suggest that clinically significant amounts of the antibiotic will not reach the embryo or the fetus.

BREASTFEEDING SUMMARY

No reports describing the use of mupirocin during human lactation have been located. The molecular weight of the free acid (about 501) is low enough for excretion into breast milk, but the minimal plasma concentrations and rapid metabolism and elimination suggest that clinically significant amounts of the antibiotic will not reach the milk.

MUROMONAB-CD3

Immunologic Agent (Immunosuppressant)

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of muromonab-CD3 in pregnancy have been located. The absence of animal and human data prevents an assessment of the risk to the embryo or fetus. If the antibody crosses the placenta, the effects of cytokine release and immunosuppression in the embryo or fetus are unknown. Preterm delivery is a potential complication because there are increased amniotic fluid levels of cytokines in women with intra-amniotic infections and subsequent preterm labor (1). The manufacturer lists known or suspected pregnancy as a contraindication to the use of this agent (2). Nonetheless, if a pregnant woman's condition requires muromonab-CD3, and there are no alternatives, the maternal benefit appears to outweigh the unknown embryo or fetal effects.

FETAL RISK SUMMARY

The immunosuppressant muromonab-CD3 is a murine monoclonal antibody to the CD3 antigen of human T cells. It is an IgG_{2a} immunoglobulin that is given IV. Muromonab-CD3 is indicated for the treatment of acute allograft rejection in renal transplant patients. It is also indicated for the treatment of steroid-resistant acute allograft rejection in cardiac and hepatic transplant patients.

Neither the effects on reproduction nor the carcinogenic potential has been studied in animals (2).

The placental passage of muromonab-CD3 has not been studied. However, because it is an IgG antibody, it may cross the placenta (2).

BREASTFEEDING SUMMARY

No reports describing the use of muromonab-CD3 during lactation have been

located. As an IgG antibody, it probably is excreted into breast milk. The effects of this exposure on a nursing infant are unknown, but it might be broken down to its constituent amino acids or fragments thereof in the infant's digestive tract. However, the adverse effects observed in adults during clinical trials involved most body systems and may be severe (2). In addition, the manufacturer lists breastfeeding as a contraindication to the use of muromonab-CD3 (2). Because of the potential for severe toxicity in a nursing infant, women who require this agent should not breastfeed.

MYCOPHENOLATE

Immunologic Agent (Immunosuppressive)

PREGNANCY RECOMMENDATION: Human and Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

The use of mycophenolate mofetil (MMF) during early pregnancy is associated with spontaneous abortions (SABs) and major birth defects that may represent a characteristic phenotype. Specific malformations involved the external ear, facial anomalies, cleft lip/palate, and defects of the distal limbs, heart, esophagus, and kidney. The animal data for both MMF and mycophenolate sodium also suggest risk of embryo–fetal death and structural defects. Although all of the reported adverse pregnancy outcomes involved MMF, the lack of reports with mycophenolate sodium is probably due to its later availability. MMF was approved by the FDA in 1995, whereas mycophenolate sodium was approved in 2004. The embryo–fetal toxicity of the two agents probably is similar. Indeed, the manufacturer of mycophenolate sodium states that there are no relevant qualitative or quantitative differences in the teratogenic potential of the two products (1). More data are needed to confirm the full spectrum of defects and especially its magnitude, but women of childbearing potential should be informed of the risks, and both agents should be avoided during pregnancy (1–3). The manufacturers recommend that women of reproductive potential should use effective contraception before and during therapy and for 6 weeks after therapy is stopped (1,2). However, the apparent half-lives suggest that a shorter waiting period might be appropriate. If mycophenolate is used in pregnancy, health care professionals are encouraged to call the toll-free number 877-311-8972 for information about patient enrollment in an Organization of Teratology Information Specialists (OTIS) study.

FETAL RISK SUMMARY

Mycophenolate is a purine synthesis inhibitor that is used as an

immunosuppressant agent in the prophylaxis of organ rejection in patients receiving allogeneic renal and liver transplants (1,2,4). It is available as MMF (the 2-morpholinoethyl ester of mycophenolic acid) and mycophenolate sodium. Following oral administration, mycophenolate mofetil undergoes rapid and complete metabolism to mycophenolic acid (MPA), the active moiety. MPA is further metabolized to an inactive metabolite, the phenolic glucuronide of MPA (MPAG). Both MPA and MPAG are bound to plasma albumin, 97% and 82%, respectively. The mean apparent half-life of MPA when mycophenolate mofetil is used is 17.9 hours (2), whereas it ranges between 8 and 16 hours when mycophenolate sodium is taken (1).

Reproductive studies have been conducted in rats and rabbits. In both species, in the absence of maternal toxicity, fetal resorptions and malformations were observed at MMF doses that were 0.03–0.92 times the recommended clinical dose in renal transplant recipients based on BSA (RCD-R) and 0.02–0.61 times the recommended clinical dose in cardiac transplant recipients based on BSA (RCD-C). In rats, a dose 0.02 times the RCD-R or 0.1 times the RCD-C produced malformations, principally of the head and eyes (2). Similar results have been observed with mycophenolate sodium (1).

In 2-year studies, mycophenolate was not carcinogenic in mice and rats but was genotoxic in two of five assays. The drug had no adverse effects on fertility or reproductive performance in male and female rats (2).

It is not known if MPA crosses the human placenta to the embryo–fetus. The molecular weight of MPA (about 319) and the moderately long elimination half-life suggest that exposure of the embryo–fetus will occur. The animal and human data support this assessment.

A 2001 case report described the use of MMF during pregnancy (5). The 33-year-old woman, with an unknown pregnancy at the time of surgery, had received a renal transplant at about 6–7 weeks' gestation. Postoperatively, she had been treated with MMF, tacrolimus, corticosteroids, cefepime, and vancomycin. After discharge from the hospital, she was maintained on acyclovir, nifedipine, trimethoprim/sulfamethoxazole, tacrolimus (14 mg/day), MMF (2 g/day), and prednisone (25 mg/day). The pregnancy was diagnosed on posttransplant day 100, at which time the two anti-infectives were discontinued and the MMF dose reduced to 1 g/day. The woman delivered a 2250-g female infant at about 34 weeks' with Apgar scores of 5 and 8 at 1 and 5 minutes, respectively. The birth weight, length, and head circumference were at the 75th, 75th–90th, and 10th–25th percentile, respectively. The infant had hypoplastic fingernails and toenails and shortened fifth fingers bilaterally. An

aberrant blood vessel between the trachea and esophagus was found later. The infant was hospitalized 3 times during her first year with pneumonia (thought to have been due in part to aspiration of stomach contents). Since then, the child has been healthy and growing and developing normally at 3 years of age (5).

Severe congenital malformations were detailed in a 2004 case report (6). A 27-year-old woman had received a renal transplant 2 years before her pregnancy and had been maintained on MMF (500 mg/day), tacrolimus (9 mg/day), and prednisone (15 mg/day). Her pregnancy was diagnosed at 13 weeks' gestation. At this time, azathioprine (50 mg/day) was substituted for MMF. Multiple malformations were detected at 22 weeks, and the pregnancy was terminated. Defects included complete agenesis of the corpus callosum, cleft lip/palate, micrognathia, ocular hypertelorism, microtia and external auditory duct atresia, and a left pelvic ectopic kidney. The fetus had a normal male karyotype. One year later, the woman had another pregnancy and delivered a normal 2640-g male infant who was growing and developing normally at follow-up. During this pregnancy, she had been maintained on azathioprine, tacrolimus, and prednisone (6).

A renal transplant unit in Spain reported the outcomes of 43 pregnancies in 35 recipients of a renal transplant that had occurred during 1976–2004 (7). Four of the pregnancies were exposed to MMF and sirolimus. In 1996, immunotherapy with these agents was stopped before conception and replaced with other immunosuppressants, such as cyclosporine, azathioprine, tacrolimus, and corticosteroids. There were 9 SABs, 10 elective abortions (EABs), and 24 successful pregnancies with healthy newborns (7).

A report from the National Transplantation Pregnancy Registry (NTPR) was published in 2005 (8). MMF was used in 26 pregnancies in 18 women who had received a kidney transplant. However, only 10 pregnancies were exposed to MMF throughout gestation, whereas in 16, the dose was decreased, discontinued, or changed to azathioprine. MMF also was used in three pregnancies in three women after a liver transplant, and three pregnancies in two women after a heart transplant. In the kidney transplant group, one or more immunosuppressants were combined with MMF. These agents were cyclosporine (N = 5), tacrolimus (N = 13), sirolimus (N = 1), and prednisone (N = 15). The pregnancy outcomes in this group were 11 SABs (61%) and 15 live births. Congenital malformations were observed in four newborns delivered from four women (exposures in addition to MMF shown in parentheses): hypoplastic nails with shortened fifth fingers (tacrolimus and prednisone) (might

be the same case described in reference 4); cleft lip and palate, microtia (tacrolimus, sirolimus, and prednisone); multiple malformations, infant died on day 1 (tacrolimus and prednisone); and microtia (tacrolimus and prednisone). In the liver transplant group, there was one SAB (also exposed to tacrolimus), and two live births without defects (also exposed to tacrolimus and prednisone in one and tacrolimus in one). MMF was discontinued in two pregnancies, one with a live birth and the other with an SAB (8).

In the heart transplant group, the pregnancy of one woman ended in an SAB, as did the first pregnancy of a second woman. In her second pregnancy, the latter woman had a live birth without defects. All three pregnancies also were exposed to tacrolimus. The combined outcomes of the 32 pregnancies were 14 SABs (44%), 14 live births (44%) without defects, and 4 newborns (4 of 18; 22%) with birth defects. The average gestational age for the live births was 35.6 weeks (range 31–39), and the average birth weight was 2397 g (range 822–3487 g) (8).

A second report from the NTPR, published in 2006, described the same pregnancy outcomes of the 26 pregnancies after kidney transplant but with additional details on the dose and timing of the exposures (9). MMF was continued in 11 pregnancies, not 10 as stated above, and the dose was decreased in 1, discontinued in 9, changed to azathioprine in 4, or changed to sirolimus in 1. Additional details were available on two of the four newborns with birth defects. The infant with cleft lip/palate and microtia had surgical repair of the clefts and, except for the need for bone conduction hearing aids, was doing well at 4 years of age. The multiple defects in the infant who died at 1 day of age were cleft lip/palate, congenital diaphragmatic hernia, and congenital heart defects. The defects might have been associated with Fryn's syndrome, an autosomal recessive anomaly (8). In addition to the six liver or heart transplants mentioned in the 2005 report, an SAB at 6 weeks occurred in a seventh woman that had been treated with MMF, tacrolimus, and prednisone after a kidney–pancreas transplant. There were 15 SABs (45%) in the combined 33 pregnancies and 4 (22%) of the 18 liveborn infants had birth defects. The authors noted the higher incidence of birth defects in those exposed to MMF compared with the overall incidence observed in kidney transplant recipient offspring (9).

A brief 2006 report from the Sindh Institute of Urology and Transplantation in Pakistan described 47 pregnancy outcomes from 31 women after kidney transplant (10). All of the women received cyclosporine and prednisone, 82% also received azathioprine, and four had MMF added. There were 7 SABs

(15%), 2 EABs, 6 preterm infants, and 32 full-term newborns. The specific therapy in the pregnancies of these outcomes was not mentioned, but none of the 38 live births had a birth defect (10).

A 36-year-old woman, 4 years after a kidney transplant, was treated with MMF and prednisolone throughout gestation (11). The woman had a history of psychoses that were treated with diazepam and haloperidol from the 4th month of pregnancy. In the last months of her pregnancy (exact dates not specified), she received darbepoetin alfa for anemia and methyldopa for hypertension. Because of fetal distress, a cesarean section was performed at 35 weeks' gestation to deliver a 2330-g male infant with Apgar scores of 5, 8, and 8 at 1, 5, and 10 minutes, respectively. Abnormalities found in the infant were severe anemia, nonimmune hydrops fetalis, and a malformed right ear. An infectious disease workup was negative. The infant had a normal 46,XY karyotype. Myoclonic movements of both arms and legs were attributed to withdrawal from diazepam and haloperidol. A magnetic resonance imaging scan of the cerebrum revealed a complete absence of the right auditory pathway, without other defects. Unable to find any other causes, the authors attributed the anemia and resulting hydrops fetalis and the ear malformation to MMF (11).

A 21-year-old woman with lupus nephritis had been treated with two 6-month courses of cyclophosphamide separated by 2 years (12). She had been on MMF (2000 mg/day) maintenance therapy for 10 months when pregnancy was diagnosed at 25 weeks' gestation. She also was receiving prednisone, hydroxychloroquine, and perindopril. The pregnancy was terminated because of multiple malformations. The fetus had a normal karyotype. Malformations affected the head (bilateral anotia, external auditory duct atresia), lower limb (polydactyilia and nail hypoplasia), heart (anterior positioning of the aorta, interventricular communication), and kidneys (asymmetric) (12).

A 2008 case report described the pregnancy outcome of a woman, with systemic lupus erythematosus involving the kidney, who had been treated with cyclophosphamide and MMF before conception, and then with MMF (1500 mg/day) until pregnancy was diagnosed at 8 2/7 weeks' gestation (13). MMF was then discontinued and azathioprine 100 mg/day was started. The pregnancy was electively terminated at 17 weeks because of major congenital anomalies. The chromosomally normal female fetus (46,XX) had a large square skull with extension of facial clefts that resulted in an almost complete defect of the midface in the presence of severe mandibulofacial dysostosis and ophthalmic anomalies. Preaxial limb defects with digitalization of the thumbs also were observed, as was hypoplasia of the thymus and lungs, a subaortic

ventricular septal defect with overriding common truncus arteriosus of the heart, an aberrant right subclavian artery, a single umbilical artery, esophageal atresia with tracheoesophageal fistula, left renal agenesis with ipsilateral streak gonad, agenesis of the corpus callosum, and mild hydrocephaly (13).

A woman with lupus nephritis took MMF (1000 mg/day) and adalimumab (40 mg every other week) during the first 8 weeks of pregnancy (14). She underwent a cesarean section for transverse position at 32 weeks' gestation to give birth to a 4422-g female infant with normal karyotype (46,XX). The infant had multiple birth defects including arched eyebrows, hypertelorism, epicanthic folds, micrognathia, thick everted lower lip, cleft palate, bilateral microtia with aural atresia, congenital tracheomalacia, and brachydactyly. Shortly after birth, a tracheostomy was done for respiratory distress and a G-tube was placed because of feeding difficulties. The cleft palate was repaired surgically. At 20 months of age, the infant had normal growth and slightly delayed motor development. The tracheostomy was still required as were G-tube feedings. She seemed to have some hearing, but had significant expressive speech delay. The defects were attributed to MMF (14).

The 10-year experience of a renal transplant center in Iran was reported in 2008 (15). A total of 61 pregnancies were reported in 53 patients. In 38 patients (72%), immunosuppressive therapy consisted of MMF, cyclosporine, and prednisolone, whereas in 15 patients (28%), therapy was azathioprine, cyclosporine, and prednisone. Adverse outcomes included 11 small-for-gestational-age newborns, 1 infant with a club foot, and 1 infant with a large facial hemangioma. Early neonatal death occurred in four infants, one from extreme prematurity. There were no significant differences in outcomes between the MMF- and azathioprine-treated groups (15).

Additional evidence that MMF exposure during the 1st trimester is associated with a recognizable phenotype was presented in a 2008 report (16). A 25-year-old Spanish woman became pregnant for the first time 2 years after receiving her second renal transplant. Immunosuppressive therapy consisted of MMF 500 mg/day and tacrolimus 12 mg/day until pregnancy was diagnosed at 10 weeks. MMF was discontinued while tacrolimus was continued until delivery by cesarean section at 41 weeks. The infant, with a normal 46,XX female karyotype, weighed 3050 g with a length of 52 cm and a head circumference of 33.5 cm. Structural anomalies evident at birth were a bilateral upper cleft lip with complete cleft palate, bilateral microtia, hypertelorism, micrognathia, and mild left ptosis. Later examinations revealed a large chorioretinal coloboma in both eyes, bilateral absence of external ear canals, and small tympanic cavities

with abnormal auditory ossicles. Bilateral conductive hearing loss was diagnosed. At 9 months of age, the infant wore hearing aids, but her physical and neurodevelopment were normal for her age. The authors considered the abnormalities to be a characteristic phenotype caused by exposure to MMF (16).

In October 2007, the manufacturer of MMF and the FDA reported that postmarketing data from the NTPR and the Roche worldwide adverse-event reporting system had revealed that 1st trimester use of MMF was associated with pregnancy loss and an increased risk of congenital malformations (17). The FDA risk category was changed from C to D. The specific malformations involved the external ear, facial anomalies, including cleft lip/palate, and anomalies of the distal limbs, heart, esophagus, and kidney (17).

BREASTFEEDING SUMMARY

No reports describing the use of MMF or mycophenolate sodium during human lactation have been located. The relatively low molecular weight of MPA (about 319), the active metabolite of MMF, and its moderately long elimination half-lives (17.9 hours when MMF is taken and 8–16 hours when mycophenolate sodium is used) suggest that excretion of MPA into breast milk should be expected. There is a potential for serious adverse effects in a nursing infant, including an increased frequency of infections and the possible development of lymphoma that has been observed in adults. Until human data are available, MMF and mycophenolate sodium should be classified as contraindicated during breastfeeding.

N

NABILONE

Gastrointestinal Agent (Antiemetic)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of nabilone in human pregnancy have been located. Dose-related developmental toxicity consisting of growth restriction and death was observed in two animal species. In addition, unspecified postnatal toxicity was observed in one species. Nabilone is structurally related to delta-9-tetrahydrocannabinol (delta-9-THC), the active ingredient in marijuana. Although additional studies are needed, there is evidence that marijuana use in pregnancy is associated with developmental toxicity, such as growth restriction, long-term neurobehavioral deficits, and potentiation of the fetal effects of alcohol. (See Marijuana.) Because of the potential for adverse effects in the embryo and fetus, as well as the absence of human pregnancy experience, the best course is to avoid nabilone during gestation. Nevertheless, the use of this drug may be acceptable if other therapies, including hospitalization and treatment with IV antiemetics, have failed.

FETAL RISK SUMMARY

Nabilone is a synthetic cannabinoid that is indicated for the treatment of nausea and vomiting associated with cancer chemotherapy in patients who have failed to respond to other antiemetic regimens. The chemical structure is similar to delta-9-THC, the active ingredient in marijuana. The drug may produce disturbing psychotomimetic reactions and psychological dependence, and has

the potential to be abused. Nabilone is extensively metabolized, but the activity of the metabolites has not been characterized. The plasma half-lives of nabilone and its metabolites are 2 and 35 hours, respectively. Terminal elimination, mainly in the feces (67%) with smaller amounts in the urine (22%), occurs within 7 days. Although no accumulation of nabilone after repeated doses has been observed, accumulation of the metabolites may occur (1).

Reproduction studies have been conducted in rats and rabbits. There was no evidence of structural defects in pregnant rats and rabbits receiving oral doses up to about 16 and 9 times, respectively, the human dose based on BSA (HD). However, dose-related developmental toxicity, consisting of embryo death, fetal resorptions, decreased fetal weight, and pregnancy disruptions, was observed. Unspecified postnatal developmental toxicity also was observed in rats (1,2).

Studies for carcinogenicity have not been conducted with nabilone, but assays for genotoxicity were negative (2). Doses up to six times the HD had no effect on fertility or reproductive performance of male and female rats (1,2).

It is not known if nabilone crosses the human placenta. The molecular weight (about 373) and lipid solubility suggest that the drug will cross to the embryo and fetus, but the very short plasma half-life of the parent compound should limit the exposure.

BREASTFEEDING SUMMARY

No reports describing the use of nabilone during human lactation have been located. Nabilone is structurally similar to delta-9-THC, the active ingredient of marijuana (2). Delta-9-THC is known to be excreted into breast milk. (See Marijuana.) The molecular weight (about 373) and lipid solubility of nabilone suggest that it also will be excreted into breast milk, but the very short plasma half-life (2 hours) should limit the amount. The metabolites, whose activity has not been characterized, have a longer plasma half-life (35 hours) and, therefore, a greater potential for clinically significant concentrations in milk. However, the metabolites of delta-9-THC have not been detected in milk; this also could be the case for the metabolites of nabilone. The effects on the nursing infant from exposure to nabilone or its metabolites in the milk are unknown, but are of concern. Although no adverse effects of marijuana exposure from breast milk have been reported, follow-up of exposed infants is inadequate. Because of the potential for long-term toxicity in nursing infants, women taking nabilone should not breastfeed.

NABUMETONE

Nonsteroidal Anti-inflammatory

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 1st and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Constriction of the ductus arteriosus in utero is a pharmacologic consequence arising from the use of prostaglandin synthesis inhibitors during pregnancy, as is inhibition of labor, prolongation of pregnancy, and suppression of fetal renal function (see also Indomethacin) (1). Persistent pulmonary hypertension of the newborn may occur if these agents are used in the 3rd trimester close to delivery (1,2). Women attempting to conceive should not use any prostaglandin synthesis inhibitor, including nabumetone, because of the findings in several animal models that indicate these agents block blastocyst implantation (3,4). Moreover, as noted in the discussion below, nonsteroidal anti-inflammatory drugs (NSAIDs) have been associated with spontaneous abortions (SABs) and congenital malformations. The risk for these defects, however, appears to be small.

FETAL RISK SUMMARY

The NSAID nabumetone is used in the acute and chronic treatment of arthritis. Nabumetone is a prodrug that partially undergoes hepatic conversion to an active metabolite. It is in an NSAID subclass (naphthylalkanones) that contains no other agents.

The drug was not teratogenic in rats and rabbits but did produce toxicity similar to other agents in this class, including delayed parturition, dystocia, decreased fetal growth, and decreased fetal survival (5,6). Increased postimplantation loss in rats was observed at a dose equal to the average human exposure at the maximum recommended dose (1).

It is not known if nabumetone crosses the human placenta. The molecular weight (about 228) is low enough that passage to the embryo and fetus should

be expected.

A combined 2001 population-based, observational cohort study and a case–control study estimated the risk of adverse pregnancy outcome from the use of NSAIDs (7). The use of NSAIDs during pregnancy was not associated with congenital malformations, preterm delivery, or low birth weight, but a positive association was discovered with SABs. A similar study, also published in 2001, failed to find a relationship, in general, between NSAIDs and congenital malformations, but did find a significant association with cardiac defects and orofacial clefts (8). In addition, a 2003 study found a significant association between exposure to NSAIDs in early pregnancy and SABs (9). (See Ibuprofen for details on these three studies.)

A brief 2003 editorial on the potential for NSAID-induced developmental toxicity concluded that NSAIDs, and specifically those with greater cyclooxygenase 2 (COX-2) affinity, had a lower risk of this toxicity in humans than aspirin (10).

BREASTFEEDING SUMMARY

No reports describing the use of nabumetone during human lactation have been located. The molecular weight (about 228) is low enough that excretion into breast milk should be expected.

One reviewer listed several NSAIDs (diclofenac, fenoprofen, flurbiprofen, ibuprofen, ketoprofen, ketorolac, and tolmetin) that were considered safer alternatives to other agents (nabumetone not mentioned) if these drugs were required during nursing (11). Because of the long serum elimination half-life (≥ 22.5 hours) of the active metabolite in adults and the unknown amounts of the drug that are excreted into milk, any of these choices probably is preferable.

NADOLOL

Sympatholytic (Antihypertensive)

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Some β -blockers may cause intrauterine growth restriction (IUGR) and reduced placental weight, especially those lacking intrinsic sympathomimetic activity (ISA) (i.e., partial agonist). Treatment beginning early in the 2nd trimester results in the greatest weight reductions, whereas treatment restricted to the 3rd trimester primarily affects only placental weight. Nadolol does not possess ISA. However, IUGR and reduced placental weight may potentially occur with all agents within this class. Although growth restriction is a serious concern, the benefits of maternal therapy with β -blockers, in some cases, might outweigh the risks to the fetus and must be judged on a case-by-case basis.

FETAL RISK SUMMARY

Nadolol is a nonselective β_1, β_2 -adrenergic blocking agent used for hypertension and angina pectoris. The drug is not teratogenic in rats, hamsters, and rabbits, but embryotoxicity and fetotoxicity were observed in the latter species (1,2).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 71 newborns had been exposed to nadolol during the 1st trimester (F. Rosa, personal communication, FDA, 1993). One (1.4%) major birth defect was observed (three expected), a cardiovascular defect (one expected).

Only one published case of the use of nadolol in pregnancy has been located (3). A mother with immunoglobulin A nephropathy and hypertension was treated throughout pregnancy with nadolol, 20 mg/day, plus a diuretic (triamterene/hydrochlorothiazide) and thyroid. The infant, delivered by emergency cesarean section at 35 weeks' gestation, was growth restricted

and exhibited tachypnea (68 breaths/minute) and mild hypoglycemia (20 mg/dL). Depressed respirations (23 breaths/minute), slowed heart rate (112 beats/minute), and hypothermia (96.5°F) occurred at 4.5 hours of age. The lowered body temperature responded to warming, but the cardiorespiratory depression, with brief episodes of bradycardia, persisted for 72 hours. Nadolol serum concentrations in cord blood and in the infant at 12 and 38 hours after delivery were 43, 145, and 80 ng/mL, respectively. The cause of some or all of the effects observed in this infant may have been β -blockade (3). However, maternal disease could not be excluded as the sole or contributing factor behind the IUGR and hypoglycemia (3). In addition, hydrochlorothiazide may have contributed to the low blood glucose (see Chlorothiazide).

The authors identified several characteristics of nadolol in the adult that could potentially increase its toxicity in the fetus and newborn, including a long serum half-life (17–24 hours), lack of metabolism (excreted unchanged by the kidneys), and low protein binding (30%) (3). Because of these factors, other β -blockers may be safer for use during pregnancy, although persistent β -blockade has also been observed with acebutolol and atenolol. As with other agents in this class, long-term effects of in utero β -blockade have not been studied but warrant evaluation.

BREASTFEEDING SUMMARY

Nadolol is excreted into breast milk (3,4). A mother taking 20 mg of nadolol/day had a concentration in her milk of 146 ng/mL 38 hours after delivery (3). In 12 lactating women ingesting 80 mg once daily for 5 days, mean steady-state levels of nadolol, approximately 357 ng/mL, were attained at 3 days. This level was approximately 4.6 times higher than simultaneously measured maternal serum levels (4). By calculation, a 5-kg infant would have received 2%–7% of the adult therapeutic dose, but the infants were not allowed to breastfeed (4).

Because experience is lacking, nursing infants of mothers consuming nadolol should be closely observed for symptoms of β -blockade. Long-term effects of exposure to β -blockers from milk have not been studied but warrant evaluation. The American Academy of Pediatrics classifies nadolol as compatible with breastfeeding (5).

NADROPARIN

[Withdrawn from the market. See 9th edition.]

NAFCILLIN

Antibiotic (Penicillin)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Although the reported pregnancy experience with nafcillin is limited, all penicillins are considered low risk in pregnancy.

FETAL RISK SUMMARY

Nafcillin is a penicillin antibiotic (see also Penicillin G). No reports linking its use with congenital defects have been located. The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 3546 of whom had 1st trimester exposure to penicillin derivatives (1, pp. 297–313). For use anytime during pregnancy, 7171 exposures were recorded (1, p. 435). In neither group was evidence found to suggest a relationship to large categories of major or minor malformations or to individual defects.

BREASTFEEDING SUMMARY

No reports describing the use of nafcillin during human lactation have been located. (See also Penicillin G.)

NAFTIFINE

Antifungal

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of naftifine in human pregnancy have been located. The animal data, although based on body weight, suggest low risk, but the absence of human pregnancy experience prevents a more complete assessment of the pregnancy risk. However, the low systemic bioavailability suggests that the amounts reaching the embryo and/or fetus are clinically insignificant. The topical use of this agent during pregnancy probably is low risk.

FETAL RISK SUMMARY

Naftifine is a broad-spectrum, antifungal agent that is available as a 1% topical cream. It has both fungicidal and fungistatic activity. Chemically, naftifine is a synthetic allylamine derivative in the same class as terbinafine. Approximately 6% of an applied dose is absorbed systemically from healthy skin. The plasma elimination half-lives of naftifine and its metabolites are about 2–3 days (1).

Reproduction studies have been conducted with oral doses in rats and rabbits. In these species, oral doses 150 or more times the human topical dose revealed no evidence of impaired fertility or fetal harm. Studies for carcinogenicity have not been performed, but in vitro and animal studies did not demonstrate mutagenicity (1).

It is not known if naftifine and/or its metabolites cross the human placenta. The molecular weight of the parent drug (about 324) and the prolonged elimination half-life suggest that the drug will cross to the embryo and/or fetus. The low systemic bioavailability should prevent clinically significant exposure of the embryo/fetus.

BREASTFEEDING SUMMARY

No reports describing the use of naftifine during human lactation have been located. The low molecular weight (about 324) and the prolonged elimination half-life from the systemic circulation suggest that it will be excreted into breast milk. The systemic bioavailability after topical application of the 1% cream is low (about 6%), so the amount in milk, if any, probably is clinically insignificant. The cream should not be applied to the nipples or breasts if breastfeeding.

NALBUPHINE

Narcotic Agonist–Antagonist Analgesic

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 3rd Trimester

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

No congenital defects have been reported in humans or in experimental animals following the use of nalbuphine in pregnancy (1). Nalbuphine has both narcotic agonist and antagonist effects. Prolonged use during pregnancy could theoretically result in fetal addiction with subsequent withdrawal in the newborn (see also Pentazocine). The use of the drug in labor may produce fetal distress and neonatal respiratory depression comparable with that produced by meperidine (1–6).

FETAL RISK SUMMARY

Nalbuphine is indicated for the relief of moderate-to-severe pain. It also is used as a supplement to balanced anesthesia, for preoperative and postoperative analgesia, and for obstetrical analgesia during labor and delivery. The plasma half-life is 5 hours (2).

Reproduction studies in rats and rabbits at doses up to 6 and 4 times, respectively, the maximum recommended human dose (MRHD) revealed no evidence of impaired fertility or fetal harm (2). Administration to rats at doses 4 times the MRHD during at least the last third of gestation and during lactation reduced both neonatal body weight and survival (2).

Nalbuphine crosses the placenta to the fetus (6–8). The cord:maternal serum ratio in five women in active labor given 20 mg as an IV bolus ranged from 0.37 to 6.03 (7). A sixth patient given 15 mg had a ratio of 1.24. Umbilical cord concentrations of nalbuphine obtained 3–10 hours after a dose varied from “not detectable” to 46 ng/mL. The terminal half-life of the drug in the mothers was 2.4 hours. In another study, the fetal:maternal ratio was 0.74 at delivery and the estimated neonatal plasma half-life was 4.1 hours (8).

A sinusoidal fetal heart rate pattern was observed after a 10-mg IV dose administered to a woman in labor at 42 weeks' gestation (9). The sinusoidal pattern persisted for at least 2.25 hours, and periodic late decelerations became evident. A cesarean section was performed to deliver a healthy female infant with Apgar scores of 8 and 9 at 1 and 5 minutes, respectively, who did well following delivery. The authors attributed the persistent sinusoidal pattern to the prolonged plasma half-life in adults (9).

A 1987 reference compared the use of nalbuphine administered during labor via either a patient-controlled analgesia (PCA) IV pump or by direct IV-push doses (10). No differences were observed between the groups in terms of fetal distress, as evidenced by late decelerations or abnormal scalp blood pH, or in Apgar scores, but specific details on the newborns were not given. However, the fetuses of women receiving nalbuphine by the PCA system had a higher incidence of variable heart rate decelerations (10).

In a 1991 study, IV nalbuphine (N = 70; 10 mg) and meperidine (N = 67; 50 mg) were compared for analgesia during the active phase of labor at term (11). Neither regimen had an advantage over the other, but, in the nalbuphine group, there were significantly more newborns with a 1-minute Apgar score <7 (10.6% vs. 1.7%, $p < 0.05$). Of note, the time interval between the dose of the two drugs and delivery was not provided although it was >1 hour (11).

BREASTFEEDING SUMMARY

No reports describing the use of nalbuphine during breastfeeding have been located. The manufacturer states that small amounts (<1% of the mother's dose) are excreted into breast milk and these amounts are clinically insignificant (2).

In a 2007 report, 18 non-breastfeeding women immediately after delivery were given IV nalbuphine (0.2 mg/kg every 4 hours) and ketoprofen (100 mg every 12 hours) for postpartum pain (12). The mean and maximum nalbuphine milk concentrations were 42 and 61 ng/mL, respectively. Assuming a milk volume of 150 mL/kg/day, the estimated mean and maximum infant doses were 7.0 and 9.0 mcg/kg/day, respectively. The relative infant dose as a percentage of the weight-adjusted maternal dose was 0.59% (12). (See Ketoprofen for additional data.)

Because nalbuphine has poor oral absorption, it is unlikely to adversely affect a nursing infant.

NALIDIXIC ACID

Urinary Germicide

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

The animal data suggest moderate risk, but the human data are limited. In a large case–control study, a possible association, based on seven cases, was found with pyloric stenosis. However, the association might have occurred by chance. Because nalidixic acid has been available for many years, the lack of other reports of developmental toxicity is reassuring.

FETAL RISK SUMMARY

No reports linking the use of nalidixic acid, a quinolone antibacterial agent, with congenital defects have been located. At oral doses six times the human dose, nalidixic acid was embryocidal and teratogenic in rats (1). Prolongation of pregnancy was also noted, especially at four times the human dose. Similar to other agents in this class, nalidixic acid causes arthropathy in immature animals (1).

Chromosomal damage was not observed in human leukocytes cultured with various concentrations of the drug (2). One author cautioned that the drug should be avoided in late pregnancy because it may produce hydrocephalus (3). However, a subsequent report examined the newborns of 63 patients treated with nalidixic acid at various stages of gestation (4). No defects attributable to the drug or intracranial hypertension were observed.

A study using the population-based dataset of the Hungarian Case-Control Surveillance of Congenital Abnormalities 1980–1996 was published in 2001 (5). There were 22,865 cases with congenital malformations and 38,151 controls without birth defects in the dataset. The control group was 1.8% of the total number of births (2,146,574) in Hungary during the study period. Exposure to nalidixic acid during gestation occurred in 242 (1.1%) cases compared with 377 (1.0%) controls (crude odds ratio [OR] 1.1, 95% confidence interval [CI] 0.9–

1.3). Seventeen congenital abnormality groups were analyzed and OR and 95% CI were calculated for exposure in the 2nd and 3rd months and the entire pregnancy. No increased risk was found with use of nalidixic acid in the 1st trimester. However, there was an increased prevalence of pyloric stenosis when the mother took the drug in the last few months of gestation (7 cases; OR 8.0, 95% CI 1.0–66.4). Although the results suggested an association, a chance relationship could not be excluded (5).

BREASTFEEDING SUMMARY

Nalidixic acid is excreted into breast milk in low concentrations (6–8). Hemolytic anemia was reported in one infant with glucose-6-phosphate dehydrogenase deficiency whose mother was taking 1 g 4 times a day (6). Milk levels were not measured in this case, but the author noted data from the manufacturer in which milk levels from four women taking a similar dose were found to be 4 mcg/mL. The milk:plasma ratio has been reported as 0.08–0.13 (7).

A 1980 report described the excretion of unmetabolized nalidixic acid into the breast milk of 13 women, 3–8 days postpartum, following a 2-g oral dose (8). Nursing was suspended on the day of the test. Milk was collected from each woman for a 24-hour period and serum samples were taken 7 hours after the dose. The highest milk concentration of the drug occurred in the sample collected from 0 to 4 hours, 0.64 mcg/mL, but the total unchanged drug excreted over 24 hours was only 0.003% of the mother's dose. The milk:serum ratio at 7 hours was 0.061, and the minimal inhibitory concentration of about 3 mcg/mL was never reached (8).

The quantities measured above are normally considered insignificant (9). Although noting the single case of hemolytic anemia described above, the American Academy of Pediatrics classifies nalidixic acid as compatible with breastfeeding (10).

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Naloxone is a narcotic antagonist that is used to reverse the effects of narcotic overdose. The drug has no intrinsic respiratory depressive actions or other narcotic effects of its own (1).

FETAL RISK SUMMARY

Reproduction studies in mice and rats at doses up to 50 times the usual human dose revealed no evidence of impaired fertility or fetal harm (2).

Naloxone crosses the human placenta, appearing in fetal blood 2 minutes after a maternal dose and gradually increasing over 10–30 minutes (3).

In three reports, naloxone was given to mothers in labor after the administration of meperidine (4–6). One study found that 18–40 mcg/kg (maternal weight) given IV provided the best results in comparison with controls who did not receive meperidine or naloxone (5). In measurements of newborn neurobehavior, groups treated in labor with either meperidine or meperidine plus naloxone (0.4 mg) were compared with a nontreated control group (6). The control group scored better in the first 24 hours than either of the treated groups and, after 2 hours, no difference was found between meperidine and meperidine plus naloxone-treated patients. Women in active labor received 1.0 mg of morphine intrathecal followed in 1 hour by a 0.4-mg IV bolus of naloxone plus 0.6 mg/hr or placebo as constant infusion for 23 hours (7). A reduction in some morphine-induced maternal side effects was seen with naloxone, but no significant differences with placebo were found for fetal heart rate or variability, Apgar scores, umbilical venous and arterial gases, neonatal respirations, or neurobehavioral examination scores. The cord blood:maternal serum ratio for naloxone was 0.50. Naloxone has also been safely given to newborns within a few minutes of delivery (8–13).

Naloxone has been used at term to treat fetal heart rate baselines with low beat-to-beat variability not caused by maternally administered narcotics (14). This use was based on the assumption that the heart rate patterns were caused by elevated fetal endorphins. In one case, however, naloxone may have enhanced fetal asphyxia, leading to fatal respiratory failure in the newborn (14). Based on the above data, naloxone should not be given to the mother just before delivery to reverse the effects of narcotics in the fetus or newborn unless narcotic toxicity is evident. Information on its fetal effects during pregnancy, other than labor, is not available.

In a study of the effects of naloxone on fetal behavior, 54 pregnant women with gestational ages between 37 and 39 weeks were evenly divided into two groups (15). One group received 0.4 mg of naloxone and the other received an equal volume of saline placebo. In the group receiving naloxone, significant increases were observed in the number, duration, and amplitude of fetal heart rate accelerations. Significant increases were also observed in the number of fetal body movements and the percentage of time spent breathing. Moreover, significantly more fetuses exposed to naloxone were actively awake than those not exposed. The investigators attributed their findings to reversal of the effects of fetal endorphins.

BREASTFEEDING SUMMARY

No reports describing the use of naloxone during human lactation have been located.

NALTREXONE

Narcotic Antagonist

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Except for the following reports in which the naltrexone was discontinued very early in gestation, no other references describing the use of the agent during human pregnancy have been located. Although naltrexone did not produce gross structural abnormalities in any of the animal studies, it did alter some opioid receptors in the brain that appeared to have long-lasting consequences. This potential for behavioral alteration in humans cannot be assessed because of the lack of data, but concern is warranted.

FETAL RISK SUMMARY

Naltrexone is an opioid antagonist that is indicated in the treatment of alcohol dependence and for the blockade of the effects of exogenously administered opioids. The agent is a synthetic congener of oxymorphone and is also related to another opioid antagonist, naloxone. The major metabolite is 6- β -naltrexol. Plasma protein binding is low (21%) and the mean elimination half-lives for naltrexone and its major metabolite are 4 and 13 hours, respectively (1).

In fertility studies, a significant increase in pseudopregnancy and a decrease in the pregnancy rate after mating were observed in rats given a dose that was 16 times the recommended human therapeutic dose based on BSA (RHTD). No adverse effects on male rat fertility were seen at this dose. A significant increase in early fetal loss was observed in rats and rabbits at 5 and 18 times the RHTD, respectively. No evidence of teratogenicity was found in either species at doses up to 32 and 65 times the RHTD, respectively, administered during organogenesis. Because rats do not form appreciable amounts of the major metabolite found in humans (6- β -naltrexol), the potential reproductive toxicity of the metabolite is unknown (1).

An animal study published in 1984 evaluated the reproductive effects of naltrexone in rats and rabbits (2). In rats, prolonged administration of naltrexone at doses that did not affect body weight produced excitatory signs in both sexes, increased production of seminal plugs in males, and decreased estrus cycling and fertility in females. No adverse effect on mating activity was observed, but there was an increase in pseudopregnancy in those receiving 100 mg/kg/day. Fertility was also reduced (i.e., fewer females became pregnant) when both sexes received this dose. No evidence of teratogenicity or embryo toxicity was noted in either pregnant rats or rabbits (2).

When administered to rats near term (20 days' gestation), naltrexone crossed the placenta and was measured in all fetal tissues (3).

In an experiment with stressed (noise and light at unpredictable frequency) pregnant rats, a continuous infusion of naltrexone (10 mg/kg/day) was administered by implanted minipumps from day 17 of gestation (4). Compared with controls receiving an infusion of vehicle only, naltrexone prevented the reduction in anogenital distance in male pups and restored the growth rate in both sexes. Other adverse fetal effects of prenatal stress were also prevented by naltrexone, leading the authors to conclude that some of the morphologic and behavioral changes induced by prenatal stress may result from excess opioid activity (4).

The effects of daily injections of naltrexone (50 mg/kg) administered to rats throughout gestation on fetal growth were described in a 1997 publication (5). Compared with controls given daily injections of saline, naltrexone-exposed pups had greater body weights, crown–rump lengths, and organ and skeletal muscle weights. Naltrexone had no effect on the length of gestation, course of pregnancy, litter size, or viability of the mother or offspring (5). The effects on growth were attributed to the blocking of endogenous opioids.

Decreased sensitivity to morphine has been observed in rat offspring exposed in utero to naltrexone (6,7). The appreciation of pain was not affected. However, insensitivity was not observed to butorphanol (7). These results raise the possibility that, later in life, morphine would provide less-effective analgesia in human offspring who were exposed during gestation to naltrexone.

Other rat studies have also demonstrated that naltrexone can modify behavior of both the mother and the offspring (8–10). Naltrexone was administered at parturition to ewes lambing for the first time (8). Compared with controls, naltrexone significantly delayed the onset of maternal behavior (licking and bleating) toward the newborn. The drug facilitated sexual behavior in adult male rats who had been exposed in utero (9). Another study found that

naltrexone exposure throughout gestation modified postnatal behavioral development of rat offspring (10). The investigators concluded that blocking the endogenous opioid systems during embryogenesis altered the somatic, physical, and behavioral development after birth. Of interest, a 1998 study found that naltrexone was present in the brains and hearts of newborn rats after maternal administration during gestation, but it was not present on postnatal days 2 and 10 (11). The investigators concluded that the somatic and neurobiological acceleration observed in previous studies was not due to opioid receptor blockade during the postnatal period (11).

It is not known if naltrexone or its metabolite crosses the human placenta. The molecular weight of naltrexone (about 342 for the free base), low plasma protein binding, and long elimination half-lives of naltrexone and the major metabolite suggest that one or both agents will cross to the embryo–fetus.

Two 1993 reports, from the same research group, described the use of naltrexone (25–150 mg/day for 4–100 weeks) in 138 women with various grades of hypothalamic or hyperandrogenic ovarian failure (12,13). A total of 24 pregnancies in 22 women were achieved. Naltrexone was discontinued as soon as pregnancy had been diagnosed. Four pregnancies ended in an early spontaneous abortion (SAB), six women had given birth (no data provided on newborn condition), eight pregnancies were ongoing, and no information was given for six cases. A 1995 study of women with functional hypothalamic amenorrhea, however, found that even after priming with exogenous estradiol and progesterone or pulsatile gonadotropin-releasing hormone, the continued use of naltrexone alone did not maintain gonadotropin secretion and eventual ovulation (14).

Continuous naltrexone (50 mg/day), either alone or with intermittent clomiphene, has been used successfully in women with clomiphene-resistant normogonadotrophic anovulation (15). In this study, 19 of 22 women achieved ovulation and 12 singleton pregnancies were documented. Naltrexone was discontinued when pregnancy was diagnosed. The outcomes of the pregnancies included two SABs and eight ongoing pregnancies (15).

BREASTFEEDING SUMMARY

Consistent with the molecular weight of naltrexone (about 342), low plasma protein binding (21%), and long elimination half-lives of naltrexone (4 hours) and 6- β -naltrexone (major metabolite) (13 hours), both agents are excreted into breast milk.

In a 2004 case report, a 30-year-old woman was taking naltrexone (50

mg/day) for opiate addiction while breastfeeding her 1.5-month-old male infant (16). The mother had started the drug during the latter part of pregnancy and had been taking it for 135 days before the study. The mean milk concentrations of the parent drug and metabolite were 1.6 and 46 mcg/L, respectively. The measured relative infant doses as a percentage of the maternal dose were 0.03% (naltrexone) and 0.83% (metabolite). The healthy infant was achieving expected milestones and had no adverse effects (16). Although this report is reassuring, additional data are warranted and use during lactation should be evaluated on a case-by-case basis.

NAPHAZOLINE

Ophthalmic (Sympathomimetic)

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The human pregnancy experience with naphazoline is very limited and animal reproduction studies have not been conducted. In addition, reports describing the amount of drug in the systemic circulation after nasal or ophthalmic use have not been located. However, it is doubtful if appropriate short-term use results in clinically significant systemic concentrations. Thus, the occasional use of naphazoline does not appear to represent a risk to the embryo and/or fetus.

FETAL RISK SUMMARY

Naphazoline is an α -adrenergic agonist that is used as a topical vasoconstrictor to relieve eye redness and as an intranasal spray to treat symptoms of nasal congestion. The drug is available over the counter (1,2).

Reproduction studies in animals have not been conducted (1,2). In addition, no studies evaluating the carcinogenicity or mutagenicity of naphazoline, or its effects on fertility have been located.

It is not known if clinically significant amounts of naphazoline cross the human placenta. The molecular weight (about 210 for the free base) is low enough, but the systemic concentrations after ocular or nasal use should be low.

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 20 of whom had 1st trimester exposure to naphazoline (3, pp. 346–347). No evidence was found to suggest a relationship between large categories of major or minor malformations or to individual defects. However, an association in the 1st trimester was found between the sympathomimetic class of drugs as a whole and minor malformations (not life-threatening or major cosmetic defects), inguinal hernia, and clubfoot (3, pp. 345–356).

A 1995 report described a case in which naphazoline nasal spray was used repeatedly throughout pregnancy (4). The newborn had cyanosis, hypertension, and ischemia of the foot. The cause of the outcome could not be determined (4).

BREASTFEEDING SUMMARY

No reports describing the use of naphazoline during human lactation have been located. The molecular weight (about 210 for the free base) is low enough for excretion into breast milk, but the expected low systemic concentrations after ocular or nasal use should limit the exposure of the infant. Thus, occasional use of naphazoline during breastfeeding appears to be compatible.

NAPROXEN

Nonsteroidal Anti-inflammatory

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 1st and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Exposure to nonsteroidal anti-inflammatory drugs (NSAIDs), including naproxen, during the 1st trimester appears to be a risk for structural anomalies and spontaneous abortions (SABs). The structural defects usually involve the heart, especially septal defects, but associations with oral clefts also have been reported. The absolute risk for these defects, however, appears to be low. When used in the 3rd trimester, NSAIDs have the potential to cause premature closure of the ductus arteriosus, which, in some cases, may result in primary pulmonary hypertension of the newborn (PPHN). In addition, the use of NSAIDs as tocolytics has been associated with an increased risk of neonatal complications, such as necrotizing enterocolitis, patent ductus arteriosus, and intraventricular hemorrhage (1), but further studies are required to confirm the magnitude of these toxicities. Because of the potential newborn toxicity, naproxen should not be used late in the 3rd trimester (1–3). Moreover, women attempting to conceive should not use any prostaglandin synthesis inhibitor, including naproxen, because of the findings in various animal models, indicating that these agents block blastocyst implantation (4,5).

Women who are pregnant or are at risk of pregnancy should be counseled on these risks. Such counseling is especially important because the use of NSAIDs during pregnancy, either prescribed or over the counter (OTC), is very common. One report stated that the use of ibuprofen in pregnancy occurred in 14.9% of the patients studied, 52% (45 of 86) of whom were exposed in the first trimester (6). NSAIDs available as OTC products in the United States include ibuprofen and naproxen, either as single-ingredient products or in decongestant/analgesic combinations. Thus, women might be exposed to NSAIDs at any time in gestation without

realizing they are taking a drug with the potential for developmental toxicity.

FETAL RISK SUMMARY

Naproxen is an NSAID used in the management of the signs and symptoms of rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, and juvenile arthritis. It is in the same subclass (propionic acids) as five other NSAIDs (fenoprofen, flurbiprofen, ibuprofen, ketoprofen, and oxaprozin). Drugs in this class have been shown to inhibit labor and to prolong the length of pregnancy (1,7).

Animal reproduction studies have been conducted in mice, rats, and rabbits. At 0.23–0.28 times, the human systemic exposure at the recommended dose, no evidence of impaired fertility or fetal harm was seen in these species (1). It was not stated if maternal toxicity prevented higher doses. A 1990 report described an investigation on the effects of several NSAIDs on mouse palatal fusion both in vivo and in vitro (8). The compounds, including naproxen, were found to induce cleft palate.

Consistent with the relatively low molecular weight (about 230), naproxen readily crosses the placenta to the fetal circulation. Twenty-eight women received two 500-mg naproxen doses, the first within 10.5–15 hours and the second within 4 hours of an elective 1st trimester pregnancy termination (9). Mean naproxen levels in maternal serum, fetal tissue, coelomic fluid, and amniotic fluid were 69.5, 6.4, 1.85, and 0.14 mcg/mL, respectively. The mean fetal:maternal drug ratio was 0.092 (9). In a woman at 30 weeks' gestation treated with 250 mg of naproxen every 8 hours for four doses, plasma levels in twins 5 hours after the last dose were 59.5 and 68 mcg/mL (10).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 1448 newborns had been exposed to naproxen during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 70 (4.8%) major birth defects were observed (62 expected). Specific data were available for six defect categories, including (observed/expected) 14/14 cardiovascular defects, 2/2 oral clefts, 0/1 spina bifida, 3/4 polydactyly, 2/2 limb reduction defects, and 3/3 hypospadias. These data do not support an association between the drug and congenital defects.

A combined 2001 population-based, observational cohort study and a case–control study estimated the risk of adverse pregnancy outcome from the use of NSAIDs (2). The use of NSAIDs during pregnancy was not associated with congenital malformations, preterm delivery, or low birth weight, but a positive

association was discovered with SABs. A similar study, also published in 2001, failed to find a relationship, in general, between NSAIDs and congenital malformations but did find a significant association with cardiac defects and orofacial clefts (11). In addition, a 2003 study found a significant association between exposure to NSAIDs in early pregnancy and SABs (12). (See Ibuprofen for details on these three studies.)

A brief 2003 editorial on the potential for NSAID-induced developmental toxicity concluded that NSAIDs, and specifically those with greater cyclooxygenase 2 (COX-2) affinity, had a lower risk of this toxicity in humans than aspirin (13).

A 2003 study using data from three Swedish health registers (1995–2001) that included maternal drug history collected prospectively identified 1142 infants with orofacial clefts (isolated or with other malformations, excluding chromosome anomalies) (14). Compared with the expected number (2.9) of orofacial clefts, there were eight naproxen-exposed cases, a relative risk of 2.72 (95% confidence interval [CI] 1.17–5.36).

A 2003 case–control study, using data from the same Swedish registers as the above study, was conducted to identify drug use in early pregnancy that was associated with cardiac defects (15). Cases (cardiovascular defects without known chromosome anomalies) (N = 5015) were compared with controls consisting of all infants born in Sweden from 1995 to 2001 (N = 577,730). Associations were identified for several drugs, some of which were probably due to confounding from the underlying disease or complaint or multiple testing, but some were thought to be true drug effects. For NSAIDs, the total exposed, number of cases, and odds ratios (ORs) with 95% CI were NSAIDs (all) (7698; 80 cases; 1.24, 0.99–1.55), naproxen (1679; 24 cases; 1.70, 1.14–2.54), diclofenac (1362; 15 cases; 1.30, 0.78–2.16), ibuprofen (4124; 37 cases; 1.08, 0.78–1.50), and aspirin (5920; 52 cases; 1.01, 0.76–1.33). Five of the defects observed with naproxen were two infants with transposition of the great vessels and three with endocardial cushion defects (one infant had both defects). The authors noted that further studies were needed to verify or reject the hypothesis (15).

A 2004 case report described a 24-year-old woman who took naproxen (550 mg about twice a week), bisoprolol (5 mg/day), and sumatriptan (100 mg about once a week) for migraine headaches during the first 5 weeks of pregnancy (16). An elective cesarean section was performed at 37 weeks' for breech presentation to deliver a 3125-g male infant. The infant had a wide bilateral cleft lip/palate, marked hypertelorism, a broad nose, and bilateral but

asymmetric toe abnormalities (missing and hypoplastic phalanges) (16).

A 2006 case–control study found a significant association between congenital anomalies, specifically cardiac septal defects, and the use of NSAIDs in the 1st trimester (17). A population-based pregnancy registry (N = 36,387) was developed by linking three databases in Quebec. The combined database covered all of the pregnancies that occurred in Quebec from January 1997 through June 2003. Inclusion criteria were mothers of singleton infants, 15–45 years of age, who were prescribed an NSAID or other medications during pregnancy. The use of OTC NSAIDs was a potential confounder but the investigators provided reasonable arguments that such exposure was unlikely. The data were adjusted for chronic comorbidities, including rheumatoid arthritis and disease-modifying anti-rheumatic drugs, hypothyroidism and thyroid drugs, and chronic or gestational hypertension. Adjustment also was made for 1st trimester use of known human teratogens (17).

Case infants were those with any congenital anomaly diagnosed in the first year of life (17). Up to 10 controls (infants without a congenital anomaly) were selected for each case and matched with cases for maternal age, urban or rural residence, gestational age, and diabetes status. There were 93 infants (8.8%) with congenital defects from 1056 mothers who had filled prescriptions for NSAIDs in the 1st trimester. In controls, there were 2478 infants (7%) with anomalies from 35,331 mothers who had not filled such a prescription. The adjusted OR (aOR) was 2.21 (95% CI 1.72–2.85). The aOR for cardiac septal closure was 3.34 (95% CI 1.87–5.98). There also was a significant association for anomalies of the respiratory system 9.55 (95% CI 3.08–29.63), but this association disappeared when cases coded as “unspecified anomaly of the respiratory system” were excluded. For the cases involving septal closure, 61% were atrial septal defects and 31% were ventricular septal defects. There were no significant associations for oral clefts or defects involving other major organ systems. The five most common NSAIDs were naproxen (35%), ibuprofen (26%), rofecoxib (15%), diclofenac (9%), and celecoxib (9%). Among these agents, the only significant association was for ibuprofen prescriptions in the 1st trimester and congenital defects ($p < 0.01$) (17).

Prostaglandin synthesis inhibitors may cause constriction of the ductus arteriosus in utero, which may result in PPHN (18–22). The dose, duration, and period of gestation are important determinants of these effects. Most studies of NSAIDs used as tocolytics have indicated that the fetus is relatively resistant to premature closure of the ductus before the 34th or 35th week of gestation (see Indomethacin). However, three fetuses (one set of twins) exposed to naproxen

at 30 weeks for 2–6 days in an unsuccessful attempt to halt premature labor had markedly decreased plasma concentrations of prostaglandin E. PPHN with severe hypoxemia, increased blood clotting times, hyperbilirubinemia, and impaired renal function were observed in the newborns. One infant died 4 days after birth, probably because of subarachnoid hemorrhage. Autopsy revealed a short and constricted ductus arteriosus. Use in other patients for premature labor at 34 weeks or earlier has not resulted in neonatal problems (23,24).

In a case report published in 2000, a mother took an OTC preparation of naproxen 220 mg twice a day over the 4 days immediately preceding birth of a term 3790-g male infant (25). Within 2 hours of birth, the infant developed typical signs and symptoms of PPHN with a closed ductus arteriosus. Conservative management was initiated and the infant was improving by the sixth postnatal day. At 6 weeks of age, the infant was doing well clinically without cyanosis (25).

A 2012 report from the National Birth Defects Prevention Study found associations between exposures to NSAIDs (aspirin, ibuprofen, and naproxen) and several birth defects (26). The data for this case–control study came from approximately 20,470 women with expected due dates in 1997–2004. Among this group, 3173 women (15.5%) were exposed to NSAIDs in the 1st trimester. Although the results suggested that NSAIDs are not a major cause of birth defects, the study did find several small-to-moderate but statistically significant increases in nine defects. The drug, aOR, and 95% CI for each defect were anencephaly/craniorachischisis— aspirin (2.1; 1.1–4.3); spina bifida—ibuprofen (1.6; 1.2–2.1); encephalocele—naproxen (3.5; 1.2–10); anophthalmia/microphthalmia— aspirin (3.0; 1.3–7.3), ibuprofen (1.9; 1.1–3.3), and naproxen (2.8; 1.1–7.3); cleft lip ± cleft palate—ibuprofen (1.3; 1.1–1.6) and naproxen (1.7; 1.1–2.5); cleft palate— aspirin (1.8; 1.1–2.9); transverse limb deficiency—naproxen (2.0; 1.0–3.8); amniotic bands/limb body wall— aspirin (2.5; 1.1–5.6) and ibuprofen (2.2; 1.4–3.5); and a heart defect (isolated pulmonary valve stenosis)—naproxen (2.4; 1.3–4.5). The analysis of the latter defect was limited to term births only. The authors acknowledged that further studies were needed because most of these associations had not been reported from other databases (26).

BREASTFEEDING SUMMARY

Naproxen passes into breast milk in very small quantities. The milk:plasma ratio is approximately 0.01 (1). Following 250 or 375 mg twice daily, maximum milk levels were found 4 hours after a dose and ranged from 0.7 to 1.25 mcg/mL

and 1.76 to 2.37 mcg/mL, respectively (27,28). The total amount of naproxen excreted in the infant's urine was 0.26% of the mother's dose. The effect on the infant from these amounts is unknown.

The American Academy of Pediatrics classifies naproxen as compatible with breastfeeding (29).

NARATRIPTAN

Antimigraine

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Naratriptan is not an animal teratogen but does produce dose-related embryo and fetal developmental toxicity. Human pregnancy experience, however, is too limited to assess the embryo–fetal risk. Although a 2008 review of triptans in pregnancy found no evidence for teratogenicity, the data did suggest a possible increase in the rate of preterm birth (1).

FETAL RISK SUMMARY

Naratriptan is an oral selective serotonin (5-hydroxytryptamine; 5-HT) receptor subtype agonist used for the acute treatment of migraine headaches. The safety and effectiveness of naratriptan have not been established for cluster headaches. Plasma protein binding is low (28%–31%) and the elimination half-life is 6 hours (2).

Developmental toxicity was observed in pregnant rats and rabbits at oral doses producing maternal plasma drug levels as low as 11 and 2.5 times, respectively, the plasma levels in humans receiving the maximum recommended daily dose of 5 mg (MRDD). Toxicity consisted of embryo lethality, minor fetal structural variations, pup mortality, and offspring growth restriction. In pregnant rats during the period of organogenesis, daily oral doses of 10, 60, and 340 mg/kg/day that resulted in maternal plasma levels 11, 70, and 470 times the human plasma levels obtained with the MRDD, respectively, were associated with dose-related increases in embryonic death and in the incidence of fetal structural variations: incomplete, irregular ossification of skull bones, sternebrae, and ribs. A no-effect dose for these toxicities was not established. The highest dose was associated with maternal toxicity as evidenced by decreased body weight gain. When naratriptan was administered before and

throughout the mating period at ≥ 60 mg/kg/day, there was an increase in preimplantation loss. Impairment of fertility in both male (testicular effects) and female (anestrus) rats occurred at higher doses. Exposure to the two highest doses—60 and 340 mg/kg/day—late in gestation and during lactation resulted in offspring behavioral impairment (tremors) and decreased viability and growth (2).

Pregnant rabbits received daily oral doses during organogenesis, which produced maternal plasma levels ranging from 2.5 to 140 times the human levels produced by the MRDD. Developmental toxicity, observed at all doses, consisted of embryonic death and fetal variations (major blood vessel variations, supernumerary ribs, and incomplete skeletal ossification). Fetal skeletal malformation (fused sternbrae) was observed in one rabbit subspecies at the highest dose. A no-effect dose for these toxicities was not established (2).

It is not known if naratriptan crosses the human placenta. The molecular weight (about 336 for the free base), low plasma protein binding, and long elimination half-life suggest that the drug will cross.

The Sumatriptan/Naratriptan/Treximet Pregnancy Registry, covering the period January 1, 1996, through April 30, 2009, has outcome data for 57 prospectively enrolled (reported before pregnancy outcome was known) pregnancies exposed to naratriptan. There were 52 with earliest exposure in the 1st trimester and 5 in the 2nd trimester. Among those with earliest exposure in the 1st trimester, the outcomes included 45 live births without defects, 1 induced abortion without defect, 5 spontaneous abortions (SABs), and 1 infant (also exposed to sumatriptan in the 1st trimester) with a small ventricular septal defect that was expected to close spontaneously. There were no birth defects in the five cases with earliest exposure in the 2nd trimester. Excluding the fetal death and SABs, the observed proportion of birth defects in the 1st trimester group was 2.2% (95% confidence interval 0.1%–13.0%). The prevalence of birth defects in women with migraine has been estimated at 3.4% (3,4).

Retrospective reports (reported after the outcome was known) are often biased (only adverse outcomes are reported). There were three retrospective reports of birth defects exposed in the 1st trimester. Review of all birth defects from prospective and retrospective reports revealed no signal or consistent pattern to suggest a common cause (4). (See Sumatriptan for required statement.)

Data from the Norwegian Mother and Child Cohort Study were published in

2010 (5). Of the 1535 pregnant women exposed to triptans, 36 were exposed to naratriptan. The exposed group was compared with 68,021 women who did not use triptans. There were no significant associations between 1st trimester exposure to triptans and major congenital anomalies (adjusted odds ratio [OR] 1.0, 95% confidence interval [CI] 0.7–1.2) or other adverse pregnancy outcomes. However, exposure in the 2nd and 3rd trimesters was significantly associated with atonic uterus (OR 1.4, 95% CI 1.1–1.8) and >500 mL blood loss during labor (OR 1.3, 95% CI 1.1–1.5) (5).

BREASTFEEDING SUMMARY

No reports describing the use of naratriptan during human lactation have been located. The molecular weight (about 336 for the free base), low plasma protein binding (28%–31%), and the long elimination half-life (6 hours) suggest that the drug will be excreted into breast milk. The effect of this exposure, if any, on a nursing infant is unknown. However, a brief 2010 review concluded that the minimal amounts of other triptans excreted into breast milk are insufficient to cause adverse effects in breastfeeding infants (6).

NATALIZUMAB

Immunologic Agent (Immunomodulator)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The extensive human pregnancy experience has not shown an increase in structural anomalies, spontaneous abortions (SABs), or fetal death. However, a study described below did find that exposure in the second half of pregnancy impaired the immune system of two newborns, a finding similar to the effect observed in adults treated with the drug. The clinical significance of this impairment requires supportive data. In 2011, the World Congress of Gastroenterology stated, “The safety of natalizumab during pregnancy is unknown. Although human data show no increased risk of birth defects, the agent is too new for adequate supportive data and there are no drugs of similar mechanism with which to compare.” (1). Nevertheless, if the maternal condition indicates that the drug is required, it should not be withheld because of pregnancy. If natalizumab is used in pregnancy, physicians are encouraged to enroll patients in the Tysabri pregnancy exposure registry by calling 800-456-2255.

FETAL RISK SUMMARY

Natalizumab is a recombinant humanized immunoglobulin G4-kappa (IgG4_K) monoclonal antibody produced in murine myeloma cells. It is an α -4 integrin inhibitor that is indicated as monotherapy for the treatment of relapsing forms of multiple sclerosis (MS) to delay the accumulation of physical disability and reduce the frequency of clinical exacerbations. It also is indicated for inducing and maintaining clinical response and remission in adult patients with moderately to severely active Crohn’s disease and evidence of inflammation, and who have had an inadequate response to, or are unable to tolerate, conventional therapies. The recommended dose is 300 mg IV every 4 weeks. The elimination half-life is approximately 10–11 days (2).

Reproduction studies have been conducted in pregnant guinea pigs and cynomolgus monkeys. In these species, there was no evidence of teratogenicity at doses up to seven times the human clinical dose based on body weight (HCD). In guinea pigs given a dose seven times the HCD during the second half of pregnancy, a small reduction in pup survival was noted at postnatal day 14. At doses seven times the HCD, a doubling of abortions (33% vs. 17%) was observed in one of five studies with monkeys, but no association with abortion was seen in guinea pigs. At this dose in both species, serum levels in fetal animals at delivery were approximately 35% of maternal levels. A dose that was 2.3 times the HCD in monkeys produced drug-related changes in the fetuses: mild anemia, reduced platelet count, increased spleen weights, and reduced liver and thymus weights associated with increased splenic extramedullary hematopoiesis, thymic atrophy, and decreased hepatic hematopoiesis. Reduced platelet counts also were observed in offspring of mothers given seven times the HCD, but this effect was reversed upon clearance of the drug. Offspring exposed in utero had no drug-related changes in the lymphoid organs and had normal immune response (2).

No carcinogenic, clastogenic, or mutagenic effects were observed in various assays and tests conducted with natalizumab. The drug had no effect on male guinea pig fertility, but, at a dose seven times the HCD, a 47% decrease in pregnancy rate relative to controls was observed in females. No such effect was observed at a dose that was 2.3 times the HCD (2).

A series of four research reports, conducted by the manufacturer, on the effects of natalizumab in guinea pigs and cynomolgus monkeys was published in 2009 (3–6). One concern was that the drug would interfere with pregnancy because α -4 integrins and their ligands appear to be critically involved in mammalian fertilization, implantation, and placental and cardiac development (3–6). The results and conclusions of the four studies were similar to those described above. However, the increase in monkey abortions in one cohort was 39.3% vs. 7.1% in controls but, in a second cohort, no increase was observed (33.3% vs. 37.5%). In cynomolgus monkeys treated with doses up to seven times the HCD, no adverse effects on the general health, survival, development, or immunologic structure and function of exposed offspring were observed (6).

Natalizumab crosses the placentas of guinea pigs and monkeys producing fetal drug concentrations approximately 35% of maternal concentrations at birth (2). Because of the similarity to the human placenta and the very long elimination half-life, passage to the fetus should be expected, regardless of the very high molecular weight (about 149,000). Moreover, immune globulin

crosses the human placenta in significant amounts near term (see Immune Globulin Intravenous).

Several reports have described the use of natalizumab during pregnancy (1,7–12).

A 2011 review mentioned 164 pregnancies treated with natalizumab during the 1st trimester for either Crohn's disease (N = 35) or MS (N = 129) (1). There was no increase in the rate of birth defects compared with the expected background occurrence.

In another 2011 report, 35 women with MS became accidentally pregnant while receiving natalizumab (7). Six of the women received the last dose before the last menstrual period (21.3 ± 13.7 days) and 29 after the last menses (22.6 ± 20 days). All of the women stopped the drug when they became aware of the pregnancy. The mean number of doses before pregnancy was 11.7 (range 2–35). The pregnancy outcomes were 28 healthy children, 1 case of hexadactyly, 5 SABs, and 1 elective abortion. There were no significant differences between the outcomes of those exposed and a control group of 23 women with MS who were not exposed to disease-modifying treatments (7).

In a 2011 case report, a 17-year-old patient, who had been treated with natalizumab for MS since she was 16, received seven doses of the drug during an unknown pregnancy (8). Pregnancy was diagnosed in the 31st gestational week. She gave birth to a healthy 2830-g female infant at term with Apgar scores of 10. The infant was doing well at 10 months of age (8).

The outcomes of two planned pregnancies were reported in 2011 (9). In the first case, a 28-year-old woman with MS became pregnant while receiving natalizumab; her last dose was on day 9 of the menstrual cycle. At 37 $\frac{3}{7}$ weeks, she gave birth to a healthy 3160-g baby girl with Apgar scores of 10 and 10. No abnormalities in the infant were found. The second case involved a 24-year-old woman with MS who did not notify her physician of her pregnancy until 20 weeks' gestation. Natalizumab, 300 mg every 4 weeks, was continued throughout pregnancy. A cesarean section at 41 weeks' delivered a 2940-g female infant with Apgar scores of 5 and 8 at 1 and 5 minutes, respectively. The infant was doing well at 6 weeks of age (9).

A preliminary report from the Tysabri (Natalizumab) Pregnancy Register was described in two references (10,11). As of May 2011, 341 pregnant patients had been prospectively enrolled with 277 known outcomes. There did not appear to be a pattern of drug-related malformations and the rate of SAB (11%) were consistent with the background rate (15%) in the US general population (10,11). Several other pregnancy outcomes following use of

natalizumab were also described in one of the references (11).

A 2013 report described the effect of natalizumab on the immune system of two neonates, both born at 38 weeks, whose mothers received the drug until 34 weeks' for MS (12). In the first case, the mother received four doses starting at 21 weeks' gestation. The 2640-g infant had Apgar scores of 9, 10, and 10. No structural anomalies were evident, but a minor intracerebral hemorrhage was detected by ultrasound that later resolved. The infant was anemic and had moderate thrombocytopenia. At age of 6 weeks, the infant was admitted to the hospital with respiratory syncytial virus bronchiolitis that resolved within a few days with symptomatic treatment. The infant was still anemic but the platelet count had normalized. At 12 weeks of age, the infant had mild anemia but otherwise was doing well. The mother in the second case was treated with methylprednisolone up to 13 weeks but, because of relapsing MS, was given four doses of natalizumab starting at 21 weeks' similar to the first case. The 2755-g newborn had Apgar scores of 9, 10, and 10. Because adults treated with natalizumab have a significant decrease in T-lymphocyte chemotaxis, both infants were examined for this decrease. The impaired effects on the immune system were found in both infants at 2 weeks of age but, in both cases, the impairment had resolved by 12 weeks of age. The authors concluded that the clinical relevance of the impaired chemotaxis in the context of host defense, especially against viral pathogens, was unclear because chemotaxis was just one of several features of altered immune cell functions under treatment with natalizumab (12).

BREASTFEEDING SUMMARY

No reports describing the use of natalizumab during human lactation have been located. The molecular weight is very high (about 149,000), but immunoglobulins are excreted into breast milk. Although given once every 4 weeks, the long elimination half-life (10–11 days) will assure that the drug is available for excretion throughout the dosing period. The effects of this potential exposure on a nursing infant are unknown.

NATEGLINIDE

Antidiabetic Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

The animal data suggest a low risk for developmental toxicity, but only one report of human pregnancy experience has been located. Insulin is the treatment of choice for pregnant diabetics if diet and exercise cannot control the maternal hyperglycemia. Insulin does not cross the placenta to the fetus and, thus, eliminates the additional concern that the drug therapy itself may adversely affect the fetus. Although a potential role in gestational diabetes may exist for some oral hypoglycemics (e.g., see Glyburide), carefully prescribed insulin therapy will provide better control of the mother's blood glucose, thereby preventing the fetal and neonatal complications that occur with this disease. In general, if oral hypoglycemics are used during pregnancy, consideration should be given to changing the therapy to insulin to lessen the possibility of prolonged hypoglycemia in the newborn. The rapid elimination and extensive protein binding of nateglinide, however, may lessen the potential for this adverse effect.

FETAL RISK SUMMARY

Nateglinide is an amino acid derivative that is used as an oral insulin secretagogue. It is structurally unrelated to the oral sulfonylurea agents. Nateglinide is indicated for the management of type 2 diabetes mellitus (non-insulin-dependent) as monotherapy to lower blood glucose when hyperglycemia cannot be adequately controlled by diet and exercise. The drug is rapidly cleared from the plasma with an elimination half-life of approximately 1.5 hours. It is protein bound (98%) primarily by serum albumin and to a lesser degree by α_1 -acid glycoprotein. Although the major metabolites are less-potent antidiabetic agents, a minor metabolite has antidiabetic potency similar to that

of the parent compound (1).

Reproduction studies with nateglinide have been conducted in rats and rabbits. In rats, no evidence of teratogenicity was observed at doses up to approximately 60 times the human therapeutic exposure from the recommended dose of 120 mg 3 times daily before meals (HTE). Decreased body weights in offspring were observed when these doses were administered in the perinatal and postnatal periods. In rabbits, a dose approximately 40 times the HTE adversely affected embryonic development and increased the incidence of gallbladder agenesis or small gallbladder (1).

It is not known if nateglinide crosses the human placenta. The molecular weight (about 317) suggests that exposure of the embryo and fetus is possible, but the short plasma elimination half-life and extensive protein binding should limit the amount of drug available to cross to the fetal compartment.

In a 2004 case report, a 39-year-old woman took pravastatin (80 mg/day), metformin (2 g/day), and nateglinide (360 mg/day) during the first 24 weeks of gestation (2). All therapy was discontinued and insulin was started for her diabetes. At term, the woman delivered a healthy 2.4-kg male infant (head circumference 34 cm, length 46 cm) with Apgar scores of 8 and 9 at 1 and 5 minutes, respectively. The infant's growth and development were normal at follow-up examinations during the first 6 months of life (2).

BREASTFEEDING SUMMARY

No reports describing the use of nateglinide during human lactation have been located. The molecular weight (about 317) suggests that excretion into breast milk may occur, but the short elimination half-life (1.5 hours) and extensive protein binding (98%) should limit the amount of drug and active metabolites available in milk. The effect on a nursing infant is unknown, but hypoglycemia is a potential complication. Thus, if a woman plans to breastfeed, changing her therapy to other agents, such as insulin or a second-generation sulfonylurea (see Glipizide and Glyburide) might be appropriate. In any case, monitoring the infant's blood glucose should be conducted.

NEBIVOLOL

Sympatholytic (Antihypertensive)

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of nebivolol in human pregnancy have been located.

Based on studies with other agents in the class, the use of nebivolol for maternal disease probably does not pose a major risk of structural defects, but the long-term effects of in utero exposure to β -blockers have not been studied. Persistent β -blockade has been observed in newborns exposed near delivery to other members of this class (see Acebutolol, Atenolol, and Nadolol). Newborns exposed in utero to nebivolol should be closely observed during the first 24–48 hours after birth for bradycardia and other symptoms. Some β -blockers may cause intrauterine growth restriction (IUGR) and reduced placental weight, especially those lacking intrinsic sympathomimetic activity (ISA) (i.e., partial agonist), and nebivolol does not possess ISA. Treatment beginning early in the 2nd trimester results in the greatest weight reductions, whereas treatment restricted to the 3rd trimester primarily affects only placental weight. Although growth restriction is a serious concern, the benefits of maternal therapy, in some cases, might outweigh the risks to the fetus and must be judged on a case-by-case basis.

FETAL RISK SUMMARY

Nebivolol, a β -adrenergic receptor blocking agent, is a racemic mixture of d- and l-nebivolol. The active isomer (d-nebivolol) has an effective half-life of about 12 hours in CYP2D6-extensive metabolizers and 19 hours in poor metabolizers. In extensive metabolizers (most of the population) and at doses ≤ 10 mg, the drug is preferentially β_1 selective, but at higher doses and in poor metabolizers,

it is a β_1/β_2 blocker. Nebivolol is indicated for the treatment of hypertension, either alone or in combination with other antihypertensives. The drug has no ISA but does have active metabolites. Plasma protein binding, primarily to albumin, is about 98% and is independent of plasma concentrations (1).

Reproduction studies have been conducted in rats and rabbits. Pregnant rats given nebivolol during organogenesis at maternally toxic doses that were 5 and 10 times the maximum recommended human dose of 40 mg/day based on BSA (MRHD) resulted in reduced fetal body weights. Additionally, at 10 times the MRHD, small reversible delays in sternal and thoracic ossification and a small increase in resorptions were observed. Doses given during late gestation, parturition, and lactation that were ≥ 1.2 times the MRHD caused decreased birth and pup weights, prolonged gestation, dystocia, and reduced maternal care with corresponding increases in late fetal deaths and stillbirths and decreased pup survival. Insufficient numbers of pups survived at 1.2 times the MRHD to evaluate the offspring for reproductive performance. In contrast, no adverse effects on embryo–fetal viability, sex, weight, or morphology were observed in pregnant rabbits given doses up to 10 times the MRHD (1).

Two-year studies for carcinogenicity were conducted in mice and rats. In mice given a dose that was 5 times the MRHD, a significant increase in testicular Leydig cell hyperplasia and adenomas was observed. The findings were not observed with doses up to 1.2 times the MRHD. The Leydig cell hyperplasia was consistent with an indirect luteinizing hormone–mediated effect of the drug and was not thought to be clinically relevant in humans. No evidence of carcinogenicity was observed in rats with doses up to 10 times the MRHD. No evidence of mutagenicity was noted in several assays (1).

It is not known if nebivolol crosses the human placenta. The molecular weight (about 406 for the free base) and moderately long effective half-life suggest that the drug will cross to the embryo–fetus. Moreover, other β -blockers readily cross the placenta (e.g., see Atenolol, Metoprolol, and Propranolol).

BREASTFEEDING SUMMARY

No reports describing the use of nebivolol during human lactation have been located. The molecular weight (about 406 for the free base) and moderately long effective half-life (12 or 19 hours) suggest that the drug will be excreted into breast milk. Moreover, other β -blockers are excreted into milk (e.g., see Atenolol, Metoprolol, and Propranolol). Although the amount in milk might not be clinically significant, nursing infants should be closely observed for signs or symptoms of β -blockade. The long-term effects of exposure to β -blockers from

milk have not been studied but warrant evaluation. The American Academy of Pediatrics classifies other similar agents as compatible with breastfeeding (e.g., see Metoprolol and Propranolol).

NEDOCROMIL SODIUM

Respiratory Anti-inflammatory (Inhaled)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The absence of animal embryo–fetal toxicity, the limited human systemic bioavailability, and the outcomes of the exposed human pregnancies appear to suggest that nedocromil sodium is not a major teratogenic risk. Although this assessment is based on limited pregnancy experience, the benefits in preventing maternal asthma probably outweigh any potential fetal harm. Because of the greater pregnancy experience, cromolyn sodium may be the preferred choice (see Cromolyn Sodium).

FETAL RISK SUMMARY

Nedocromil sodium is an inhaled anti-inflammatory agent used in the prevention of asthma. Because of its mast cell–stabilizing properties, it is also available as a 2% ophthalmic solution for the treatment of itching associated with allergic conjunctivitis. Its respiratory action appears to be similar to that of cromolyn sodium. Each activation of the meter delivers 1.75 mg nedocromil from the mouthpiece. In asthmatic patients, the absolute bioavailability after chronic dosing (two activations 4 times a day for 1 month) was approximately 5% of the administered dose (1). No accumulation was observed after chronic use. With chronic administration in the eye, <4% of the total dose is absorbed systemically (2).

No effects on fertility in male and female mice and rats were observed with an SC dose of nedocromil sodium that was about 30 and 60 times, respectively, the maximum recommended human daily inhalation dose based on BSA (MRHID), respectively (1). In reproduction studies, no evidence of teratogenicity or fetal harm was revealed when an SC dose was given to pregnant mice, rats, and rabbits that was about 30, 60, and 116 times the

MRHID, respectively (1). The SC dose was >1600 times the maximum recommended human daily ocular dose on a body weight basis (2).

It is not known if nedocromil sodium crosses the human placenta. The molecular weight of the drug (about 415) is low enough that transfer to the fetus should be expected. The low systemic bioavailability (e.g., mean peak plasma concentrations in the 1.6- to 2.8-ng/mL range [1]) suggests that the amounts reaching the embryo or fetus are clinically insignificant.

A report published in 1988 described three women who became pregnant while enrolled in a trial of nedocromil (3). All three were withdrawn from the study because of their pregnancy. One woman stopped the therapy 5 weeks after her last menstrual period. She and another woman (gestational age when therapy stopped not specified) had normal pregnancies. The third woman stopped nedocromil therapy at 8 weeks' gestation and had a spontaneous abortion 5 days later. The abortion was thought to be unrelated to treatment (3).

A 1998 noninterventional observational cohort study described the outcomes of pregnancies in women who had been prescribed one or more of 34 newly marketed drugs by general practitioners in England (4). Data were obtained by questionnaires sent to the prescribing physicians 1 month after the expected or possible date of delivery. In 831 (78%) of the pregnancies, a newly marketed drug was thought to have been taken during the 1st trimester with birth defects noted in 14 (2.5%) singleton births of the 557 newborns (10 sets of twins). In addition, two birth defects were observed in aborted fetuses. However, few of the aborted fetuses were examined. Nedocromil was taken during the 1st trimester in 35 pregnancies. The outcomes of these pregnancies included 1 spontaneous abortion, 8 elective abortions, 3 cases lost to follow-up, 22 normal-term infants, and 1 newborn with a birth defect (4). The birth defect, in an infant born to a 22-year-old woman, was categorized as congenital heart disease (no details given). Other maternal drug exposures in this case included aminophylline, corticosteroids, and salbutamol. Although the cause of the one major congenital malformation observed is unknown, the study lacks the sensitivity to identify minor anomalies because of the absence of standardized examinations. Late-appearing major defects may also have been missed because of the timing of the questionnaires.

BREASTFEEDING SUMMARY

No reports describing the use of nedocromil sodium during human lactation have been located. Although the molecular weight of the drug (about 415) is

low enough to allow excretion into breast milk, the very small amounts in the systemic circulation (see above) suggests that the potential for harm in a nursing infant is nil.

NEFAZODONE

Antidepressant

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Nefazodone, a phenylpiperazine antidepressant, is structurally related to trazodone. Although its exact mechanism of action is unknown, it inhibits neuronal reuptake of serotonin and norepinephrine. Although the animal data suggest moderate risk, the limited human pregnancy experience suggests that the risk of developmental toxicity is low. However, long-term studies on functional and/or neurobehavioral deficits have not been conducted.

FETAL RISK SUMMARY

No teratogenic effects were observed with the use of nefazodone in reproductive toxicity studies involving rats and rabbits dosed, respectively, at 5 and 6 times the maximum human daily dose based on BSA (MHDD) (1). Increased early pup mortality was observed, however, when dosing at 5 times the MHDD in rats began during gestation and continued until weaning. Moreover, decreased pup weights were seen at this and lower doses. The no-effect dose for pup mortality was 1.3 times the MHDD (1).

A 2003 prospective controlled study described the outcomes of 147 pregnancies exposed in the 1st trimester (52 exposed throughout gestation) to either nefazodone or trazodone (2). The outcomes were compared with two control groups (one exposed to other antidepressants and the other exposed to nonteratogens). There were no significant differences among the three groups in terms of spontaneous abortions, elective abortions, stillbirths, major malformations, gestational age at birth, or birth weights. In the study group, there were two (1.4%) major malformations: neural tube defect and Hirschsprung's disease (2).

A 2005 meta-analysis of seven prospective comparative cohort studies involving 1774 patients was conducted to quantify the relationship between seven newer antidepressants and major malformations (3). The antidepressants were bupropion, fluoxetine, fluvoxamine, nefazodone, paroxetine, sertraline, and trazodone. There was no statistical increase in the risk of major birth defects above the baseline of 1%–3% in the general population for the individual or combined studies (3).

A prospective cohort study evaluated a large group of pregnancies exposed to antidepressants in the 1st trimester to determine if there was an association with major malformations (4). The patient population came from the Motherisk database and involved 928 cases that met their criteria. The 928 matched (for age, smoking, and alcohol use) controls were pregnancies not exposed to antidepressants or known teratogens. In addition to the 39 nefazodone cases, the other cases were 113 bupropion, 184 citalopram, 21 escitalopram, 61 fluoxetine, 52 fluvoxamine, 68 mirtazapine, 148 paroxetine, 61 sertraline, 17 trazodone, and 154 venlafaxine. In the antidepressant group, there were 24 (2.5%) major defects compared with 25 (2.6%) in controls (odds ratio 0.9, 95% confidence interval 0.5–1.61). There was one major anomaly, Hirschsprung disease, in the nefazodone group. There were no major defects in the pregnancies exposed to bupropion, escitalopram, or trazodone (4).

BREASTFEEDING SUMMARY

Nefazodone is excreted into breast milk. A 1999 report described an analytical method for determining the concentrations of nefazodone and its metabolites in human plasma and milk (5). In addition, in one woman taking 200 mg twice daily, the paired concentrations of nefazodone in milk and plasma (trough) were 57 and 617 ng/mL, respectively; the milk:plasma ratio was 0.09. In two other subjects, one taking 50 mg twice daily and the other 50 mg in the morning and 100 mg in the evening, the trough plasma levels were <50 ng/mL, whereas the paired milk concentrations were 687 and 213 ng/mL, respectively (5).

Two mothers breastfeeding their infants 21 and 4 weeks postpartum, respectively, were being treated with nefazodone for depression (6). One patient was taking 150 mg/day (50 mg in the morning and 100 mg in the evening) and the other 400 mg/day (200 mg in the morning and evening). Milk and plasma samples were obtained from both patients. Two of the metabolites were not detected in any sample, and hydroxynefazodone was not detected in the plasma of the first patient or in the milk of the second patient (concentrations in both <50 ng/mL). Based on 150 mL/kg/day of milk

consumption, the infant doses as a percentage of the mothers' weight-adjusted doses were 2.2% and 0.4%. No adverse effects were observed in the two nursing infants (6).

A 35-year-old woman gave birth to a premature female infant at 27 weeks' gestation (7). The infant was fed the mother's breast milk from a bottle while in the hospital. The mother was started on nefazodone, 200 mg in the morning and 100 mg at night, because of depression 7 weeks after delivery. One week later, the mother began breastfeeding. At 9 weeks of age, the 2.1-kg infant was readmitted to the hospital because of drowsiness, lethargy, failure to maintain body temperature, and poor feeding. Breastfeeding was stopped 1 week later and the infant's symptoms resolved gradually over 72 hours. Maternal blood and breast milk were collected immediately before the 200-mg morning dose and at intervals ≤ 6 hours (for milk) or 12 hours (for blood). The milk:plasma ratio (based on AUC over 12 hours) for nefazodone was 0.27, and 0.02–0.19 for three metabolites that were identified. The maximum concentrations in milk and plasma were 358 ng/mL (at 3 hours) and 1270 ng/mL (at 1 hour), respectively. The estimated infant dose, relative to the weight-adjusted total daily maternal dose, was 0.3% for nefazodone and 0.45% for the parent drug plus metabolites. The investigators speculated that the sedative effects might have resulted from reduced clearance of the drug secondary to the infant's prematurity (7).

The long-term effects on neurobehavior and development from exposure to antidepressants during a period of rapid CNS development have not been studied. The American Academy of Pediatrics classifies the effects of other antidepressants on nursing infants as unknown but may be of concern (8).

NELARABINE

Antineoplastic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of nelarabine in human pregnancy have been located. The animal reproduction data and the properties of the drug suggest that there are significant embryo–fetal risks. Nelarabine should be avoided in pregnancy, especially in the 1st trimester. If a pregnant woman requires this agent or if an inadvertent pregnancy occurs, the woman should be advised of the potential risk for severe adverse effects in the embryo and fetus.

FETAL RISK SUMMARY

Nelarabine is a prodrug of a cytotoxic deoxyguanosine analog, 9- β -D-arabinofuranosylguanine (ara-G) that is given as an IV infusion. As a DNA demethylation agent, it is in the same antineoplastic subclass as azacitidine and decitabine. Nelarabine is indicated for the treatment of T-cell acute lymphoblastic leukemia and T-cell lymphoblastic lymphoma that have not responded to or have relapsed following treatment with at least two chemotherapy regimens. Nelarabine is rapidly converted in vivo to ara-G, and then to the active compound, 5'-triphosphate, ara-GTP. The ara-GTP accumulates in leukemic blasts where the drug produces cell death. The plasma half-lives of nelarabine and ara-G are about 30 minutes and 3 hours, respectively, but the terminal elimination half-life could not be accurately estimated because of the prolonged intracellular levels of ara-GTP. Plasma protein binding is less than 25% (1).

Reproduction studies have been conducted in rabbits. Pregnant rabbits given IV infusions of doses ranging from 0.25 to 2 times the human dose based on BSA (HD) had increased incidences of fetal malformations and variations: absent gall bladder, absent accessory lung lobes, fused or extra sternebrae,

and delayed ossification (all doses); cleft palates (about 2 times the HD); and absent digits (about 0.75 times the HD). Maternal body weight gain and fetal body weight were reduced at about 3 times the HD, but this toxicity could not account for the increased incidence of malformations (1).

It is not known if nelarabine or ara-G can cross the human placenta. The molecular weight (about 297) of nelarabine and the lack of protein binding suggest that these agents will reach the embryo and fetus. The short plasma half-lives should decrease the exposure.

BREASTFEEDING SUMMARY

No reports describing the use of nelarabine during lactation have been located. The molecular weight (about 297) and lack of protein binding suggest that nelarabine and ara-G will be excreted into breast milk. The short plasma half-lives, 30 minutes and 3 hours, respectively, should decrease the exposure, but the terminal elimination half-life of the intracellular active metabolite ara-GTP has not been determined. Severe neurologic toxicity has been observed in adults receiving this drug, including severe somnolence, convulsions, peripheral neuropathy, and ascending peripheral neuropathies similar in appearance to Guillain-Barré syndrome (1). Therefore, the best course is to not breastfeed while receiving nelarabine.

NELFINAVIR

Antiviral

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo/Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

The lack of animal toxicity and the human pregnancy data suggest that nelfinavir is not a major teratogen. If indicated, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Nelfinavir is an inhibitor of HIV protease. In in vitro tests, the agent was found to be active against both HIV types 1 and 2 (HIV-1 and HIV-2) (1). Other drugs in this class are amprenavir, indinavir, ritonavir, and saquinavir. Protease is an enzyme that is required for the cleavage of viral polyprotein precursors into active functional proteins found in infectious HIV. Nelfinavir, usually in combination with other antiretroviral agents, is indicated for the treatment of HIV infections.

Reproduction studies with nelfinavir have been conducted in rats and rabbits (1). No effects on fertility, mating, embryo survival, or fetal development were observed in rats given doses that produced plasma concentrations comparable with those measured in humans with therapeutic doses. Exposure of pregnant rats from mid-gestation through lactation had no effect on survival, growth, development to weaning, or subsequent fertility of the offspring (1). In rabbits, doses up to a maternal toxic dose (decreased maternal body weight) had no effect on fetal development. However, even at the highest dose, the systemic exposure in rabbits was significantly less than that observed in humans (1).

It is not known if nelfinavir crosses the human placenta to the fetus. The molecular weight of the free base (about 568) is low enough that transfer to the embryo and fetus should be expected.

A 2004 study, using data (through July 2002) from the Antiretroviral Pregnancy Registry (see below), reported 301 1st trimester exposures to

nelfinavir (2). The prevalence rate of birth defects, based on nine cases, was 3.0% (95% confidence interval [CI] 1.4–5.6). This rate was similar to the expected rate of 3.1% in the CDC population-based surveillance system (2).

The Antiretroviral Pregnancy Registry reported, for the period January 1989 through July 2009, prospective data (reported before the outcomes were known) involving 4702 live births that had been exposed during the 1st trimester to one or more antiretroviral agents (3). Congenital defects were noted in 134, a prevalence of 2.8% (95% CI 2.4–3.4). In the 6100 live births with earliest exposure in the 2nd/3rd trimesters, there were 153 infants with defects (2.5%, 95% CI 2.1–2.9). The prevalence rates for the two periods did not differ significantly. There were 288 infants with birth defects among 10,803 live births with exposure anytime during pregnancy (2.7%, 95% CI 2.4–3.0). The prevalence rate did not differ significantly from the rate expected in a nonexposed population. There were 3272 outcomes exposed to nelfinavir (1075 in the 1st trimester and 2197 in the 2nd/3rd trimesters) in combination with other antiretroviral agents. There were 98 birth defects (37 in the 1st trimester and 61 in the 2nd/3rd trimesters). In reviewing the birth defects of prospective and retrospective (pregnancies reported after the outcomes were known) registered cases, the Registry concluded that, except for isolated cases of neural tube defects with efavirenz exposure in retrospective reports, there was no other pattern of anomalies (isolated or syndromic) (3). (See Lamivudine for required statement.)

A study published in 1999 evaluated the safety, efficacy, and perinatal transmission rates of HIV in 30 pregnant women receiving various combinations of antiretroviral agents (4). Many of the women were substance abusers. Protease inhibitors (nelfinavir [N = 7], indinavir [N = 6], and saquinavir [N = 1] in combination with nelfinavir) were used in 13 of the women. Antiretroviral therapy was initiated at a median of 14 weeks' gestation (range preconception to 32 weeks). In spite of previous histories of extensive antiretroviral experience and of vertical transmission of HIV, combination therapy was effective in treating maternal disease and in preventing transmission to the current newborns. The outcomes of the pregnancies treated with protease inhibitors appeared to be similar to the 17 cases that did not receive these agents, except that the birth weights were lower (4).

The FDA issued a public health advisory in 1998 on the association between protease inhibitors and diabetes mellitus (5). Because pregnancy is a risk factor for hyperglycemia, there was concern that these antiviral agents would exacerbate this risk. The manufacturer's product information also notes the

potential risk for new-onset diabetes, exacerbation of preexisting diabetes, and hyperglycemia in HIV-infected patients receiving protease inhibitor therapy (1). An abstract published in 2000 described the results of a study involving 34 pregnant women treated with protease inhibitors (30 with nelfinavir) compared with 41 controls that evaluated the association with diabetes (6). No association between protease inhibitors and an increased incidence of gestational diabetes was found.

A 1999 abstract reported the effect of protease inhibitors (nelfinavir, indinavir, ritonavir, or saquinavir) in combination with two or more other antiretroviral agents in 39 pregnant women (7). Nelfinavir was the most commonly used protease inhibitor. The mean gestational age at the start of protease inhibitor therapy was 31 weeks (range 8–39 weeks). All of the newborns tested HIV-negative. Based on these outcomes, and the lack of congenital anomalies and serious neonatal complications, and the mother's response to therapy, the authors concluded that protease inhibitor therapy during pregnancy was effective for maternal HIV disease and contributed to the very low rate of perinatal HIV transmission (7).

A multicenter, retrospective survey of pregnancies exposed to protease inhibitors was published in 2000 (8). There were 92 liveborn infants delivered from 89 women (3 sets of twins) at six healthcare centers. One nonviable infant, born at 22 weeks' gestation, died. The surviving 91 infants were evaluated in terms of adverse effects, prematurity rate, and frequency of HIV-1 transmission. Most of the infants were exposed in utero to a single protease inhibitor, but a few were exposed to more than one because of sequential or double combined therapy. The number of newborns exposed to each protease inhibitor was indinavir (N = 23), nelfinavir (N = 39), ritonavir (N = 5), and saquinavir (N = 34). Protease inhibitors were started before conception in 18, and during the 1st, 2nd, or 3rd trimester in 12, 44, and 14, respectively, and not reported in 1. Other antiretrovirals used with the protease inhibitors included four nucleoside reverse transcriptase inhibitors (NRTIs) (didanosine, lamivudine, stavudine, and zidovudine). The most common NRTI regimen was a combination of zidovudine and lamivudine (65% of women). In addition, seven women were enrolled in the AIDS Clinical Trials Group Protocol 316 and, at the start of labor, received either a single dose of the non-NTRI nevirapine, or placebo. Maternal conditions thought possibly or likely to be related to therapy were mild anemia in eight, severe anemia in one (probably secondary to zidovudine), and thrombocytopenia in one. Gestational diabetes mellitus was observed in three women (3.3%), a rate similar to the expected prevalence of

2.6% in a nonexposed population. One mother developed postpartum cardiomyopathy and died 2 months after birth of twins, but the cause of death was not known. For the surviving newborns, there was no increase in adverse effects over that observed in previous clinical trials of HIV-positive women, including the prevalence of anemia (12%), hyperbilirubinemia (6%; none exposed to indinavir), and low birth weight (20.6%). Premature delivery occurred in 19.1% of the pregnancies (close to the expected rate). The percentage of infants infected with HIV was 0 (95% CI 0%–3%) (8).

Two reviews, one in 1996 and the other in 1997, concluded that all women currently receiving antiretroviral therapy should continue to receive therapy during pregnancy and that treatment of the mother with monotherapy should be considered inadequate therapy (9,10). The same conclusion was reached in a 2003 review with the added admonishment that therapy must be continuous to prevent emergence of resistant viral strains (11). In 2009, the updated U.S. Department of Health and Human Services guidelines for the use of antiretroviral agents in HIV-1-infected patients continued the recommendation that therapy, with the exception of efavirenz, should be continued during pregnancy (12). If indicated, therefore, protease inhibitors, including nelfinavir, should not be withheld in pregnancy because the expected benefit to the HIV-positive mother outweighs the unknown risk to the fetus. Pregnant women taking protease inhibitors should be monitored for hyperglycemia. Updated guidelines for the use of antiretroviral drugs to reduce perinatal HIV-1 transmission also were released in 2010 (13). Women receiving antiretroviral therapy during pregnancy should continue the therapy, but, regardless of the regimen, zidovudine administration is recommended during the intrapartum period to prevent vertical transmission of HIV to the newborn (13).

BREASTFEEDING SUMMARY

No reports describing the use of nelfinavir during human lactation have been located. The molecular weight of the free base (about 568) is low enough that excretion into breast milk should be expected.

Reports on the use of nelfinavir during human lactation are unlikely because the antiviral agent is used in the treatment of HIV infections. HIV-1 is transmitted in milk, and in developed countries, breastfeeding is not recommended (9,10,12,14–16). In developing countries, breastfeeding is undertaken, despite the risk, because there are no affordable milk substitutes available. Until 1999, no studies had been published that examined the effect of any antiretroviral therapy on HIV-1 transmission in milk. In that year, a study of

zidovudine measured a 38% reduction in vertical transmission of HIV-1 infection in spite of breastfeeding when compared with controls (see Zidovudine).

NEOMYCIN

Antibiotic (Aminoglycoside)

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Neomycin is an aminoglycoside antibiotic. Ototoxicity, which is known to occur in patients after oral, topical, and parenteral neomycin therapy, has not been reported as an effect of in utero exposure. However, eighth cranial nerve toxicity in the fetus is well known following exposure to kanamycin and streptomycin and may potentially occur with neomycin.

FETAL RISK SUMMARY

Small amounts of neomycin (about 3%) are absorbed from the normal gastrointestinal (GI) tract after oral and rectal administration (1). Larger systemic amounts may be obtained if GI motility is impaired. A single 4-g oral dose has produced peak plasma concentrations of 2.5–6.1 mcg/mL 1–4 hours after the dose (1).

No reports describing the passage of neomycin across the placenta to the embryo and fetus have been located, but this should be expected (see other aminoglycosides: Amikacin, Gentamicin, Kanamycin, Streptomycin, and Tobramycin).

Oral neomycin therapy, 2 g daily, depresses urinary estrogen excretion, apparently by inhibiting steroid conjugate hydrolysis in the gut (2). The fall in estrogen excretion resembles the effect produced by ampicillin but occurs about 2 days later. Urinary estriol was formerly used to assess the condition of the fetoplacental unit with depressed levels being associated with fetal distress.

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 30 of whom had 1st trimester exposure to neomycin (3). No evidence was found to suggest a relationship to large categories of major or minor malformations or to individual defects.

The population-based dataset of the Hungarian Case-Control Surveillance of

Congenital Abnormalities, covering 1980–1996, was used to evaluate the teratogenicity of aminoglycoside antibiotics (parenteral gentamicin, streptomycin, tobramycin, and oral neomycin) in a study published in 2000 (4). A case group of 22,865 women who had fetuses or newborns with congenital malformations were compared with 38,151 women who had newborns with no structural defects. A total of 38 cases and 42 controls were treated with aminoglycosides. There were 12 cases (0.05%) and 14 controls (0.04%) treated with oral neomycin (odds ratio 1.4, 95% confidence interval 0.7–3.1). A case–control pair analysis for the 2nd and 3rd months of gestation also failed to show a risk for teratogenicity. The investigators concluded that there was no detectable teratogenic risk for structural defects for any of the aminoglycoside antibiotics (4). They also concluded, although it was not investigated in this study, that the risk of deafness after in utero aminoglycoside exposure was small.

BREASTFEEDING SUMMARY

No reports describing the use of neomycin during human lactation have been located. Small amounts of other aminoglycosides (e.g., see Gentamicin) are excreted into breast milk and absorbed by the nursing infant. The very limited systemic bioavailability of oral neomycin (about 3% for a normal GI tract) suggests that the amounts of neomycin in breast milk are clinically insignificant.

NEOSTIGMINE

Parasympathomimetic (Cholinergic)

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Neostigmine is a quaternary ammonium compound with anticholinesterase activity used in the diagnosis and treatment of myasthenia gravis and to reverse muscle relaxation from competitive (nondepolarizing) muscle relaxants. Multiple studies have reported its use for this indication without observing embryo–fetal harm.

FETAL RISK SUMMARY

Although neostigmine is ionized at physiologic pH, the molecular weight (about 223) is low enough that transfer of the nonionized fraction to the embryo and fetus should be expected. Circumstantial evidence for neostigmine placental transfer was presented in a 1996 case report (1). A woman at 31 weeks' gestation, undergoing surgery for a fractured elbow, was given IV neostigmine (5 mg) and glycopyrrolate (1 mg) to reverse muscle paralysis at the end of the procedure. The fetal heart rate immediately decreased from 115–130 beats/minute to 90–110 beats/minute and then gradually returned to 130 bpm within 1 hour. Four days later, surgical repair of the elbow was again required. At the end of this surgery, neostigmine (5 mg) and atropine (0.4 mg) were given IV and no change in the fetal heart rate was observed. The authors attributed the different effects on the fetal heart rate to the greater placental transfer of atropine in comparison with glycopyrrolate (see also Glycopyrrolate), which resulted in blocking the transplacental muscarinic effects of neostigmine (1).

The safe use of neostigmine in the treatment of maternal myasthenia gravis or other conditions has been reported (2–12). One study described 22 exposures to neostigmine in the 1st trimester (2). No relationship to congenital

defects was found. A 1973 study reported the use of IM neostigmine (0.5 mg/day) for 3 days as a pregnancy test in 27 women with “uncertain pregnancies” at 5–14 weeks’ gestation (3). Although vaginal bleeding occurred in 7 (26%) patients, only 1 aborted and the remaining 26 went to term without complications. In a 1983 report, two women with myasthenia gravis were treated throughout gestation with neostigmine, 105 mg/day (combined with pyridostigmine and ambenonium) and 300 mg/day (combined with pyridostigmine), respectively, without apparent fetal harm (12).

One investigator considers neostigmine to be one of the drugs of choice for pregnant patients with myasthenia gravis (4). This author also cautioned that IV anticholinesterases should not be used in pregnancy because of the potential for inducing premature labor and suggested that IM neostigmine be used in place of IV edrophonium for diagnostic purposes (4). This recommendation, however, should be approached with caution in view of the high rate of vaginal bleeding following IM neostigmine described above.

Transient muscular weakness has been observed in about 20% of newborns of mothers with myasthenia gravis (10). The neonatal myasthenia is caused by transplacental passage of anti-acetylcholine receptor immunoglobulin G antibodies (10).

BREASTFEEDING SUMMARY

No reports describing the use of neostigmine during lactation have been located. Two publications have stated that the drug is not excreted into breast milk (11,13). However, pyridostigmine, another quaternary ammonium compound, is found in breast milk (see Pyridostigmine). Thus, although neostigmine is ionized at physiologic pH, the molecular weight (about 223) is low enough that the nonionized fraction should be excreted into milk. The effects, if any, on a nursing infant from exposure to neostigmine in milk are unknown.

NEPAFENAC

Ophthalmic Nonsteroidal Anti-inflammatory

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of the nonsteroidal anti-inflammatory drug (NSAID) nepafenac in human pregnancy have been located. The animal reproduction data suggest low risk, but the absence of human pregnancy experience prevents a more complete assessment of the embryo–fetal risk. The manufacturer recommends avoiding use of the drug in late pregnancy because of the known toxicity on the fetal cardiovascular system (premature closure of the ductus arteriosus) (1).

FETAL RISK SUMMARY

Nepafenac is an NSAID available as an ophthalmic suspension. It is indicated for the treatment of pain and inflammation associated with cataract surgery. The drug penetrates the cornea and is converted by ocular tissue enzymes to the NSAID drug amfenac, the active agent. After bilateral 3-times-daily dosing, low concentrations of nepafenac and amfenac were detected in the plasma with peak concentrations of 0.3 and 0.4 ng/mL, respectively, 2–3 hours postdose. No information on plasma protein binding or elimination half-life was provided (1).

Reproduction studies with nepafenac and amfenac have been conducted in rats and rabbits. When rats were given oral doses of nepafenac and amfenac that produced plasma exposures up to about 260 and 2400 times, respectively, the human plasma exposures at the recommended human ophthalmic dose (RHOD), no evidence of teratogenicity was observed. However, maternal toxicity, observed at the highest dose or higher, was associated with dystocia, increased postimplantation loss, reduced fetal weights and growth, and reduced fetal survival. No evidence of teratogenicity was observed in rabbits

with oral doses producing exposures up to about 80 and 680 times, respectively, the human plasma exposures at the RHOD. Maternal toxicity also was observed at the highest dose (1).

Nepafenac has not been evaluated in long-term carcinogenicity studies. The drug increased chromosomal aberrations in hamster ovary cells but was not mutagenic in multiple assays. No effects on fertility in male and female rats were observed with nepafenac or amfenac (1).

It is not known if nepafenac or amfenac crosses the human placenta. The molecular weight of nepafenac (about 254) is low enough to cross the placenta. Although the molecular weight of amfenac was not provided, it is probably similar to the prodrug and also should cross. However, the systemic concentrations of both drugs are very low.

BREASTFEEDING SUMMARY

No reports describing the use nepafenac during human lactation have been located. The molecular weight of nepafenac (about 254) is low enough for excretion into breast milk. Although the molecular weight of the active agent, amfenac, was not provided, it is probably similar to the prodrug and also should be excreted into milk. However, the systemic concentrations of both drugs are very low. Consequently, the risk to a nursing infant from exposure is probably low or nonexistent.

NESIRITIDE

Vasodilator

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of nesiritide in human pregnancy have been located. The animal data suggest low risk, but the absence of human pregnancy experience prevents an accurate assessment of the embryo–fetal risk. However, nesiritide is a recombinant formulation of human B-type natriuretic peptide, a naturally occurring peptide produced in the ventricular myocardium. Although the indication suggests that use in pregnancy will be uncommon; if indicated, it should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Nesiritide is indicated for the IV treatment of patients with acutely decompensated congestive heart failure who have dyspnea at rest or with minimal activity. Nesiritide is metabolized to inactive metabolites and the terminal elimination half-life is about 18 minutes (1).

Reproduction studies have been conducted in rabbits. In this species, no adverse effects on live births or fetal development were observed at a dose given by continuous infusion for 13 days, producing exposures that were about 70 times higher than the human exposure at the recommended dose (1).

Studies of carcinogenicity or effects on fertility have not been conducted. The drug was not mutagenic in an in vitro assay (1).

It is not known if nesiritide crosses the human placenta. The relatively high molecular weight (3464) and very short terminal elimination half-life suggest that exposure of the embryo and/or fetus will be minimal.

BREASTFEEDING SUMMARY

No reports describing the use of nesiritide during human lactation have been

located. The relatively high molecular weight (3464) and very short terminal elimination half-life (about 18 minutes) suggest that the peptide will not be excreted into breast milk in clinically significant amounts. Moreover, as a peptide, any amounts in milk probably will be digested in the infant's gut.

NEVIRAPINE

Antiviral

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo/Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

The human data for nevirapine suggest that the risk for embryo–fetal harm is low. At least at term, the drug readily crosses the human placenta. If indicated, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Nevirapine is used in combination with other antiviral agents in the treatment of HIV infections. It is a non-nucleoside reverse transcriptase inhibitor (nnRTI). Other agents in this class include delavirdine and efavirenz (1).

No teratogenic effects were observed in reproductive studies with rats and rabbits. In rats, however, a significant decrease in fetal weight occurred at doses producing systemic levels approximately 50% higher (based on AUC) than those seen with the recommended human dose. Moreover, impaired fertility was noted in female rats at doses producing levels approximately equal to those seen with the recommended human dose (1).

Nevirapine readily crosses the human placenta to the fetus. In a study reported by the manufacturer, nevirapine crossed the placentas of 10 HIV type 1 (HIV-1)-infected women given a single oral dose of 100 or 200 mg a mean 5.8 hours before delivery (1). The placental transfer is consistent with the low molecular weight of about 266.

A study published in 1998 described the pharmacokinetics of nevirapine in 18 HIV-1-infected women who received the drug in active labor (2). In the first cohort, 10 women were treated with 100 or 200 mg of nevirapine, but no drug was given to their infants. Based on the pharmacokinetic data in the first cohort, eight additional women were given a 200-mg dose of nevirapine during active labor and their infants received a 2-mg/kg dose 48–72 hours after birth. In this latter cohort, delivery was a median 5.4 hours after dosing. The median

cord blood nevirapine concentration was 1106 ng/mL, resulting in a median ratio of cord blood:maternal plasma of 82.9% (range 71.9%–120.2%). The median calculated nevirapine concentration 7 days after birth was 215 ng/mL (range 112–275 ng/mL). Maintaining the concentration above 100 ng/mL (10 times the in vitro 50% inhibitory concentration [IC₅₀] against HIV) during labor and in the neonate during the 7 days of life was a specific goal of the study. No adverse effects due to nevirapine or HIV-infected infants were observed (2).

A 1999 study also described the pharmacokinetics of a single 200-mg dose of nevirapine given to 20 HIV-infected women during labor and to 13 of the neonates at 72 hours (3). The median cord:maternal blood ratio was 0.75. The target drug level (>100 ng/mL; 10 times the IC₅₀) in the neonates was maintained in all infants at 7 days of age, whether or not they received nevirapine at 72 hours. No serious adverse effects attributable to nevirapine were observed (3).

The Antiretroviral Pregnancy Registry reported, for January 1989 through July 2009, prospective data (reported before the outcomes were known) involving 4702 live births that had been exposed during the 1st trimester to one or more antiretroviral agents (4). Congenital defects were noted in 134, a prevalence of 2.8% (95% confidence interval [CI] 2.4–3.4). In the 6100 live births with earliest exposure in the 2nd/3rd trimesters, there were 153 infants with defects (2.5%, 95% CI 2.1–2.9). The prevalence rates for the two periods did not differ significantly. There were 288 infants with birth defects among 10,803 live births with exposure anytime during pregnancy (2.7%, 95% CI 2.4–3.0). The prevalence rate did not differ significantly from the rate expected in a nonexposed population. There were 2007 outcomes exposed to nevirapine (842 in the 1st trimester and 1165 in the 2nd/3rd trimesters) in combination with other antiretroviral agents. There were 45 birth defects (18 in the 1st trimester and 27 in the 2nd/3rd trimesters). In reviewing the birth defects of prospective and retrospective (pregnancies reported after the outcomes were known) registered cases, the Registry concluded that, except for isolated cases of neural tube defects with efavirenz exposure in retrospective reports, there was no other pattern of anomalies (isolated or syndromic) (4). (See Lamivudine for required statement.)

A 2000 case report described the pregnancy outcomes of two pregnant women with HIV infection who were treated with the anti-infective combination, trimethoprim/sulfamethoxazole, for prophylaxis against *Pneumocystis carinii*, concurrently with antiretroviral agents (5). One of the cases involved a 31-year-old woman, who presented at 15 weeks' gestation. She was receiving

trimethoprim/sulfamethoxazole, didanosine, stavudine, nevirapine, and vitamin B supplements (specific vitamins and dosage not given) that had been started before conception. A fetal ultrasound at 19 weeks' gestation revealed spina bifida and ventriculomegaly. The patient elected to terminate her pregnancy. The fetus did not have HIV infection. Defects observed at autopsy included ventriculomegaly, an Arnold-Chiari malformation, sacral spina bifida, and a lumbo-sacral meningocele. The authors attributed the neural tube defects to the antifolate activity of trimethoprim (5).

A study published in 1999 evaluated the safety, efficacy, and perinatal transmission rates of HIV in 30 pregnant women receiving various combinations of antiretroviral agents (6). Many of the women were substance abusers. Nevirapine was used in combination with zidovudine, didanosine, and/or lamivudine in two of the women. Antiretroviral therapy was initiated at a median of 14 weeks' gestation (range preconception to 32 weeks). Despite previous histories of extensive antiretroviral experience and of vertical transmission of HIV, combination therapy was effective in treating maternal disease and in preventing transmission to the current newborns. No adverse outcomes were noted in the two nevirapine-exposed cases (6).

A 1999 study compared the safety and efficacy of a short course of nevirapine to zidovudine for the prevention of mother-to-child transmission of HIV-1 (7). At the onset of labor, women were randomly assigned to receive either a single dose of nevirapine (200 mg) plus a single dose (2 mg/kg) to their infants 24–72 hours after birth (N = 310) or zidovudine (600 mg then 300 mg every 3 hours until delivery) plus 4 mg/kg twice daily for 7 days to their infants (N = 308). Nearly all (98.8%) of the women breastfed their infants immediately after birth. Up to age 14–16 weeks, significantly fewer infants in the nevirapine group were HIV-1 infected, lowering the risk of infection or death, compared with zidovudine, by 48% (95% CI, 24–65) (7). The prevalence of maternal and infant adverse effects was similar in the two groups. In an accompanying study, the nevirapine regimen was shown to be cost-effective in various seroprevalence settings (8).

If nevirapine is used in the 2nd/3rd trimesters, in utero exposure may induce hepatic cytochrome P450 CYP3A metabolism, thereby increasing the drug's clearance in the newborn (9). Therefore, offspring of pregnant women chronically treated with nevirapine may not receive protection from HIV infection for the full 7 days observed in those not exposed to chronic dosing (9).

A review published in 2000 reviewed seven clinical trials that have been effective in reducing perinatal transmission, five with zidovudine alone, one with

zidovudine plus lamivudine, and one with nevirapine (10). Six of the trials were in developing countries. Prolonged use of zidovudine in the mother and infant was not only the most effective for preventing vertical transmission, but also the most expensive. Single-dose nevirapine (in the mother and infant) was the least expensive and the simplest regimen to administer (10).

Two reviews, one in 1996 and the other in 1997, concluded that all women currently receiving antiretroviral therapy should continue to receive therapy during pregnancy and that treatment of the mother with monotherapy should be considered inadequate therapy (11,12). The same conclusion was reached in a 2003 review with the added admonishment that therapy must be continuous to prevent emergence of resistant viral strains (13). In 2009, the updated U.S. Department of Health and Human Services guidelines for the use of antiretroviral agents in HIV-1-infected patients continued the recommendation that therapy, with the exception of efavirenz, should be continued during pregnancy (14). If indicated, nevirapine should not be withheld in pregnancy because the expected benefit to the HIV-positive mother outweighs the unknown risk to the fetus. Updated guidelines for the use of antiretroviral drugs to reduce perinatal HIV-1 transmission also were released in 2010 (15). Women receiving antiretroviral therapy during pregnancy should continue the therapy, but, regardless of the regimen, zidovudine administration is recommended during the intrapartum period to prevent vertical transmission of HIV to the newborn (15).

BREASTFEEDING SUMMARY

Nevirapine is excreted into breast milk. In a study reported by the manufacturer, nevirapine was found in the breast milk of 10 women with HIV-1 infection given a single oral dose of 100 or 200 mg a mean 5.8 hours before delivery (1). In 21 HIV-infected women who had received a single 200-mg dose of nevirapine during labor, the median milk:maternal plasma ratio was 60.5% (range 25.3%–122.2%) (3). At 48 hours after birth, the median breast milk concentration was 454 ng/mL (range 219–972 ng/mL), declining to 103 ng/mL (range 50–309 ng/mL) 7 days after birth (3).

HIV-1 is transmitted in milk, and in developed countries, breastfeeding is not recommended (11,12,14,16–18). In developing countries, breastfeeding is undertaken, despite the risk, because there are no affordable milk substitutes available. Zidovudine, zidovudine plus lamivudine, and nevirapine have all been shown to reduce, but not eliminate, the risk of HIV-1 transmission during breastfeeding (see also Lamivudine and Zidovudine) (10).

NIACIN

Vitamin/Antilipemic Agent

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Niacin, a B complex vitamin, is converted in humans to niacinamide, the active form of vitamin B₃. See Niacinamide.

BREASTFEEDING SUMMARY

See Niacinamide.

NIACINAMIDE

Vitamin

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Niacinamide, a water-soluble B complex vitamin, is an essential nutrient required for lipid metabolism, tissue respiration, and glycogenolysis (1). Both niacin, which is converted to niacinamide in vivo, and niacinamide are available commercially and are collectively known as vitamin B₃. The National Academy of Sciences' recommended dietary allowance (RDA) for niacin in pregnancy is 17 mg (1).

FETAL RISK SUMMARY

Only two reports have been located that link niacinamide with maternal or fetal complications. A 1948 study observed an association between niacinamide deficiency and pregnancy-induced hypertension (PIH) (2). Other B complex vitamins have also been associated with this disease, but any relationship between vitamins and PIH is controversial (see other B complex vitamins). One patient with hyperemesis gravidarum presented with neuritis, reddened tongue, and psychosis (3). She was treated with 100 mg of niacin plus other B complex vitamins, resulting in the rapid disappearance of her symptoms. The authors attributed her response to the niacin.

Niacinamide is actively transported to the fetus (4,5). Higher concentrations are found in the fetus and newborn, rather than in the mother (5–8). Deficiency of niacinamide in pregnancy is uncommon except in women with poor nutrition (6,7). At term, the mean niacinamide value in 174 mothers was 3.9 mcg/mL (range 2.0–7.2 mcg/mL) and in their newborns was 5.8 mcg/mL (range 3.0–10.5 mcg/mL) (6). Conversion of the amino acid, tryptophan, to niacin and then to niacinamide is enhanced in pregnancy (9).

BREASTFEEDING SUMMARY

Niacin, the precursor to niacinamide, is actively excreted into breast milk (10). Reports on the excretion of niacinamide in milk have not been located, but it is probable that it also is actively transferred. In a study of lactating women with low nutritional status, supplementation with niacin in doses of 2.0–60.0 mg/day resulted in mean milk concentrations of 1.17–2.75 mcg/mL (10). Milk concentrations were directly proportional to dietary intake. A 1983 English study measured niacin levels in pooled human milk obtained from mothers of preterm (26 mothers, 29–34 weeks) and term (35 mothers, ≥39 weeks) infants (11). Niacin in milk from preterm mothers rose from 0.65 (colostrum) to 2.05 mcg/mL (16–196 days), whereas that in milk from term mothers increased during the same period from 0.50 to 1.82 mcg/mL.

The National Academy of Sciences' RDA for niacin during lactation is 20 mg (1). If the diet of the lactating woman adequately supplies this amount, supplementation with niacinamide is not needed. Maternal supplementation with the RDA for niacinamide is recommended for those patients with inadequate nutritional intake.

NICARDIPINE

Calcium Channel Blocker

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Nicardipine has caused dose-related embryo toxicity, but not teratogenicity, in animals. Human data early in gestation are insufficient to assess the risk to the embryo or fetus. Only a few of the 10 calcium channel blockers have any human data on exposure during early gestation. Based on this very limited information, these agents do not appear to be major human teratogens. However, more information is required before any conclusion can be reached as to the potential teratogenic risk of these agents. In addition, maternal hypotension caused by nicardipine is a theoretical complication that could jeopardize the fetus.

FETAL RISK SUMMARY

Nicardipine is a calcium channel-blocking agent used in the treatment of angina and hypertension. The drug has also been used as a tocolytic in premature labor.

Dose-related embryotoxicity, but not teratogenicity, was observed in reproduction studies using IV nicardipine in rats and rabbits (1). Embryotoxic doses were about 2.5 and 0.5 times, respectively, the maximum recommended human dose (MRHD). At 50 times the MRHD in rats, dystocia, reduced birth weights, reduced neonatal survival, and reduced neonatal weight gain were noted (1). In one type of rabbit, but not in another, high doses (about 75 times the MRHD) were embryocidal (1). Two studies with rats reported that in utero exposure had no effect on postnatal function or subsequent fertility (2,3).

Nicardipine 20 mcg/kg/minute was infused for 2 minutes in 15 near-term ewes given angiotensin II 5 mcg/minute (4). Transient bradycardia was observed in the fetuses, followed by hypercapnia and acidemia. These changes

were associated with a decrease in fetal placental blood flow and an increase in fetal vascular resistance, and five fetuses died 65 minutes after nicardipine was given. In the second part of this study in the pregnant ewe, nicardipine was found to reverse maternal angiotensin II-induced systemic vasoconstriction, including that of the renal and endomyometrial vascular beds, but it caused a significant increase in placental vascular resistance (5).

The use of nicardipine as a tocolytic agent was first investigated in an experiment using excised rabbit uterus and in laboring (either spontaneous or induced) rats (6). In both species, the calcium channel blocker was effective in abolishing uterine contractions. A 1983 study investigated the effect of nicardipine and nifedipine on isolated human pregnant-term and nonpregnant myometrium (7). Nicardipine was a more potent tocolytic than nifedipine in pregnant myometrium, but its onset of action was slower.

Because the cardiovascular and myometrial responses of pregnant rabbits are similar to those observed in human pregnancies (8), a series of studies was conducted in the rabbit with nicardipine to determine its effectiveness as a tocolytic agent and its safety for the mother and the fetus (8–10). A statistically significant inhibition of uterine contractions was recorded in each study, but this effect was accompanied by maternal tachycardia, an increase in cardiac output, a drop in both diastolic and systolic blood pressure and mean arterial pressure, and a decrease in uteroplacental blood flow. The authors of these studies cautioned that further trials were necessary because the decrease in uteroplacental blood flow would seriously jeopardize the fetus (9,10).

In a study to determine the tocolytic effects of nicardipine in a primate species, pregnant rhesus monkeys with spontaneous uterine contractions were treated with an IV bolus of 500 mcg, followed by a continuous infusion of 6 mcg/kg/minute for 1 hour (11). Placental transfer of nicardipine was demonstrated with peak fetal concentrations ranging from 7 to 35 ng/mL compared with maternal peak levels of 175 to 865 ng/mL. Although a marked tocolytic effect was observed, significant acidemia and hypoxemia developed in the fetuses.

It is not known if nicardipine crosses the human placenta. The molecular weight (about 480 for the free base) suggests that exposure of the embryo–fetus should be expected.

The tocolytic effects of nicardipine have been reported (12–14). The agent compared favorably with albuterol (12) and magnesium sulfate (13,14). No adverse effects in the newborns attributable to nicardipine were observed.

The direct effects of nicardipine on the fetus were investigated in a study

using fetal sheep (15). Infusions of nicardipine, either 50 or 100 mcg, had minimal, nonsignificant effects on mean arterial and diastolic blood pressure and no effect on fetal heart rate, fetal arterial blood gas values, and maternal cardiovascular variables. The authors concluded that the fetal hypoxia observed in other animal studies, when nicardipine was administered to the mother, was not due to changes in umbilical or ductal blood flow but to a decrease in maternal uterine blood flow (15).

A single 10-mg dose of nicardipine was given to eight women with acute hypertension (diastolic blood pressure >105 mmHg) in the 3rd trimester of pregnancy (16). A significant decrease in maternal diastolic, but not in systolic, pressure was observed during the next 60 minutes with an onset at 15 minutes.

Nicardipine has been used in human pregnancy for the treatment of hypertension (17,18). Forty women with mild or moderate hypertension (25 with gestational hypertension, 3 with preeclampsia, and 12 with chronic hypertension) were treated with oral nicardipine 20 mg 3 times a day, beginning at 28 weeks' gestation through the 7th postpartum day, a mean duration of 9 weeks (17). An additional 20 women were treated with IV nicardipine for severe preeclampsia, 5 of whom also had chronic hypertension, beginning at a mean 33 weeks' gestation (range 27–40 weeks). The IV dose used was based on body weight: 2 mg/hr (N = 9; <80 kg), 4 mg/hr (N = 8; 80–90 kg), and 6 mg/hr (N = 3; >90 kg). The mean duration of IV therapy was 5.3 days (range 2–15 days). Low placental passage of nicardipine was demonstrated in 10 women, 7 on oral therapy, and 3 receiving IV therapy, but no accumulation of the drug was observed in the fetus. No perinatal deaths, fetal adverse effects, or adverse neonatal outcomes attributable to nicardipine were observed during treatment. Both umbilical and cerebral Doppler velocimetry remained stable throughout the study (17).

A study published in 1994 compared nicardipine and metoprolol in the treatment of hypertension (gestational, preeclampsia, and chronic) during pregnancy (18). Fifty patients were treated in each group starting at a gestational age of about 29 weeks. Nicardipine decreased maternal systolic and diastolic blood pressure and umbilical artery resistance significantly more than metoprolol and significantly fewer patients required a cesarean section for fetal distress (6% vs. 28%). The difference in birth weights in the two groups was 201 g (2952 vs. 2751 g) (ns) (18).

A prospective, multicenter, cohort study of 78 women (81 outcomes; 3 sets of twins) who had 1st trimester exposure to calcium channel blockers (none of whom took nicardipine) was reported in 1996 (19). Compared with controls, no

increased risk of congenital malformations was found.

BREASTFEEDING SUMMARY

No reports describing the use of nifedipine during human lactation have been located. The molecular weight (about 480 for the free base) suggests that the drug will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown.

NICOTINE REPLACEMENT THERAPY

Central Nervous System Agent (Smoking Deterrent)

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >> Embryo/Fetal Risk Contraindicated (with any use of tobacco)

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Nicotine is a toxic, highly addictive compound. Although additional studies are needed to determine the magnitude of the embryo/fetal risk from using nicotine replacement therapy (NRT), the risk from cigarette smoking is well known. Cigarette smoke contains more than 3000 different compounds, including nicotine, carbon monoxide, ammonia, polycyclic aromatic hydrocarbons, hydrogen cyanide, and vinyl chloride (see Cigarette Smoking).

Nonpharmacologic approaches to smoking cessation are the safest for the mother and her embryo/fetus, but if these methods have failed, the use of nicotine replacement therapy (NRT) during pregnancy might be reasonable. Women must be counseled that if they continue to smoke while using NRT, such as the dermal patch, the risk to their embryo and/or fetus might be greater than when either is used alone. Reducing smoking before or early in gestation and before starting the dermal patch should be attempted. Other strategies that might lessen the fetal risk include starting the patches after organogenesis, wearing the patches for 16 hours a day, and adherence to the tapering schedule so that the patches can be discontinued after 8–10 weeks. These strategies apply to all NRTs. Nevertheless, a pregnant woman should be informed that exposure to any nicotine, whatever the source, carries a risk of embryo and/or fetal harm.

FETAL RISK SUMMARY

Nicotine is a stimulant that is a major component of tobacco smoke. NRT is used to reduce withdrawal symptoms, including nicotine craving, associated with quitting smoking. The products include skin patches (nicotine transdermal

patches), chewing gum (nicotine polacrilex [nicotine resin complex]), nicotine inhaler, and nicotine nasal sprays. Only the inhaler and nasal sprays require a prescription in the United States.

Shepard (1) briefly reviewed a number of animal studies that found widespread nicotine-induced toxicity during pregnancy. The animal species included mice, rats, and rabbits, and accidentally exposed swine. Toxicity included stillbirths, reduced fetal body weight, skeletal defects, cleft palate, limb deformities, hydrocephalus, changes in the brain, toxicity to germ cells and oocytes, and retarded placental development. Schardein also discusses the teratogenicity of tobacco in livestock and experimental animals (2).

The pharmacokinetics of nicotine, its effects on uterine blood flow, and its presence in the fetal compartment are described in the review of cigarette smoking (see Cigarette Smoking). NRT avoids the high nicotine levels associated with cigarette smoking (1). However, it may actually deliver more nicotine to the embryo and fetus (see reference 12 below).

In 2006, a study using data from the Danish National Birth Cohort (1997–2003) evaluated the outcomes of 20,603 women who smoked during the first 12 weeks of pregnancy compared with 56,165 nonexposed controls (3). In the smoking group, there were 1034 (5.0%) liveborn infants with congenital malformations compared with 2733 (4.9%) liveborn infants in the control group (not significant). Malformations of cleft lip, the digestive tract, and the cardiovascular system had significantly high odds ratios. There were 19 (7.6%) liveborn infants with congenital malformations among 250 women who used NRT during the first 12 weeks of pregnancy. Six of the defects were major musculoskeletal congenital malformations. After exclusion of seven cases of dislocation of the hip and one minor defect, the relative prevalence rate ratio (RPR) for major malformations was 1.13 (95% confidence interval [CI] 0.62–2.07) and for musculoskeletal defects was 2.05 (95% CI 0.91–4.63). For smokers, the RPR ranged from 1.01 to 1.09 with no indication of a dose–response association. However, early spontaneous abortions in smokers may have altered the findings. The authors concluded that the data suggested an increased risk of congenital defects in nonsmokers using NRT (3).

Four groups of authors criticized the above study for various reasons, but all were most concerned over the study's conclusion that smoking may be safer for the fetus than NRT (4–7). Other concerns included the small size of the NRT group, the absence of maternal history, when the NRT was started, the levels of nicotine obtained with smoking compared with NRT, lack of a statistical power estimation, lack of statistical significance, differences between subjects

and controls, and the potential for misclassification. In a reply, the authors responded to the concerns and stated that while they did not claim the association to be causal, causality could not be excluded (8).

Women who are attempting to conceive and those who are pregnant should be encouraged to stop smoking (9–13). In addition to the obvious health benefits for the woman, smoking cessation can significantly decrease the known risks to the embryo, fetus, newborn, infant, and adolescent. For example, women who quit smoking in the first 3 or 4 months of pregnancy can lower the risk of a low-birth-weight infant to that of nonsmoking women (9). Smoking cessation also reduces the risk of prematurity and perinatal deaths, and results in fewer infant/adolescent complications (9). Many different strategies have been developed to promote smoking cessation (9–13). A nonpharmacologic approach is preferred, but many women may be heavily addicted to smoking and require NRT and other agents. However, NRT has not been adequately studied in pregnancy. One concern is the potential for nicotine-induced decreased uterine blood flow and increased uterine vascular resistance that could result in impaired fetal growth and other complications.

Transdermal systems appear to be more effective than chewing gum because of improper use and taste of the latter (10). On the other hand, transdermal patches may actually deliver more nicotine to the embryo/fetus because continuous blood levels of nicotine, in contrast to periodic levels from episodic smoking, are available to cross the placenta (12). One strategy to reduce the amount of embryo–fetal nicotine exposure is to apply the patches for only 16 hours a day (4).

Based on four published studies of NRT in pregnancy, two involving patches, gum in one, and any type of NRT in one, a 2010 review concluded that the therapy decreased the risk for low birth weight and preterm delivery compared with continued smoking (14).

BREASTFEEDING SUMMARY

No reports describing the use of NRT during lactation have been located. Nicotine is excreted into breast milk (see Cigarette Smoking). Although there are significant risks from cigarette smoking for the mother and her nursing infant, the risks of exposure to NRT have not been defined. The American Academy of Pediatrics encourages smoking cessation during lactation, but makes no recommendation for or against NRT because of insufficient data (15).

NIFEDIPINE

Calcium Channel Blocker

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

The experience with nifedipine in human pregnancy is limited, although the agent has been used for tocolysis and as an antihypertensive agent in pregnant women. The agent does not appear to be a major human teratogen based on the results of two studies. Severe adverse reactions, however, have occurred when the drug was combined with IV magnesium sulfate.

FETAL RISK SUMMARY

The use of nifedipine, a calcium channel-blocking agent, during pregnancy is controversial. Studies in pregnant sheep with IV infusions of the drug indicate that a progressive decrease in mean maternal arterial blood pressure occurs without a significant alteration of uterine vascular resistance (1). The hypotensive effect of nifedipine resulted in a decrease in uterine blood flow and fetal arterial oxygen content. Other investigators have reported similar results in animals with other calcium channel blockers (2). Although these studies indicated the potential problems with nifedipine, the investigators cautioned that their findings were preliminary and needed to be confirmed in humans (1,3).

Reproduction studies with nifedipine have been conducted in mice, rats, and rabbits (4). The drug was teratogenic (digital anomalies similar to those reported with phenytoin) in rats and rabbits, an effect that might have resulted from compromised uterine blood flow. Other toxicities were noted in the embryos and fetuses of mice, rats, and rabbits at doses 3.5 to 42 times the maximum recommended human dose (MRHD) on a weight basis, or doses higher or lower than the MRHD based on BSA (4). These toxicities included stunted fetuses (mice, rats, rabbits), rib deformities (mice), cleft palate (mice), embryo and fetal deaths (mice, rats, rabbits), and prolonged pregnancy and

decreased neonatal survival (rats; not evaluated in other species) (4). Small placentas and underdeveloped chorionic villi were observed in monkeys at doses equivalent to or less than the MRHD based on BSA (4). IV nifedipine in pregnant rhesus monkeys has been associated with fetal hypoxemia and acidosis (5).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 37 newborns had been exposed to nifedipine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Two (5.4%) major birth defects were observed (two expected), one of which was a cardiovascular defect (0.5 expected). No anomalies were observed in five other categories of defects (oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available.

A human study was reported in 1988 in which nine hypertensive pregnant women in the 3rd trimester were treated with 5 mg of nifedipine sublingually and compared with nine hypertensive women treated with placebo (6). The women were randomly assigned to the two groups, but treatment was not blinded. Both maternal arterial blood pressure and uterine artery perfusion pressure were significantly lowered by nifedipine, but no apparent reduction in uteroplacental blood flow was detected. The investigators interpreted their findings as suggestive of a relative uterine vasodilation and a relative decrease in uterine vascular resistance that was proportional to the decrease in blood pressure (6).

Nifedipine has been used during the 2nd and 3rd trimesters for the treatment of severe hypertension (7). No fetal heart rate changes were observed after reduction of maternal blood pressure, nor were other adverse effects noted in the fetus or newborn. In a 1987 study, 23 women with severe hypertension of various causes (4 gestational, 17 essential, 1 renal, and 1 systemic lupus erythematosus) who either failed to respond to first-line therapy (atenolol, methyldopa, or hydralazine) and had slow-release nifedipine, 40–120 mg/day, added to their regimens (N = 22), or nifedipine, 40 mg/day, was used as initial therapy (N = 1) (8). Good blood pressure control was obtained in 20 women. The mean duration of therapy was 8.75 weeks (range 1–24 weeks). There were three perinatal deaths (rate 130/1000), but none could be attributed to drug therapy. The mean gestational age at delivery was 35 weeks (range 29–39 weeks), and 15 (71%) of the 21 liveborn infants were delivered by cesarean section. A high percentage of the 22 infants with accessible data were growth restricted, 9 (41%) had birth weights at or below the 3rd percentile, and 20

(91%) were at or below the 10th percentile for body weight. The investigators could not determine whether this outcome was caused by the severe maternal disease, drug therapy, or a combination of both (8).

Nifedipine has been used as a tocolytic agent. An in vitro study using pregnant human myometrium found that nifedipine caused a dose-related decrease in contraction strength and lengthened the period of contraction in a non-dose-related manner (9). In three studies totaling 31 women, nifedipine was used for this purpose (10–12). In one patient, nifedipine, 20 mg 3 times daily combined with terbutaline, was given for a total of 55 days (11). A study involving 60 women in presumed early labor was reported in 1986 (12). Women were included in this open trial if they had a singleton pregnancy and intact membranes, were between 20 and 35 weeks' gestation, and were contracting at least once every 10 minutes, and if their cervix was <4 cm dilated. Included among the various exclusions was a history of mid-trimester abortion or previous preterm delivery. The women were equally divided into three groups: nifedipine, ritodrine, and no treatment. Nifedipine dosage was 30 mg orally followed by 20 mg every 8 hours for 3 days. Ritodrine was initially administered as a standard IV infusion, followed by 48 hours of oral therapy. The days from presentation to delivery in the nifedipine, ritodrine, and no treatment groups were 36.3, 25.1, and 19.3 days ($p < 0.001$ nifedipine compared with the other two groups), respectively (12). No complications of the therapy were found in any of the infants from the three studies. Two of the studies conducted follow-up examinations of the infants at 5–12 months of age and all were alive and well (10,11).

Two apparently clinically significant drug interactions when nifedipine and magnesium were used concurrently have been reported (13,14). A woman, at 32 weeks' gestation in premature labor, was treated with 60 mg of nifedipine orally for 3 hours, followed by 20 mg every 8 hours. Uterine contractions returned 12 hours later and IV magnesium sulfate was started, followed by the onset of pronounced muscle weakness after 500 mg had been administered. Her symptoms consisted of jerky movements of the extremities, difficulty in swallowing, paradoxical respirations, and an inability to raise her head from the pillow (13). The muscle weakness resolved 25 minutes after the magnesium was stopped. The effects were attributed to nifedipine potentiation of the neuromuscular-blocking action of magnesium. In a second report, two women were hospitalized for hypertension at 30 and 32 weeks' gestation (14). In both cases, oral methyldopa (2 g) and IV magnesium sulfate (20 g) daily were ineffective in lowering the mother's blood pressure. Oral nifedipine 10 mg was

given and a marked hypotensive response occurred 45 minutes later. The blood pressures before nifedipine were 150/110 and 140/105 mmHg, respectively, and then decreased to 80/50 and 90/60 mmHg, respectively, after administration of the calcium channel blocker. The blood pressures returned to the previous levels 25–30 minutes later. Both infants were delivered following the hypotensive episodes, but only one survived.

The pharmacokinetics of nifedipine in pregnant women have been studied (15).

A prospective, multicenter, cohort study of 78 women (81 outcomes; 3 sets of twins) who had 1st trimester exposure to calcium channel blockers, including 44% to nifedipine, was reported in 1996 (16). Compared with controls, no increase in the risk of major congenital malformations was found.

BREASTFEEDING SUMMARY

Nifedipine is excreted into breast milk (17). A woman with persistent hypertension after premature delivery at 26 weeks' gestation was treated with nifedipine 30 mg every 8 hours for 48 hours, then 20 mg every 8 hours for 48 hours, then 10 mg every 8 hours for 36 hours. Concentrations of the drug in milk were related to dosage and the time interval between the dose and milk collection. Peak concentrations and time of occurrence were 53.35 ng/mL 30 minutes after 30 mg, 16.35 ng/mL 1 hour after 20 mg, and 12.89 ng/mL 30 minutes after 10 mg. The estimated milk half-lives after the three doses were 2.4 hours (30 mg), 3.1 hours (20 mg), and 1.4 hours (10 mg). In comparison with controls, nifedipine had no effect on milk composition. The authors concluded that these amounts, representing <5% of a therapeutic dose, posed little risk to a nursing infant. If desired, delaying breastfeeding by 3–4 hours after a dose would significantly decrease the amount of drug ingested by the infant (17). The American Academy of Pediatrics classifies nifedipine as compatible with breastfeeding (18).

NILOTINIB

Antineoplastic (Tyrosine Kinase Inhibitor)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of nilotinib in human pregnancy have been located.

In animal studies, developmental toxicity (embryo–fetal death) without maternal toxicity was observed in one species. The absence of human pregnancy experience prevents a complete assessment of the embryo–fetal risk. However, the drug should be avoided in pregnancy. If it must be given for the mother’s benefit, avoiding the 1st trimester should be considered.

FETAL RISK SUMMARY

Nilotinib is an oral tyrosine kinase inhibitor. It is in the same subclass as several other agents (see Appendix). Nilotinib is indicated for the treatment of chronic-phase and accelerated-phase Philadelphia chromosome-positive chronic myelogenous leukemia in adults resistant to or intolerant to prior therapy that include imatinib. It is metabolized to inactive metabolites. Serum protein binding is about 98%, and the apparent elimination half-life is about 17 hours (1).

Reproduction studies have been conducted in rats and rabbits. In pregnant rats, doses producing systemic exposures that were about ≥ 1.7 times the exposure (AUC) from the recommended human dose (RHD) resulted in increased resorptions and postimplantation losses. Maternal toxicity (decreased body weight, uterine weight, weight gain, and food consumption) was evident at exposures that were about 5.7 times the RHD. At this exposure, there was a decrease in viable fetuses. In pregnant rabbits, a dose about half of the RHD was maternal toxic (death and decreased weight and food consumption) and was associated with embryo death (resorptions) and minor skeletal anomalies. Nilotinib did not cause structural anomalies in these two species (1).

Carcinogenicity studies have not been conducted with nilotinib. The drug was not mutagenic or clastogenic in multiple assays. Nilotinib had no effect on mating or fertility in male and female rats at doses up to about 4–7 times the RHD or in female rabbits at doses that were about half the RHD. When male and female rats were given doses that were about 1–6.6 times the RHD during pre-mating and mating and then continued in pregnant rats through gestation day 6, there was an increase in postimplantation loss and early resorption, and a decrease in the number of viable fetuses and litter size at all doses tested (1).

It is not known if nilotinib crosses the human placenta. Although the serum protein binding is high, the molecular weight (about 512 for the nonhydrated free base) and long elimination half-life suggest that the drug will cross to the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use of nilotinib during human lactation have been located. Although the serum protein binding (98%) is high, the molecular weight (about 512 for the nonhydrated free base) and long elimination half-life (about 17 hours) suggest that the drug will be excreted into breast milk. The effects of this exposure on a nursing infant are unknown, but there is potential for severe toxicity based on the adult data. The most common adverse reactions in adults were rash, pruritus, nausea, vomiting, fatigue, headache, and constipation and/or diarrhea. Thrombocytopenia and neutropenia also have been observed (1). Because of the risk, women receiving nilotinib should not breastfeed.

NIMODIPINE

Calcium Channel Blocker

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Nimodipine is teratogenic and toxic in experimental animals. However, human data early in gestation are insufficient to assess the risk to the embryo or fetus. Only a few of the 10 calcium channel blockers have any human data on exposure during early gestation. Based on this very limited information, these agents do not appear to be major human teratogens. However, more information is required before any conclusion can be reached as to the potential teratogenic risk of these agents.

FETAL RISK SUMMARY

Nimodipine is a dihydropyridine calcium channel blocker used to reduce the incidence and severity of ischemic deficits in patients with subarachnoid hemorrhage after rupture of congenital aneurysms. Nimodipine shares similar hemodynamic effects with other calcium channel blockers, but does not usually produce a marked lowering of blood pressure. In clinical studies involving nonpregnant patients, only about 5% of the subjects experienced a marked lowering of blood pressure (1).

In studies with male and female rats, nimodipine had no effect on fertility or reproductive performance at doses up to about four times the equivalent human dose of 60 mg every 4 hours in a 50-kg patient (EHD) (1). Reproduction studies have been conducted in rats and rabbits. Nimodipine was teratogenic in rabbits, producing an increase in the incidence of malformations and stunted fetuses at oral doses of 1–10 mg/kg/day (1). In rats, nimodipine dosing during organogenesis was embryotoxic, causing resorptions and stunted fetal growth, but except for skeletal variations, caused no malformations (1). The dose used in rats was about 12 times the EHD. Oral doses about 4 times the EHD

administered late in organogenesis and continued to nearly the end of gestation or for 21 days after delivery were associated with an increase in skeletal variations, stunted fetuses, and stillbirths but no malformations (1).

The placental transfer of nimodipine early in human gestation has apparently not been studied. Consistent with its molecular weight (about 418), nimodipine crosses the human placenta at term.

An abstract and later full report described the use of nimodipine for the management of preeclampsia (2,3). Ten women at about 38 weeks' gestation with preeclampsia were treated with nimodipine, 30 mg orally every 4 hours. Delivery occurred within 24 hours of starting nimodipine and continued for 24 hours after delivery. Both systolic and diastolic blood pressures were significantly reduced after nimodipine administration without evidence of fetal distress. At delivery, the median nimodipine concentrations in the maternal and umbilical cord serum were 7.32 and 2.6 ng/mL, respectively (fetal:maternal ratio 0.36). In four patients who were delivered by cesarean section within 2 hours of the first dose, the maternal and cord serum levels were 9.68 and 3.46 ng/mL, respectively (fetal:maternal ratio 0.36). The median Apgar scores were 8 (range 6–10) and 9 (range 8–10) at 1 and 5 minutes, respectively. No adverse effects of the drug treatment were observed in the newborns and all were doing well at 6-week follow-up (3). One newborn was excluded from the above data because the mother suffered a ruptured uterus. Although severely depressed at birth (Apgar scores 1 and 5 at 1 and 5 minutes, respectively), the infant was successfully resuscitated and was developing normally at 6 weeks of age (3).

A prospective, multicenter, cohort study of 78 women (81 outcomes; 3 sets of twins) who had 1st trimester exposure to calcium channel blockers, including 11% to nimodipine, was reported in 1996 (4). Compared with controls, the women experienced no increase in major congenital malformations.

Nimodipine also has been used for its cerebral vasodilator characteristics in the treatment of eclampsia complicated by cerebral vasospasm and edema (5–7). In the first two cases, delivery of the fetus had occurred before initiation of therapy (5,6). The use of nimodipine in combination with magnesium sulfate was not recommended because of the risk for maternal heart block (6). In the third report, seizures in four pregnant patients were halted with IV clonazepam (average dose 3 mg, range 1–5 mg), followed by IV nimodipine (1 mg/hr for 20 minutes, then 2 mg/hr) to control blood pressure (mean dose 1.83 mg) (7). The four liveborn infants were delivered by cesarean section once maternal blood pressure was controlled. The mean birth weight was 1822 g (range 1460–

2800 g). Individual Apgar scores were not provided, but two infants had 5-minute Apgar scores <7. One mother died of severe postpartum complications, and another developed multiorgan disease secondary to severe preeclampsia/eclampsia (7).

A 1998 abstract described an ongoing international, multicenter, randomized, controlled trial comparing the effects of nimodipine and magnesium sulfate in the prevention of eclampsia (8). Another study involving 21 women with severe preeclampsia compared oral nimodipine with IV magnesium sulfate for the prevention of seizures (9). Neither report provided data on newborns.

Maternal hypotension caused by nimodipine is a potential, but yet unreported, complication that could jeopardize the fetus. An in vitro study has examined the potential use of nimodipine as a tocolytic agent (10). Thus, additional data on the potential for nimodipine-induced maternal hypotension may be forthcoming.

BREASTFEEDING SUMMARY

Nimodipine is excreted into breast milk. In a 1996 case report, a 36-year-old woman at 3 weeks postpartum experienced a transient clinical syndrome of paresthesias (arm and face) associated with motor dysphasia (11). The symptoms resolved, but perioral dysesthesia and motor dysphasia recurred after cerebral angiography. Because the symptoms were thought possibly to be vascular spasm secondary to angiographic examination, the woman was treated with IV nimodipine (formulation not available in the United States). Over a 24-hour interval, she received a total dose of 46 mg (1 mg/hr for 2 hours, then 2 mg/hr). Milk samples were collected (50–60 mL/collection) by the patient every 3–4 hours during nimodipine therapy and blood samples were drawn about every 6 hours. The infant was not allowed to nurse during this period. Nimodipine milk concentrations ranged from 0.42 ng/mL (0.5 hours) to 4.70 ng/mL (26 hours; 2 hours after the infusion ended), whereas the maternal serum concentrations ranged from 3.54 to 10.83 ng/mL. The milk:serum ratios at 0.5, 7.5, and 13.5 hours were 0.12, 0.06, and 0.15, respectively. Assuming a milk intake of 150 mL/kg/day, the authors estimated that the infant would have received 0.008% to 0.092% of the mother's weight-adjusted dose. This exposure was thought to be clinically insignificant (11).

NISOLDIPINE

Calcium Channel Blocker

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Although the lack of human pregnancy experience prevents a complete assessment of the embryo–fetal risk, the absence of teratogenicity and the observance of fetotoxicity only at maternal toxic doses in animals are reassuring. Other calcium channel blockers have been extensively used in human pregnancy as antihypertensives and tocolytics without evidence of major congenital defects or fetal toxicity (see Nifedipine, Nifedipine, and Verapamil).

FETAL RISK SUMMARY

Nisoldipine is a calcium channel blocker indicated for the treatment of hypertension, either alone or in combination with other antihypertensive agents. The elimination half-life (about 7–12 hours) of this agent allows for once-daily dosing.

Animal reproduction studies have been conducted in three species (1). No teratogenicity was observed in rats and rabbits, but fetotoxicity, most likely due to maternal toxicity, did occur in both species. Decreased fetal weight was observed in pregnant rats given doses about 5 and 16 times the maximum recommended human dose based on BSA (MRHD). At the higher dose, increased postimplantation loss (resorption) was also noted. In pregnant rabbits, decreased fetal and placental weights occurred at doses approximately 10 times the MRHD. At a dose 30 times the MRHD in pregnant monkeys, the only surviving fetus had forelimb and vertebral abnormalities not previously seen in control monkeys of the same strain (1). In this particular study, control monkeys also had increased rates of abortion and mortality (1).

It is not known if nisoldipine crosses the human placenta. The molecular

weight (about 388) is low enough that placental transfer should be expected.

No reports describing the use of nisoldipine during human pregnancy have been located. A 1992 abstract did report the successful use of the agent in 12 women for the treatment of severe postpartum pregnancy-induced hypertension (2). Other calcium channel blockers (e.g., see Nicardipine, Nifedipine, and Verapamil) have been used for maternal hypertension and as tocolytic agents.

BREASTFEEDING SUMMARY

No reports describing the use of nisoldipine in human lactation have been reported. The molecular weight (about 388) is low enough that excretion into breast milk should be expected. The effect of this exposure on a nursing infant is unknown. Other calcium channel blockers are excreted in milk and are classified as compatible with breastfeeding by the American Academy of Pediatrics (see Diltiazem, Nifedipine, and Verapamil).

NITAZOXANIDE

Anti-Infective (Antiprotozoal)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of nitazoxanide in human pregnancy have been located. Although the animal data are suggestive of low risk, the absence of human pregnancy experience prevents an assessment of risk that the drug represents to an embryo or fetus. If indicated, nitazoxanide should not be withheld during pregnancy. However, until human pregnancy data are available, exposure to the agent should be avoided in the 1st trimester, if possible.

FETAL RISK SUMMARY

Nitazoxanide is an oral synthetic antiprotozoal agent approved for the treatment of diarrhea caused by *Cryptosporidium parvum* and *Giardia lamblia* in pediatric patients between the ages of 1 and 11 years (1). However, the drug has been used in children and adults for a wide variety of gastrointestinal and hepatic infections, including those associated with AIDS (2–10). Nitazoxanide is a prodrug that is rapidly hydrolyzed during absorption to the active metabolites, tizoxanide and tizoxanide glucuronide (1). The parent compound, nitazoxanide, is not detected in plasma. Tizoxanide is extensively bound to plasma proteins (>99.9%) (1). The terminal elimination half-life of tizoxanide is 7.3 hours (11).

Reproduction studies have been conducted in rats and rabbits. In rats, doses up to 48 times the human clinical dose based on BSA (HCD) revealed no evidence of fetal harm. Higher doses (up to 66 times the HCD) had no effect on fertility in male and female rats. In rabbits, doses up to three times the HCD revealed no evidence of impaired fertility or fetal harm (1).

It is not known if the active metabolites of nitazoxanide cross the human placenta (nitazoxanide itself is not detected in the plasma). The molecular

weight of one of the active metabolites, tizoxanide (about 265), is low enough for placental passage, but the extensive plasma protein binding will limit the amount of drug transferred to the embryo or fetus.

BREASTFEEDING SUMMARY

No reports describing the use of nitazoxanide during human lactation have been located. It is not known if the active metabolites of nitazoxanide are excreted into breast milk (nitazoxanide itself is not detected in the plasma). The molecular weight of one of the active metabolites, tizoxanide (about 265), is low enough to be excreted into breast milk, but the extensive plasma protein binding (>99.9%) will limit the amount. The effect of this exposure on a nursing infant is unknown, but probably is not clinically significant. However, the nursing infant should be monitored for gastrointestinal symptoms.

NITROFURANTOIN

Urinary Germicide

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 3rd Trimester

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Nitrofurantoin is not an animal teratogen with doses close to those used in humans and, although two retrospective studies reported associations with congenital anomalies, there are no confirmed data suggesting that it is a human teratogen. The two studies require confirmation. However, there appears to be risk of hemolytic anemia in newborns, including those who are not glucose-6-phosphate dehydrogenase (G6PD) deficient, who are exposed in utero to nitrofurantoin close to delivery. Although the incidence is unknown, the rare reports of this toxicity combined with the popularity of the drug for urinary tract infections in pregnant women suggest that the risk is rare. The safest course, however, is to avoid nitrofurantoin close to delivery.

FETAL RISK SUMMARY

The anti-infective agent nitrofurantoin is commonly used in pregnancy for the treatment and prophylaxis of urinary tract infections.

Neither impaired fertility, teratogenicity, nor other fetal adverse effects were observed in rats and rabbits treated with nitrofurantoin before and during gestation (1,2). Doses used were up to six times the human dose based on body weight (HD) (1). In mice, a dose 68 times the HD was associated with fetal growth restriction and a low incidence of minor and common malformations (1). When a dose 25 times the HD was administered, fetal malformations were not observed (1). A dose 19 times the HD induced lung papillary adenomas in mice offspring, but the relationship of this to potential human carcinogenesis is unknown (1).

In a surveillance study of Michigan Medicaid recipients involving 229,101

completed pregnancies conducted between 1985 and 1992, 1292 newborns had been exposed to nitrofurantoin during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 52 (4.0%) major birth defects were observed (55 expected). Specific data were available for six defect categories, including (observed/expected) 15/12 cardiovascular defects, 1/2 oral clefts, 0/2 spina bifida, 4/4 polydactyly, 3/2 limb reduction defects, and 5/3 hypospadias. These data do not support an association between the drug and congenital defects.

One manufacturer (Norwich-Eaton Laboratories) has collected more than 1700 case histories describing the use of this drug during various stages of pregnancy (95 references) (personal communication, 1981). None of the reports observed deleterious effects on the fetus. In a published study, a retrospective analysis of 91 pregnancies in which nitrofurantoin was used yielded no evidence of fetal toxicity (3). Other studies have also supported the safety of this drug in pregnancy (4).

In a 1995 report, 22 studies of nitrofurantoin use in pregnancy were evaluated for a meta-analysis (5). Only four of the studies met the inclusion criteria of the investigators. The pooled odds ratio (OR) for malformations after use of the drug in the 1st trimester was 1.29 (95% confidence interval [CI] 0.25–6.57). These results demonstrated no significant correlation between nitrofurantoin use in early gestation and congenital malformations (5).

In contrast to the above reports, a 2003 case–control study, using data from three Swedish health registers, was conducted to identify drug use in early pregnancy that was associated with cardiac defects (6). Cases (cardiovascular defects without known chromosome anomalies) (N = 5015) were compared with controls consisting of all infants born in Sweden from 1995 to 2001 (N = 577,730). Associations were identified for several drugs, some of which were probably due to confounding from the underlying disease or complaint or multiple testing, but some were thought to be true drug effects. For nitrofurantoin, there were 30 cases in 2060 exposures (OR 1.68, 95% CI 1.17–2.40) (6).

A 2009 report from the National Birth Defects Prevention Study estimated the association between antibacterial agents and more than 30 selected birth defects (7). The authors conducted a population-based, multiple site, case–control study of women who gave birth to an infant with one of >30 selected defects. The outcomes were identified in a 10-state birth defect surveillance program and involved 13,155 cases and 4941 controls selected from the same geographical regions. Exposure to an antibacterial was determined by a

detailed telephone interview conducted within 24 months after the estimated date of delivery. Women were considered exposed if they had used an antibacterial drug during the month before the estimated date of conception through the end of the 1st trimester (defined as the end of the 3rd month of pregnancy). Significant associations with multiple selected birth defects were found (total number of exposed cases/controls) with sulfonamides (145/42) (probably combined with trimethoprim) and nitrofurantoin (150/42). The adjusted ORs and 95% CIs (in parentheses) for nitrofurantoin were anophthalmia or microphthalmos 3.7 (1.1–12.2), hypoplastic left heart syndrome 4.2 (1.9–9.1), atrial septal defects 1.9 (1.1–3.4), and cleft lip with cleft palate 2.1 (1.2–3.9). Significant associations (total number of exposed cases–controls; number of associations) also were found for penicillins (716–293; 1), erythromycins (202–78; 2), cephalosporins (128–47; 1), quinolones (42–14; 1) and tetracyclines (36–6; 1). The results for quinolones and tetracyclines, however, were based on small numbers of exposed cases and controls (7).

As with all retrospective case–control studies, the data can determine associations, but not causative associations (7). Moreover, several limitations were identified by the authors, including spurious associations caused by the large number of analyses, interviews were conducted 6 weeks to 2 years after the pregnancy making recall difficult for cases and controls, recall bias, and inability to distinguish between drug-induced defects and defects resulting from the infection (7).

Nitrofurantoin may induce hemolytic anemia in G6PD-deficient patients and in patients whose red blood cells are deficient in reduced glutathione (8). One manufacturer considers nitrofurantoin to be contraindicated in pregnant women at term (38–42 weeks' gestation), when the onset of labor is imminent, or during labor and delivery, because of the risk of hemolytic anemia in the newborn secondary to immature erythrocyte enzyme systems (glutathione instability) (1). A 1990 reference, citing data from a manufacturer's database, mentioned nine cases of hemolytic anemia in newborns whose mothers had taken the drug late in pregnancy (9). None of the mothers or infants were tested for G-6-PD deficiency and there was no information available as to whether the mothers were also affected. A 2000 case report published in France described hemolytic anemia in a full-term newborn whose mother had taken nitrofurantoin during the last month of pregnancy (10). The authors attributed the toxicity to the drug.

Nitrofurantoin has been reported to cause discoloration of the primary teeth

when given to an infant; by implication, this could occur from in utero exposure (11). However, the fact that the baby was also given a 14-day course of tetracycline, an antibiotic known to cause this adverse effect, and the lack of other confirming reports make the likelihood of a causal relationship remote (12).

The effect of postcoital prophylaxis with a single oral dose of either cephalexin (250 mg) or nitrofurantoin macrocrystals (50 mg) starting before or during pregnancy in 33 women (39 pregnancies) with a history of recurrent urinary tract infections was described in a 1992 reference (13). A significant decrease in the number of infections was documented without fetal toxicity.

Long-term, low-dose (50 mg at bedtime) nitrofurantoin for prophylaxis after acute pyelonephritis was shown to be effective in pregnant women (14). Nitrofurantoin was started after treatment of the infection and continued until 1 month after delivery. There were no additional cases of pyelonephritis (14). No mention was made on the fetal outcomes.

When given orally in high doses of 10 mg/kg/day to young males, nitrofurantoin may produce slight-to-moderate transient spermatogenic arrest (15). The lower doses used clinically do not seem to have this effect.

BREASTFEEDING SUMMARY

Nitrofurantoin is excreted into breast milk. In one study, the drug could not be detected in 20 samples from mothers receiving 100 mg 4 times daily (16). In a second study, nine mothers were given 100 mg every 6 hours for 1 day, then either 100 mg or 200 mg the next morning (17). Only two of the four patients receiving the 200-mg dose excreted measurable amounts of nitrofurantoin, 0.3–0.5 mcg/mL. Although these amounts are negligible, infants with G6PD deficiency may develop hemolytic anemia from this exposure (17).

A 2001 study concluded that nitrofurantoin is actively transported into milk, by an unknown mechanism, resulting in a milk:plasma ratio of 6.21 (18). The observed milk:plasma ratio was about 22-fold greater than the predicted ratio (0.28) that was determined in the study. Four lactating women, who did not breastfeed during the study, were given a single 100-mg capsule of nitrofurantoin macrocrystals with a standardized high-fat breakfast. Nine serum and milk samples were drawn after the dose over a 12-hour interval. The mean milk drug concentration in each patient during the 12-hour interval was approximately 1.3 mcg/mL. Based on this, the investigators estimated that if a 60-kg woman was taking 100 mg twice daily, the infant dose would be 0.2 mg/kg, or about 6% of the mother's weight-adjusted dose. Although this

exposure was thought to be low, nursing infants younger than 1 month of age and those with a high frequency of G6PD deficiency or sensitivity to nitrofurantoin may be at risk for toxicity (18).

In a 1993 cohort study, diarrhea was reported in 32 (19.3%) nursing infants of 166 breastfeeding mothers who were taking antibiotics (19). For the six women taking nitrofurantoin, decreased milk volume was observed in one woman and diarrhea was observed in two (33%) infants. Both effects were considered minor because they did not require medical attention (19).

The above studies suggest that there is a potential for nitrofurantoin-induced toxicity from exposure to the drug in breast milk. Determining the magnitude of the risk will require more data, but the risk appears to be rare. The American Academy of Pediatrics classifies nitrofurantoin as compatible with breastfeeding (20).

NITROFURAZONE

Anti-infective

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The reported human pregnancy experience is limited to one large surveillance study that found 1 (0.4%) major defect among 234 1st trimester exposures. The animal studies in one species used systemic exposures that probably were much higher than those obtained in humans from topical application and, most likely, have little clinical significance. Based on these data, if the drug is indicated, it should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Nitrofurazone is a bactericidal nitrofuran anti-infective that is used topically (1) and as bladder irrigation (2). It is available as 0.2% topical solution, ointment, and cream. Nitrofurazone is indicated as adjunctive therapy for patients undergoing treatment for severe burns when bacterial resistance to other agents is a real or potential problem. It also is indicated for patients undergoing skin grafting when contamination with resistant bacteria might cause graft rejection (1,2).

In mice, reproduction studies with systemic nitrofurazone induced a low frequency of limb reduction defects in one study (3,4), but not in another (3). In rabbits, doses up to 30 times the usual human dose (assumed to be based on weight) were embryocidal (5).

It is not known if nitrofurazone is absorbed into the systemic circulation or if it crosses the human placenta. However, some absorption should be expected when it is used topically for burns or as bladder irrigation. The molecular weight (about 198) and lipid solubility suggest that the drug will cross the placenta if it is absorbed, but the clinical significance of this is unknown.

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 234 of whom had exposure to nitrofurazone in lunar months 1–4 (6). Structural anomalies were observed in seven cases, one major and six minor defects. These outcomes were not statistically significant.

BREASTFEEDING SUMMARY

No reports describing the use of nitrofurazone during human lactation have been located. It is not known if nitrofurazone is absorbed into the systemic circulation or if it is excreted into breast milk. However, some absorption should be expected when it is used topically for burns or as bladder irrigation. The molecular weight (about 198) and lipid solubility suggest that the drug will be excreted into milk, but the clinical significance of this is unknown.

NITROGLYCERIN

Vasodilator

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The use of nitroglycerin during pregnancy does not seem to present a risk to the fetus. However, the number of women treated during pregnancy is limited, especially during the 1st trimester. With the smaller doses reported, transient decreases in the mother's blood pressure may occur, but these do not appear to be sufficient to jeopardize placental perfusion. Nitroglycerin appears to be a safe, effective, rapid-onset, short-acting tocolytic agent. The use of transdermal nitroglycerin patches may also prove to be effective when longer periods of tocolysis are required. With any route of administration, however, additional studies are required to determine the safest effective dose.

FETAL RISK SUMMARY

Nitroglycerin (glyceryl trinitrate) is primarily indicated for the treatment or prevention of angina pectoris. Because of the nature of this use, experience in pregnancy is limited. The drug, a rapid-onset, short-acting vasodilator, has been used to control severe hypertension during cesarean section (1,2). The use of nitroglycerin sublingually for angina during pregnancy without fetal harm has also been reported (3). Recent investigations, discussed below, have explored the use of nitroglycerin as both an emergency and a routine tocolytic agent.

Reproductive studies in rats and rabbits have been conducted with nitroglycerin (4–6). No adverse fetal effects or postnatal changes were observed in these experiments.

The Collaborative Perinatal Project recorded seven 1st trimester exposures to nitroglycerin and amyl nitrite plus eight other patients exposed to other vasodilators (7). From this small group of 15 patients, 4 malformed children

were produced, a statistically significant incidence. The data did not indicate whether nitroglycerin was taken by any of the mothers of the affected infants. Because of the lack of specific information and the small number of patients, no conclusions as to the relative safety of nitroglycerin in the 1st trimester can be made from this study. Moreover, the authors of this study emphasized that statistical significance could not be used to infer causal relationships and that independent confirmation from other studies was required.

The use of nitroglycerin in gestational hypertension has been described (8–11). In three patients, IV infusions of nitroglycerin were effective in rapidly correcting the hemodynamic disturbances of gestational hypertension complicated by hydrostatic pulmonary edema, but a rapid improvement in arterial oxygenation did not occur (8). In another study by the same investigators, the effectiveness of IV nitroglycerin to decrease blood pressure in six women with gestational hypertension was dependent on the patient's volume status (9). When volume expansion was combined with nitroglycerin therapy, a marked resistance to the hypotensive effect of the drug was observed. In two of the women treated with IV nitroglycerin alone, significant reductions in blood pressure occurred, resulting in fetal heart rate changes that included late decelerations and bradycardia. Recovery occurred after nitroglycerin therapy was terminated and then restarted at a lower dose. In three other fetuses, a loss of beat-to-beat variability (average variability <5 beats/minute) was noted. Therapy was continued and no abnormalities were observed in the umbilical blood gases or Apgar scores.

An abstract published in 1996 described the use of transdermal nitroglycerin patches (releasing 10 mg in 24 hours) in the treatment of gestational hypertension (10). The 24-hour mean systemic and diastolic blood pressures were significantly decreased (5% and 7%, respectively). In a 1995 study, 12 women with severe preeclampsia received an infusion of nitroglycerin starting at 0.25 mcg/kg/minute with stepwise dosage increases until a diastolic blood pressure of 100 mmHg was achieved (11). The mean systolic blood pressure decreased from 161 to 138 mmHg, whereas diastolic pressure decreased from a mean of 116 to 103 mmHg. The umbilical artery pulsatility index changed significantly but not the uterine pulsatility index, implying vasodilation in the umbilical circulation and avoidance of adverse impairment of fetoplacental perfusion (11).

Lowering of maternal blood pressure and a lessening of the hemodynamic responses to endotracheal intubation were beneficial effects obtained from IV nitroglycerin in six women with severe preeclampsia (12). A progressive

flattening of fetal heart rate beat-to-beat variability was observed in all six patients. Prevention of an increase in mean arterial pressure of >20% was achieved in only two of the women, and all had nausea, retching, and vomiting that was apparently not dose-related.

Myocardial infarction, secondary to development of a thrombus on an artificial aortic valve, occurred in a 25-year-old woman at 26 weeks' gestation (13). A portion of her initial treatment consisted of both oral and IV nitroglycerin, with the latter being continued for an unspecified interval. Maternal diastolic blood pressure was maintained above 50 mmHg while on nitroglycerin and, apparently, no fetal distress was observed. A viable 2608-g male infant was eventually delivered at 35 weeks' gestation, but specific details were not provided on his condition.

A 1993 reference described two women, one with triplets, who suffered myocardial infarctions during pregnancy, at 16 and 28 weeks' gestation, and who were treated with IV nitroglycerin and other agents (14). In addition, mild chest pain occurring during labor was successfully treated with sublingual nitroglycerin in one of the women. Both patients survived and eventually delivered infants apparently unaffected by the treatment. Another report described a woman at 26 weeks' gestation who was treated with IV nitroglycerin and other agents for a myocardial infarction (15). She eventually delivered a healthy female infant by cesarean section at 39 weeks.

In gravid ewes, IV nitroglycerin was effective in counteracting norepinephrine-induced uterine vasoconstriction (16). The antihypertensive effect resulted in a significantly decreased mean aortic pressure but did not significantly change uterine blood flow or uterine vascular conductance. A 1994 abstract reported no adverse effects on fetal cardiorespiratory function in sheep from a 2-hour IV infusion of nitroglycerin at 3 times the minimum effective tocolytic dose (17).

The use of nitroglycerin during cesarean section to allow delivery of babies entrapped by a contracted uterus has been described in two case reports (18,19). In the first case, the head of a baby presenting as a double footling breech was trapped in the hypertonic upper segment (18). Uterine relaxation was achieved with a 1000-mcg IV bolus of nitroglycerin. The mother's blood pressure fell to 70/30 mmHg but responded to ephedrine. The Apgar scores of the 3090-g, term infant were 5 and 9 at 1 and 5 minutes, respectively. In the second case, a woman received a 100-mcg bolus of nitroglycerin to quickly relax a contracted uterus and to allow the successful delivery of her twins (19). Other than a systolic blood pressure decrease (preoperative pressure 120 mmHg; after nitroglycerin 85 mmHg) that responded rapidly to ephedrine, no

other adverse effects from nitroglycerin were encountered in the mother or her newborns.

Two references have discussed the use of IV nitroglycerin as a short-acting tocolytic agent during intrapartum external cephalic version (20,21) and one involving internal podalic version (22). A woman in premature labor (uterine contractions every 2 minutes with the cervix dilated to 9 cm) at 30 weeks 5 days was given a 50-mcg IV bolus of nitroglycerin (20). The uterus relaxed palpably within 20 seconds and the fetus was repositioned to allow for vaginal delivery. A decrease in the maternal blood pressure was noted (145/100 to 130/75 mmHg, then stabilizing at 130/85 mmHg within 2 minutes), but the heart rate and oxygen saturation remained unchanged. The premature infant was delivered vaginally shortly after rupture of the membranes and start of an oxytocin infusion. A second mother at 39 weeks 4 days of gestation received a 100-mcg IV bolus dose before external cephalic version (blood pressure decreased from 120/60 to 112/60 mmHg within 1 minute) and subsequently underwent a vaginal delivery of a healthy infant.

In the second report, a woman delivered one twin vaginally and then received a 50-mcg IV nitroglycerin bolus to allow external version of the second transverse-lie twin (21). No significant maternal adverse effects (e.g., headache or dizziness) or changes in blood pressure or heart rate were observed. The healthy twin was delivered vaginally 45 minutes after the version.

Internal podalic version and total breech extraction of the second twin was accomplished in a third case with sublingual nitroglycerin by aerosol after the uterus had contracted down on the operator's forearm (22). Two 400-mcg boluses were given, resulting in uterine relaxation within 30 seconds. No adverse effects on the newborn were observed.

Three cases of total breech extraction, with internal podalic version in two, of the second twin were aided by the use of nitroglycerin spray (0.4 mg) administered sublingually after either contraction of the uterine corpus and lower segment or uterine or cervical contractions with failure of the fetal head to engage (23). Minimal changes were observed in the maternal blood pressures and pulses. All three newborns were doing well.

A 1996 report described nine cases of internal podalic version of a second nonvertex twin with the assistance of an IV bolus of nitroglycerin (1 mg in eight and 1.5 mg in one) (24). One of the women had a panic attack that required general anesthesia for sedation, although the version was successful. In another case, nitroglycerin failed to induce uterine relaxation and an emergency

cesarean section was required for fetal distress. Postpartum hemorrhage (2000 mL) occurred in a third woman. A significant fall in maternal blood pressure was observed in all cases, but no adverse effects from the decrease occurred in the mothers or newborns (24).

Transdermal patches of nitroglycerin have been tested as tocolytics in 13 women in preterm labor (23–33 weeks' gestation) (25). Most of the women received a single patch that delivered 10 mg of nitroglycerin for 24 hours, but some patients were given a second patch if uterine contractions had not subsided within 1 hour. Patches were changed every 24 hours. The mean prolongation of pregnancy, as of the date of a subsequent report (one woman was still pregnant), was 59 days (26). The babies who had been delivered were all doing well.

Small IV bolus doses of nitroglycerin (60 or 90 mcg for one or two doses) were used in 24 laboring women for severe fetal distress, related to uterine hyperactivity that was unresponsive to standard measures (27). Six of the patients developed hypotension with a mean nadir of 93.2 mmHg (minimum 85 mmHg) that was reversed with a single dose of ephedrine (4.5–6 mg). Four newborns had low 1-minute Apgar scores (3, 4, 5, and 6, respectively), but all newborns had Apgar scores of 9 or 10 and were vigorous at 5 minutes.

Nitroglycerin has also been used to relax the uterus in postpartum cases with retained placenta (28–31), two of which occurred in patients with an inverted uterus (30,31). The IV bolus dose was 500 mcg in 15 women (28), 50 mcg (some patients required two doses) in 23 cases (29,30), and 100 mcg in 1 woman (31). No significant changes in blood pressure or heart rate were recorded, and no adverse effects, such as headache, palpitations, or prolonged uterine relaxation, were observed.

BREASTFEEDING SUMMARY

No reports describing the use of nitroglycerin during human lactation have been located. The molecular weight (about 227) suggests that the drug will be excreted into breast milk.

NITROPRUSSIDE

Antihypertensive

PREGNANCY RECOMMENDATION: Human and Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports linking the use of sodium nitroprusside with congenital defects have been located. Nitroprusside has been used in pregnancy to produce deliberate hypotension during aneurysm surgery or to treat severe hypertension (1–8). Transient fetal bradycardia was the only adverse effect noted (1). One advantage of nitroprusside is the very rapid onset of action and the return to pretreatment blood pressure levels when the drug is stopped (8). Balanced against this is the potential accumulation of cyanide in the fetus.

FETAL RISK SUMMARY

Nitroprusside crosses the placenta and produces fetal cyanide concentrations higher than maternal levels in animals (9). This effect has not been studied in humans.

A 1984 article reviewed the potential fetal toxicity of nitroprusside (6). Avoidance of prolonged use and the monitoring of serum pH, plasma cyanide, red blood cell cyanide, and methemoglobin levels in the mother were recommended. Standard doses of nitroprusside apparently do not pose a major risk of excessive accumulation of cyanide in the fetal liver (6).

BREASTFEEDING SUMMARY

No reports describing the use of nitroprusside during human lactation have been located.

NITROUS OXIDE

General Anesthetic

PREGNANCY RECOMMENDATION: Human and Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

The animal reproduction data suggest risk, but the exposures to the gas were usually much higher and longer than the exposures that occur in humans. In animals, nitrous oxide is an embryo and fetal toxin that may have long-lasting consequences. The evidence for human reproductive and developmental toxicity is not as clear. Much of the data relating to spontaneous abortions (SABs), infertility, and decreased birth weight are based on voluntary responses to surveys that involved self-reported outcomes. These retrospective reports are subject to self-selection and/or recall bias. Moreover, many studies have evaluated exposure to nitrous oxide in operating rooms or dental offices, rather than in individuals and have not quantified the amount and type of anesthetic gas exposure (1,2). In addition, the studies have not always accounted for confounding variables, such as the introduction of scavenging equipment and ventilation, maternal age, smoking, and other drug exposures, and have characterized nitrous oxide exposure based only on job title (3). Nevertheless, there does appear to be an increase in the incidence of SAB and infertility related to chronic exposure to nitrous oxide, but the dose and magnitude of these effects need further study. Moreover, general anesthesia in the 1st and 2nd trimesters has been associated with reduced birth weight, but the causative agents have not been identified.

The information for nitrous oxide and congenital malformations is less confusing, but many of the limitations identified earlier also apply to this population. However, the available data do not appear to suggest that acute or chronic exposure to nitrous oxide at any time in pregnancy represents a major risk for structural anomalies. Although nitrous oxide is the most commonly used general anesthetic agent, it is never administered alone, being combined with several other agents. Therefore, the safest course is to postpone elective surgical procedures until after pregnancy or,

at the minimum, until after the period of organogenesis. Moreover, because even operating rooms that are scavenged and ventilated are not entirely free of waste anesthetic gases, women who might become pregnant and are working in these areas should be counseled as to the potential risks and offered positions in areas free of nitrous oxide contamination. Recent data have shown that offspring of mothers with occupational exposure could have long-term neurodevelopmental deficits. Finally, long-term neurotoxicity studies of infants exposed in utero to nitrous oxide during the 3rd trimester or during the first few years after birth are warranted.

FETAL RISK SUMMARY

Nitrous oxide (N_2O ; laughing gas) is a nonflammable, nonexplosive gas that is widely used as an analgesic and general anesthetic. It is always administered with at least 20% oxygen to prevent hypoxia. The blood–gas coefficient is relatively low (0.47) as is tissue solubility (brain–gas coefficient 0.50) (4).

Animal Studies

In a 1967 study, pregnant rats were exposed to 45%–50% nitrous oxide for 2, 4, or 6 days starting on gestational day 8 (5). Compared with nonexposed controls, there was a dose-related increase in embryonic death and resorptions, growth restriction, and skeletal malformations (vertebrae and ribs), and the male–female sex ratio of surviving fetuses was lower (5). Resorptions and fetal deaths were significantly increased in rats exposed to nitrous oxide (0.1% or 1.5%) mixed with oxygen for 8 or 24 hours per day for several days during mid-gestation (6). A lower concentration (0.01%) had no effect on the incidence of resorptions but did increase the number of fetal deaths.

A 1978 study did not observe teratogenic effects, changes in surviving fetal sex ratio, or increased fetal loss in pregnant rats exposed 8 hours/day throughout gestation to nitrous oxide (1%, 10%, or 50%) or nitrous oxide (10%) plus halothane (0.16%) (7). However, fetal growth restriction was observed in all four groups exposed to nitrous oxide. Exposure of pregnant rats to 50% nitrous oxide for 25 minutes/day for three consecutive days in mid-gestation resulted in an increase in fetal death rate, but no effects on fetal growth were observed (8). In another study, pregnant rats were exposed to nitrous oxide either alone (0.005% or 0.05%) or a mixture of nitrous oxide (0.05%) and halothane (0.001%) for 7 hours/day during the first 15 days of gestation (9,10). No adverse embryo or fetal effects were observed.

Continuous exposure of gravid rats to nitrous oxide (0.5%) from gestational day 1 to day 19 resulted in a significant increase in the incidence of resorptions, growth restriction, and skeletal anomalies, and a lower male–female sex ratio of surviving fetuses (11). In a follow-up to this study, the threshold dose required to produce some of these effects was determined using exposures of 0%, 0.1%, 0.05% and 0.025% (12). Only the group exposed to 0.1% had an increased incidence of resorptions and growth restriction. The same group of investigators reported a third study in which gravid rats were intermittently exposed (6 hours per day, 5 days per week) to nitrous oxide 0%, 0.025%, 0.05%, 0.1%, and 0.5% throughout gestation (13). A significant reduction in litter size was noted only in the highest exposure group, but no signs of fetal resorption or skeletal malformations were found in any group.

Pregnant hamsters were exposed to nitrous oxide (70%–95%) mixed with oxygen for 24 hours during organogenesis (14). An increased incidence of fetal death was observed only at concentrations of 90%–95%, but hypoxia-induced mortality could not be excluded. A small but significant number of fetuses had malformations (cleft palate, limb defects, gut herniation, and fetal edema), but a dose–effect relationship was not observed (14). The effects on pregnant hamsters from exposure to a combination of nitrous oxide (60%) and halothane (0.6%) for 3 hours per day on gestational days 9, 10, or 11 was reported in 1974 (15). No effects were noted on the sex ratio of surviving fetuses. Compared with controls, resorptions were increased on day 11, and decreased fetal weight was noted in the groups exposed on days 10 and 11 (15).

In a 1980 study, pregnant rats were exposed to nitrous oxide (70%–75%) or xenon (70%–75%) for 24 hours on gestational day 9 (16). Compared with controls and the xenon-exposed group, the nitrous oxide group had a significant increase in the incidence of resorptions and congenital malformations (delayed maturation of the skeletal system, fused ribs, encephalocele, hydrocephalus, anophthalmia, microphthalmia, gastroschisis, and gonadal agenesis) (16). The above experiment was repeated by another group with four different concentrations of nitrous oxide: 0.75%, 7.5%, 25%, and 75% (17). The threshold for toxicity was determined to be >25% because only those animals exposed to the 75% concentration had increased incidences of resorptions and both major and minor congenital malformations. However, all exposures caused a significant increase in minor variants involving the ribs and sternum (17).

In another study by the above investigators, the effect of nitrous oxide in pregnant rats was compared with three other general anesthetic agents (see also Enflurane, Halothane, and Isoflurane) (18). The nitrous oxide dose was

75% (0.55 minimum alveolar anesthetic concentration [MAC]). (Note: MAC is the concentration that causes immobility in 50% of patients exposed to a noxious stimulus such as a surgical incision; it represents the ED₅₀ [19].) Each agent was administered for 6 hours on each of three consecutive days in one of three periods: gestational days 8–10, 11–13, or 14–16. Compared with controls, significantly decreased maternal weight gain was observed in three of the groups (nitrous oxide, isoflurane, and enflurane) after exposure on days 14–16. Exposure on those days resulted in significantly decreased fetal weight in all four groups; when exposure occurred on days 8–10, the effect was noted in three groups (all except nitrous oxide). Nitrous oxide exposure during days 14–16 resulted in significant increases in total fetal wastage and resorptions (threefold increase). However, no major or minor congenital defects were observed in any of the groups (18).

No evidence of reproductive toxicity was observed in mice exposed to nitrous oxide (0.5%, 5%, or 50%) for 4 hours per day on days 6–15 of gestation (20). In the same experiment, the fertility of male mice exposed in the same way for 9 weeks was not affected. Based on their previous work, they concluded that the order of reproductive toxicity was halothane > enflurane > methoxyflurane > nitrous oxide (20). Of interest, a 1990 study found that brief exposure of two-cell mouse preimplantation embryos to nitrous oxide/oxygen (60%/40%) caused disruption to subsequent embryo cleavage and blastocyst development (21).

A 1989 study determined the susceptible period for nitrous oxide teratogenicity in rats (22). Pregnant rats were exposed to 60% nitrous oxide for 24 hours on each of gestational days 6–12. There were no differences among the seven groups in the number of live fetuses, fetal weight, and sex ratio. However, compared with controls, there was a significant increase in the mean percentage of resorptions/litter and number of litters with resorptions on days 8 and 11. Major skeletal anomalies (ribs and vertebrae) were increased only on day 9, but minor skeletal defects were increased on days 8 and 9. Right-sided aortic arch and left-sided umbilical artery, defects indicative of altered laterality, were increased on day 8 and hydrocephalus was increased on gestational day 9 (22).

A 1986 mouse study tested the hypothesis that prenatal nitrous oxide exposure (75% with 25% oxygen for 6 hours on gestational day 14) or postnatal exposure (same mixture for 4 hours on postnatal day 2) would cause permanent damage to the developing brain and behavioral effects (23). Compared with controls, offspring (postnatal day 6 to 6 months of age) exposed prenatally or postnatally were noted to have several abnormal

behavioral effects that included preweaning motor development and general activity. When they reached adulthood, their brains were also noted to have significant morphologic changes (23). A 1986 rat study also found that in utero exposure caused permanent alterations in the spontaneous motor output of the brain that affected females more than males (24). Using a slightly different exposure protocol during rat pregnancy, these same investigators did observe subtle differences from controls in growth rates at 14 and 21 days and reduced reflex suspension, indicating that normal development had been interrupted (25). In a fourth study, mouse offspring exposed in utero to nitrous oxide during organogenesis had hyporeactivity of the startle reflex at 60 and 95 days of age (26).

The effects of nitrous oxide on growing neural tips (growth cones) in the forebrains of neonatal rat pups were described in a 1993 report (27). The pups were exposed to three concentrations of nitrous oxide (25%, 50%, and 75%) over a 6-hour period on postnatal day 1. A dose–response on the activity of a growth cone enzyme (protein kinase C, PKC) was found, with the lowest concentration having no effect on the enzyme. The 75% concentration, however, reduced the activity to about 63%. The 50% dose also reduced the PKC activity but to a lesser degree. The authors thought that the reduced enzyme activity could be related to long-term morphologic or behavioral neuroabnormalities in the pups (27).

The effect of nitrous oxide on rat fertility was described in a 1990 study (28). Adult virgin female rats were exposed to the gas during their 4-day ovulatory cycles. Nitrous oxide disrupted luteinizing hormone-releasing hormone (LH-RH) (now known as gonadotropin-releasing hormone) cells in the hypothalamus. This disruption resulted in the inhibition of LH-RH release and, thus, ovulation (28).

Human Studies

PLACENTAL PASSAGE Nitrous oxide rapidly crosses the human placenta to the fetus obtaining amounts in the fetal circulation nearly equivalent to those in the mother (29–34). In a 1970 study, umbilical vein and artery nitrous oxide concentrations ranged up to 91% of maternal levels and increased progressively with increasing duration of anesthesia (30).

SPONTANEOUS ABORTION A number of reports have described the association between SAB and exposure to anesthetic gasses in the operating room, the dental office, or during surgery (1,35–48). In addition, several reviews have examined this topic (49–57).

The principal concern for chronic exposure to anesthetic gasses relates to unscavenged environments in which high concentrations of gases, such as nitrous oxide, have been measured. A 1972 reference cited studies that measured levels of nitrous oxide in the operating room averaging 130 ppm (0.013%) but with peak concentrations as high as 428 ppm (0.048%) (35). Even higher levels (e.g., 9700 ppm or 0.97%) were measured in the anesthesiologist's inhalational zone. A 1970 report described the results of a survey from a group of nurses (67 operating room/92 general duty) and physicians (50 anesthesiologists/81 specialists other than anesthesia) that were routinely exposed to anesthetics in the operating room (36). In the first group, 29.7% of the pregnancies of operating room nurses ended in SAB, compared with 8.8% in the controls. In the second group, the SAB incidence was 37.8% and 10.3%, respectively. In both exposed groups, the SAB occurred earlier than that in the controls (8th vs. 10th week). However, the study could not identify a specific anesthetic agent, nor could it establish a cause-and-effect relationship (36).

The results of a national survey of operating room personnel was reported in 1974 (37). The survey included the memberships of four organizations, essentially covering all personnel in the United States who were continuously exposed to low levels of anesthetic gases: the American Society of Anesthesiologists (ASA), the American Association of Nurse Anesthetists (AANA), the Association of Operating Room Nurses (AORN), and the Association of Operating Room Technicians (AORT). Two control groups were surveyed: the American Academy of Pediatrics (AAP) and the American Nurses Association (ANA). At the time of the survey, about 21% of the operating rooms were ventilated and anesthetic-scavenged. The rates of SAB among the respondents (organization and total number of pregnancies shown in parentheses) were 17.1% (ASA; 468), 17.0% (AANA; 1826), and 19.5% (AORN/AORT; 2781). The results were statistically significant when compared with women working outside of the operating room. However, no difference was found with the controls for the time (in gestational weeks) of the abortions or for a decrease in the sex ratio of exposed pregnancies (37).

A survey of women physicians in England and Wales to determine the outcome of pregnancies was reported in 1977 (38). The analysis involved 9044 pregnancies that were classified into three groups: working anesthesiologists (N = 670), other medical specialties (includes medical students but excludes radiologists) (N = 6377), and physicians not currently working (N = 1997). The adjusted SAB rates were 13.8%, 13.8%, and 12.0%, respectively. For

stillbirths, the rates were 17.3%, 8.3%, and 10.3% (ns), respectively (38). Another survey in England of anesthetists exposed to anesthetics, male and female, appeared in 1979 (39). The SAB rates (percentages of known conceptions) for exposed fathers, mothers, both parents, and nonexposed controls were 15.7%, 34.4%*, 23.1%*, and 9.8%, respectively (*significant compared with controls).

Because dentists and their assistants may be exposed to even higher concentrations of anesthetic gases than personnel in hospital operating rooms, a survey of this population was undertaken and reported in 1980 (40). The responding sample size involved >22,000 dentists (98.5% male) and >21,000 chairside assistants (99.1% female). Only about 19% of the individuals were exposed to halogenated anesthetic gases in addition to nitrous oxide. The two groups were further classified by the amount of exposure in the year before conception (nonusers, light [1–2999 hours in the past decade], and heavy [>3000 hours in the past decade]). After adjustment for smoking, age, and pregnancy history, a significant association was found between use of anesthetics and the rate of SAB in chairside assistants (8.1% nonusers, 14.2% light, and 19.1% heavy). The association also was significant for wives of dentists but the rates of SAB were about half of those for the assistants (40). In a brief 1986 report, six SAB were observed in four female personnel over a 17-month interval (41). These persons worked in an oral surgery department that used 35% nitrous oxide in oxygen as a sedative during procedures. In the operating rooms, the range of nitrous oxide concentrations were 0.01%–0.04% but were as high as 0.07% when the patient talked (41). A 1995 study found a significant increase in SAB among female dental assistants who worked for 3 or more hours per week in offices not using scavenging equipment (42). After adjustment for age, smoking, and number of amalgams prepared, the relative risk (RR) was 2.6 (95% confidence interval [CI] 1.3–5.0).

In contrast to the above reports, two studies found no association between chronic exposure to nitrous oxide and SAB, and a third found only a partial association (43–45). In comparison with unexposed controls, the adjusted odds ratios (ORs) for SAB in dental assistants working in unscavenged clinics or dental school services in Denmark were 0.9 (95% CI 0.4–2.1) and 0.3 (95% CI 0.0–1.8), respectively (43). In a Swedish study of 1711 midwives, the use of nitrous oxide (>50% of deliveries) was not associated with an increased risk of SAB (OR 0.95, 95% CI 0.62–1.47) (44). The study could not determine if scavenging equipment for waste gas was used. The investigators concluded that night work and high workload increased the risk of SAB (44). In an earlier

study, the rates of SAB were compared for 563 married female anesthetists, working and not working, to 828 female physician controls (45). The rates were 18.3%, 13.7%, and 14.7%, respectively.

A 1980 report described the outcomes of 187 women who had been exposed to inhalational anesthetics (mostly nitrous oxide) during work or by their husbands, and who had surgery during pregnancy (46). This was an extension of the study involving occupational exposure to inhalational anesthetics and SAB in wives of dentists and dental assistants (N = 12,929) (see reference 37). The rates of 1st trimester SAB in four groups classified as controls (N = 8654; no exposure or surgery), exposure/no surgery (N = 4088), no exposure/surgery (N = 122), and exposure/surgery (N = 65) were 5.1%, 8.6%, 8.0%, and 14.8%, respectively. The rates for 2nd trimester SAB were 1.4%, 2.6%, 6.9%, and 0, respectively (46). A Canadian study compared pregnant women undergoing incidental surgery with pregnant women not undergoing surgery (47). Surgery (usually gynecologic) under general anesthesia in the 1st or 2nd trimester was associated with an increased risk of SAB (estimated risk ratio [ERR] 2.0, 95% CI 1.10–3.64). The risk was also increased following procedures under general anesthesia that were remote from the conceptus (ERR 1.54, 95% CI 1.03–2.30) (47). A 1986 study of general anesthesia with nitrous oxide in 433 women (9 sets of twins) given in the 1st and 2nd trimesters was unable to find an association between the anesthetic and SAB (48).

Finally, a 1985 study combined the data from six studies to determine the risk of SAB in operating room personnel (1). The low RR was 1.3 (95% CI 1.2–1.4) for pregnant physicians and nurses.

INFERTILITY—FEMALE An increased rate of infertility in anesthetists was noted in a 1972 study (45). In this survey of women anesthetists in the United Kingdom, 65 (12%) of the 563 married anesthetists reported infertility of unknown cause compared with 6% of controls. However, 36 (44%) eventually conceived even though 92% of them continued to work (45). A 1979 survey reported that 30% of anesthetists (includes both sexes) had difficulty in conceiving, but unexpected infertility occurred in only 3% (40).

A 1992 study examined the effect of environmental nitrous oxide on the fertility of dental assistants (58). A group of 7000 female dental assistants was surveyed and 459 were determined to be eligible for the study because they had met all inclusion criteria, including conception within the previous 4 years. Of those eligible, 418 (91%) completed the telephone interview. Data were collected over 13 menstrual cycles (about 1 year). The primary statistical

analysis involved a comparison of the adjusted fecundability ratio (an estimate of the conception rate for exposed women relative to that for unexposed women in each menstrual cycle of unprotected intercourse). No difference in the ratio was observed in the 121 assistants who worked <5 hours/week (N = 85; ratio 1.05) or ≥5 hours/week (N = 36; ratio 1.15) in scavenged offices. In contrast, among the 60 assistants who worked in unscavenged offices, the 41 working <5 hours/week had a significantly higher adjusted ratio (1.01) than the 19 working ≥5 hours/week (0.41). Thus, the latter group was only 41% as likely as unexposed women to conceive during each menstrual cycle. In addition, the study examined the occurrence of SAB. Among the 325 pregnancies (93 excluded because they were pregnant at the time of data collection), 10 were in the “high exposure” unscavenged group. Their SAB rate was 50% (5/10), whereas 25 (8%) of the remaining 315 pregnancies aborted (58). An accompanying editorial and later correspondence discussed the implications of the study (59–63).

A 1996 study involving Swedish midwives obtained results similar to those above (64). As in the above study, data were collected over 13 menstrual cycles. In the 84% of responders (N = 3985) to a mailed questionnaire, the adjusted fecundability ratios of three groups, compared with those working in the day time, were two-shift rotations 0.78, three-shift rotations 0.77, night-shift only 0.82, respectively. The effect of nitrous oxide was noted only for midwives exposed to >30 deliveries/month where the gas was used (ratio 0.64) (64).

The effects of general anesthesia on pregnancy rates in patients undergoing embryo transfer after in vitro fertilization were described in a 1995 study (65). Analgesia for ovum retrieval and embryo transfer was sedation (opiates, diazepam, promethazine)/local anesthesia (120 cycles; 88 patients), epidural block (139 cycles; 111 patients), and general anesthesia (nitrous oxide, halothane, opiates, and barbiturates) (173 cycles; 112 patients). The groups did not differ in embryo yield or number or quality of embryos transferred. However, the clinical pregnancy rates for the general anesthesia group were significantly lower than the other two groups: 25.8%, 23.7%, and 14.5%, respectively. The delivery rate also was significantly lower for the general anesthesia group: 19.2%, 20.1%, and 8.7%, respectively. The authors concluded that the adverse effect of general anesthesia occurred after embryo transfer and was probably related to nitrous oxide exposure (65). However, a 1999 study with data from seven fertility programs involving gamete intrafallopian transfer found no significant difference in the clinical pregnancy or delivery rates between women who had received nitrous oxide (or other

anesthetic agents) and those who did not (66).

INFERTILITY—MALE A survey of 5507 male anesthetists in the United Kingdom found no association between paternal work in operating rooms and SAB, infertility, or the frequency of congenital anomalies (67). However, if the mother is also exposed, the risk of SAB may be increased by 158%–271%. A 1987 review suggested that male fertility could be affected by direct nitrous oxide-inactivation of vitamin B₁₂ (cyanocobalamine) (68). The inactivation of this vitamin could result in a reduction of methionine synthetase that is essential for normal cell division (68). A later review discussed the effect of nitrous oxide on cyanocobalamine-dependent methionine synthetase and other factors that eventually impair DNA synthesis and could cause infertility (69).

CONGENITAL MALFORMATIONS Several studies have examined the relationship between 1st trimester exposure to nitrous oxide and congenital malformations (1,37–39,45–48,70–76). Two early studies did not find such a relationship, but the number of exposed cases was small (70,71). A larger study also found no relationship between surgical anesthesia and congenital malformations (47). In another previously cited study, the overall rate of birth defects in live births was no different in 583 anesthetists (5.2%) and 828 controls (4.9%) (45). However, when analyzed separately, working anesthetists had a significantly higher rate of offspring with defects (6.5%) than those who were not working (2.5%), but not significantly higher than controls.

A 1974 survey of 621 female nurse-anesthetists, with a response rate of 84.5%, found an incidence of birth defects (major and minor) in offspring of working mothers of 16.4%, compared with 5.7% when the mother was not working (72). Nearly one-half of the defects in the exposed group were cutaneous anomalies. In another 1974 national survey cited above, the congenital abnormality rates (all skin anomalies were excluded) in the groups (unexposed vs. exposed) were ASA (3.4% vs. 5.9%), AANA (5.9% vs. 9.6%), and AORN/AORT (7.0% vs 7.7%) (37). The first two comparisons were statistically significant. The survey also provided the congenital malformation rates (excluding skin anomalies) for wives of the male survey respondents in the three groups: 5.4%, 8.2%, and 6.4%, respectively (37). A 1977 survey found a significant rate of heart/great vessels defects in working anesthetists (13.8%) in comparison with a combined group of other physicians (3.6%), or an earlier population-based study (6.6%) (38). However, no differences were found for other congenital anomalies (neural tube defects [NTDs], oral clefts, talipes, congenital hip dislocation, hydrocele, hypospadias, and epispadias, and genitourinary). The rates of development or congenital abnormalities

(percentage of live births) in a 1979 survey of anesthetists exposed to anesthetics were 9.3% (N = 22) for exposed fathers, 4.8% (N = 1) for exposed mothers, and 15.0% (N = 3) when both parents were exposed (39). These rates did not differ significantly from nonexposed controls.

No significant increase in the incidence of birth defects was found in a 1980 study of surgery during early pregnancy (46). Anesthetics for surgery were used in 187 women during the 1st trimester and in 100 women during the 2nd trimester. The rates of defects in the offspring of mothers who had surgery in the 1st and 2nd trimesters, but no occupational exposure to inhalational anesthetics, were 3.1% and 5.8%, respectively. For surgery plus occupational exposure, the rates were 7.2% and 2.3%, respectively. The differences were not significant (46). A 1986 study analyzed the outcomes of 375 cases (8 sets of twins) of cervical cerclage and 58 other surgeries (1 set of twins) conducted under general anesthesia with nitrous oxide (48). Cases were further stratified by the gestational week when surgery was conducted (>16 weeks or ≤16 weeks). None of the observed birth defects could be attributed to anesthetic exposure (48). A 1985 study combined the results from six studies to derive an RR for congenital abnormalities of 1.2 (95% CI 1.0–1.4) for pregnant physicians and nurses working in operating rooms (1).

Using data from three Swedish health care registries for 1973–1981, a 1989 study analyzed 5405 cases of nonobstetric surgical operations that occurred during pregnancy (73). The types of anesthesia were general (about 54%; 99% using combinations with nitrous oxide), regional (about 14%), and unknown (32%). The rates of congenital malformations, stillbirths, infant death within 7 days of birth, and decreased birth weights were determined by the trimester of operation. For congenital malformations, the RR and 95% CI (in parentheses) for the 1st, 2nd, and 3rd trimesters and the total group were 1.0 (0.8–1.4), 0.9 (0.6–1.2), 1.5 (1.1–2.2) and 1.1 (0.9–1.3), respectively. The rate for all defects was about 5%; and 1.9% for major anomalies. Both rates were similar to those in the total Swedish population. The risk for stillbirths also was not significantly different from the general population (RR 1.4, 95% CI 1.0–1.8), but the risk of infant death within 7 days of birth was increased (RR 2.1, 95% CI 1.6–2.7). Most of the infant deaths (70%) occurred in infants of very low birth weight. The rates of low-birth-weight (<2500 g) and very-low-birth-weight (<1500 g) infants were increased in all trimesters and for the total the RRs (95% CI) were 2.0 (1.8–2.2) and 2.2 (1.8–2.8). The reduced weights were due to prematurity and intrauterine growth restriction. For all mothers operated on, the prematurity rate was 7.47% vs. 5.13% in controls ($p < 0.001$) (73).

Using the same data as in the above study, a possible association between surgery in the 1st trimester and NTDs was published in 1990 (74). The investigators studied 2252 infants whose mothers had surgery during the 1st trimester. Six of the infants had NTD (expected 2.5), one of whom was thought to have Meckel's syndrome. An additional infant had a diagnosis of hydranencephaly, but the autopsy report indicated the diagnosis was uncertain and it may have been a very large encephalocele. In the total group, 572 infants had operations during the period of neural tube closure (gestational weeks 4 and 5). Mothers of five of the six infants with NTD (expected 0.6) had surgery during this period, but only three had been exposed to nitrous oxide. The mother of the hydranencephaly case had surgery in gestational week 8 and was not exposed to nitrous oxide. The authors could not determine whether the findings represented a causal association with surgery or just a random occurrence (74).

In a 1994 population-based, case-control study, 12 (1.7%) of 694 mothers of infants with CNS defects had surgery under general anesthesia in the 1st trimester, compared with 34 (1.1%) of 2984 controls (75). Analysis of total CNS defects and 1st trimester exposure to general anesthesia revealed the following: NTD (345 cases; 3 exposed), OR 0.7, 95% CI 0.2–2.4; microcephaly (91 cases; 1 exposed), OR 1.7, 95% CI 0.2–13.5; and hydrocephalus (198 cases; 7 exposed), OR 3.8, 95% CI 1.6–9.1. When isolated CNS defects were analyzed, the OR and 95% CI for the three defects were 1.1 (0.3–4.9), 3.8 (0.4–33.0), and 0.0 (0.00–4.1) (all ns). However, when the analysis included multiple CNS defects, there were 70 cases (7 exposed) of hydrocephalus (OR 9.6, 95% CI 3.8–24.6), 8 cases (3 exposed) of hydrocephalus and eye defects (OR 39.6, 95% CI 7.5, 209.2), and 2 cases (2 exposed) of hydrocephalus and cataracts (OR infinity, 95% CI 1329, infinity). Although the investigators identified several limitations of their study, including the inability to identify the specific medications used for general anesthesia, the findings do warrant additional study (75).

The Collaborative Perinatal Project monitored 50,282 mother-child pairs, 76 of whom were exposed to nitrous oxide during the 1st trimester (76). Four malformed infants were observed, a hospital standardized RR of 0.75. There was no evidence of an association between the gas and the defects (76).

NEUROTOXICITY The mechanism of the action of nitrous oxide, at anesthetic concentrations, is thought to involve blockade of N-methyl-D-aspartate (NMDA) glutamate receptors (77–81). This action also produces neurotoxic effects, which can be prevented by drugs (e.g., benzodiazepines, barbiturates,

halothane, isoflurane, propofol, scopolamine, and atropine) that enhance GABAergic (γ -amino-n-butyric acid) inhibition (77,79). However, the addition of ketamine, another NMDA antagonist, to nitrous oxide without concomitant use of a GABA agonist has been shown in animals to potentiate the neurotoxicity of nitrous oxide (82). Recent evidence has shown that the neurotoxicity of ethanol, an NMDA antagonist and a potentiator of GABA transmission, is different in immature brains from what it is in adult brains (83). Therefore, the potential exists that the common use of nitrous oxide and GABAergic agents together during general anesthesia in obstetrics and pediatrics could cause neuroteratogenicity during human brain growth spurts (synaptogenesis; 3rd trimester to several years after birth) (83–85). Animal studies in 7-day-old rats have demonstrated this teratogenicity as evidenced by widespread apoptotic neurodegeneration, deficits in hippocampal synaptic function, and persistent impairment of memory and learning (86).

A 2004 study examined the association between exposure of mothers to waste anesthetic gases during pregnancy and development of their offspring (87). Although the specific gases were not identified, the timing of the exposures (1983–1996) and practice patterns suggested that nitrous oxide, halothane, and isoflurane were the most likely agents. Forty children (age 5–13 years) born to female anesthesiologists and operating room nurses who were exposed to waste anesthetic gases were compared with 40 female physicians and nurses (matched for children's age, gender, and maternal occupation) who worked in hospitals during their pregnancies but did not work in operating rooms (unexposed controls). All children underwent standardized developmental tests to evaluate their medical and neurodevelopmental state and the mothers were interviewed. The developmental milestones in the two groups were similar, but the exposed children had a significantly lower gross motor ability and more evidence of inattention/hyperactivity. Moreover, the level of exposure was significantly and negatively correlated with fine motor ability and IQ performance. The investigators concluded that the results supported the hypothesis that occupational exposure to waste anesthetic gases during pregnancy might be a risk factor for minor neurological deficits in the offspring (87).

MISCELLANEOUS EFFECTS Subanesthetic doses of nitrous oxide have been used for analgesia in laboring patients (88–95). The effects on the fetus do not appear to be any different from other general anesthetics (94). When used as an analgesic, nitrous oxide has no direct effect on uterine activity (89,96). In contrast, prolonged general anesthesia with nitrous oxide may cause neonatal

acidosis and an increased incidence of low Apgar scores (97). A 1988 study concluded that the use of high intermittent doses of nitrous oxide used for obstetric analgesia was associated with a risk of developing amphetamine addiction in later life (98). The mechanism was thought to be an effect of imprinting. However, this study has been criticized for several design flaws and conclusions (90).

A 2-minute inhalation dose of 30% nitrous oxide with oxygen for analgesia at term resulted in a decrease in both maternal and fetal central vascular resistance (99). Although this dose is usually safe for the mother or fetus, the cerebral hyperemia induced by nitrous oxide might increase the risk of intracranial hemorrhage in preterm infants (99).

Decreased birth weight, but not preterm birth, was associated with occupational exposure to nitrous oxide in a 1999 study based on a survey of the Swedish Midwives Association (100). Chronic nitrous oxide exposure during the 2nd trimester was associated with a 77-g decrease in birth weight (95% CI -129, -24) and an increase in the odds of infants being small for gestational age (OR 1.8, 95% CI 1.1–2.8) (98). In a 1977 survey, the offspring of working anesthetists had significantly lower birth weights and a higher proportion of infants weighing ≤ 2500 g than two other physician groups (38). Lower birth weights also were observed in offspring of female anesthetists in a 1979 survey (39). Female infants were particularly underweight. Moreover, there was a lower male:female sex ratio in the offspring of female anesthetists (36). The author, however, has had to defend his research (101).

A 1991 population-based case–control study conducted in Sweden found an association between childhood leukemia and nitrous oxide anesthesia during delivery (102). Mothers of the 411 cases were more likely than controls to have received the anesthetic (OR 1.3, 95% CI 1.0–1.6).

BREASTFEEDING SUMMARY

No reports describing the use of nitrous oxide during lactation have been located. The solubility in blood and tissue is low. Moreover, the plasma half-life is very short (<3 minutes) and, thus, it is unlikely that a nursing infant would be exposed to the agent in milk or that it would be orally bioavailable to the infant (103).

NIZATIDINE

Gastrointestinal Agent (Antisecretory)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Nizatidine is an H₂-receptor antagonist (H₂ blocker) that inhibits gastric acid secretion. Although the animal reproduction data suggest low risk, the limited human pregnancy experience prevents a complete assessment of the embryo–fetal risk. A study showing an association between in utero exposure to gastric acid-suppressing drugs and childhood allergy and asthma requires confirmation.

FETAL RISK SUMMARY

Nizatidine is a competitive, reversible H₂ blocker, particularly those in the gastric parietal cells. It is indicated for the treatment of active duodenal and gastric ulcer, esophagitis, including erosive and ulcerative esophagitis, and associated heartburn due to gastroesophageal reflux disease (GERD). Nizatidine undergoes minimal metabolism (<7%) to an active metabolite. Plasma protein binding, primarily to α_1 -acid glycoprotein, is low (about 35%) and the elimination half-life is 1–2 hours (1).

In reproduction studies reported by the manufacturer, no evidence of impaired fertility or fetal harm was observed in rats given oral doses up to 40.5 times the recommended human dose based on BSA (RHD) or rabbits at doses up to 14.6 times the RHD (1). In a 1987 animal study, pregnant rats and rabbits were given oral doses ≤ 506 mg/kg/day (2). No adverse effects were observed on fertility, and no teratogenic effects occurred with doses ≤ 1500 mg/kg/day, although some abortions occurred in rabbits, but not in rats, at the highest dose (highest dose in rabbits is about 80 times the RHD) .

A single cotyledon perfusion model was used to determine the placental transfer of nizatidine in both term human and preterm baboon placentas (3). In

both systems, nizatidine was transferred at about 40% of the freely diffusible reference compound. Nizatidine transfer across the placentas was the same in both directions (i.e., mother to fetus and fetus to mother). The transfer across the placenta is consistent with the low molecular weight (about 331) and plasma protein binding.

Based on studies in male humans (4) and animals (5,6), nizatidine does not appear to have antiandrogenic effects like those observed with cimetidine (see Cimetidine). Reversible impotence, however, has been described in men treated with nizatidine for therapeutic indications (7).

A genetic counselor was consulted about a woman who had taken nizatidine during the 14th through the 16th postconception weeks (T.M. Gardner, personal communication, Jefferson Medical College, 1996). The woman delivered a healthy, about 3547-g, male infant at 37 weeks' gestation who was doing well at 1 month of age.

A 1996 prospective cohort study compared the pregnancy outcomes of 178 women who were exposed during pregnancy to H₂ blockers with 178 controls matched for maternal age, smoking, and heavy alcohol consumption (8). All of the women had contacted a teratology information service concerning gestational exposure to H₂ blockers (subjects) or nonteratogenic or nonfetotoxic agents (controls). Among subjects (mean daily dose in parentheses), 71% took ranitidine (258 mg), 16% cimetidine (487 mg), 8% famotidine (32 mg), and 5% nizatidine (283 mg). There were no significant differences between the outcomes of subjects and controls in terms of live births, spontaneous abortions (SABs) and elective abortions (EABs), gestational age at birth, delivery method, birth weight, infants small for gestational age, or major malformations. Among subjects, there were 3 birth defects (2.1%) among the 142 exposed to H₂ blockers in the 1st trimester: one each of atrial septal defect, ventricular septal defect, and tetralogy of Fallot. There were 5 birth defects (3.0%) among the 165 exposed anytime during pregnancy. For controls, the rates of defects were 3.5% (1st trimester) and 3.1% (anytime). There were also no differences between the groups in neonatal health problems and developmental milestones, but two children (one subject and one control) were diagnosed as developmentally delayed. The investigators concluded that 1st trimester exposure to H₂ blockers did not represent a major teratogenic risk (8).

Data from the Swedish Medical Birth Registry were presented in 1998 (9). A total of 553 infants (6 sets of twins) were delivered from 547 women who had used acid-suppressing drugs early in pregnancy. Nizatidine was the only acid-

suppressing drug exposure in three infants, none of whom had birth defects (see Omeprazole for additional details of this study) (9).

A population-based, observational cohort study formed by linking data from three Swedish national healthcare registers over a 10-year period (1995–2004) was reported in 2009 (10). The main outcome measures were a diagnosis of allergic disease or a prescription for asthma or allergy medications. The drug types included in the study were gastric acid suppressors, including H2 blockers, prostaglandins, proton pump inhibitors, combinations for eradication of *Helicobacter pylori*, and drugs for peptic ulcer and gastroesophageal reflux disease. Of 585,716 children, 29,490 (5.0%) met the diagnosis and 5645 (1%) had been exposed to gastric acid suppression therapy in pregnancy. Of these children, 405 (0.07%) were treated for allergic disease. For developing allergy, the odds ratio (OR) was 1.43, 98% confidence interval (CI) 1.29–1.59, irrespective of the drug, time of exposure during pregnancy, and maternal history of allergy. For developing childhood asthma, but not other allergic diseases, the OR was 1.51, 95% CI 1.35–1.69, irrespective of the type of acid-suppressive drug and the time of exposure in pregnancy. The authors proposed three possible mechanisms for their findings: (a) exposure to increased amounts of allergens could cause sensitization to digestion labile antigens in the fetus; (b) the maternal Th2 cytokine pattern could promote an allergy-prone phenotype in the fetus; and (c) maternal allergen-specific immunoglobulin E could cross the placenta and sensitize fetal immune cells to food- and airborne allergens. Several limitations of the study that might have affected their findings were identified, including a general increase in childhood asthma but not necessarily an increase in allergic asthma (10). The study requires confirmation.

A 2005 study evaluated the outcomes of 553 pregnancies after exposure to H2 blockers, 501 (91%) in the 1st trimester (11). The data were collected by the European Network of Teratology Information Services (ENTIS). The agents and number of cases were nizatidine 15, cimetidine 113, famotidine 75, ranitidine 335, and roxatidine 15. No increase in the number of major malformations were noted (11).

A 2009 meta-analysis of published studies was conducted to assess the safety of H2 blockers that were used in 2398 pregnancies (12). Compared with 119,892 nonexposed pregnancies, the OR for congenital malformations was 1.14 (95% CI 0.89–1.45), whereas the ORs and 95% CIs for SABs, preterm birth, and small for gestational age were 0.62 (0.36–1.05), 1.17 (0.94–1.147), and 0.28 (0.06–1.22), respectively. The authors concluded that H2 blockers

could be used safely in pregnancy (12).

Five reviews on the treatment of GERD have concluded that H₂ blockers, with the possible exception of nizatidine, could be used in pregnancy with relative safety (13–17). Nizatidine was not recommended because of the adverse animal reproduction data (16). However, no consideration of the high doses used in animals was mentioned. Nevertheless, the very limited human pregnancy data suggest that other agents in this class are preferred.

A 2010 study from Israel identified 1148 infants exposed in the 1st trimester to H₂ blockers (18). No association with congenital malformations was found (OR 1.03, 95% CI 0.80–1.32). Moreover, no association was found with EABs, perinatal mortality, premature delivery, low birth weight, or low Apgar scores (18).

BREASTFEEDING SUMMARY

Small amounts of nizatidine are excreted into breast milk (19). Three women, who had been breastfeeding for 3–8 months, were administered nizatidine (150 mg) as a single dose and as multiple doses given every 12 hours for five doses. Serum and milk samples from both breasts were collected at intervals ≤12 hours after a dose. The mean total amount of drug measured in the milk from both breasts during a 12-hour interval was 96.1 mcg. This amount represented 0.064% of the maternal dose. Peak concentrations of the drug in milk occurred between 1 and 2 hours after a dose (19).

Although the infants were not allowed to breastfeed during the above study, the small amounts excreted into the milk are probably not clinically significant. Other drugs in this class are excreted into milk (see Cimetidine and Ranitidine). The American Academy of Pediatrics classifies one of these agents as compatible with breastfeeding (see Cimetidine).

NONOXYNOL-9/OCTOXYNOL-9

Vaginal Spermicides

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: No Human Data—Possible Toxicity

PREGNANCY SUMMARY

The available evidence indicates that the use of vaginal spermicides, either before or during early pregnancy, does not pose a risk of congenital malformations to the fetus. Three authors of the original 1981 paper reporting a relationship between spermicides and congenital defects (1) have commented that available data now argue against a causal association (2). In addition, the FDA has issued a statement that spermicides do not cause birth defects (3). There is also controversy on whether the 1981 study should have been published (4,5). The data for spontaneous abortions (SABs), low birth weight, stillbirths, sex ratios at birth, frequency of multiple births, and premature delivery also indicate that it is unlikely that these factors are influenced by spermicide use.

FETAL RISK SUMMARY

Nonoxynol-9 and octoxynol-9 are vaginal spermicides used to prevent conception. These agents, applied intravaginally, act by inactivating sperm after direct contact. Although human data are lacking, nonoxynol-9 rapidly crossed the vaginal wall into the systemic circulation in animals (6). Octoxynol should also be expected to act in a similar manner. The use of vaginal spermicides just before conception or inadvertently during the early stages of pregnancy has led to investigations of their effects on the fetus. The effects studied include congenital malformations, SABs, low birth weight, stillbirth, sex ratio at birth, frequency of multiple births, and premature delivery.

A causal relationship between vaginal spermicides and congenital abnormalities was first tentatively proposed in a 1981 study comparing 763 spermicide users and 3902 nonuser controls (1). The total number of infants with malformations was low: 17 (2.2%) in the exposed group and 39 (1.0%) in

the nonexposed group. Malformations thought to be associated with spermicide use were limb reduction deformities (3 cases), neoplasms (2 cases), chromosomal abnormalities (Down's syndrome) (3 cases), and hypospadias (2 cases). An earlier investigation, published in 1977, had concluded there was no causal relationship between spermicides and congenital defects, although there was an increased incidence of limb reduction defects in infants of users (11 of 93) as compared with nonusers (8 of 186) (7). Three reports appeared in 1982 that suggested a possible relationship between spermicide use and congenital malformations (8–10). In a case–control study conducted by one of the co-authors of the 1981 investigation, a positive association with Down's syndrome was proposed when in a group of 16 affected infants, 4 were from users of spermicides (8). In another case–control study, increased risk ratios after spermicide use, although not statistically significant, were reported for limb reduction defects (relative risk 2.00; six infants) and hypospadias (relative risk 4.00; eight infants) (9). Finally, an English study observed, among other defects, 2 cases each of hypospadias, limb reduction deformity, and Down's syndrome among infants of 1103 spermicide users (10). The authors stated that their data were not conclusive, but the occurrence rates of these particular defects were higher than those observed in a comparative nonuser group.

Several criticisms have been directed at the original 1981 study (11–14). First, an infant was presumed exposed if the mother had a prescription filled at a designated pharmacy within 600 days of delivery. No attempt was made to ascertain actual use of the product or whether the mothers, either users or nonusers, had purchased a spermicide without a prescription (11–13). In a subsequent correspondence, all of the study's exposed cases of limb reduction deformity (three cases), Down's syndrome (three cases), and neoplasm (two cases) were reexamined in terms of the exact timing of spermicide use (14). The data suggested that spermicides were not used near the time of conception in these cases. However, this does not eliminate the possibility that spermicides may act directly on the ovum before conception (15). Second, the four types of malformations lack a common cause and time of occurrence (13). Even a single type of defect, such as limb reduction deformity, has a varied origin (13). Third, the total number of infants with malformations was low (2.2% vs. 1.0%). Because these values are comparable with the 2%–5% reported incidence of major malformations in hospital-based studies, the apparent association may have been caused by a lower than expected rate of defects in the nonexposed group rather than an increase in the exposed infants (11,13). Fourth, no confounding variables other than maternal age were adjusted (13).

A number of investigators have been unable to reproduce the results published in 1981 (12,16–23). In a study examining 188 infants with chromosomal abnormalities or limb reduction defects, no relationship between periconceptual use of spermicides and these defects was observed (12). No association between spermicide use at conception and any congenital malformation was observed in a study comparing 1427 cases with 3001 controls (16). In a prospective study of 34,660 women controlled for age, time in pregnancy, concentration of spermicide used, and other confounding variables, the malformation rate of spermicide users was no greater than in users of other contraceptive methods (17–19). A cohort study, the Collaborative Perinatal Project involving 50,282 mother–child pairs, found no greater risk for limb reduction deformities, neoplasm, Down’s syndrome, or hypospadias in children exposed in utero to spermicides (20). One group of investigators interviewed 12,440 women during delivery and found no relationship between the last contraceptive method used and congenital malformations (21). Spermicides were the last contraceptive method used by 3891 (31%) of the women. A 1987 case–control study of infants with Down’s syndrome (N = 265), hypospadias (N = 396), limb reduction defects (N = 146), neoplasms (N = 116), or neural tube defects (N = 215) compared with 3442 control infants with a wide variety of other defects was unable to establish any causal relationship to maternal spermicide use (22). The authors investigated spermicide usage at three different time intervals—preconceptional (1 month before to 1 month after the last menstrual period), first trimester (first 4 lunar months), and any use during lifetime—without producing a positive association. A similar study, involving 13,729 women who had produced 154 fetuses with trisomy, 98 with trisomy 21 (i.e., Down’s syndrome), also failed to find any association with spermicides (23). In addition, a letter correspondence from one researcher argued that an association between vaginal spermicides, or any environmental risk factor for that matter, and trisomies was implausible based on an understanding of the origin of these defects (24).

An association between vaginal spermicides and SABs was found in five studies (25–29). A strong association was found among subjects who had obtained a spermicide within 12 weeks of conception (25). Another study demonstrated approximately twice the rate of SABs in women who continued to use spermicides after conception compared with users before or close to the time of conception (26). However, a 1985 critique concluded that both sets of investigators had seriously biased their results by failing to adjust for potentially confounding variables (13). In a study involving women aborting spontaneously

before the 28th week of gestation and controls delivering after the 28th week, women who used spermicides at the time of conception demonstrated a five-fold increase in chromosomal anomalies on karyotype examinations in 929 cases (27). Although no association between spermicide use and chromosomally normal abortion was found in a study involving 6339 women, spermicide use of more than 1 year was more common in cases aborting trisomic conception than in controls (28). In an earlier report, the same authors observed an odds ratio of 4.8 for the association between abortuses with anomalies and unexposed controls (29). Two of these latter studies (27,29) did not adjust for confounding variables.

Three studies have found no association with SABs (10,18,30). No significant risk for SAB was observed in a large cohort study involving 17,032 subjects (10) or in another study examining periconceptual spermicide use (18). In a well-designed, large prospective study involving 32,123 subjects, spermicide use before conception was associated with a significant reduction in SAB during the 2nd trimester (30).

Three studies found no association between spermicide use and birth weight (10,18,26), but one study did find such an association (9). In this latter investigation, spermicide use after the last menstrual period was significantly associated with a lower mean birth weight among female infants of both smoking and nonsmoking mothers. For male births, an association with lower birth weight was found only when the mothers smoked. The authors were unable to determine whether these relationships were causal. Spermicide use before the last menstrual period had no effect on birth weight (9).

Under miscellaneous effects, a case-control study of 73 nontraumatic stillbirths found no relationship with the use of vaginal spermicides (31). No association between sex ratio at birth or frequency of multiple births and spermicides was found in one study (10). However, in a 1976 national survey, female births were approximately 25% higher among women using spermicides near the time of conception compared with nonusers, a statistically significant difference (26). Finally, a 1985 study found no evidence of a relationship between spermicide use and preterm delivery (18).

A 1990 reference reported the meta-analysis of previous studies to determine whether maternal spermicide use is detrimental to the developing fetus (32). Negative associations were found between the periconceptual or postconceptual maternal use of spermicides and teratogenicity, SAB, stillbirth, reduced fetal weight, prematurity, or an increased incidence of female births.

BREASTFEEDING SUMMARY

No reports describing the use of nonoxynol-9 during human lactation have been located. If excretion into milk occurs, the effect on the nursing infant is unknown.

NOREPINEPHRINE

Sympathomimetic (Adrenergic)

PREGNANCY RECOMMENDATION: Human and Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Uterine vessels are normally maximally dilated, and they have only α -adrenergic receptors (1). Use of the α - and β -adrenergic stimulant, norepinephrine, could cause constriction of these vessels and reduce uterine blood flow, thereby producing fetal hypoxia (bradycardia). Norepinephrine may also interact with oxytocics or ergot derivatives to produce severe persistent maternal hypertension (1). Rupture of a cerebral vessel is possible. If a pressor agent is indicated, other drugs, such as ephedrine, should be considered.

FETAL RISK SUMMARY

Norepinephrine (noradrenaline; levarterenol) is a direct-acting adrenergic agent that is used for acute hypotension and as an adjunct in the treatment of cardiac arrest. It is a mixture of the racemic stereoisomer and is given by IV infusion. Norepinephrine readily crosses the placenta (2), consistent with its relatively low molecular weight (about 169).

In animal reproduction studies, norepinephrine has caused situs inversus (rat embryos) (l-isomer only; no effect from d-form) (3); cataract (rat embryos) (4); hemorrhages of cephalic, skin, and extremity structures (chick embryo) (5); and microscopic liver abnormalities and delayed skeletal ossification (hamsters) (6).

In a 1995 study in pregnant ewes (123–137 days gestation), a high maternal dose (40 mcg/minute) of norepinephrine given by IV infusion caused a significant decrease in maternal placental blood flow (7). Although fetal arterial pressure did not change, transient (≤ 2.5 hours) but statistically significant decreases in fetal oxygenation, fetal urine flow, and lung liquid flow were observed. Because the average human maintenance dose is much less (about 2–4 mcg/minute), the clinical significance of these changes to a human fetus is

unknown.

BREASTFEEDING SUMMARY

No reports describing the use of norepinephrine in lactation have been located. Use of the agent during breastfeeding would not be expected because of the indications for use.

NORETHINDRONE

Progestogenic Hormone

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Norethindrone is a progestogen derived from 19-nortestosterone. It is used in oral contraceptives and hormonal pregnancy tests (no longer available in the United States). Masculinization of the female fetus has been associated with norethindrone (1–3). One researcher observed an 18% incidence of masculinization of female infants born to mothers given norethindrone (2). A more conservative estimate for the incidence of masculinization caused by synthetic progestogens has been reported as 0.3% (4).

FETAL RISK SUMMARY

The Collaborative Perinatal Project monitored 866 mother–child pairs with 1st trimester exposure to progestational agents (including 132 with exposure to norethindrone) (5, pp. 389, 391). Evidence of an increased risk of malformation was found for norethindrone. An increase in the expected frequency of cardiovascular defects and hypospadias was also observed for progestational agents as a group (5, p. 394; 6). Reevaluation of these data in terms of timing of exposure, vaginal bleeding in early pregnancy, and previous maternal obstetric history, however, failed to support an association between female sex hormones and cardiac malformations (7). An earlier study also failed to find any relationship with nongenital malformations (3). One investigator observed two infants with malformations who were exposed to norethindrone (8). The congenital defects included spina bifida and hydrocephalus. The relationship between norethindrone and the anomalies is unknown.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 238 newborns had been exposed to norethindrone (see also Oral Contraceptives) shortly before or after conception (F. Rosa, personal communication, FDA, 1993). A total of

20 (8.4%) major birth defects were observed (10 expected). Specific data were available for six defect categories, including (observed/expected) 2/2 cardiovascular defects, 1/0.5 oral clefts, 0/0 spina bifida, 0/1 polydactyly, 0/0.5 limb reduction defects, and 1/1 hypospadias. The total number of congenital malformations suggests a moderate association between the drug and the incidence of congenital defects, but the study could not determine the percentage of women who presumably stopped the hormone before conception or the number of anomalies as a result of prematurity (F. Rosa, personal communication, FDA, 1993).

BREASTFEEDING SUMMARY

Norethindrone exhibits a dose-dependent suppression of lactation (9). Lower infant weight gain, decreased milk production, and decreased composition of nitrogen and protein content of human milk have been associated with norethindrone and estrogenic agents (10–13). The magnitude of these changes is low. However, the changes in milk production and composition may be of nutritional importance in malnourished mothers. If breastfeeding is desired, the lowest dose of oral contraceptives should be chosen. Monitoring of infant weight gain and the possible need for nutritional supplementation should be considered. The American Academy of Pediatrics classifies norethindrone as compatible with breastfeeding (14).

NORETHYNODREL

[Withdrawn from the market. See 9th edition.]

NORFLOXACIN

Anti-infective (Quinolone)

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The use of norfloxacin during human gestation does not appear to be associated with an increased risk of major congenital malformations. Although various birth defects have occurred in the offspring of women who had taken this drug during pregnancy, the lack of a pattern among the anomalies is reassuring. However, a causal relationship with some of the birth defects cannot be excluded. Because of this and the available animal data, the use of norfloxacin during pregnancy, especially during the 1st trimester, should be approached with caution. A 1993 review on the safety of fluoroquinolones concluded that these antibacterials should be avoided during pregnancy because of the difficulty in extrapolating animal mutagenicity results to humans and because interpretation of this toxicity is still controversial (1). The authors of this review were not convinced that fluoroquinolone-induced fetal cartilage damage and subsequent arthropathies were a major concern, even though this effect had been demonstrated in several animal species after administration to both pregnant and immature animals and in occasional human case reports involving children (1). Others have also concluded that fluoroquinolones should be considered contraindicated in pregnancy, because safer alternatives are usually available (2).

FETAL RISK SUMMARY

Norfloxacin is an oral, synthetic, broad-spectrum antibacterial agent. As a fluoroquinolone, it is in the same class as ciprofloxacin, enoxacin, levofloxacin, lomefloxacin, ofloxacin, and sparfloxacin. Nalidixic acid is also a quinolone drug.

In rats, high doses of norfloxacin administered before and at various intervals during gestation, including during organogenesis, did not produce an increase in

congenital abnormalities, adverse effects on fertility, fetotoxicity, or changes in postnatal function in the offspring (3,4). Embryo lethality, but not teratogenicity, was observed in rabbits given 100 mg/kg (1), and in cynomolgus monkeys given 200 or 300 mg/day (≥ 200 mg/kg/day) (5). In the monkeys, plasma concentrations (about three times human therapeutic levels) were high enough to produce maternal toxicity (5). In the second part of this study, the cause of the embryotoxicity was found to be directly related to a decrease in placental-derived progesterone production (6).

In reproductive studies reported by the manufacturer, no evidence of teratogenicity was found in mice, rats, rabbits, or monkeys at 6–50 times the maximum daily human dose on a weight basis (MDHD). Embryonic loss was observed in monkeys with doses 10 times the MDHD (peak plasma levels about twice those obtained in humans) (7).

A 1991 reference evaluated the toxic effects of norfloxacin on rat liver and kidney DNA in mothers and their fetuses (8). Single oral doses of the antibiotic, ranging from 1 to 8 mmol/kg (319–2552 mg/kg), about 30 times the human dose, were administered to pregnant rats on the 17th day of gestation. No DNA damage was observed in the female rats at any dose, but at 4 and 8 mmol/kg, a statistically significant decrease in the percentage of double-stranded DNA (i.e., an increase in DNA damage) was observed in fetal tissues. Because a dose–response relationship with the DNA fragmentation was lacking, and because of the very high doses administered, the investigators concluded that the results did not indicate genotoxicity, but most likely a nonspecific consequence of fetal toxicity. Thus, the potential for mutagenic and carcinogenic risk in humans was probably nil (8).

The effects of norfloxacin on spermatogenesis and sperm abnormalities were studied using a mouse sperm morphology test following either single or five consecutive daily doses of 2 and 4 mmol/kg (9). Norfloxacin stimulated spermatogenesis, presumably through a hormonal action, and may have had a mutagenic effect that resulted in an increase in abnormal sperm morphology. However, because a significant dose–response relationship for adverse morphology was not observed, the investigators could not conclude with certainty that the antibiotic induced abnormal sperm (9).

In humans, norfloxacin crosses the placenta, appearing in cord blood and in amniotic fluid (T.P. Dowling, personal communication, Merck & Co, Inc., 1987). Following a single oral 200-mg dose given to nine patients, cord blood and amniotic fluid levels varied from undetectable to 0.18 mcg/mL and undetectable to 0.19 mcg/mL, respectively. Cord blood levels were about one-half of

maternal serum levels. In another 14 women administered a single 200-mg dose, the peak maternal serum, cord blood, and amniotic fluid levels were 1.1, 0.38, and 0.92 mcg/mL, respectively.

No congenital malformations were observed in the infants of 38 women who received either norfloxacin (N = 28) or ciprofloxacin (N = 10) during pregnancy (35 in the 1st trimester) (10). Most (N = 35) received the drugs for the treatment of urinary tract infections. Matched to a control group, the fluoroquinolone-exposed pregnancies had a significantly higher rate of cesarean section for fetal distress and their infants were significantly heavier. No differences were found between the groups in infant development or in the musculoskeletal system.

A surveillance study on the use of fluoroquinolones during pregnancy was conducted by the Toronto Motherisk Program among members of the Organization of Teratology Information Specialists (OTIS) and briefly reported in 1995 (11). Pregnancy outcome data were available for 134 cases, of which 61 were exposed to norfloxacin, 68 to ciprofloxacin, and 5 to both drugs. Most (90%) were exposed during the first 13 weeks postconception. Fluoroquinolone-exposed pregnancies were compared with matched controls and there were no differences in live births (87% vs. 86%), terminations (3% vs. 5%), miscarriages (10% vs. 9%), abnormal outcomes (7% vs. 4%), cesarean section rate (12% vs. 22%), fetal distress (15% vs. 15%), and pregnancy weight gain (15 kg vs. 16 kg). The birth weights of exposed infants were a mean 162 g higher than those in the control group and their gestations were a mean 1 week longer (11).

In a prospective follow-up study conducted by the European Network of Teratology Information Services (ENTIS), data on 549 pregnancies exposed to fluoroquinolones (318 to norfloxacin) were described in a 1996 reference (2). Data on another 116 prospective and 25 retrospective pregnancy exposures to the antibacterials were also included. From the 549 follow-up cases, 509 were treated during the 1st trimester, 22 after the 1st trimester, and in 18 cases the exposure occurred at an unknown gestational time. The liveborn infants were delivered at a mean gestational age of 39.4 weeks and had a mean birth weight of 3302 g, length of 50.3 cm, and head circumference of 34.9 cm. Of the 549 pregnancies, there were 415 liveborn infants (390 exposed during the 1st trimester), 356 of which were normal-term deliveries (including 1 set of twins), 15 were premature, 6 were small for gestational age (intrauterine growth restriction [IUGR], <10th percentile), 20 had congenital anomalies (19 from mothers exposed during the 1st trimester; 4.9%), and 18 had postnatal

disorders unrelated to either prematurity, low birth weight, or malformations. Of the remaining 135 pregnancies, there were 56 spontaneous abortions or fetal deaths (none late) (1 malformed fetus), and 79 elective abortions (4 malformed fetuses) (2). A total of 116 (all involving ciprofloxacin) prospective cases were obtained from a manufacturer's registry (10). Among these, there were 91 liveborn infants, 6 of whom had malformations. Of the remaining 25 pregnancies, 15 were terminated (no malformations reported), and 10 aborted spontaneously (1 embryo with acardia, no data available on a possible twin). Thus, of the 666 cases with known outcome, 32 (4.8%) of the embryos, fetuses, or newborns had congenital malformations. From previous epidemiologic data, the authors concluded that the 4.8% frequency of malformations did not exceed the background rate. Finally, 25 retrospective reports of infants with anomalies, who had been exposed in utero to fluoroquinolones, were analyzed, but no specific patterns of major congenital malformations were detected (2).

The defects observed in 12 infants followed up prospectively and in 16 infants reported retrospectively who were exposed to norfloxacin were as follows (2):

Source: Prospective ENTIS

Trisomy 18, heart defect

Diastasis recti, mild hypospadias

Patent ductus arteriosus (term)

CNS calcification, cataract

Urogenital malformation (no uterus and gonad)

Fossa posterior hypoplasia

Bilateral uretero-vesical reflux, hydronephrosis

Herniation of abdominal viscera, rudimentary umbilical cord, severe kyphoscoliosis, absent diaphragm and pericardium, ectopia cordis, imperforated anus, ambiguous genitalia, urinary bladder not identifiable (pregnancy terminated)

Anencephaly (pregnancy terminated)

Trisomy 21

Unilateral cryptorchidism

Macroglossia (2nd trimester exposure) (pregnancy terminated)

Source: Retrospective Reports

1st trimester exposure:

Abdominal and thoracic wall defects, lungs outside of thoracic cavity,

- pericardium visible (pregnancy terminated)
- Achondroplastic dwarfism (pregnancy terminated)
- Renal and ureteral agenesis, pulmonary hypoplasia
- Supraumbilical hernia
- Intestinal cystic duplication
- Ventricular septal defect
- Penoscrotal hypospadias

2nd trimester exposure:

- Dysplastic hips
- Hypertelorism, cryptorchism, small penis, short thorax, heart valves dysplasia
- Urachal abnormality

3rd trimester exposure:

- Microretrognathia
- Two nevi, 4 × 2 and 2 × 2 cm
- Talipes valgus
- Hands and feet syndactyly
- Trisomy 21
- Short limbs (possibly familial)

The authors of the above study concluded that pregnancy exposure to quinolones was not an indication for termination, but that this class of antibacterials should still be considered contraindicated in pregnant women (2). Moreover, this study did not address the issue of cartilage damage from quinolone exposure, and the authors recognized the need for follow-up studies of this potential toxicity in children exposed in utero. Because of their own and previously published findings, they further recommended that the focus of future studies should be on malformations involving the abdominal wall and urogenital system, and on limb reduction defects (2).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 139 newborns had been exposed to norfloxacin, 79 during the 1st trimester (F. Rosa, personal communication, FDA, 1994). Among those exposed in the 1st trimester, four (5.1%) had a major birth defect (three expected). In addition, a brain defect was noted in an infant whose mother consumed the drug after the 1st trimester. Details of the remaining cases were not available, but none of the abnormalities was included in seven other categories of defects (cardiovascular defects, oral clefts, spina bifida, polydactyly, limb reduction defects, hypospadias, and eye defects) for which specific data were available.

A 1998 prospective, multicenter study reported the pregnancy outcomes of 200 women exposed to fluoroquinolones compared with 200 matched controls (12). Subjects were pregnant women who had called one of four teratogen information services concerning their exposure to fluoroquinolones. The agents and number of subjects, and daily doses (in parentheses) were ciprofloxacin (N = 105; 500–1000 mg), norfloxacin (N = 93; 400–800 mg), and ofloxacin (N = 2; 200–400 mg). The most common infections involved the urinary tract (69.4%) or the respiratory tract (24%). The fewer live births in the fluoroquinolone group (173 vs. 188, $p = 0.02$) were attributable to the greater number of spontaneous abortions (18 vs. 10, $p = 0.17$) and induced abortions (9 vs. 2, $p = 0.06$). There were no differences between the groups in terms of premature birth, fetal distress, method of delivery, low birth weight (<2500 g), or birth weight. Among the liveborn infants exposed during organogenesis, major malformations were observed in 3 infants of 133 subjects and 5 of 188 controls ($p = 0.54$). The defects in subject infants were two cases of ventricular septal defect and one case of patent ductus arteriosus, whereas those in controls were two cases of ventricular septal defect, one case of atrial septal defect with pulmonic valve stenosis, one case of hypospadias, and one case of displaced hip. There were also no differences between the children of the groups in gross motor development milestone achievements (musculoskeletal functions: lifting, sitting, crawling, standing, or walking) as measured by the Denver Developmental Scale (12).

BREASTFEEDING SUMMARY

The administration of norfloxacin during breastfeeding is not recommended because of the potential for arthropathy and other serious toxicity in the nursing infant (7). Phototoxicity has been observed with some members of the quinolone class of drugs when exposure to excessive sunlight (i.e., ultraviolet [UV] light) has occurred. Well-differentiated squamous cell carcinomas of the skin have been produced in mice who were exposed chronically to some quinolones and periodic UV light (e.g., see Lomefloxacin), but studies to evaluate the carcinogenicity of norfloxacin in this manner have not been conducted (7).

The manufacturer reports that the drug was not detected in milk following a single 200-mg oral dose administered to nursing mothers (7). However, this dose is one-fourth of the normal recommended daily dose and, thus, may not be indicative of excretion after normal use. Similarly, a 1991 review cited a study that the antibacterial was undetectable in milk, but no details on dosage

were given (13).

Although it is not known whether norfloxacin is excreted into human milk, the relatively low molecular weight (about 319), and the excretion of other quinolones suggest that the drug will probably be present in milk. Both ciprofloxacin and ofloxacin are classified by the American Academy of Pediatrics as compatible with breastfeeding (see individual agents).

NORGESTREL

Progestogenic Hormone

Norgestrel is commonly used as an oral contraceptive either alone or in combination with estrogens (see Oral Contraceptives).

NORTRIPTYLINE

Antidepressant

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Nortriptyline is a tricyclic antidepressant. The limited human pregnancy experience does not support a major association with congenital defects.

FETAL RISK SUMMARY

Limb reduction anomalies have been reported with nortriptyline (1,2). However, one of these children was not exposed until after the critical period for limb development (3). The second infant was also exposed to sulfamethizole and heavy cigarette smoking (1). Evaluation of data from 86 patients with 1st trimester exposure to amitriptyline, the active precursor of nortriptyline, does not support the drug as a major cause of congenital limb deformities (see Amitriptyline). Urinary retention in the neonate has been associated with maternal use of nortriptyline (4).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 61 newborns had been exposed to nortriptyline during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Two (3.3%) major birth defects were observed (two expected), both cardiovascular anomalies (0.5 expected).

In a 1996 descriptive case series, the European Network of the Teratology Information Services (ENTIS) prospectively examined the outcomes of 689 pregnancies exposed to antidepressants (5). Multiple drug therapy occurred in about two-thirds of the mothers. There were four exposures to nortriptyline. The outcomes of these pregnancies were four normal newborns (one premature) without birth defects (5).

A 2002 prospective study compared two groups exposed to antidepressants throughout gestation, either to tricyclics (N = 46 including 3 to nortriptyline) or to fluoxetine (N = 40), with 36 nonexposed, not depressed controls (6). Offspring

were studied between the ages 15 and 71 months for effects of antidepressant exposure in terms of IQ, language, behavior, and temperament. Exposure to antidepressants did not adversely affect the measured parameters, but IQ was significantly and negatively associated with the duration of depression, and language was negatively associated with the number of depression episodes after delivery (6).

BREASTFEEDING SUMMARY

Nortriptyline is excreted into breast milk in low concentrations (7–11). A milk level in one patient was 59 ng/mL, representing a milk:serum ratio of 0.7 (8). A second patient was treated with nortriptyline 100 mg daily during the 2nd and 3rd trimesters, and then stopped 2 weeks before an elective cesarean section (10). Treatment was restarted at 125 mg every night on the first postpartum day, then decreased to 75 mg nightly over the next 7 weeks. The mother was also receiving flupenthixol. Milk concentrations of nortriptyline, measured 11–13.5 hours after a dose on postpartum days 6 (four samples), 20 (two samples), and 48 (two samples), ranged from 90 to 404 ng/mL, mean 230 ng/mL. The milk:serum ratios for these samples ranged from 0.87 to 3.71 (mean 1.62). No effects of the drug exposure were observed in the nursing infant, who had normal motor development for the first 4 months. Infant serum concentrations were not determined (10).

Nortriptyline was not detected in the serum of other breastfed infants when their mothers were taking the drug (8,9,11); however, low levels (5–11 ng/mL) of the metabolite, 10-hydroxynortriptyline, were measured in the serum of two infants in one study (11). In this latter study, no evidence of accumulation in nursing infants after long-term (e.g., >50 days) maternal use of the antidepressant was observed (11). A 1996 review of antidepressant treatment during breastfeeding found no information that nortriptyline exposure during nursing resulted in quantifiable amounts of the parent compound in an infant or that the exposure caused adverse effects (12).

The significance of chronic exposure of the nursing infant to the antidepressant is unknown, but concern has been expressed about the effects of long-term exposure on the infant's neurobehavioral mechanisms (10). The American Academy of Pediatrics classifies nortriptyline as a drug for which the effect on nursing infants is unknown but may be of concern (13).

NOVOBIOCIN

[Withdrawn from the market. See 9th edition.]

NUTMEG

Herb

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Nutmeg, the dried aromatic seeds of the tree *Myristica fragrans*, is used as a common spice. The seeds contain a toxic chemical, myristicin, that has anticholinergic properties.

FETAL RISK SUMMARY

A 1987 case report described an accidental overdose of grated nutmeg in a pregnant woman at 30 weeks' gestation (1). The woman used 1 tablespoon of the spice (equivalent to approximately 7 g, or one whole grated nutmeg) instead of the suggested amount of 1/8 teaspoon in a recipe for cookies (1). After ingesting some of the cookies, she developed a sinus tachycardia (170 beats/minute), hypertension (170/80 mmHg), and a sensation of impending doom, but no mydriasis. The fetal heart rate was 160–170 beats/minute with loss of long-term variability. It returned to its normal baseline of 120–140 beats/minute within 12 hours. A diagnosis of atropine-like poisoning was made based on the history and physical findings (1). Following nonspecific treatment for poisoning, the mother made an uneventful recovery and was discharged home after 24 hours. Approximately 10 weeks later, she delivered a healthy infant.

BREASTFEEDING SUMMARY

No reports describing the use of nutmeg during human lactation have been located. Because the herb is commonly used as a spice, the risk to a nursing infant is probably nil.

NYLIDRIN

[Withdrawn from the market. See 9th edition.]

NYSTATIN

Antifungal

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Nystatin is poorly absorbed after oral administration and from intact skin and mucous membranes. Animal studies have not been conducted with this antifungal agent.

FETAL RISK SUMMARY

The Collaborative Perinatal Project found a possible association with congenital malformations after 142 1st trimester exposures to nystatin, but this was probably related to its use as an adjunct to tetracycline therapy (1, p. 313). No association was found following 230 exposures anytime in pregnancy (1, p. 435). Other investigators have reported its safe use in pregnancy (2–5).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 489 newborns had been exposed to nystatin during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 20 (4.1%) major birth defects were observed (21 expected). Specific data were available for six defect categories, including (observed/expected) 3/5 cardiovascular defects, 1/1 oral clefts, 0/0 spina bifida, 1/1 polydactyly, 1/1 limb reduction defects, and 2/1 hypospadias. These data do not support an association between the drug and congenital defects.

BREASTFEEDING SUMMARY

Because nystatin is poorly absorbed, if at all, serum and milk levels would not occur.

O

OCRIPLASMIN

Ophthalmic

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of ocriplasmin in human pregnancy have been located. Animal reproduction studies have not been conducted. However, detectable concentrations of the drug in the systemic circulation drug are not expected. Use of the drug during pregnancy appears to be compatible.

FETAL RISK SUMMARY

Ocriplasmin, given as a single intravitreal injection, is a recombinant truncated form of human plasmin produced by recombinant DNA technology. It is indicated for the treatment of symptomatic vitreomacular adhesion. Ocriplasmin has proteolytic activity against components of the vitreous body and the vitreoretinal interface, thereby dissolving the protein matrix responsible for the vitreomacular adhesion. Because of the small dose (0.125 mg) and its rapid inactivation, detectable concentrations in the systemic circulation are not expected (1).

Animal reproduction studies have not been conducted. No carcinogenicity, mutagenicity, or impairment of fertility studies have been conducted (1).

It is not known if ocriplasmin crosses the human placenta. The molecular weight (about 27,000) and the predicted absence of detectable concentrations in the systemic circulation indicate that exposure of the embryo–fetus to clinically significant amounts will not occur.

BREASTFEEDING SUMMARY

No reports describing the use of ocriplasmin during human lactation have been located. The molecular weight (about 27,000) and the predicted absence of detectable concentrations in the systemic circulation indicate that the drug will not be excreted into breast milk.

OCTREOTIDE

Endocrine/Metabolic (Somatostatin Analog)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Octreotide is not teratogenic or toxic in two animal species, but published reports have described only five women who were treated during portions of their pregnancies. Although all of the outcomes were normal, the data are too limited to assess the human embryo–fetal risk. The drug crosses the placenta to the fetus and has been measured in the newborn.

FETAL RISK SUMMARY

This cyclic octapeptide (Octreotide; SMS-201-995), an analog of the natural hormone somatostatin, is used to reduce blood levels of growth hormone and somatomedin C in patients with acromegaly and for the symptomatic treatment of patients with profuse watery diarrhea as a result of metastatic carcinoid tumors or vasoactive intestinal peptide-secreting tumors. It has also been used to reduce insulin requirements for patients with diabetes mellitus; to reduce output from gastrointestinal, enteric, and pancreatic fistulas; to treat variceal bleeding; and for various other indications.

No evidence of impaired fertility, teratogenicity, or fetal harm was observed in pregnant rats and rabbits given up to 16 times the highest human dose based on BSA (1).

Octreotide crosses the human placenta to the fetus (2,3). A 31-year-old infertile woman was treated with octreotide 300 mcg/day for hyperthyroidism induced by a thyroid-stimulating hormone (TSH)–secreting macroadenoma (2,3). The patient became euthyroid, with return of normal menstruation, after 3 months of therapy. She was found to be pregnant 1 month later and octreotide treatment was stopped. Because her symptoms recurred, therapy was reinstated at 6 months' gestation and continued until an elective cesarean

section at 8 months' gestation delivered a normal infant (weight 3300 g, length 51 cm, sex not specified). The concentration of octreotide in umbilical cord serum at delivery was 359 pg/mL compared with the mean maternal level (measured on two different occasions 1 month earlier) of 890 pg/mL (range 764–1191 pg/mL) (2). Although the amount of drug in the newborn was only about 40% that in the mother, the authors concluded that octreotide crossed the placenta by passive diffusion for two reasons (3). First, only the unbound fraction of octreotide is available for placental transfer and, second, the drug is 60%–65% bound to maternal lipoprotein. Thus, assuming that the mother's concentration had not changed significantly, the unbound maternal fraction and the infant's serum level were close to unity. Subsequently, the concentration of octreotide in the infant's serum decreased to 251 pg/mL at 3 hours of age and was undetectable (<20 pg/mL) when next measured (at 40 days).

The cord serum concentrations of TSH, thyroid hormones, prolactin, and growth hormone were normal at birth, at 3 hours, and at 40 and 104 days of age (3). Because the infant's pituitary–thyroid function was not affected by exposure to octreotide at these concentrations, the authors speculated that the somatostatin receptors on thyrotroph cells, as suggested by studies in animals, are not completely functional at birth (3).

The pregnancy of a previously infertile 37-year-old woman who was treated with octreotide for acromegaly during the first 8 weeks of gestation was described in a 1989 reference (4). Treatment (100 mcg) SC 3 times daily, was started within approximately 4 days of conception and discontinued when pregnancy was diagnosed at 8 weeks. A healthy male infant (weight 2530 g, length 46.0 cm) was delivered by cesarean section 2 weeks before term because of the mother's age and imminent fetal asphyxia. No malformations were apparent and his subsequent development at the time of report (age not specified but estimated to be about 9 months) was normal.

A 37-year-old woman with primary amenorrhea was discovered to have acromegaly as a result of pituitary macroadenoma (5). She was treated with octreotide and bromocriptine with reappearance of her menses occurring 7 months later. Treatment with octreotide (300 mcg) 3 times daily and bromocriptine (20 mg/day) was continued for an additional 7 months until a 1-month pregnancy was diagnosed. She eventually delivered, by emergency cesarean section for fetal distress, a term 3540 g, 50 cm male infant with no evidence of congenital defects. Except for requiring mechanical ventilation for 3 days because of neonatal asphyxia, his subsequent development was satisfactory.

A 1999 case report described the pregnancy of a 36-year-old woman who was treated with octreotide (240 mcg/day) for a pituitary adenoma (6). The woman had clinical and laboratory signs of acromegaly. Treatment was started at 13 weeks' gestation and continued until delivery at 40 weeks' of a 3288-g normal female infant with Apgar scores of 8 and 9 at 1 and 5 minutes, respectively, who was developing normally. Cord concentrations of growth hormone, thyrotropin, and prolactin were within normal limits.

In another 1999 case report, a 27-year-old woman with acromegaly was treated throughout the 1st trimester of an unknown pregnancy with SC octreotide (7). At 4 months of pregnancy, she received a continuous infusion of octreotide immediately before surgical resection of the tumor. Postoperative treatment consisted of hydrocortisone, thyroxine, and bromocriptine. Pregnancy was diagnosed at 6 months and at 39 weeks, she delivered a 3780-g healthy female infant who was doing well (7).

BREASTFEEDING SUMMARY

It is not known whether octreotide is transferred to breast milk, but this should be expected because of the documented placental passage. No reports have been located that described the use of this agent during lactation. However, because of probable digestion following oral therapy, the risk to the nursing infant appears to be nonexistent.

OFATUMUMAB

Antineoplastic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of ofatumumab in human pregnancy have been located. In monkeys, the antibody caused fetal B-cell depletions, and decreased placental, spleen, and thymus weights at doses similar to those used in humans. The potential long-term effects of these toxic effects have not been studied in animals. However, refractory chronic lymphocytic leukemia is a serious disease and the maternal benefit appears to outweigh the risks to the fetus. If the antibody must be used in pregnancy, the woman should be informed of the absence of human pregnancy data and the potential fetal risks.

FETAL RISK SUMMARY

Ofatumumab is an IgG1k human monoclonal antibody. It is indicated for the treatment of chronic lymphocytic leukemia refractory to fludarabine and alemtuzumab. The mean half-life, between the 4th and 12th IV infusion doses was about 14 days (range 2.3–61.5 days). The antibody does not bind normal human tissues other than B lymphocytes (1). Data on metabolism have not been found.

Reproduction studies have been conducted in monkeys. Doses that were 0.7 and 3.5 times the recommended human dose (assumed to be based on body weight) were given weekly during organogenesis (gestation days 20–50). No maternal toxicity or teratogenicity was observed. However, both doses depleted circulating B cells in the dams. Ofatumumab crossed the placenta and fetuses, delivered at gestational day 100, had decreased mean peripheral B-cell counts (about 10% of control values), splenic B-cell counts (about 15%–20% of control values), spleen weights (15% for the low dose and 30% for the

high dose, compared with control values), and thymus weight (15% compared with controls). In addition, there also was a 10% decrease in placental weights. The potential long-term effects of B-cell depletions or decreases in spleen and thymus weights have not been studied in animals (1).

Studies for carcinogenic or mutagenic potential or effects on fertility have not been conducted (1).

It is not known if ofatumumab crosses the human placenta. The molecular weight (about 149,000) is high, but immunoglobulin G crosses the placenta late in pregnancy (see Immune Globulin Intravenous). Placental transfer of IgG was a function of dose, as well as gestational age. Moreover, ofatumumab crossed to the fetus in monkeys and, because the placentas in monkeys are similar to those in humans, the antibody should be expected to cross to the human fetus.

BREASTFEEDING SUMMARY

No reports describing the use of ofatumumab during human lactation have been located. It is not known if the antibody is excreted into breast milk. The molecular weight (about 149,000) is high, but the terminal half-life is very long (about 14 days). Because immunoglobulins are excreted into milk, exposure of a nursing infant might occur. The effect of this exposure is unknown, but published data suggest that neonatal and infant consumption of breast milk does not result in substantial absorption of maternal antibodies into the circulation (1). Nevertheless, cytopenia, progressive multifocal leukoencephalopathy, and small intestine obstruction have been observed in human adults treated with ofatumumab and, if a woman chooses to nurse while receiving this agent, her infant should be monitored for these toxicities.

OFLOXACIN

Anti-infective (Quinolone)

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

The use of ofloxacin during human gestation does not appear to be associated with an increased risk of major congenital malformations. Although a number of birth defects have occurred in the offspring of women who had taken this drug during pregnancy, the lack of a pattern among the anomalies is reassuring. However, a causal relationship with some of the birth defects cannot be excluded. Because of this and the available animal data, the use of ofloxacin during pregnancy, especially during the 1st trimester, should be approached with caution. A 1993 review on the safety of fluoroquinolones concluded that these antibacterials should be avoided during pregnancy because of the difficulty in extrapolating animal mutagenicity results to humans and because interpretation of this toxicity is controversial (1). The authors of this review were not convinced that fluoroquinolone-induced fetal cartilage damage and subsequent arthropathies were a major concern, even though this effect had been demonstrated in several animal species after administration to both pregnant and immature animals and in occasional human case reports involving children (1). Others have also concluded that fluoroquinolones should be considered contraindicated in pregnancy, because safer alternatives are usually available (2).

FETAL RISK SUMMARY

Ofloxacin is a synthetic, broad-spectrum antibacterial agent available in oral and parenteral formulations. As a fluoroquinolone, it is in the same class as ciprofloxacin, enoxacin, lomefloxacin, norfloxacin, and sparfloxacin.

A study published in 1986 observed no ofloxacin-induced malformations with high doses in pregnant rats and rabbits (3). Similarly, no evidence of

teratogenicity was observed in pregnant rats and rabbits at doses 11 times the recommended maximum human dose based on BSA (RMHD) or 4 times the RMHD, respectively (4). These doses were fetotoxic, however, causing reduced birth weight, increased mortality, and, in rats only, minor skeletal variations. In rats dosed at 5 times the RMHD, no adverse effects were seen on late fetal development, labor, delivery, lactation, neonatal viability, or subsequent growth of the newborn (4).

In a study investigating the pharmacokinetics of ofloxacin, 20 pregnant women, between 19 and 25 weeks' gestation (mean 22.2 weeks), were scheduled for pregnancy termination because the fetuses were affected with β -thalassemia major (5). Two doses of ofloxacin, 400 mg IV every 12 hours, were given before abortion. Serum and amniotic fluid concentrations were determined concomitantly at 6, 10, and 12 hours after dosing. Mean maternal serum concentrations at these times were 0.68, 0.21, and 0.07 mcg/mL, respectively, compared with mean amniotic fluid levels of 0.25, 0.15, and 0.13 mcg/mL, respectively. The amniotic fluid:maternal serum ratios were 0.37, 0.71, and 1.86, respectively (5).

A 2005 study measured the amount of three fluoroquinolones (ciprofloxacin, ofloxacin, levofloxacin) that crossed the perfused human placenta (6). All three agents crossed the placenta from the maternal to the fetal compartment, but the amounts crossing were small: 3.2%, 3.7%, and 3.9%, respectively.

In a prospective follow-up study conducted by the European Network of Teratology Information Services (ENTIS), data on 549 pregnancies exposed to fluoroquinolones (93 to ofloxacin) were described in a 1996 reference (2). Data on another 116 prospective and 25 retrospective pregnancy exposures to the antibacterials were also included. From the 549 follow-up cases, 509 were treated during the 1st trimester, 22 after the 1st trimester, and in 18 cases, the exposure occurred at an unknown gestational time. The liveborn infants were delivered at a mean gestational age of 39.4 weeks' and had a mean birth weight of 3302 g, length of 50.3 cm, and head circumference of 34.9 cm. Of the 549 pregnancies, there were 415 liveborn infants (390 exposed during the 1st trimester), 356 of which were normal term deliveries (including 1 set of twins), 15 were premature, 6 were small for gestational age (intrauterine growth restriction [IUGR], <10th percentile), 20 had congenital anomalies (19 from mothers exposed during the 1st trimester; 4.9%), and 18 had postnatal disorders unrelated to either prematurity, low birth weight, or malformations. Of the remaining 135 pregnancies, there were 56 spontaneous abortions or fetal deaths (none late) (1 malformed fetus), and 79 elective abortions (4 malformed

fetuses). A total of 116 (all involving ciprofloxacin) prospective cases were obtained from the manufacturer's registry. Among these, there were 91 liveborn infants, 6 of whom had malformations. Of the remaining 25 pregnancies, 15 were terminated (no malformations reported), and 10 aborted spontaneously (1 embryo with acardia, no data available on a possible twin). Thus, of the 666 cases with known outcome, 32 (4.8%) of the embryos, fetuses, or newborns had congenital malformations. From previous epidemiologic data, the authors concluded that the 4.8% frequency of malformations did not exceed the background rate. Finally, 25 retrospective reports of infants with anomalies, who had been exposed in utero to fluoroquinolones, were analyzed but no specific patterns of major congenital malformations were detected (2).

The defects observed in seven infants followed up prospectively (no ofloxacin-exposed cases among the retrospective reports), all exposed to ofloxacin during the 1st trimester, were as follows (2):

Myelomeningocele, hydrocephaly

Ureterostenosis

Maldescensus testis

Hypospadias

Hernia inguinalis left side

Bilateral hip dysplasia

Small atrial septal defect

The authors of the above study concluded that pregnancy exposure to quinolones was not an indication for pregnancy termination, but that this class of antibacterials should still be considered contraindicated in pregnant women. Moreover, this study did not address the issue of cartilage damage from quinolone exposure and the authors recognized the need for follow-up studies of this potential toxicity in children exposed in utero. Because of their own and previously published findings, they further recommended that the focus of future studies should be on malformations involving the abdominal wall and urogenital system, and on limb reduction defects (2).

A 1998 prospective multicenter study reported the pregnancy outcomes of 200 women exposed to fluoroquinolones compared with 200 matched controls (7). Subjects were pregnant women who had called one of four teratogen information services concerning their exposure to fluoroquinolones. The agents, number of subjects, and daily doses were ciprofloxacin, (N = 105; 500–1000 mg), norfloxacin (N = 93; 400–800 mg), and ofloxacin (N = 2; 200–400 mg). The most common infections involved the urinary tract (69.4%) or the

respiratory tract (24%). The fewer live births in the fluoroquinolone group (173 vs. 188, $p = 0.02$) were attributable to the greater number of spontaneous abortions (18 vs. 10, ns) and induced abortions (9 vs. 2, ns). There were no differences between the groups in terms of premature birth, fetal distress, method of delivery, low birth weight (<2500 g), or birth weight. Among the liveborn infants exposed during organogenesis, major malformations were observed in 3 infants of 133 subjects and 5 of 188 controls (ns). The defects in subject infants were two cases of ventricular septal defect and one case of patent ductus arteriosus, whereas those in controls were two cases of ventricular septal defect, one case of atrial septal defect with pulmonic valve stenosis, one case of hypospadias, and one case of displaced hip. There were also no differences between the children of the groups in gross motor development milestone achievements (musculoskeletal functions: lifting, sitting, crawling, standing, or walking) as measured by the Denver Developmental Scale (7).

BREASTFEEDING SUMMARY

When first marketed, ofloxacin use during lactation was not recommended because of the potential for arthropathy and other serious toxicity in the nursing infant (4). Phototoxicity has been observed with quinolones when exposure to excessive sunlight (i.e., ultraviolet [UV] light) has occurred (4). Well-differentiated squamous cell carcinomas of the skin have been produced in mice exposed chronically to some fluoroquinolones and periodic UV light (e.g., see Lomefloxacin), but studies to evaluate the carcinogenicity of ofloxacin in this manner have not been conducted.

Ofloxacin is excreted into breast milk in concentrations approximately equal to those in maternal serum (4,5). The manufacturer reports that following a single 200-mg dose, milk and serum concentrations of ofloxacin were similar (4). Ten lactating women were given three oral doses of ofloxacin, 400 mg each (5). Six simultaneous serum and milk samples were drawn between 2 and 24 hours after the third dose of the antibiotic. The mean peak serum level occurred at 2 hours (2.45 mcg/mL), then steadily fell to 0.03 mcg/mL at 24 hours. Milk concentrations exhibited a similar pattern, with a mean peak level measured at 2 hours (2.41 mcg/mL), and the lowest amount at 24 hours (0.05 mcg/mL). The mean milk:serum ratio varied from 0.98 to 1.66, with the highest ratio occurring 24 hours after the last dose (5).

The American Academy of Pediatrics classifies ofloxacin as compatible with breastfeeding (8).

OLANZAPINE

Antipsychotic

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although no structural malformations attributable to olanzapine or other agents in this subclass have been reported, the number of exposures is too low to fully assess the embryo–fetal risk. In addition, there is a risk of extrapyramidal and/or withdrawal symptoms in the newborn if the drug is used in the 3rd trimester. Nevertheless, olanzapine is indicated for severe debilitating mental disease and the benefits to the mother appear to outweigh the potential embryo–fetal risks. One inadvertent pregnancy was attributed to olanzapine-induced normalization of prolactin levels, but the opposite effect (i.e., hyperprolactinemia) is reported by the manufacturer. More study of this potential concern is warranted. Olanzapine has been associated with hyperglycemia and new-onset diabetes, and blood glucose levels should be monitored because poorly controlled diabetes mellitus is a well-known cause of developmental toxicity. A 1996 review on the management of psychiatric illness concluded that patients with histories of chronic psychosis or severe bipolar illness represent a high-risk group (for both the mother and the fetus) and should be maintained on pharmacologic therapy before and during pregnancy (1). However, a 2000 review stated that the human pregnancy data were too limited to recommend olanzapine (2). Folic acid 4 mg/day has been recommended for women taking atypical antipsychotics because they may have a higher risk of neural tube defects due to inadequate folate intake and obesity (3).

FETAL RISK SUMMARY

Olanzapine, a thienobenzodiazepine-class psychotropic agent, is indicated for the management of schizophrenia and bipolar mania. The drug has a relatively

long elimination half-life (mean 30 hours, range 21–54 hours) (4). The long half-life is partially a result of extensive protein binding to albumin (90%) and to α_1 -acid glycoprotein (77%) (5).

In reproduction studies in rats and rabbits, no evidence of teratogenicity was observed at doses up to 9 and 30 times the maximum recommended human dose based on BSA (MRHD), respectively. In rats, early resorption and increased numbers of nonviable fetuses were observed at 9 times the MRHD. In addition, prolonged gestations were noted at 5 times the MRHD. In rabbits administered a maternal toxic dose (30 times the MRHD), increased resorptions and decreased fetal weight were indications of fetotoxicity (4).

Consistent with the molecular weight (about 312), an in vitro experiment demonstrated that olanzapine crosses the human placenta (5). In a 1999 study that used a near-term human placenta-perfused single-cotyledon system, up to 14% of [¹⁴C]-olanzapine crossed from the maternal to the fetal compartment over 4 hours. The initial concentration (10 ng/mL) was equal to the peak human plasma concentration observed after a 10-mg dose. Although no placental oxidative metabolites were found, the glucuronide metabolite did cross the placenta, but at a slightly slower rate than the parent drug (5). In another study, 14 women taking a staple dose (mean 8.9 mg/day) of olanzapine for a mean 18.4 weeks before delivery had maternal and cord concentrations of the drug determined at birth (6). The cord blood concentration was 72.1% of the maternal concentration. The pregnancy outcomes include three premature infants (<37 weeks) and four growth-restricted infants (<2500 g). The mean Apgar scores were 7.6 and 8.8 at 1 and 5 minutes, respectively. There were eight neonatal complications (three cardiovascular, four respiratory, one hypotonia; complications were not further described), and four infants were admitted to the neonatal intensive care unit (reasons not provided) (6).

In its product information, the manufacturer reported seven pregnancies exposed to olanzapine during clinical trials (4). The outcomes of these pregnancies were one spontaneous abortion (SAB), three elective abortions (EAs), one neonatal death due to a cardiovascular defect (no specific data given), and two normal births.

A 2000 report expanded the above database, describing the outcomes of 37 prospectively identified pregnancies that had been exposed to olanzapine during clinical trials (7). The mean daily maternal dose, in 30 of these pregnancies, was 12.9 mg (range 5–25 mg/day). There were 3 SABs, 13 EAs, and 1 ectopic pregnancy that was aborted. There was one stillbirth at 37 weeks' gestation after premature rupture of the membranes. This pregnancy,

exposed to an unknown dose in the 2nd and 3rd trimesters, had been complicated by gestational diabetes, thrombocytopenia, hepatitis, and polydrug abuse. In 19 pregnancies, there were 16 normal newborns without complications (exposure times: 8 in 1st trimester, 1 in 1st and 2nd trimesters, 6 throughout, and 1 unknown). Among the remaining three outcomes, one infant exposed in utero to 20 mg/day was delivered by cesarean section at 30 weeks. The birth weight and length were 2.13 kg and 40 cm, respectively. The pregnancy had been complicated by gestational diabetes, hypothyroidism, preeclampsia, and abnormal liver enzymes. The infant recovered from respiratory distress and hypoglycemia after 2 weeks of therapy. A second infant, whose mother had taken 10 mg/day throughout gestation, was delivered 10 days after term because of fetal distress (birth weight 3.66 kg). The neonatal examination was normal. Finally, one infant, exposed only during the 1st trimester to an unknown dose, had meconium aspiration after a cesarean section for postmaturity. The eventually neonatal outcome of this case was not given. No congenital malformations were observed in the 19 newborns (7).

In addition to the prospective cases, the above report also described the outcomes of 11 retrospectively identified olanzapine-exposed pregnancies (7). Although retrospective reports are considered to be biased, they are useful as early indicators of fetal risks if a cluster of defects or abnormalities is observed. The results of these pregnancies were as follows: SABs (two cases; 1st trimester, dose unknown); fetal death (olanzapine and risperidone overdose, timing and doses unknown); unilateral dysplastic kidney (1st trimester, dose unknown); and Down's syndrome (timing and dose unknown). The case of unilateral dysplastic kidney does not appear to be related to the drug exposure. Most likely, a chemical insult during development would have produced bilateral kidney damage. Three infant complications also are worth noting, but their relationship to olanzapine is unknown: (a) cardiomegaly, jaundice, somnolence, heart murmur (1st and 3rd trimesters, 5 mg/day); (b) convulsion at 12 days of age (1st and 3rd trimesters, 20 mg/day; electroencephalogram and laboratory tests were normal); and (c) heart murmur, sudden infant death at 2 months of age (throughout gestation, 10 mg/day) (7).

In a 2002 reference, the authors briefly reported the outcomes of 96 olanzapine-exposed pregnancies in a further expansion of the above prospective case registry (8). The new material was based on a 2001 written communication with the manufacturer. The outcomes included 69 normal births, 12 SABs, 3 stillbirths, 2 premature births, 7 had perinatal complications, and 1

major malformation. Neither the perinatal complications nor the malformation were provided (8).

Another report of olanzapine use in human pregnancy appeared in 2000 (9). A 40-year-old obese woman with a 24-year complicated history of schizophrenia and chronic hypertension was treated throughout pregnancy with olanzapine. During the first month she received 20 mg/day and then, because of sedation, 15 mg/day for the remainder of gestation. Her mental disease was stable throughout, but pregnancy was complicated by excessive weight gain (79 lb; 35.9 kg), gestational diabetes, and severe preeclampsia (hypertension, proteinuria, and elevated liver function tests). Because of worsening preeclampsia, a cesarean section was performed at 30 weeks' gestation to deliver a female 2128-g infant. Apgar scores were 7 and 9 at 1 and 5 minutes, respectively. No other information on the infant was provided (9).

A 31-year-old woman with paranoid schizophrenia was treated with olanzapine (10 mg/day) from the 2nd trimester until delivery and then continued during breastfeeding (10). The patient was hospitalized for treatment of a psychotic episode in the 18th gestational week and olanzapine was started at this time. Hospitalization was continued for over 3 months. A normal 3190-g female infant was born at term with Apgar scores of 9, 10, and 10 at 1, 5, and 10 minutes, respectively. Olanzapine plasma levels in the mother and infant on the first day after delivery were 33.4 and 11.3 ng/mL. The infant was breastfed (see Breastfeeding Summary). At 7 months of age, the infant was not able to roll from the back to the ventral position, possibly suggesting impaired motor development. No impairment, however, was noted at 11 months. At this age, head circumference was approximately at the 50th percentile, whereas height and weight were around the 97th percentile (10).

A 2001 case report described the pregnancy of a 38-year-old woman who was treated with olanzapine (7.5 mg/day) for maintenance treatment of schizoaffective disorder (11). She took the drug throughout a 38-week pregnancy, eventually delivering a 3883-g female infant by cesarean section. Apgar scores were 9 and 9 at 1 and 5 minutes, respectively. The infant's length and head circumference were 21.75 and 14.75 inches, respectively. No abnormalities were noted. The mother, who was advised not to breastfeed, required a dose increase to 12.5 mg/day after delivery. The infant's growth was described as normal with weights at 6, 18, and 24 months of age of 6.8 kg (25th percentile), 10.4 kg (50th percentile), and 12.2 kg (75th percentile), respectively. No other measurements were available. She was doing well at age 26 months (11).

A postmarketing surveillance study of olanzapine that was conducted in England identified 18 pregnancies, 11 of the women took the drug in the 1st trimester and 3 during the 2nd/3rd trimesters (12). The outcomes were 11 live births, 2 SABs, 3 EAs, and 1 unknown outcome. In another case, exposure to the drug was uncertain. One of the EAs was for a fetus with a lumbar myelomeningocele (12).

A 37-year-old woman with paranoid schizophrenia was started on olanzapine in the 8th week of gestation (13). She had not received antipsychotics for 3 months prior to this time. Her daily dose was titrated to 25 mg over the next 3 months. She discontinued therapy against medical advice at 32 weeks' gestation because she felt well. She remained well and eventually delivered a healthy 3-kg male infant at 39 weeks' gestation. The Apgar scores were 9 and 10 at 1 and 5 minutes, respectively (13).

Concern that switching a patient from typical neuroleptics (e.g., fluphenazine) to an atypical agent, such as olanzapine, may result in pregnancy was expressed in a brief 1998 communication (14). An unmarried 41-year-old woman with a 22-year history of schizophrenia, paranoid type, and bipolar disorder had been unsuccessfully treated with multiple agents. Her regimen, immediately prior to olanzapine, was depot fluphenazine decanoate (75 mg IM every 2 weeks) and carbamazepine (400 mg/day). Because she remained chronically delusional and thought disordered, her regimen was changed to olanzapine, eventually reaching a maintenance dose of 12.5 mg/day. An 8-week pregnancy was diagnosed 14 weeks after the start of olanzapine. An EA was performed at the patient's request. The authors attributed the pregnancy to a normalization of prolactin levels, such as that observed with clozapine, another atypical neuroleptic (14). However, the manufacturer states that hyperprolactinemia does occur with olanzapine and that a modest elevation of prolactin levels persists during chronic therapy (4).

A 27-year-old woman at 24 weeks' gestation was started on olanzapine when she developed a recurrence of her psychosis (15). The initial dose of 2.5 mg/day had to be gradually increased to 20 mg/day to control her symptoms. After 1 month at 20 mg/day, her dose was tapered over a period of 8 weeks and then discontinued 10 days before delivery. At term, she delivered 2.9-kg male infant with Apgar scores of 8 and 9 at 1 and 5 minutes, respectively. The infant was growing and developing normally at 3 months of age (15).

A 2005 study, involving women from Canada, Israeli, and England, described 151 pregnancy outcomes in women using atypical antipsychotic drugs (16). The exposed group was matched with a comparison group (N = 151) who had not

been exposed to these agents. The drugs and number of pregnancies were olanzapine (N = 60), risperidone (N = 49), quetiapine (N = 36), and clozapine (N = 6). In those exposed, there were 110 live births (72.8%), 22 SABs (14.6%), 15 EAs (9.9%), and 4 stillbirths (2.6%). Among the live births, one infant exposed in utero to olanzapine had multiple anomalies including midline defects (cleft lip, encephalocele, and aqueductal stenosis). The mean birth weight was 3341 g. There were no statistically significant differences, including rates of neonatal complications, between the cases and controls, with the exceptions of low birth weight (10% vs. 2%, $p = 0.05$) and EAs (9.9% vs. 1.3%, $p = 0.003$). The low birth weight may have been caused by the increased rate of cigarette smoking (38% vs. 13%, $p \leq 0.001$) and heavy/binge alcohol use (5 vs. 1) in the exposed group (16).

A 2006 review of prophylactic therapy of bipolar disorder briefly described the effects in pregnancy and breastfeeding of a number of drugs, including olanzapine (17). Untreated pregnant and nursing women with the disorder are at an increased risk of poor obstetrical outcomes and relapse of affective symptoms. Although the limited data prevented conclusions on the relative safety of the drugs, the author did state that each case needed to be considered separately (17).

BREASTFEEDING SUMMARY

Consistent with the molecular weight (about 312) and the prolonged elimination half-life (mean 30 hours, range 21–54 hours), olanzapine is excreted into breast milk (18–20). Several reports have described the use of olanzapine in lactating women.

One mother took 5 mg/day in the 1st and 3rd trimesters and continued the drug during breastfeeding (7). The infant had cardiomegaly, jaundice, somnolence, and a heart murmur. At 7 days of age, the infant was changed to bottle-feeding, but sedation and jaundice continued. No other details were provided, but the authors stated that the continued sedation and jaundice suggested that they were not drug-induced. However, the elimination half-life of olanzapine in adults is prolonged and, although the neonatal half-life is unknown, it may be longer because of immature hepatic and renal function. If comparable, it would take about 4–11 days for the infant to eliminate from its system approximately 97% of the drug that was obtained during pregnancy and/or nursing. Thus, a causal relationship cannot be excluded without knowing additional information. In a second case, the mother started olanzapine 10 mg/day for paranoid schizophrenia 2 months after delivery (7). She was also

taking paroxetine, trifluoperazine, and procyclidine. No adverse effects were reported in the infant.

The third case involved a woman who took olanzapine 10 mg/day throughout the second half of pregnancy and during 2 months of lactation (10). Plasma levels in the mother and infant 1 day after delivery were 33.4 and 11.3 ng/mL, respectively. The infant's level is attributable to drug acquired while in utero. During nursing, the mother's and infant's plasma levels were determined at 2 and 6 weeks postpartum. Maternal levels were 39.5 and 32.8 ng/mL, respectively, whereas those in the infant were <2 and <2 ng/mL, respectively. No adverse effects of this exposure were noted in the infant (see Fetal Risk Summary for development and growth measures at 11 months of age) (10).

In a 2002 study, five lactating women were started on olanzapine for postpartum psychosis (18). After 5 days of therapy, one to three paired samples per patient (nine samples) of maternal plasma and milk were drawn 11–23 hours after a dose. The mean milk:plasma ratio was 0.46 (range 0.2–0.84). The median infant dose was 1.6% (range 0%–2.5%) of the weight-adjusted maternal dose. The highest milk concentrations (21 mg/L at 11 hours postdose and 16 mg/mL at 23 hours postdose) occurred in the woman taking the highest dose (10 mg/day). The other women were taking 2.5 mg/day and their milk levels ranged from <1 to 8 mg/L. The olanzapine plasma level in one infant 15 hours after the mother's 2.5-mg dose was <1 mcg/L. No adverse effects in the infants were observed (18).

A 2003 study reported the milk concentrations of olanzapine in seven women, two of whom started treatment during pregnancy (19). The women had been taking olanzapine for a mean of 114 days (range 19–395 days) and the mean age of the infants was 2.4 months (range 0.1–4.3 months). Multiple maternal plasma and milk samples were collected over 12- or 24-hour intervals. In six women, the median maternal dose was 7.5 mg/day (range 5–20 mg/day) or 131.5 mcg/kg (range 75–286 mcg/kg) and the median peak plasma concentration and time postdose were 29 mcg/L (range 15–73 mcg/L) and 2.5 hours (1.5–4.5 hours), respectively. The median peak drug concentration in milk occurred 5.2 hours (range 0.7–13.2 hours) after the dose and the median concentration was 8.8 mcg/L (range 1.2–22.7 mcg/L). The median milk:plasma AUC ratio was 0.38. Olanzapine plasma levels in the infants were below the detection limit (1–5 mcg/L). No adverse effects were observed or measured in the nursing infants. For the seventh woman, the milk:plasma ratio was 0.75 at 6 hours postdose based on a single sample collection. Sedation had been noted in her infant 3 weeks before the study and her dose had been halved to 5

mg/day. Sedation was not observed in infant at the time of the study (19).

Olanzapine 20 mg/day was given to a 32-year-old woman hospitalized 9 days after delivery for a postpartum psychotic disorder (20). Although she had been breastfeeding her infant, she decided to stop nursing on admission. Serial milk samples were drawn for 10 days with olanzapine concentrations ranging from 7.6 (day 2) to 27.5 ng/mL. The milk:plasma ratio ranged from 0.35 to 0.42. If nursing had been continued, the infant would have consumed a dose that was approximately 4% of the maternal weight-adjusted dose, or about 0.011 mg/kg/day (18). Therefore, the infant exposure would have been very low (20).

Sedation is a frequent adverse effect in adults treated with olanzapine and has occurred in nursing infants whose mothers were taking the drug. Reducing the maternal dose may eliminate this problem, but the potential effect on control of the mother's disease must be considered. The prolonged adult elimination half-life and the potential for long-term neurodevelopment toxicity in a nursing infant should be considered before olanzapine is prescribed during lactation. The American Academy of Pediatrics classifies other antipsychotics (e.g., see Clozapine) as drugs whose effect on the nursing infant is unknown but may be of concern (21).

OLEANDOMYCIN

[Withdrawn from the market. See 9th edition.]

OLMESARTAN

Antihypertensive

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The antihypertensive mechanisms of action of olmesartan and angiotensin-converting enzyme (ACE) inhibitors are very close. That is, the former selectively blocks the binding of angiotensin II to AT₁ receptors, whereas the latter prevents the formation of angiotensin II itself. Therefore, use of this drug during the 2nd and 3rd trimesters may cause teratogenicity and severe fetal and neonatal toxicity identical to that seen with ACE inhibitors (see Captopril or Enalapril). Fetal toxic effects may include anuria, oligohydramnios, fetal hypocalvaria, intrauterine growth restriction, prematurity, and patent ductus arteriosus. Anuria-associated oligohydramnios may produce fetal limb contractures, craniofacial deformation, and pulmonary hypoplasia. Severe anuria and hypotension, resistant to both pressor agents and volume expansion, may occur in the newborn following in utero exposure to olmesartan. Newborn renal function and blood pressure should be closely monitored.

FETAL RISK SUMMARY

The prodrug olmesartan medoxomil is hydrolyzed to olmesartan during absorption from the gastrointestinal tract. No additional metabolism occurs. Olmesartan is a selective angiotensin II receptor blocker (ARB) that is indicated, either alone or in combination with other antihypertensive agents, for the treatment of hypertension. Olmesartan blocks the vasoconstrictor and aldosterone-secreting effects of angiotensin II by preventing angiotensin II from binding to the AT₁ receptors. Other drugs in this class include candesartan, eprosartan, irbesartan, telmisartan, and valsartan. The terminal elimination half-life is about 13 hours (1).

Reproduction studies with olmesartan have been conducted in rats and rabbits. No evidence of teratogenicity was observed in either species at doses up to 240 and 0.5 times, respectively, the maximum recommended human dose based on BSA (MRHD). Higher doses in rabbits could not be administered because they caused maternal death. In rats, doses equal to or greater than about 0.4 times the MRHD caused fetal toxicity (decreases in pup birth weight and weight gain). Higher doses (equal to or greater than about twice the MRHD) resulted in delays in developmental milestones and dose-related increases in the incidence of dilation of the renal pelvis. The no-observed effect dose for developmental toxicity was about 0.1 times the MRHD (1).

The case report below strongly suggests that olmesartan crosses the human placenta. This would be consistent with the molecular weight (about 559) and relatively long terminal elimination half-life.

A woman took olmesartan (dose not specified) for hypertension in the last month of pregnancy (2). Severe oligohydramnios developed and she delivered a 3.045-kg female infant by cesarean section at 36 weeks' gestation. Apgar scores were 7 and 7. The infant received dialysis for renal failure but died on day 45. Autopsy revealed severe tubular dysgenesis and the renal arteries and arteriole walls were thickened (2).

A 2012 review of the use of ACE inhibitors and ARBs in the 1st trimester concluded that there may be an elevated teratogenic risk, but the risk appeared to be related to other factors (3). The factors, that typically coexist with hypertension in pregnancy, included diabetes, advanced maternal age, and obesity.

BREASTFEEDING SUMMARY

No reports describing the use of olmesartan during human lactation have been located. The molecular weight (about 559) is low enough that excretion into breast milk should be expected. The effect of this exposure on a nursing infant is unknown. The American Academy of Pediatrics, however, classifies ACE inhibitors, a closely related group of antihypertensive agents, as compatible with breastfeeding (see Captopril or Enalapril).

OLOPATADINE

Antihistamine

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of olopatadine in human pregnancy have been located. The animal reproduction data and the very low plasma concentrations suggest that the risk in humans is negligible. Moreover, antihistamines, in general, are not thought to cause human developmental toxicity at recommended doses.

FETAL RISK SUMMARY

The antihistamine olopatadine is administered topically to the eye for treatment of the signs and symptoms of allergic conjunctivitis. Low concentrations, ranging from 0.5 to 1.3 ng/mL, have been detected in the plasma of nonpregnant volunteers within 2 hours of a dose. The plasma elimination half-life was about 3 hours (1).

Reproduction studies have been conducted in rats and rabbits. No evidence of teratogenicity was observed in either species at oral doses up to 93,750 and 62,500 times, respectively, the maximum recommended ocular human dose (MROHD). However, at the maximum dose during organogenesis, there was a decrease in live fetuses. In male and female rats, an oral dose 62,500 times the MROHD resulted in a slight decrease in the fertility index and implantation rate. The no-effect dose on animal reproductive function was 7800 times the MROHD (1).

It is not known if olopatadine crosses the human placenta. The molecular weight (about 374) is low enough, but the very small amounts in the systemic circulation suggest that clinically significant amounts of the antihistamine will not reach the embryo and/or fetus.

BREASTFEEDING SUMMARY

No reports describing the use olopatadine during human lactation have been located. Because ocular use in humans results in very low plasma concentrations, the risk to a nursing infant is probably negligible.

OLSALAZINE

Anti-inflammatory Bowel Disease Agent

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing adverse fetal effects following the use of olsalazine in human pregnancy have been located. The use of 5-aminosalicylic acid, the active metabolite of olsalazine, in human pregnancy is discussed under Mesalamine.

FETAL RISK SUMMARY

Olsalazine is used to maintain remission of ulcerative colitis in patients who cannot tolerate sulfasalazine. It is poorly absorbed, approximately 2.4% after oral administration, with the remainder reaching the colon intact where it is converted into two molecules of 5-aminosalicylic acid (mesalamine) by colonic bacteria (1). The history, pharmacology, and pharmacokinetics of mesalamine and olsalazine were extensively reviewed in a 1992 reference (2).

Reproductive studies with olsalazine in rats have revealed reduced fetal weights, retarded ossifications, and immaturity of the fetal visceral organs with doses 5–20 times the recommended human dose on a weight basis (1).

BREASTFEEDING SUMMARY

The active metabolite of olsalazine, 5-aminosalicylic acid (mesalamine), is excreted into human milk (see Mesalamine). In one study, however, only a metabolite of mesalamine, acetyl-5-aminosalicylic acid, was detected in breast milk after the ingestion of olsalazine (see Mesalamine) (3). Because diarrhea has occurred in a nursing infant of a mother receiving mesalamine (see Mesalamine), nursing infants of women being treated with olsalazine should be closely observed for changes in stool consistency.

OMACETAXINE

Antineoplastic (Protein Synthesis Inhibitor)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of omacetaxine in human pregnancy have been located. Reproduction studies conducted in one species suggest risk, but the absence of human pregnancy experience prevents a more complete assessment of embryo–fetal risk. Moreover, based on the mechanism of action, the drug may cause fetal harm.

FETAL RISK SUMMARY

Omacetaxine is a protein synthesis inhibitor that is given by SC injection. It is indicated for the treatment of adult patients with chronic or accelerated phase chronic myeloid leukemia with resistance and/or intolerance to two or more tyrosine kinase inhibitors. The drug is metabolized by plasma esterases to apparently inactive metabolites. Plasma protein binding is $\leq 50\%$ and the mean half-life is about 6 hours (1).

Reproduction studies have been conducted in mice. In this species during organogenesis, doses that were about 50% of the recommended daily human dose based on BSA (RDHD) caused fetal toxicity, including embryo death, an increase in unossified bones/reduced bone ossification, and decreased fetal weights (1).

Carcinogenicity studies have not been conducted with omacetaxine. The drug was genotoxic in one assay but negative in two other assays. Studies in mice demonstrated adverse effects on male reproductive organs. SC doses that were about 2–3 times the clinical dose based on BSA caused bilateral degeneration of the seminiferous tubular epithelium in testes and hypospermia/aspermia in the epididymides.

It is not known if omacetaxine crosses the human placenta. The molecular weight (about 546), moderate plasma protein binding, and the mean half-life suggest that the drug will cross to the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use of omacetaxine during human lactation have been located.

The molecular weight (about 546), moderate plasma protein binding ($\leq 50\%$), and the mean half-life (about 6 hours) suggest that the drug will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown, but the infant should be monitored for the most common (frequency $\geq 20\%$) adverse effects seen in adults. These effects include thrombocytopenia, anemia, neutropenia, diarrhea, nausea, fatigue, asthenia, pyrexia, infection, and lymphopenia (1).

OMALIZUMAB

Respiratory Drug (Monoclonal Antibody)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

The limited animal data suggest that the risk of human embryo–fetal harm is low. The rate of spontaneous abortions (SABs) (14%) in women who conceived while under treatment with omalizumab is within the normal background rate for clinically recognized pregnancies. However, the minimal information regarding the other outcomes of the early pregnancy exposures prevents a better assessment of the risk. Other immunoglobulins have been used in pregnancy without causing embryo–fetal harm (see Immune Globulin Intramuscular and Intravenous). Therefore, if indicated, omalizumab should not be withheld because of pregnancy. If a woman has received omalizumab within 8 weeks prior to conception or during pregnancy, health care professionals or patients are encouraged to call 1-866-496-5247 for information about enrollment in the Xolair Pregnancy Registry (EXPECT).

FETAL RISK SUMMARY

Omalizumab is a recombinant DNA-derived humanized immunoglobulin (IgG1_k) monoclonal antibody that is administered SC for patients with moderate to severe persistent asthma. Omalizumab selectively binds to human IgE. Patients should have had a positive skin test or in vitro reactivity to a perennial aeroallergen and symptoms inadequately controlled by inhaled corticosteroids. Because of its slow absorption, it takes an average of 7–8 days to reach peak serum concentrations. The serum elimination half-life averaged 26 days (1).

Reproduction studies have been conducted in cynomolgus monkeys. At SC doses up to 12 times the maximum human dose based on body weight (MHD) throughout organogenesis, no evidence of maternal toxicity, embryotoxicity, or

teratogenicity was observed. The same dose administered throughout late gestation, delivery, and nursing did not cause adverse effects on fetal or neonatal growth. In fertility studies with monkeys, no effect was observed on male or female reproductive capability, including implantation in females, with weekly SC doses 2–5 times the human exposure based on AUC over the range of adult clinical doses (1).

The transplacental passage of omalizumab in humans has not been studied. Although the molecular weight (about 149,000) is high, immune globulin G is known to cross the human placenta and, combined with the long elimination half-life, exposure of the human embryo or fetus should be expected.

No published reports describing the use of omalizumab in human pregnancy have been located. In its safety data, the manufacturer reported 29 pregnancies exposed to omalizumab during clinical trials, but in each case, the drug was discontinued when pregnancy was diagnosed (2). In the completed studies, the outcomes of 17 pregnancies were 3 SABs, 3 elective abortions, and 11 normal deliveries. Of the 12 pregnancies in ongoing studies, 1 ended in a SAB. The outcomes of the remaining 11 were normal deliveries or awaiting delivery (number of each not specified). The 4 SABs occurred within 3 months of the last menstrual period. In one case, the woman had a prior history of a SAB. No information (e.g., sex, weight, anomalies, or abnormalities) on the newborn infants was provided (2).

BREASTFEEDING SUMMARY

No reports describing the use of omalizumab during human lactation have been located. If the drug is excreted into milk, the effect of this exposure on a nursing infant is unknown.

OMEGA-3 FATTY ACID SUPPLEMENTS

Dietary Supplement

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Omega-3 fatty acids, including alpha-linoleic acid (ALA), docosahexaenoic acid (DHA), and eicosapentaenoic acid (EPA), are present in foods, particularly fish. Omega-3 fatty acids are thought to play a role in normal development of the central nervous system, retina, inflammatory and immune responses (1). Although there is no recommended daily allowance (RDA) for omega-3 fatty acids, the “adequate intake” level for pregnant women, as established by the U.S. Institute of Medicine and the Food and Nutrition Board, is 1.4 g/day (2). It is thought that many pregnant women do not achieve this level of intake from the diet due in part to the recommendation to limit fish consumption during pregnancy to no more than two servings per week (3). Additional sources of omega-3 fatty acids include fish oil supplements and some prenatal vitamin supplements that contain DHA. Evolving evidence suggests that use of supplements in addition to dietary sources of omega-3 fatty acids to achieve the recommended adequate intake level has positive benefits for pregnancy outcome (4).

FETAL RISK SUMMARY

Omega-3 fatty acids are polyunsaturated fatty acids (PUFAs) consisting of three types. The parent compound, ALA, is found in plant foods such as nuts, seeds, and vegetable oils and is an essential fatty acid because it cannot be synthesized by humans and prevents symptoms of deficiency (1). DHA and EPA are long-chain PUFAs (LC-PUFAs) that can be synthesized from ALA; however, the process of conversion is not very efficient in humans, and therefore fish in the diet is the major source of LC-PUFAs (5). Recent population trends in reduced dietary fat intake have led to the likelihood of suboptimal levels of omega-3 fatty acids in pregnancy, in particular DHA and

EPA (6). In addition, dietary intake of LC-PUFAs is limited in pregnant women because they are advised to restrict intake of fish to no more than two servings per week due to concerns for mercury contamination (3).

Although no official RDA for omega-3 fatty acids has been established to date, the U.S. Institute of Medicine and the Food and Nutrition Board have suggested an adequate intake of 1.4 g/day during pregnancy, and the International Society for the Study of Fatty Acids and Lipids (ISSFAL) has established a recommended minimum dose of 500 mg EPA+DHA for adults and 200–300 mg DHA daily for pregnant and lactating women (2,7).

Although research is still evolving regarding the effects of LC-PUFA during pregnancy, the majority of human studies show that increased intake of EPA and DHA has potential benefits on maternal and fetal health outcomes including reduced incidence of preterm birth (8), increased birth length, weight, and head circumference (9), improved infant and child cognitive development (6,9), improved visual development (10), and reduced risk of allergies in infants (11). Although it is generally agreed that more studies are needed, there is broad consensus that improving LC-PUFA status during pregnancy is desirable (7,12).

Similar to dietary fish, omega-3 fatty acid supplements made from fish oil may be contaminated by mercury and other toxins; however, evidence suggests that with high-quality manufacturing processes, the level of contamination and the amount of mercury consumed with the recommended supplement dose is far less than that in fish and unlikely to be of any concern (13). No studies have been located that report substantial adverse effects of LC-PUFA supplementation when given in the recommended doses during pregnancy (12).

BREASTFEEDING SUMMARY

DHA and EPA are present in breast milk. The infant need for DHA during breastfeeding is about 70–80 mg daily (14). Levels of maternal DHA decline during pregnancy and decrease even further during the lactation period. Recent studies have established that the diet of Western pregnant and lactating women contains only 20%–60% of the recommended DHA+EPA daily intake of 200–300 mg/day and these low levels are reflected in breast milk composition. Supplementation with omega-3 fatty acids results in increased levels in breast milk (15).

Although no official RDA for omega-3 fatty acids during lactation has been established to date, the U.S. Institute of Medicine and the Food and Nutrition Board have suggested an adequate intake of 1.3 g/day during lactation which

may be achieved through a combination of diet and supplements (2).

OMEPRAZOLE

Gastrointestinal Agent (Antisecretory)

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

The lack of teratogenicity in animals and the bulk of the human 1st trimester exposure data suggest that omeprazole can be classified as low risk in pregnancy. A study showing an association between in utero exposure to gastric acid-suppressing drugs and childhood allergy and asthma requires confirmation. None of the other studies measured a significant increase in the rates of major birth defects with proton pump inhibitors (PPIs), but they lacked the power to detect small increases in birth defects or rare malformations. The small cluster of cardiac defects observed in one study after omeprazole exposure appears to be an errant signal because it has not been confirmed in other studies. Most likely, cardiac and other defects observed in all studies were the result of many factors, including possibly the severity of the disease and concurrent use of other drugs. The data, however, do warrant continued investigation. In addition, the studies lacked the sensitivity to detect minor anomalies because of the absence of standardized examinations. Late appearing major defects may also have been missed due to the timing of some of the data collection. If omeprazole is required or if inadvertent exposure does occur early in gestation, the known risk to the embryo–fetus appears to be low. Long-term follow-up of offspring exposed during gestation is warranted.

FETAL RISK SUMMARY

The antisecretory agent, omeprazole, a PPI, suppresses gastric acid secretion by a direct inhibitory effect on the gastric parietal cell (1). It is used for the treatment of duodenal and gastric ulcers, erosive esophagitis, and pathologic hypersecretory conditions, such as Zollinger-Ellison syndrome. Omeprazole is

in the same class of PPIs as dexlansoprazole, esomeprazole, lansoprazole, pantoprazole, and rabeprazole. The drug has a short plasma half-life (0.5–1.0 hour) and is extensively metabolized to metabolites that have little or no antisecretory activity (1).

In reproductive studies in pregnant rats and rabbits, doses up to approximately 345 and 172 times, respectively, the normal human dose produced no evidence of teratogenicity, but dose-related embryo and fetal mortality was observed (1). A dose-dependent increase in gastric cell carcinoid tumors has been observed in rats (1). The in vitro Ames mutagen assay was negative. Other tests for genotoxicity in mice and rats were either borderline or negative (1).

Omeprazole crosses the placenta to the fetus in sheep (2) and in humans (3). In sheep, the fetal:maternal ratio of total omeprazole, after both low and high dose, was 0.2, but the ratio of unbound drug was 0.5 (2). Urinary clearance of the drug was low in both the mother and the fetus.

Placental passage of omeprazole in humans was demonstrated in a study published in 1989 (3). Twenty women were administered a single 80-mg oral dose of omeprazole the night before scheduled cesarean sections with a mean dosing-to-general anesthesia induction time interval of 853 minutes (range 765–977 minutes) (3). At the time of surgery, maternal omeprazole levels ranged from 0 to 271 nmol/L. The drug concentration in 13 of the 20 infants (both arterial and venous umbilical samples were drawn in most cases) was either 0 or below the minimum detection limit (20 nmol/L). In the remaining seven infants, omeprazole cord blood concentrations ranged from 21 to 109 nmol/L. No adverse effects attributable to the drug were observed either at birth or at follow-up in 7 days (3).

The FDA has received reports of 11 birth defects following pregnancy exposure to omeprazole, 4 of which were anencephaly and 1 of which was a hydranencephaly that developed de novo after starting omeprazole in the 13th gestational week (F. Rosa, personal communication, FDA, 1996).

A paper published in 1995 described the use of omeprazole, 20 mg daily for esophageal reflux, by a woman in two consecutive pregnancies that were terminated because of severe congenital anomalies—anencephaly in one and severe talipes in the other (4). The first pregnancy was the result of a gamete intrafallopian transfer (GIFT) procedure, and the second occurred after a natural conception. Both aborted fetuses had normal chromosomal patterns.

A woman with Zollinger-Ellison syndrome was treated in two of her three pregnancies with omeprazole (5). In her first pregnancy, she had been treated

with ranitidine (300 mg/day) and with other therapy during the 2nd and 3rd trimesters and delivered a healthy, 2560-g boy at 37 weeks' gestation. She then presented at 11 weeks' gestation in her second pregnancy, complaining of abdominal pain and vomiting. Her symptoms were controlled with omeprazole (120 mg/day) which was continued until delivery of a healthy, 2610-g girl. During the third pregnancy, she was treated throughout gestation with omeprazole (180 mg/day) and cimetidine (450 mg/day) and delivered a healthy term 2550-g male infant (5).

Data from the Swedish Medical Birth Registry were presented in 1998 (6). A total of 553 infants (6 sets of twins) were delivered from 547 women who had used acid-suppressing drugs early in pregnancy. A number of other pharmaceutical agents, identified only by drug category, were also used by these women. Nineteen infants with birth defects were identified (3.1%, 95% confidence interval [CI] 1.8–4.9) compared with the crude malformation rate of 3.9% in the Registry. The odds ratio (OR) for a congenital malformation, stratified for birth year, maternal age, parity, and smoking was 0.72 (95% CI 0.41–1.24) (6). The OR for malformations after PPI exposure was 0.91 (95% CI 0.45–1.84) compared with 0.46 (95% CI 0.17–1.20) for H₂-receptor antagonists (OR 0.86, 95% CI 0.33–2.23; $p = 0.13$). Of the 19 infants with birth defects, 10 had been exposed to PPIs, 8 to H₂ antagonists, and 1 to both classes of drug. Six of the defects in the PPI group were cardiovascular defects (see also Lansoprazole), whereas only one such defect occurred in those exposed to H₂ antagonists. Omeprazole was the only acid-suppressing drug exposure in 262 infants. Twenty other offspring were exposed in utero to omeprazole combined either with cimetidine (2 infants) or ranitidine (18 infants). Eight birth defects (3.1%) were observed in the group where omeprazole was the only acid-suppressing agent used (defects described below) (6).

A 2001 study expanded the above data to 955 infants who had been exposed to omeprazole during pregnancy (7). Of these, 863 infants were exposed during the 1st trimester and 39 of these, plus an additional 92 infants, were exposed after the 1st trimester. Twenty-eight infants (3.2%) had congenital malformations, 16 of which were exposed to other medications. Eight infants had cardiac defects, seven of which were considered mild or unspecified: ventricular septal defects (N = 5), unspecified (N = 2). The infant with the severe cardiac defect had tetralogy of Fallot plus an eye defect (coloboma plus posterior segment malformation). The other, noncardiac defects were (one each) hypospadias, urethral stenosis, bladder exstrophy, plagiocephaly, facial anomaly, Down's syndrome, valgus foot deformity, jejunal

atresia, and nevus. Defects that appeared two or more times were persistent ductus arteriosus at term (N = 2), hydronephrosis (N = 2), undescended testicle (N = 2), unstable hip (N = 3), and pylorostenosis (N = 2). The adjusted OR for any malformation was 0.82, 95% CI 0.50–1.34. In addition to the defects, five infants were stillborn. The author thought that the slight increase in cardiac malformations and the stillbirths may have been random effects (7).

A prospective cohort study published in 1998 described the pregnancy outcomes of 113 women exposed to omeprazole (101 during organogenesis) matched with 113 disease-paired controls (exposed to H₂-receptor antagonists) and 113 controls who were exposed to nonteratogenic agents (8). All of the subjects and controls had contacted a teratogen information service to inquire about drug exposures during their pregnancy. Omeprazole-exposed women were from Canada (N = 59), Italy (N = 41), and France (N = 13), whereas all of the 226 controls were from Canada (Motherisk Program in Toronto). There were no significant differences between the groups in alcohol use and smoking. However, omeprazole-exposed women used significantly more anti-peptic and prokinetic agents (histamine blockers, antacids, sucralfate, bismuth subsalicylate, calcium carbonate, and cisapride) than women in the two control groups. Pregnancy outcomes were determined from information supplied by the women shortly after delivery. No significant differences between the three groups in terms of live births, spontaneous abortions (SABs), elective abortions (EABs), gestational age at birth, preterm delivery, Cesarean section, and birth weight were observed (8). The incidence of major anomalies in live births exposed during the 1st trimester in the three groups were 4 of 78 (5.1%), 3 of 98 (3.1%), and 2 of 66 (3.0%), respectively. The four malformations in omeprazole-exposed infants were ventricular septal defect, polycystic kidneys, ureteropelvic junction stenosis, and patent ductus arteriosus. In disease-paired controls, the three defects were atrial septal defect and two cases of ventricular septal defect, whereas in nonteratogenic controls the two malformations were atrial septal defect with pulmonary stenosis and developmental delay. Although the study lacked the statistical power to detect a small increase in major malformations, the authors concluded that it was unlikely that omeprazole was a major teratogen (8).

A 1998 noninterventional observational cohort study described the outcomes of pregnancies in women who had been prescribed ≥ 1 of 34 newly marketed drugs by general practitioners in England (9). Data were obtained by questionnaires sent to the prescribing physicians 1 month after the expected or possible date of delivery. In 831 (78%) of the pregnancies, a newly marketed

drug was thought to have been taken during the 1st trimester with birth defects noted in 14 (2.5%) singleton births of the 557 newborns (10 sets of twins). In addition, two birth defects were observed in aborted fetuses. However, few of the aborted fetuses were examined. Omeprazole was taken during the 1st trimester in five pregnancies. The outcomes of these pregnancies included one EAB and four normal, full-term infants (9).

The pregnancy outcomes of nine women who had taken omeprazole (20–60 mg/day) during gestation were described in a 1998 publication (10). Four of the women took omeprazole during the 1st trimester and five started treatment in the 2nd or 3rd trimesters. No complications or congenital malformations were observed in the offspring or during subsequent follow-up periods ranging from 2 to 12 years (10).

In a study published in 1999, investigators linked data from a Danish prescription database to a birth registry to evaluate the risks of PPIs for congenital malformations, low birth weight, and preterm delivery (<37 weeks') (11). From a total of 51 women who had filled a prescription for these drugs sometime during pregnancy, 38 (omeprazole N = 35, lansoprazole N = 3) had done so during the interval of 30 days before conception to the end of the 1st trimester. A control group, consisting of 13,327 pregnancies in which the mother had not obtained a prescription for reimbursed medication from 30 days before conception to the end of her pregnancy, was used for comparison. The prevalence of major congenital anomalies in the controls was 5.2%. Three major birth defects (7.9%), two of which were cardiovascular anomalies, were observed from the 38 pregnancies possibly exposed in the 1st trimester (specific drug exposure not given): ventricular septum defect; pyloric stenosis; and one case of patent ductus arteriosus, atrial septum defect, hydronephrosis, and agenesis of the iris. Compared with controls, the adjusted (for maternal age, birth order, gestational age, and smoking, but not for alcohol abuse) relative risks for the three outcomes were congenital malformations 1.6 (95% CI 0.5–5.2), low birth weight 1.8 (95% CI 0.2–13.1), and preterm delivery (not adjusted for gestational age) 2.3 (95% CI 0.9–6.0). Although the study found no elevated risks for the three outcomes, the investigators cautioned that more data were needed to assess the possible association between PPIs and cardiac malformations or preterm delivery (11).

Two databases, one from England and the other from Italy, were combined in a study published in 1999 that was designed to assess the incidence of congenital malformations in women who had received a prescription for an acid-suppressing drug (omeprazole, cimetidine, or ranitidine) during the 1st

trimester (12). Nonexposed women were selected from the same databases to form a control group. SABs and EABs (except two cases of prenatally diagnosed congenital anomalies that were grouped with stillbirths) were excluded from the analysis. Stillbirths were defined as any pregnancy loss occurring at 28 weeks' gestation or later. Omeprazole was taken in 134 pregnancies, resulting in 139 live births (11 [7.9%] premature), 5 (3.7%) of whom had a congenital malformation. There were no stillbirths or neonatal deaths. The malformations were (shown by system): head/face (tongue tie), heart (septal defects N = 2), muscle/skeletal (dysplastic hip/dislocation/clicking hip), and genital/urinary (congenital hydrocele/inguinal hernia). In addition, three newborns had a small head circumference for gestational age. In comparison, the outcomes of 1547 nonexposed pregnancies included 1560 live births (115 [7.4%] premature), 15 stillbirths (includes 2 EABs for anomalies), and 10 neonatal deaths. Sixty-four (4.1%) of the newborns had malformations that involved the central nervous system (N = 2), head/face (N = 13), eye (N = 2), heart (N = 7), muscle/skeletal (N = 13), genital/urinary (N = 18), and gastrointestinal (N = 2), or were polyformation (N = 3) or known genetic anomalies (N = 4). Twenty-one newborns were small for gestational age and 78 had a small head circumference for gestational age. The relative risk of malformation (adjusted for mother's age and prematurity) associated with omeprazole was 0.9 (95% CI 0.4–2.4), with cimetidine 1.3 (95% CI 0.7–2.6), and with ranitidine 1.5 (95% CI 0.9–2.6) (12).

A 1998 case report described a 41-year-old woman with refractory gastroesophageal reflux disease (GERD) who was treated with omeprazole (20 mg/day) starting at 29 weeks' gestation (13). Previous treatment with ranitidine (late 1st trimester), cisapride (2nd trimester), or a combination of the two had been unsuccessful. A slightly premature male child (birth weight not given) with fetal bradycardia was delivered in the 36th week with Apgar scores of 6 and 9 at 1 and 5 minutes, respectively. He was doing well at 1 year of age (13).

A 2002 study conducted a meta-analysis involving the use of PPIs in pregnancy (14). In the five cohort studies analyzed, there were 593 infants, mostly exposed to omeprazole, but also including lansoprazole and pantoprazole. The relative risk (RR) for major malformations was 1.18, 95% CI 0.72–1.94 (14).

A 2005 study by the European Network of Teratology Information Services reported the outcomes of pregnancies exposed to omeprazole (N = 295), lansoprazole (N = 62), or pantoprazole (N = 53) (15). In the pantoprazole

group, the median duration of treatment was 14 days (range 7–23 days) and the dose used was 40 mg/day. The outcomes consisted of 1 SAB, 3 EABs (none for congenital anomalies), 1 stillbirth, and 48 live births. One infant exposed early in gestation (week 2 for 8 days) had congenital toxoplasmosis. Compared with a nonexposed control group, there was no difference in the rate of major malformations between the pantoprazole and control groups (RR 0.95, 95% CI 0.46–1.98). Similar results were observed for lansoprazole and pantoprazole (15).

A population-based observational cohort study formed by linking data from three Swedish national health care registers over a 10-year period (1995–2004) was reported in 2009 (16). The main outcome measure was a diagnosis of allergic disease or a prescription for asthma or allergy medications. The drug types included in the study were gastric acid suppressors, including H₂-receptor antagonists, prostaglandins, PPIs, combinations for eradication of *Helicobacter pylori*, and drugs for peptic ulcer and gastro-esophageal reflux disease. Of 585,716 children, 29,490 (5.0%) met the diagnosis and 5645 (1%) had been exposed to gastric acid-suppression therapy in pregnancy. Of these children, 405 (0.07%) were treated for allergic disease. For developing allergy, the odds ratio (OR) was 1.43, 98% confidence interval (CI) 1.29–1.59, irrespective of the drug, time of exposure during pregnancy, and maternal history of allergy. For developing childhood asthma, but not other allergic diseases, the OR was 1.51 95% CI 1.35–1.69, irrespective of the type of acid-suppressive drug and the time of exposure in pregnancy. The authors proposed three possible mechanisms for their findings: (a) exposure to increased amounts of allergens could cause sensitization to digestion labile antigens in the fetus; (b) maternal Th2 cytokine pattern could promote an allergy-prone phenotype in the fetus; and (c) maternal allergen-specific IgE could cross the placenta and sensitize fetal immune cells to food and airborne allergens. Several limitations of the study that might have affected their findings were identified, including a general increase in childhood asthma but not necessarily an increase in allergic asthma (16). The study requires confirmation.

Several investigations have studied the effect of omeprazole for prophylaxis against aspiration pneumonitis in emergency cesarean section (17–22). No adverse effects were noted in the newborns.

A second meta-analysis of PPIs in pregnancy was reported in 2009 (23). Based on 1530 exposed compared with 133,410 not exposed pregnancies, the OR for major malformations was 1.12, 95% CI 0.86–1.45. There also was no increased risk for SABs (OR 1.29, 95% CI 0.84–1.97) or preterm birth (OR

1.13, 95% CI 0.96–1.33). When the analysis was conducted for exposure to omeprazole alone, the OR for major malformations was 1.17, 95% CI 0.90–1.53 (23).

In a 2010 study from Denmark, covering the period 1996–2008, there were 840,968 live births among whom 5082 were exposed to PPIs between 4 weeks before conception to the end of the 1st trimester (24). In the exposed group there were 174 (3.4%) major malformations compared with 21,811 (2.6%) not exposed to PPIs (adjusted prevalence odds ratio [aPOR] 1.23, 95 CI 1.05–1.44). When the analysis was limited to exposure in the 1st trimester, there were 118 (3.2%) major malformations among 3651 exposed infants (aPOR 1.10, 95% CI 0.91–1.34). For exposure to omeprazole in the 1st trimester, there were 52 (2.9%) major birth defects among 1800 live births (aPOR 1.05, 95% CI 0.79–1.40) (see Esomeprazole, Lansoprazole, Pantoprazole, and Rabeprazole for their data). The data showed that exposure to PPIs in the 1st trimester was not associated with a significantly increased risk of major birth defects (24). An accompanying editorial discussed the strengths and weaknesses of the study (25).

In a 2012 publication, the National Birth Defects Prevention study, a multisite population-based case–control study, examined whether nausea/vomiting of pregnancy (NVP) or its treatment were associated with the most common noncardiac defects (nonsyndromic cleft lip with or without cleft palate [CL/P], cleft palate alone [CP], neural tube defects [NTDs], and hypospadias) (26). PPI exposure included esomeprazole, lansoprazole, and omeprazole. There were 4524 cases and 5859 controls. NVP was not associated with cleft palate or NTDs, but modest risk reductions were observed for CL/P and hypospadias. Increased risks were found for PPIs (N = 7) and hypospadias (adjusted OR [aOR] 4.36, 95% CI 1.21–15.81), steroids (N = 10) and hypospadias (aOR 2.87, 95% CI 1.03–7.97), and ondansetron (N = 11) and CP (aOR 2.37, 95% CI 1.18–4.76) (26).

Another 2012 study, using the Danish nationwide registries, evaluated the risk of hypospadias after exposure to PPIs during the 1st trimester and throughout gestation (27). The study period, 1997 through 2009, included all liveborn boys that totaled 430,569 of whom 2926 were exposed to maternal PPI use. Hypospadias was diagnosed in 20 (0.7%) exposed boys, whereas 2683 (0.6%) of the nonexposed had hypospadias (adjusted prevalence ratio [aPR] 1.1, 95% CI 0.7–1.7). For the 5227 boys exposed throughout pregnancy, 32 (0.6%) had hypospadias (PR 1.0, 95% CI 0.7–1.4). When the analysis was restricted to mothers with two or more PPI prescriptions, the aPR of overall

hypospadias was 1.7 (95% CI 0.9–3.3) and 1.6 (95% CI 0.7–3.9) for omeprazole. The authors concluded that PPIs were not associated with hypospadias (27).

A large retrospective cohort study from Israel covering the period 1998–2009 was published in 2012 (28). Among 114,960 live births, there were 110,783 singletons and 1239 elective abortions. Major malformations were observed in 6037 (5.5%) singletons and in 468 abortuses. Exposure to a PPI (lansoprazole, omeprazole, or pantoprazole) during the 1st trimester occurred in 1186 (1159 infants and 27 abortuses). In the exposed infants and abortuses, 80 (6.7%) had a major malformation compared with 6425 (5.9%) not exposed (aOR 1.06, 95% CI 0.84–1.33). In the 955 infants–abortuses exposed to omeprazole, 67 (7.0%) had a major malformation compared with 6438 (5.9%) not exposed (aOR 1.11, 95% CI 0.87–1.43). The data showed that exposure to PPIs during the 1st trimester was not associated with an increased risk of major defects. Moreover, additional analysis revealed that exposure during the 3rd trimester was not associated with increased risk of perinatal mortality, premature delivery, low birth weight, or low Apgar scores (28).

Five reviews on the treatment of GERD have concluded that PPIs can be used in pregnancy with relative safety (29–33). Because there are either very limited or no human pregnancy data for the three newest agents in this class (dexlansoprazole, esomeprazole, and rabeprazole), other drugs in the class are preferred.

BREASTFEEDING SUMMARY

Only one report describing the use of omeprazole during human lactation has been located. A woman with refractory GERD was treated with omeprazole (20 mg/day) for 7–8 weeks before delivering a premature male infant (birth weight not given) at 36 weeks' gestation (see above) (13). Treatment was continued during breastfeeding. During this time, she fed her infant son just before taking her dose at 8 AM, refrained from nursing for 4 hours, then expressed and discarded her milk at 12 noon. At 3 weeks postpartum, blood and milk samples were obtained at 8 AM and then every 30 minutes for 4 hours (i.e., until 12 noon). The milk was obtained by expressing but the volume of the samples was not specified. Maternal serum concentrations began to rise 90 minutes after the dose, reached 950 nM at 12 noon, and appeared to be still rising. Breast milk levels also began to rise at 90 minutes and peaked at 180 minutes at 58 nM. The infant was doing well at 1 year of age (13).

The above case report estimated a maximum daily omeprazole exposure of 4

mcg, but the calculation was based on a consumption of only 200 mL of milk/day for a 5-kg infant (40 mL/kg/day). A more acceptable value is 150 mL/kg/day (34). Moreover, the milk samples were obtained by expression and the volumes expressed were not given. This is clinically relevant because hindmilk obtained at the end of a feeding is 4–5 times higher in fat than foremilk (35). For lipid-soluble drugs, such as omeprazole, hindmilk would be expected to contain most of the drug in milk.

In concurrence with the above case report, the molecular weight of omeprazole (about 345) suggests that it will be excreted into human milk. One source stated that the safety of a drug during breastfeeding can be arbitrarily defined as no more than 10% of the adult dose standardized by weight if a therapeutic dose for infants is not known (34). Until additional studies show that omeprazole meets this criterion, the use of omeprazole during breastfeeding should probably be avoided. Other concerns, such as the carcinogenicity observed in animals and the potential for suppression of gastric acid secretion in the nursing infant, also warrant further study.

ONDANSETRON

Antiemetic

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Consistent with the animal data, most human pregnancy data for ondansetron suggest that the risk of birth defects is low. However, in many studies ondansetron was started after organogenesis. Moreover, a large Danish study reported a 2-fold increased risk of cardiac anomalies. Thus, additional data are required to determine the risk. Consequently, if indicated, starting ondansetron therapy after 10 weeks of gestation should be considered.

FETAL RISK SUMMARY

Ondansetron is a selective 5-HT₃ receptor antagonist. It is an antiemetic that is indicated for the prevention and treatment of nausea and vomiting induced by chemotherapy, radiotherapy, and postoperative. The drug is extensively metabolized to metabolites that are unlikely to contribute to the parent drug's biological activity. The mean elimination half-life of a single 8-mg dose in women of reproductive age (18–40 years) is 3.5 hours (1).

No adverse effects on fertility or on the fetus were observed in reproduction studies in rats and rabbits with oral doses up to 15 and 30 mg/kg/day, respectively (1).

It is not known if ondansetron crosses the human placenta. The molecular weight (about 293) and the moderate elimination half-life suggest that the drug will cross to the embryo–fetus, but the extensive metabolism may limit the amount of parent drug crossing the placenta.

Ondansetron has been used in the treatment of hyperemesis gravidarum (2–6). A 21-year-old primigravida with severe nausea and vomiting was treated unsuccessfully for approximately 4 weeks, beginning at 6 weeks' gestation, with IV metoclopramide, 10 mg 3 times daily, rectal dimenhydrinate, 100 mg

twice daily, and IV fluids (2). Because her condition was considered life-threatening for both her and her fetus, ondansetron 8 mg IV 3 times daily was instituted at 11 weeks' gestation and continued for 14 days. Significant improvement was noted in the patient's condition from the second day of therapy. The woman eventually gave birth at term to a healthy 3.2-kg girl.

A second report on the use of ondansetron for severe NVP involved a 22-year-old woman with renal impairment and nephrotic syndrome (3). Treatment with the antiemetic was begun at 30 weeks' gestation with 8 mg IV 3 times daily for 1 day, then orally (dose not specified) until 33 weeks' gestation. A healthy 2052-g female infant was delivered at 36 weeks by elective cesarean section. The infant remained in good health at an unspecified follow-up period.

A randomized, double-blind study, first published as an abstract (4) and then as a full report (5), compared IV ondansetron (10 mg) (N = 15) with IV promethazine (50 mg) (N = 15) for the treatment of hyperemesis gravidarum. Both drugs were given as an initial dose followed by as-needed doses every 8 hours. The mean gestational ages of the two groups at the start of therapy were 11.0 and 10.2 weeks, respectively. No differences were observed between the two groups in terms of duration of hospitalization, nausea score, number of doses received, treatment failures, and daily weight gain. The only adverse effect observed was sedation in 8 women who received promethazine compared with none in the ondansetron group. No mention was made of the pregnancy outcomes in either group.

Ondansetron, 8 mg IV twice daily, was administered to a woman at 14 weeks' gestation after 6 weeks of unsuccessful therapy with intermittent use of promethazine, prochlorperazine, metoclopramide, and IV hydration (6). IV ondansetron was able to control her vomiting, but not her nausea, and 2 days later she was converted to oral therapy (4 mg) that was taken intermittently (1–2 times daily) until 33 weeks' gestation. Nausea occurred throughout her pregnancy, with occasional episodes of vomiting. She eventually delivered a healthy, 2.7-kg male infant at 39 weeks' who was doing well at early follow-up.

A prospective comparative observational study, published in 2004, compared three groups of pregnant women (N = 176 in each group) for the treatment of NVP: ondansetron, other antiemetics, and nonteratogen exposures (7). There were no significant differences between the three groups in terms of live births, spontaneous abortions (SABs), elective abortions, stillbirths, birth weight, and gestational age at birth. In the ondansetron group, there were six (3.5%) major anomalies compared with three (1.8%) in each of the other two groups ($p = 0.52$). There were three cases of hypospadias in the ondansetron group

compared with one in the other groups ($p = 0.25$) (7).

A 2012 study, using data from the National Birth Defects Prevention Study (NBDPS), examined whether NVP or its treatment was associated with the most common noncardiac birth defects in the NBDPS: nonsyndromic cleft lip with or without cleft palate, cleft palate alone, neural tube defects, and hypospadias (8). For NVP, there were modest risk reductions for cleft lip/palate (adjusted odds ratio [aOR] 0.87, 95% confidence interval [CI] 0.77–0.98) and hypospadias (aOR 0.84, 95% CI 0.72–0.98). For NVP treatments in the 1st trimester, there were increased risks for proton pump inhibitors and hypospadias (aOR 4.36, 95% CI 1.21–15.81), corticosteroids and hypospadias (aOR 2.87, 95% CI 1.03–7.97), and ondansetron and cleft palate (aOR 2.37, 95% CI 1.18–4.76), whereas antacids had a reduced risk for cleft lip/palate (aOR 0.58, 95% CI 0.38–0.89). The authors commented that the three associations could be chance findings but warranted further study (8).

In a 2013 study from Denmark, pregnant women exposed to ondansetron were compared in a 1:4 ratio with women not exposed (9). There was no increased risk for SAB that occurred in 1.1% of exposed compared with 3.7% of unexposed women during weeks 7–12 (hazard ratio [HR] 0.49, 95% CI 0.27–0.91) or for weeks 13–22 (1.0% vs. 2.1%, respectively, HR 0.60, 95% CI 0.29–1.21). There also was no increased risk for stillbirth (0.3% vs. 0.40%, respectively, HR 0.42, 95% CI 0.10–1.73), any major birth defect (2.9% vs. 2.9%, prevalence OR [pOR] 1.12, 95% CI 0.69–1.82), preterm birth (6.2% vs. 5.2%, pOR 0.90, 95% CI 0.66–1.25), low-birth-weight infant (4.1% vs. 3.7%, pOR 0.76, 95% CI 0.51–1.13), or small-for-gestational-age infant (10.4% vs. 9.2%, pOR 1.13, 95% CI 0.89–1.44)(9).

Although this study found no association with an increased risk of some adverse fetal outcomes, the question whether ondansetron causes birth defects remains unanswered. This is true because the median gestational age when the first ondansetron prescription was filled was 10 weeks. Thus, half of the exposed women were beyond the period (i.e., organogenesis) when a drug could cause structural anomalies.

A 2014 letter noted that the above study and a second study from Denmark were presented at the 2013 International Society of Pharmacoepidemiology meeting in Montreal (10). The second Danish study (11), using the same national registries but covering more years (1997–2010 vs. 2004–2011) and more pregnant women (897,108 vs. 608,835), reported a 2-fold increased risk of cardiac anomalies (OR 2.0, 95% CI 1.3–3.1). Other issues raised in the letter were concerns for maternal harm caused from QT prolongation, torsade

de pointes, and serotonin syndrome (10).

BREASTFEEDING SUMMARY

No reports describing the use of ondansetron during human lactation have been located. The molecular weight (about 293) and the moderate elimination half-life (3.5 hours) suggest that the drug will be excreted into breast milk, but the extensive metabolism may limit the amount in milk. The effect of this exposure on a nursing infant is unknown.

OPIPRAMOL

[Withdrawn from the market. See 9th edition.]

OPIUM

Narcotic Antidiarrheal

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 3rd Trimester

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The effects of opium are caused by morphine (see Morphine). Neonatal withdrawal is a potential complication if used for prolonged periods or in high doses close to term.

FETAL RISK SUMMARY

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 36 of whom had 1st trimester exposure to opium (1, pp. 287–95). For use anytime during pregnancy, 181 exposures were recorded (1, p. 434). Four of the 1st trimester exposed infants had congenital defects, but these numbers are too small to draw any conclusion about a relationship between the drug and major or minor malformations. A possible association with inguinal hernia based on seven cases after anytime exposure was suggested (1, p. 485) (see also Morphine for similar findings). The statistical significance of these associations is unknown and independent confirmation is required.

Narcotic withdrawal was observed in a newborn whose mother was treated for regional ileitis with deodorized tincture of opium during the 2nd and 3rd trimesters (2). Symptoms of withdrawal in the infant began at 48 hours of age.

BREASTFEEDING SUMMARY

No reports describing the use of opium during human lactation. (See Morphine.)

OPRELVEKIN

Hematopoietic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of oprelvekin in human pregnancy have been located. The animal data suggest a risk of toxicity but not teratogenicity. However, the absence of human pregnancy experience prevents an assessment of the risk the drug represents to the embryo and fetus.

FETAL RISK SUMMARY

Oprelvekin is a protein, produced by recombinant DNA technology from *Escherichia coli* that differs from natural interleukin-11 (IL-11) by one terminal amino acid. This difference does not affect its bioactivity as a thrombopoietic growth factor that indirectly stimulates increased platelet production. It is indicated to prevent severe thrombocytopenia and to reduce the need for platelet transfusions following myelosuppressive chemotherapy. The terminal half-life is about 6.9 hours (1).

Reproduction studies have been conducted in rats and rabbits. Oprelvekin was embryocidal in rats at doses 2–20 times the human dose based on body weight (HD). Maternal toxicity (transient hypoactivity and dyspnea) and prolonged estrus cycle were evident at these doses. Embryo–fetal effects included increased early embryonic deaths and decreased numbers of live fetuses. At 20 times the HD, retarded fetal development occurred as evidenced by low fetal weight, and reduced number of ossified sacral and caudal vertebrae. Doses ≥ 2 times the HD used throughout gestation and lactation resulted in increased newborn mortality, decreased viability index on day 4 of lactation, and decreased pup body weights. In pregnant rabbits, doses 0.02–2 times the HD were maternal toxic (decreased fecal/urine eliminations, decreased food consumption and body weight loss). These doses caused

abortion, increased embryonic and fetal deaths, and decreased numbers of live fetuses. No teratogenicity was observed in rabbits at doses ≤ 0.6 times HD (1).

It is not known if oprelvekin crosses the human placenta. Oprelvekin is a 177-amino acid protein with a molecular weight of about 19,000, but proteins can cross to the embryo and fetus.

BREASTFEEDING SUMMARY

No reports describing the use of oprelvekin during lactation have been located. Oprelvekin is a 177-amino acid protein with a molecular weight of about 19,000. Although it may be excreted into breast milk, it would most likely be digested in the infant's gastrointestinal tract. Therefore, the risk to a nursing infant from exposure to the drug in milk appears to be very low or nonexistent.

ORAL CONTRACEPTIVES

Estrogenic/Progestogenic Hormones

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

The use of oral contraceptives is contraindicated in pregnancy primarily because there are no benefits for such use. The absolute risk of embryo–fetal harm after inadvertent exposure early in gestation appears to be low. Use later in pregnancy of products containing synthetic progestogens may be associated with masculinization of female fetuses.

FETAL RISK SUMMARY

Oral contraceptives contain a 19-nortestosterone progestin and a synthetic estrogen (see Mestranol, Norethindrone, Norethynodrel, Ethinyl Estradiol, Hydroxyprogesterone, Ethisterone). Because oral contraceptives are primarily combination products, it is difficult to separate entirely the fetal effects of progestogens and estrogens. Two groups of investigators have reviewed the effects of these hormones on the fetus (133 references) (1,2). Several potential problems were discussed: congenital heart defects, central nervous system defects, limb reduction malformations, general malformations, and modified development of sexual organs. Except for the latter category, no firm evidence has appeared that establishes a causal relationship between oral contraceptives and various congenital anomalies.

The acronym VACTERL (vertebral, anal, cardiac, tracheal, esophageal, renal or radial, and limb) has been used to describe the fetal malformations produced by oral contraceptives or the related hormonal pregnancy test preparations (no longer available in the United States) (2,3). The use of this acronym should probably be abandoned in favor of more conventional terminology because a large variety of malformations has been reported with estrogen–progestogen-containing products (1–11). The Population Council estimates that even if the study findings for VACTERL malformations are accurate, such abnormalities would occur in only 0.07% of the pregnancies exposed to oral contraceptives

(12). Some reviewers have concluded that the risk to the fetus for nongenital malformations after in utero exposure to these agents is small, if indeed it exists at all (2).

In contrast to the above, the effect of estrogens and some synthetic progestogens on the development of the sexual organs is well established (2). Masculinization of the female infant has been associated with norethindrone, norethynodrel, hydroxyprogesterone, medroxyprogesterone, and diethylstilbestrol (2,13,14). The incidence of masculinization of female infants exposed to synthetic progestogens is reported to be approximately 0.3% (15). Pseudohermaphroditism in the male infant is not a problem, because of the low doses of estrogen employed in oral contraceptives (14).

Increased serum bilirubin in neonates of mothers taking oral contraceptives or progestogens before and after conception has been observed (16). Icterus occasionally reached clinically significant levels in infants whose mothers were exposed to the progestogens.

Concern that oral contraceptives may be a risk factor for preeclampsia has been suggested based on the known effects of oral contraceptives on blood pressure (17). However, a retrospective controlled review of 341 patients found no association between this effect and the drugs (17).

Possible interactions between oral contraceptives and tetracycline, rifampin, ampicillin, or chloramphenicol resulting in pregnancy have been reported (18–25). The mechanism for this interaction may involve the interruption of the enterohepatic circulation of contraceptive steroids by inhibiting gut hydrolysis of steroid conjugates, resulting in lower concentrations of circulating steroids.

BREASTFEEDING SUMMARY

Use of oral contraceptives during lactation has been associated with shortened duration of lactation, decreased infant weight gain, decreased milk production, and decreased composition of nitrogen and protein content of milk (26–29). The American Academy of Pediatrics has reviewed this subject (30) (37 references). Although the magnitude of these changes is low, the changes in milk production and composition may be of nutritional importance in malnourished mothers.

In general, progestin-only contraceptives demonstrate no consistent alteration of breast milk composition, volume, or duration of lactation (30). The composition and volume of breast milk varies considerably even in the absence of steroidal contraceptives (29). Both estrogens and progestins cross into milk. An infant consuming 600 mL of breast milk daily from a mother using

contraceptives containing 50 mcg of ethinyl estradiol will probably receive a daily dose in the range of 10 ng (30). This is in the same range as the amount of natural estradiol received by infants of mothers not using oral contraceptives. Progestins also pass into breast milk, although naturally occurring progestins have not been identified. One study estimated 0.03, 0.15, and 0.3 mcg of d-norgestrel/600 mL in milk from mothers receiving 30, 150, and 250 mcg of the drug, respectively (31). A milk:plasma ratio of 0.15 for norgestrel was calculated by the authors (31). A ratio of 0.16 was calculated for lynestrenol (31,32).

Reports of adverse effects are lacking except for one child with mild breast tenderness and hypertrophy who was exposed to large doses of estrogen (30). If breastfeeding is desired, the lowest effective dose of oral contraceptives should be chosen. Infant weight gain should be monitored, and the possible need for nutritional supplements should be considered. The American Academy of Pediatrics classifies combination oral contraceptives as compatible with breastfeeding (33).

ORLISTAT

Gastrointestinal Agent (Lipase Inhibitor)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

One report describing the use of orlistat during human pregnancy has been located. Because of its minimal systemic bioavailability, orlistat appears to present a very low risk, if any, to the embryo or fetus. Orlistat may cause a deficiency of fat-soluble vitamins (vitamins A [both retinol and β -carotene], D, and E) if a daily multiple vitamin supplement is not taken. The vitamin should be taken 2 hours either before or after an orlistat dose (1). Maternal deficiency of these vitamins may result in fetal adverse effects (see also Vitamin A, Vitamin D, and Vitamin E). If orlistat is used in pregnancy, health care professionals are encouraged to call the toll-free number 800-670-6126 for information about patient enrollment in the Motherisk study.

FETAL RISK SUMMARY

Orlistat is a lipase inhibitor used in the management of obesity. The agent inhibits the absorption of dietary fats. The mechanism of action of orlistat involves bonding to gastric and pancreatic lipases, thereby inactivating these enzymes. The inactive enzymes are unable to hydrolyze dietary fat to absorbable free fatty acids and monoglycerides (1). The systemic bioavailability of orlistat is minimal (1).

Reproduction studies in rats and rabbits at doses up to 23 and 47 times the recommended human daily dose based on BSA (RHD) revealed no evidence of embryotoxicity or teratogenicity (1). In two rat studies, but not in two others, doses of 6 and 23 times the RHD were associated with an increased incidence of dilated cerebral ventricles. At 12 times the RHD in rats, no evidence of impaired fertility was observed (1).

It is not known if orlistat crosses the placenta. Although the molecular weight

(about 496) is low enough for passage to the fetus, the minimal systemic bioavailability of the agent following oral administration suggests that little, if any, of the agent would be available for transfer from the maternal circulation.

A 2005 case report described the pregnancy outcome of a 33-year-old woman treated with orlistat in the first 8 weeks of an unplanned pregnancy (2). Diseases in the patient included morbid obesity, type 2 diabetes mellitus, hypertension, and hypercholesterolemia. Other drugs used by the woman were glimepiride, ramipril, thiocolchicoside (a muscle relaxant), simvastatin, metformin, ciprofloxacin, and aspirin. When pregnancy was diagnosed at 8 weeks all medications were stopped, and she was started on methyldopa and insulin. She gave birth at 38 weeks to a 3.470-kg female infant with Apgar scores of 5 and 7 at 1 and 5 minutes, respectively. No minor or major malformations were observed in the infant (2).

BREASTFEEDING SUMMARY

No reports describing the use of orlistat during human lactation have been located. The minimal systemic bioavailability suggests that the drug would not be found in breast milk, but maternal hypovitaminosis A, D, and E may occur (see above).

ORPHENADRINE

Skeletal Muscle Relaxant

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Orphenadrine is an anticholinergic agent used in the treatment of painful skeletal muscle conditions. No published reports of its use in human pregnancy have been located (see also Atropine).

FETAL RISK SUMMARY

An animal study in pregnant rats using large oral doses (15 and 30 mg) produced enlarged bladders containing blood but no other anomalies in 8 of 159 fetuses (1).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 411 newborns had been exposed to orphenadrine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 11 (2.7%) major birth defects were observed (16 expected), including (observed/expected) 2/4 cardiovascular defects and 1/1 polydactyly. No anomalies were observed in four other defect categories (oral clefts, spina bifida, limb reduction defects, and hypospadias) for which specific data were available. These data do not support an association between the drug and congenital defects.

BREASTFEEDING SUMMARY

No reports describing the use of orphenadrine during human lactation have been located (see also Atropine).

OSELTAMIVIR

Antiviral

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Limited reports describing the use of oseltamivir during human pregnancy do not suggest a significant risk of developmental toxicity. The drug is used for the treatment and prophylaxis of influenza, including novel influenza A (H1N1). Because influenza infection in pregnancy is a high-risk condition, the maternal benefit far outweighs the unknown risk, if any, to the embryo or fetus. Moreover, hyperthermia, a common condition of influenza infections, occurring during the 1st trimester doubles the risk of neural tube defects (1). In addition, maternal hyperthermia during labor is a risk factor for neonatal seizures, encephalopathy, cerebral palsy, and neonatal death. Thus, in either case, hyperthermia should be promptly treated with acetaminophen and, in the 1st trimester, combined with multivitamins containing folic acid (1).

FETAL RISK SUMMARY

Oseltamivir is an ethyl ester prodrug that is rapidly metabolized by hepatic esterases to oseltamivir carboxylate, the active antiviral agent. Systemic exposure to oseltamivir is <5% of the total exposure. It is a neuraminidase inhibitor in the same antiviral subclass as zanamivir. Plasma protein binding of oseltamivir carboxylate is low (3%), but the elimination half-life is prolonged (6–10 hours). Oseltamivir is indicated for the treatment of uncomplicated acute illness due to influenza infection in patients 1 year of age and older who have been symptomatic for no more than 2 days. It also is indicated for the prophylaxis of influenza in patients aged 1 year and older (2). In April 2009, the FDA issued an Emergency Use Authorization to allow the drug to be used to treat and prevent influenza in children under 1 year of age, and to provide alternate dosing recommendations for children older than 1 year (3).

Oseltamivir is active against novel influenza A (H1N1) (formerly known as swine flu), either as treatment of acute illness or as chemoprophylaxis in patients at high risk of complications, such as pregnant women (4).

In reproduction studies, doses up to 100 times the human systemic exposure based on AUC of oseltamivir carboxylate (HSE) had no effects on fertility or mating performance in male and female rats, or on embryo–fetal development. The highest dose was associated with minimal maternal toxicity. In rabbits, doses up to 50 times the HSE also had no effect on embryo–fetal development. Maternal toxicity was observed in rabbits with doses 15 times the HSE or higher. In both species, fetal exposure to the antiviral agent was documented. Although a dose-dependent increase in the incidence rates of skeletal abnormalities and variants was observed in both species, the individual incidence rate of each defect remained within the expected background rate of occurrence (2).

Oseltamivir and its active metabolite were not carcinogenic in 2-year studies in mice and rats. Oseltamivir was not mutagenic in several assays, but was positive in one. The active metabolite was negative in all assays (2).

Although the relatively low molecular weight (about 312 and 284 for the parent drug free base and metabolite, respectively), minimal plasma protein binding, and prolonged elimination half-life suggest that both the parent drug and the metabolite will cross to the embryo–fetus, a 2008 study (5) found otherwise. In the ex vivo human placenta model, extensive metabolism of oseltamivir to the active metabolite was observed, but neither the parent drug nor its metabolite could be detected on the fetal side when concentrations 5–6-fold above the therapeutic concentration were used. Concentrations 20–830-fold above the therapeutic range were required for detectable levels on the fetal side. The mean clearance index for these high levels was 0.13 and fetal accumulation was minimal (5).

The Centers for Disease Control and Prevention has published information on two cases of H1N1 virus infection in pregnancy that were treated with oseltamivir (4). A 29-year-old woman at 23 weeks' gestation presented at a family practice clinic. She had a 1-day history of cough, sore throat, chills, fever, and weakness. Rapid influenza diagnostic testing was positive, and H1N1 virus was later confirmed. The mother was prescribed oseltamivir and her symptoms were resolving without complication. Her pregnancy was proceeding normally. The clinic physician who evaluated the mother was also pregnant (13 weeks' gestation). She began prophylactic oseltamivir and had remained asymptomatic (4).

A 2005 report from the manufacturer briefly mentioned the use of oseltamivir in 61 pregnant women without specifying the timing of the exposures (6). Among these, there were four spontaneous abortions (SABs) and six elective abortions (EABs). In addition, there were single cases of trisomy 21 (Down's syndrome) and anencephaly, neither of which was thought to be related to the drug therapy. The remaining cases resulted in the birth of normal infants (6).

A 2009 report summarized the safety of neuraminidase inhibitors in pregnant and breastfeeding women (7). The data, from two Japanese teratogen information services, involved 90 pregnancies exposed during the 1st trimester to therapeutic doses of oseltamivir (75 mg twice a day for up to 5 days). The outcomes of the pregnancies were three SABs, one EAB, four preterm births, seven infants with low birth weight, and one major malformation (ventricular septal defect). The malformation incidence (1.2%; 1 in 86 live births) is well within the background incidence of major malformations (7).

A retrospective cohort study, covering the period 2003–2008, described 239 pregnancies that were treated with antiviral agents during pregnancy (8). Of these, 104 women received M2 ion channel inhibitors (rimantadine, amantadine, or both) and 135 received oseltamivir. The pregnancy outcomes of these patients were compared with 82,097 controls from the site's overall obstetric patient population. The exposure timing for the combined treated groups was 13% 1st trimester, 32% 2nd trimester, and 55% 3rd trimester. There were no significant differences between the treated groups and controls in terms of maternal and delivery characteristics except that M2 inhibitors had more multiple gestations. For M2 inhibitors, oseltamivir vs. controls, there also was no differences in stillbirths (0%, 0% vs. 1%), major defects (1% [trisomy 21], 0% vs. 2%), and minor defects (19%, 15% vs. 22%). The only significant finding in the characteristics of liveborn, singleton neonates, after exclusion of twins and major anomalies, was a higher risk of necrotizing enterocolitis in both treatment groups compared with controls—1.0%, 0.8% vs. 0.02% (8).

BREASTFEEDING SUMMARY

Oseltamivir and its active metabolite are excreted into breast milk. A woman who was breastfeeding her 9-month-old child twice daily accidentally stuck herself with a novel influenza A (H1N1)-contaminated needle (9). She was treated with oseltamivir 75 mg twice daily for 5 days. Breastfeeding was stopped during this period because of possible adverse effects in the infant. Milk samples (N = 11) were collected twice daily over the 5-day period by completely emptying both breasts. The timings of the samples were distributed

at various times, with eight of the samples collected 30 minutes before or after a dose. The steady state concentration of the metabolite (37–39 ng/mL) was reached after 3 days. The authors estimated that the maximum relative infant dose (oseltamivir plus the metabolite) was 0.012 mg/kg/day or about 0.5% of the mother's weight-adjusted dose (based on an assumed maternal weight of 60 kg) (9).

Based on the above study, in which the infant did not nurse, the concentration of the drug in breast milk appears to be clinically insignificant. In addition, the potential dose for a nursing infant is much less than the pediatric dose. Moreover, breastfeeding is recommended for women infected with novel influenza A (H1N1), regardless of whether they are being treated, because of the advantages of breast milk for the infant's immune system (10).

OUABAIN

[Withdrawn from the market. See 9th edition.]

OXACILLIN

Antibiotic (Penicillin)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Although the reported pregnancy experience with oxacillin is limited, all penicillins are considered low risk in pregnancy.

FETAL RISK SUMMARY

Oxacillin is a penicillin antibiotic (see also Penicillin G). The drug crosses the placenta in low concentrations. Cord serum and amniotic fluid levels were <0.3 mcg/mL in 15 of 18 patients given 500 mg orally 0.5–4 hours before cesarean section (1). No effects were seen in the infants.

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 3546 of whom had 1st trimester exposure to penicillin derivatives (2, pp. 297–313). For use anytime during pregnancy, 7171 exposures were recorded (2, p. 435). In neither group was evidence found to suggest a relationship to large categories of major or minor malformations or to individual defects.

A 1999 study used the population-based database of the Hungarian Case–Control Surveillance of Congenital Abnormalities (1980–1996) to evaluate the teratogenicity of oxacillin (3). The database contained 22,865 fetuses or newborns with congenital malformations and 38,151 matched control newborns without birth defects. The mothers of 14 cases (4 in the 1st trimester) and 19 controls (8 in the 1st trimester) were treated with oxacillin during pregnancy. No associations were discovered based on a comparison with the expected rates in 24 congenital anomaly groups (3).

An interaction between oxacillin and oral contraceptives resulting in pregnancy has been reported (4). Other penicillins (e.g., see Ampicillin) have been suspected of this interaction, but not all investigators believe that it occurs. Although controversial, an alternate means of contraception may be a practical solution if both drugs are consumed at the same time.

BREASTFEEDING SUMMARY

Oxacillin is excreted in breast milk in low concentrations (1). Although no adverse effects have been reported, three potential problems exist for the nursing infant: modification of bowel flora, direct effects on the infant (e.g., allergic response), and interference with the interpretation of culture results if a fever workup is required.

OXALIPLATIN

Antineoplastic

PREGNANCY RECOMMENDATION: Contraindicated (1st Trimester)

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

The human pregnancy experience is limited and the animal data in one species suggest risk. Although two infants exposed in utero had no complications attributable to oxaliplatin, both were exposed only in the 2nd and 3rd trimesters. Exposure during organogenesis and/or in any portion of the 1st trimester has the potential for causing embryo–fetal harm and should be avoided.

FETAL RISK SUMMARY

Oxaliplatin is indicated, in combination with infusional fluorouracil/leucovorin (5-FU/LV), for the treatment of patients with metastatic carcinoma of the colon or rectum whose disease has recurred or progressed during or within 6 months of completion of first-line therapy with the combination of 5-FU/LV and irinotecan. The drug undergoes rapid and extensive nonenzymatic biotransformation to several reactive oxaliplatin derivatives. Preceded by two relatively short distribution phases (0.43 and 16.8 hours), the terminal elimination half-life is 391 hours (about 16 days). Following a 2-hour infusion, only about 15% of the dose is in the systemic circulation, with the remaining 85% in tissues or eliminated in the urine. Plasma protein binding (>90%) primarily to albumin and γ -globulins is irreversible (1).

Reproduction studies have been conducted in rats. In this species, a dose <0.1 times the recommended human dose based on BSA (RHD) given before implantation and before and during organogenesis was associated with early resorptions, decreased body weight, and delayed ossification (1).

Long-term carcinogenicity studies have not been conducted. The drug was mutagenic and clastogenic in animal and human assays. A dose <1/7th the RHD in male and female rats did not affect pregnancy rates, but did cause increased early resorptions, decreased live fetuses, decreased live births, and

decreased fetal weight. In dogs, a dose about 1/6th the RHD given for 5 days every 28 days for three cycles caused testicular damage (characterized by degeneration, hypoplasia, and atrophy) (1).

It is not known if oxaliplatin or any of its reactive derivatives cross the human placenta. The molecular weight of oxaliplatin (about 397 and about 309 without the oxalate ligand) and the long terminal half-life suggest that the parent drug and/or its derivatives will cross to the embryo–fetus. However, the relatively small amount of the dose in the systemic circulation and the irreversible binding to albumin and γ -globulins should limit the amount transferred.

A 2009 case report described the use of oxaliplatin at 20 weeks' gestation in a 25-year-old woman with metastatic rectal cancer (2). Therapy involved a modified FOLFOX-6 regimen consisting of oxaliplatin 85 mg/m² and leucovorin 400 mg/m², and 5-fluorouracil 400 mg/m² bolus followed by a 5-fluorouracil 2400 mg/m² 46-hour infusion given biweekly. After six biweekly courses, the woman gave birth vaginally at 33.6 weeks' gestation to a normal, about 2440-g (5 pounds, 6 ounces), female infant with Apgar scores of 8 and 8 at 1 and 5 minutes, respectively. At 3.5 years of age, the child was growing normally with her height and weight at the 60th and 45th percentile, respectively (2).

A 40-year-old woman (gravida 4, para 3) was diagnosed at 23 weeks' gestation with advanced metastatic colorectal cancer (3). At 27 weeks', treatment was begun with the same FOLFOX-6 regimen described above at 2-week intervals except that the oxaliplatin dose was 100 mg/m². The woman received four treatments before a planned cesarean section was performed at 31.5 weeks' to give birth to a small-for-gestational-age 1175-g female infant. In addition to the typical complications associated with prematurity, the infant also was hypothyroid. At 11.75 months of age, the infant's height, weight, and head circumference were at the 50th, 80th, and 90th percentiles (corrected for prematurity), respectively. The infant had a flaky red spot on the top of her head but no other abnormalities. Except for gastroesophageal reflux (treated with lansoprazole) and hypothyroidism (treated with levothyroxine), the infant was developing normally (3).

BREASTFEEDING SUMMARY

No reports describing the use of oxaliplatin during human lactation have been located. The molecular weight of oxaliplatin (about 397 and about 309 without the oxalate ligand) and the long terminal half-life (391 hours) suggest that the parent drug and/or its derivatives will be excreted into breast milk. However,

the relatively small amount of a dose in the systemic circulation and the irreversible binding to albumin and γ -globulins should limit the amount excreted. The effect of the potential exposure on a nursing infant is not known. However, the safest course for the infant is to not breastfeed if the mother is receiving this antineoplastic.

OXAPROZIN

Nonsteroidal Anti-inflammatory

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 1st and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Constriction of the ductus arteriosus in utero is a pharmacologic consequence arising from the use of prostaglandin synthesis inhibitors during pregnancy, as is inhibition of labor, prolongation of pregnancy, and suppression of fetal renal function (see also Indomethacin) (1). Persistent pulmonary hypertension of the newborn may occur if these agents are used in the 3rd trimester close to delivery (1,2). Women attempting to conceive should not use any prostaglandin synthesis inhibitor, including oxaprozin, because of the findings in a variety of animal models that indicate these agents block blastocyst implantation (3,4). Moreover, as noted below, nonsteroidal anti-inflammatory drugs (NSAIDs) have been associated with spontaneous abortions (SABs) and congenital malformations. The absolute risk for these defects, however, appears to be low.

FETAL RISK SUMMARY

Oxaprozin is an NSAID used in the treatment of acute and chronic arthritis. It is in the same subclass (propionic acids) as five other NSAIDs (fenoprofen, flurbiprofen, ibuprofen, ketoprofen, and naproxen).

The drug produced infrequent congenital malformations in rabbits treated with doses in the usual human range, but not in mice and rats (5). No teratogenic effects were observed in two other studies of pregnant rats and rabbits (6–9). A dose-dependent constriction of the ductus arteriosus, similar to that produced by other nonsteroidal anti-inflammatory agents, was observed in fetal rats (9).

It is not known if oxaprozin crosses the human placenta. The molecular weight (about 293) is low enough that passage to the fetus should be

expected.

A combined 2001 population-based observational cohort study and a case–control study estimated the risk of adverse pregnancy outcome from the use of NSAIDs (10). The use of NSAIDs during pregnancy was not associated with congenital malformations, preterm delivery, or low birth weight, but a positive association was discovered with SABs. A similar study, also published in 2001, failed to find a relationship, in general, between NSAIDs and congenital malformations, but did find a significant association with cardiac defects and orofacial clefts (11). In addition, a 2003 study found a significant association between exposure to NSAIDs in early pregnancy and SABs (12). (See Ibuprofen for details on these three studies.)

A brief 2003 editorial on the potential for NSAID-induced developmental toxicity concluded that NSAIDs, and specifically those with greater COX-2 affinity, had a lower risk of this toxicity in humans than aspirin (13).

BREASTFEEDING SUMMARY

No reports describing the use of oxaprozin during human lactation have been located. The molecular weight (about 293) is low enough that excretion into breast milk should be expected. One reviewer listed several NSAIDs (diclofenac, fenoprofen, flurbiprofen, ibuprofen, ketoprofen, ketorolac, and tolmetin) that were considered safer alternatives to other agents (oxaprozin not mentioned) if a NSAID was required while nursing (14). Because of the long terminal elimination half-life (approximately 42 hours or longer) in adults and the unknown amount of oxaprozin that is excreted into milk, any of these choices is probably preferable.

OXAZEPAM

Sedative

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 1st and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

The effects of benzodiazepines, including oxazepam, on the human embryo and fetus are controversial. Although a number of studies have reported an association with various types of congenital defects including the study below, other studies with this class of drugs have not found such associations. Maternal denial of exposure and the concurrent exposure to other toxic drugs and substances (e.g., alcohol and smoking) may be confounding factors. Continuous use during gestation or close to delivery might result in neonatal withdrawal or a dose-related syndrome similar to that observed with diazepam. The safest course is to avoid oxazepam during gestation. (See Diazepam.)

FETAL RISK SUMMARY

Oxazepam is an active metabolite of diazepam (see also Diazepam). It is a member of the benzodiazepine group. The drug, both free and conjugated forms, crosses the placenta achieving average cord:maternal serum ratios of 0.6 during the 2nd trimester and 1.1 at term (1). Large variations between patients for placental transfer have been observed (1–3). Passage of oxazepam is slower than that of diazepam, but the clinical significance of this is unknown (4). Two reports have suggested that the use of oxazepam in preeclampsia would be safer for the newborn infant than diazepam (5,6). However, it is doubtful whether either drug is indicated for this condition.

A 1989 report described characteristic dysmorphic features, growth restriction, and central nervous system defects in eight infants exposed either to oxazepam (≥ 75 mg/day) or diazepam (≥ 30 mg/day) (7) (see Diazepam for a detailed description of the infants). The authors concluded that the clinical

characteristics observed in the infants probably represented a teratogenic syndrome related to benzodiazepines (7).

BREASTFEEDING SUMMARY

Specific data relating to oxazepam use in lactating women have not been located. Oxazepam, an active metabolite of diazepam, was detected in the urine of an infant exposed to high doses of diazepam during lactation (8). The infant was lethargic and demonstrated an electroencephalographic pattern compatible with sedative medication (see Diazepam).

OXCARBAZEPINE

Anticonvulsant

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Oxcarbazepine is embryo and fetal toxic and teratogenic in some animal species. Mild facial defects have been observed with oxcarbazepine and, a closely related agent carbamazepine has been associated with neural tube defects and minor craniofacial malformations (see Carbamazepine). The human data are too limited to assess the risk to the embryo–fetus. The effect of oxcarbazepine on folic acid levels or metabolism is unknown (1). Until this information is available, the safest course is to give folic acid supplementation with oxcarbazepine, as is done with other antiepileptic agents. In addition, metabolism of oxcarbazepine does not result in epoxide metabolites (1–3). Because these intermediate arene oxide metabolites have been associated with teratogenicity (see Carbamazepine, Phenytoin, and Valproic Acid), this may indicate a lower risk of teratogenicity with oxcarbazepine compared with the other agents.

FETAL RISK SUMMARY

Oxcarbazepine is an orally active anticonvulsant agent used as either monotherapy or adjunctive therapy in the treatment of partial seizures. The chemical structure of oxcarbazepine is closely related to that of another anticonvulsant, carbamazepine. Oxcarbazepine is rapidly metabolized to an active 10-monohydroxy metabolite (10-hydroxy-10,11-dihydrocarbamazepine; MHD) that is primarily responsible for the anticonvulsant activity (4).

In fertility studies with the active metabolite MHD, an oral dose, 2 times the maximum recommended human dose based on BSA (MRHD) administered to rats before and during mating and during early gestation caused disruption of the estrous cyclicity and a reduction in the numbers of corpora lutea,

implantations, and live embryos. In pregnant rats, the administration of oral oxcarbazepine during organogenesis, at doses approximately 1.2 and 4 times the MRHD, caused increased incidences of fetal malformations (craniofacial, cardiovascular, and skeletal) and variations. Developmental toxicity (embryo–fetal death and growth restriction) was observed with oxcarbazepine at 4 times the MRHD. Oxcarbazepine (0.6 times the MRHD) or its active metabolite (equal to the MRHD) given during the latter part of gestation and throughout lactation were associated with persistent reductions in offspring body weights and, in the case of oxcarbazepine, altered behavior (decreased activity). Embryo and fetal death but no birth defects were observed in rabbits given oral doses of the active metabolite (1.5 times the MRHD) during organogenesis (4).

In a strain of mice susceptible to the teratogenic effects of carbamazepine, the highest tolerable oral dose of oxcarbazepine (1100 mg/kg/day) produced a lower incidence of teratogenicity (8% vs. 5% in controls; ns) than the epoxide metabolite of carbamazepine (14%–27% vs. 6% in controls; $p < 0.05$). Concurrent treatment with phenobarbital did not increase the incidence of congenital malformations over that observed with oxcarbazepine alone (5).

In agreement with the molecular weight (about 252) of the parent drug, oxcarbazepine and its metabolite have been found in the fetus (2,6). In a woman who was taking oxcarbazepine monotherapy (300 mg 3 times daily) throughout gestation, maternal and term newborn plasma concentrations of the drug and its metabolite MHD were approximately equal (6). The healthy 3700-g female infant had mild facial dysmorphism with a discrete epicanthus and a broad nasal bridge. Her development at 13 months of age was normal without signs of mental retardation or neurologic deficit.

In three women taking oxcarbazepine (600–1800 mg/day; time of last dose not specified), maternal and cord blood were obtained at delivery and analyzed for the parent drug, active metabolite MHD, and the inactive metabolite of MHD (2). The three agents were detected in all samples. In another part of the study, oxcarbazepine was metabolized to MHD in a dual recirculating human placental perfusion system, suggesting that the same metabolic process occurs in vivo. MHD, however, was not metabolized to the inactive metabolite by the placenta. No placental metabolism of carbamazepine was observed in the perfusion system (2).

The author of a 1994 report very briefly reviewed the pregnancy outcomes of 27 women treated with oxcarbazepine (7). The outcomes included 1 infant born with “some dysmorphic features” (which disappeared later in life), 3 spontaneous abortions (SABs), 1 infant with spina bifida (whose mother also

received valproate), 1 newborn with “amniotic bands,” and 22 normal infants (including 1 set of twins).

A 1996 review discussed the effects of oxcarbazepine and other anticonvulsants (1). Compared with carbamazepine, oxcarbazepine causes less induction of the cytochrome P450 enzyme system. However, oxcarbazepine may compromise the efficacy of hormonal contraception. The outcomes of 12 pregnancies treated with oxcarbazepine (3 SABs and 9 normal newborns) were listed without further details (1).

The Lamotrigine Pregnancy Registry, an ongoing project conducted by the manufacturer, was first published in January 1997 (8). The final report was published in July 2010. The Registry is now closed. Among 34 prospectively enrolled pregnancies exposed to oxcarbazepine and lamotrigine, with or without other anticonvulsants, 31 were exposed in the 1st trimester resulting in 27 live births without defects, 2 SABs, and 2 birth defects. There were three exposures in the 2nd/3rd trimesters resulting in live births without defects (8).

A 2006 review of prophylactic therapy of bipolar disorder briefly described the effects in pregnancy and breastfeeding of a number of drugs, including oxcarbazepine (9). Untreated pregnant and nursing women with the disorder are at an increased risk of poor obstetrical outcomes and relapse of affective symptoms. Although the limited data prevented conclusions on the relative safety of the drugs, the author did state that each case needed to be considered separately (9).

BREASTFEEDING SUMMARY

Only one published report describing the use of oxcarbazepine during human lactation has been located. In a woman who took oxcarbazepine (900 mg/day) throughout gestation and during lactation (see case discussion above), the milk:plasma ratios of the drug and its active metabolite MHD were 0.5 (6). No adverse effects in the nursing infant from the exposure were mentioned. The manufacturer also states that the milk:plasma ratio for both agents is 0.5 (4). Nursing infants should be monitored for poor suckling, vomiting, and sedation (10). However, because the American Academy of Pediatrics classifies carbamazepine as compatible with breastfeeding (see Carbamazepine), oxcarbazepine can probably be similarly classified.

OXICONAZOLE

Antifungal

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of oxiconazole in human pregnancy have been located. The drug is used topically and the systemic bioavailability is minimal. The animal reproduction data suggest that the risk to the embryo or fetus is low. Moreover, there is no evidence suggesting that similar topical imidazole derivative antifungal agents cause embryo–fetal harm, and there is no reason to believe that oxiconazole would be different.

FETAL RISK SUMMARY

Oxiconazole is available for topical use as a cream or lotion. It is in the same antifungal class of imidazole derivatives as butoconazole, clotrimazole, econazole, ketoconazole, miconazole, sertaconazole, sulconazole, and tioconazole. Oxiconazole is indicated for the treatment of tinea pedis, tinea cruris, and tinea corporis due to *Trichophyton rubrum*, *T. mentagrophytes*, or *Epidermophyton floccosum*. The cream also is indicated for the treatment of tinea (pityriasis) versicolor due to *Malassezia furfur*. Neither the cream nor the lotion should be applied intravaginally. Systemic absorption from the skin is low, with <0.3% of the applied dose recovered in the urine of healthy adults (1). Information regarding the metabolism, plasma protein binding, and elimination half-life has not been located.

Reproduction studies with orally administered oxiconazole have been conducted in pregnant mice, rats, and rabbits. No evidence of fetal harm was observed in these species at doses that were 27, 40, and 57 times, respectively, the human dose based on BSA (1).

Studies evaluating the carcinogenic potential of oxiconazole have not been conducted by the manufacturer. No evidence of mutagenicity was found in

multiple assays. In female and male rats, oral doses that were 1 and 4 times, respectively, the human dose based on BSA did not impair fertility. At higher doses, there was a decrease in fertility parameters in both females and males, decreased number of sperm in vaginal smears, extended estrous cycle, and a decrease in mating frequency (1).

It is not known if oxiconazole crosses the human placenta. The molecular weight (about 492) is low enough for passage, but the minimal systemic bioavailability suggests that exposure of the embryo or fetus is clinically insignificant.

BREASTFEEDING SUMMARY

No reports describing the use of oxiconazole during human lactation have been located. The molecular weight (about 492) is low enough for excretion into breast milk, but the minimal systemic bioavailability suggests that exposure of the nursing infant would be clinically insignificant.

OXPRENOLOL

[Withdrawn from the market. See 9th edition.]

OXTRIPHYLLINE

[Withdrawn from the market. See 9th edition.]

OXYBUTYNIN

Urinary Tract Agent (Antispasmodic)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

One report described the use of oxybutynin throughout pregnancy. The drug is a tertiary amine that is a direct inhibitor of smooth muscle spasm of the urinary tract. It also possesses antimuscarinic activity (about one-fifth of the anticholinergic activity of atropine). Oxybutynin is used for the relief of symptoms associated with bladder instability and nocturnal enuresis. It is in the same subclass as darifenacin, flavoxate, solifenacin, tolterodine, and trospium.

FETAL RISK SUMMARY

Reproduction studies in the hamster, mouse, rat, and rabbit have not demonstrated definite evidence of impaired fertility or fetal harm (1–3). No fetal harm was noted in female rats dosed orally with oxybutynin, 20–160 mg/kg/day (maximum recommended human dose is 20 mg/day or less than 0.5 mg/kg/day for an average adult) (4).

It is not known if the drug crosses the placenta to the fetus. The molecular weight (about 358 for the free base) is low enough that exposure of the embryo–fetus should be expected.

A 2001 case report described a paraplegic woman who had used baclofen 80 mg/day (the maximum recommended daily oral dose), oxybutynin 9 mg/day, and trimethoprim 100 mg/day throughout an uneventful pregnancy (5). The fetus developed tachycardia at an unspecified gestational age and an apparently healthy female infant was delivered (birth weight not given). Apgar scores were 10 at 1 and 5 minutes. At 7 days of age, the infant was admitted to the hospital for generalized seizures, but the mother had noted abnormal movements 2 days after birth. All diagnostic test results were negative and the

seizures did not respond to phenytoin, phenobarbital, clonazepam, lidocaine, or pyridoxine. Because seizures had been reported in adults after abrupt withdrawal of baclofen, a dose of 1 mg/kg divided into four daily doses was started and the seizures stopped 30 minutes after the first dose. Baclofen was slowly tapered and then discontinued after 2 weeks. Magnetic resonance imaging of the infant's brain on day 17 suggested a short hypoxic ischemic insult that was thought to have been secondary to the seizures (5).

BREASTFEEDING SUMMARY

No reports describing the use of oxybutynin during human lactation have been located. The molecular weight (about 358 for the free base) is low enough that excretion into milk should be expected. The effect of this exposure on a nursing infant is unknown. However, other anticholinergics are classified by the American Academy of Pediatrics as compatible with breastfeeding (see Atropine and Scopolamine).

OXYCODONE

Narcotic Agonist Analgesic

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

The National Birth Defects Prevention Study discussed below found evidence that opioid use during organogenesis is associated with a low absolute risk of congenital birth defects. Use for prolonged periods or in high doses at term has the potential to cause withdrawal or respiratory depression in the newborn.

FETAL RISK SUMMARY

Oxycodone is a narcotic analgesic available as a single agent or in combination with nonnarcotic analgesics, such as acetaminophen or aspirin. The drug is rapidly metabolized in the liver to noroxycodone (weakly active), oxymorphone (active), and their glucuronides. Plasma protein binding is about 45%. The elimination half-lives of the extended-release and immediate-release formulations are 4.5 and 3.2 hours, respectively (1).

Reproduction studies in rats and rabbits at doses up to 3 and 46 times the human dose of 160 mg/day based on BSA, respectively, found no evidence of fetal harm (1).

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 8 of whom had 1st trimester exposure to oxycodone (2). No evidence was found to suggest a relationship to large categories of major or minor malformations or to individual defects.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 281 newborns had been exposed to oxycodone during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 13 (4.6%) major birth defects were observed (12 expected), including (observed/expected) 3/3 cardiovascular defects and 1/1 hypospadias. No anomalies were observed in four other defect

categories (oral clefts, spina bifida, polydactyly, and limb reduction defects) for which specific data were available. These data do not support an association between the drug and congenital defects.

At a 1996 meeting, data were presented on 118 women using oxycodone (N = 78) or hydrocodone (N = 40) during the 1st trimester for postoperative pain, general pain, or upper respiratory infection who were matched with a similar group using codeine for these purposes (3). Six (5.1%) of the infants exposed to oxycodone or hydrocodone had malformations, an odds ratio of 2.61 (95% confidence interval 0.6–11.5, $p = 0.13$). There was no pattern evident among the six malformations (3).

A 26-year-old woman with chronic pain and depression took oxycodone 60 mg/day, quetiapine 400 mg/day, and fluoxetine 40 mg/day throughout pregnancy (4). She gave birth at 37 weeks' gestation to an apparently normal 3.4-kg (50th percentile) male infant, and then continued these drugs during breastfeeding. The infant's weight at 3 months of age was 5.6 kg (25th percentile), but the Denver development assessment was consistent with his chronological age (4).

Neonatal withdrawal associated with maternal use of oxycodone has been reported (5,6). A 37-year-old woman underwent a cesarean section to give birth to a normal 3685-g female infant with Apgar scores of 8 and 9 (5). The infant was excessively irritable during the first 48 hours but did not require any therapeutic intervention. When the mother suffered an acute abstinence syndrome after delivery, it was discovered that she had taken Percodan (oxycodone + aspirin) daily throughout pregnancy (5). The second case involved a 24-year-old woman who had used IV oxycodone (120–500 mg/day) and oral methadone during pregnancy (6). At 39 weeks', she gave birth to a 2864-g (>25th percentile) male infant, Apgar scores 7 and 10, without structural anomalies. The infant's length (47 cm, <5th percentile) and head circumference (33 cm, <5th percentile) were restricted. The infant had a shrill cry at birth and developed severe neonatal abstinence syndrome. The infant's urine was positive for oxymorphone (a metabolite of oxycodone) but not for methadone. The infant was discharged to foster care on day 16 of life (6).

Results of a National Birth Defects Prevention Study (1997–2005) were published in 2011 (7). This population-based case–control study examined the association between maternal use of opioid analgesics and >30 types of major structural birth defects. In 17,449 case mothers, therapeutic opioid use was reported by 454 (2.6%) compared with 134 (2.0%) of 6701 control mothers. Indications for use of opioid analgesics were surgical procedures (41%),

infections (34%), chronic diseases (20%), and injuries (18%). Dose, duration, and frequency were not evaluated. The exposure period evaluated was from 1 month before to 3 months after conception. Limiting the exposure period to the first 2 months after conception produced similar results. Infants with >1 defect were included in multiple birth defect categories. The following opioids were included (number of cases for each agent not specified): codeine, hydrocodone, hydromorphone, fentanyl, meperidine, methadone, morphine, oxycodone, pentazocine, propoxyphene, and tramadol. The birth defect, total number, number exposed, and the adjusted odds ratio (aOR) with 95% confidence interval (CI) were as follows:

| Birth Defect | Total | Cases | aOR (95% CI) |
|--|-------|-------|---------------|
| Spina bifida | 718 | 26 | 2.0 (1.3–3.2) |
| <i>Any heart defect (20 types)</i> | 7724 | 211 | 1.4 (1.1–1.7) |
| Atrioventricular septal defect | 175 | 9 | 2.4 (1.2–4.8) |
| Teratology of Fallot | 672 | 21 | 1.7 (1.1–2.8) |
| Conotruncal defect | 1481 | 41 | 1.5 (1.0–2.1) |
| Conoventricular septal defect | 110 | 6 | 2.7 (1.1–6.3) |
| Left ventricular outflow tract obstruction defect | 1195 | 36 | 1.5 (1.0–2.2) |
| Hypoplastic left heart syndrome | 357 | 17 | 2.4 (1.4–4.1) |
| Right ventricular outflow tract obstruction defect | 1175 | 40 | 1.6 (1.1–2.3) |
| Pulmonary valve stenosis | 867 | 34 | 1.7 (1.2–2.6) |
| Atrial septal defect (ASD) | 511 | 17 | 2.0 (1.2–3.6) |
| Ventricular septal defect + ASD | 528 | 17 | 1.7 (1.0–2.9) |
| Hydrocephaly | 301 | 11 | 2.0 (1.0–3.7) |
| Glaucoma/anterior chamber defects | 103 | 5 | 2.6 (1.0–6.6) |
| Gastroschisis | 726 | 26 | 1.8 (1.1–2.9) |

The authors speculated that the activity of opioids and their receptors as growth regulators during development of the embryo might be a mechanism to explain the above findings. The exposure data were obtained by retrospective maternal self-report; the authors acknowledged that recall bias and

misclassification might have affected their results. They concluded that the absolute risk was a modest absolute increase above the baseline risk for birth defects (7).

BREASTFEEDING SUMMARY

Oxycodone is excreted into breast milk. Six healthy postpartum women received a combination product of oxycodone and acetaminophen, one or two capsules every 4–7 hours, while breastfeeding their newborn infants (8). Maternal plasma levels were in the expected range of 14–35 ng/mL and milk concentrations ranged from <5 to 226 ng/mL. Peak milk concentrations occurred 1.5–2.0 hours after the first dose, and then at variable times after multiple doses. Although a large degree of variability was present, the mean milk:plasma ratio was 3.4:1. No mention was made of any effects observed in the nursing infants (8).

In a 2012 report, neonatal central nervous system (CNS) depression was assessed in three cohorts of breastfeeding mother–infant pairs exposed to oxycodone (N = 139), codeine (N = 210), or acetaminophen only (N = 184) (9). More infants had CNS depression with oxycodone (20.1%) compared with 0.5% in the acetaminophen cohort (20.1%; OR 46.16, 95% CI 6.2–344.2; $p < 0.0001$) and 16.7% in the codeine cohort (16.7%; OR 0.79, 95% CI 0.46–1.38; $p > 0.05$). In the oxycodone and codeine cohorts, mothers of infants with symptoms took significantly higher doses compared with mother of infants with no symptoms in the same cohorts: oxycodone—median 0.4 mg/kg/day (range 0.03–4.06 mg/kg/day) vs. median 0.15 mg/kg/day (range 0.02–2.25 mg/kg/day); $p = 0.005$; codeine—median 1.4 mg/kg/day (range 0.7–10.5 mg/kg/day) vs. median 0.9 mg/kg/day (range 0.18–5.8 mg/kg/day); $p \leq 0.001$. In addition, significantly more mothers in the oxycodone cohort had sedation compared with the codeine cohort. Based on these results, the authors concluded that oxycodone was not a safer alternative to codeine in breastfed infants (9).

If a mother is receiving oxycodone, her nursing infant should be monitored for sedation and other adverse effects, such as gastrointestinal effects and changes in feeding patterns.

OXYMETAZOLINE

Sympathomimetic (Adrenergic)

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Oxymetazoline, an α -adrenergic agent, is a long-acting vasoconstrictor used topically in nasal decongestant sprays. No reports associating oxymetazoline with congenital abnormalities have been located.

FETAL RISK SUMMARY

The Collaborative Perinatal Project recorded only 2 cases of exposure from 50,282 mother–child pairs (1). Although there was no indication of risk for malformations, the number of women exposed is too small for any conclusion.

Uterine vessels are normally maximally dilated and have only α -adrenergic receptors (2). Use of the α -adrenergic agent, oxymetazoline, could cause constriction of these vessels and reduce uterine blood flow, thus producing fetal hypoxia and bradycardia. A 1985 case report illustrated this toxicity when a nonreactive nonstress test and a positive contraction stress test were discovered in a 20-year-old woman at 41 weeks' gestation (3). Persistent late fetal heart rate decelerations were observed, and blood obtained from the fetal scalp revealed a pH of 7.23. The mother had self-administered a nasal spray containing 0.05% oxymetazoline, two sprays in each nostril, 6 times in a 15.5-hour interval before the nonstress test with the last dose administered 0.5 hour before testing. The recommended dosage interval for the preparation was every 12 hours. Approximately 6 hours after the last dose, the late decelerations disappeared and the normal beat-to-beat variability returned about 0.5 hour later. A normal male infant with Apgar scores of 9 and 9 at 1 and 5 minutes, respectively, was spontaneously delivered 14 hours after the last dose.

In contrast to the above case, a 1990 report described the results of a single

dose (two full squirts) of 0.05% oxymetazoline (4). The drug was self-administered by 12 women with allergic rhinitis, sinusitis, or an upper respiratory tract infection. The otherwise healthy women were between 27 and 39 weeks' gestation. The effects of this dose on the maternal and fetal circulations were measured at 15-minute intervals for 2 hours after the dose. No significant changes were observed for maternal blood pressures or pulse rates, fetal aortic blood flow velocity, and fetal heart rate, or for the systolic to diastolic ratios in the uterine arcuate artery and umbilical artery. The investigators concluded that oxymetazoline, when administered at the recommended frequency, did not pose a risk for the healthy patient. Women with borderline placental reserve, however, should use the agent cautiously (4).

BREASTFEEDING SUMMARY

No reports describing the use of oxymetazoline during human lactation have been located.

OXYMORPHONE

Narcotic Agonist Analgesic

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although oxymorphone was not included in a National Birth Defects Prevention Study, the use of other opioid agonists during organogenesis was associated with a low absolute risk of congenital birth defects (see Morphine). In addition, the use of any opioid agonist during labor or close to delivery may cause neonatal respiratory depression.

FETAL RISK SUMMARY

Oxymorphone is an opioid agonist that is available in both oral and injectable formulations. It is highly metabolized in the liver to active and inactive metabolites (1).

Reproduction studies have been conducted in rats, rabbits, and hamsters. Oxymorphone did not cause malformations in rats and rabbits at daily oral doses that were about 2 and 8 times, respectively, the total human daily oral dose of 120 mg based on BSA (THDD). Fetal weights were decreased in both species at doses that were about 0.8 and 4 times the THDD. In rats given the drug daily during gestation and postnatally at a dose that was about 2 times the THDD, there was an increase in stillborn pups and neonatal deaths, as well as low pup birth weight and a decrease in postnatal weight gain. In hamsters, a single SC dose that was about 10 times the THDD produced malformations in offspring but also produced 83% maternal death (1).

Although no studies have been found indicating that oxymorphone crosses the human placenta, the molecular weight (about 338) and experience with other opioid analgesics (e.g., see Morphine) indicates that the drug will rapidly cross to the embryo–fetus.

Use of oxymorphone during labor produces neonatal respiratory depression to the same degree as other narcotic analgesics (2–5).

BREASTFEEDING SUMMARY

No reports describing the use of oxymorphone during human lactation have been located. However, the molecular weight (about 338) and experience with other opioid analgesics (e.g., see Morphine) indicates that the drug will be excreted into breast milk. Although occasional maternal doses would probably not produce adverse effects in the nursing infant, higher doses and prolonged use could cause toxicity. Moreover, long-term effects on neurobehavior and development are unknown but warrant study.

P

PACLITAXEL

Antineoplastic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Paclitaxel produces embryo–fetal toxicity, including teratogenicity, in animals. In addition, the drug was clastogenic with in vitro and in vivo tests. In animals, compared with the free drug, liposome encapsulation of paclitaxel appears to markedly increase the dose at which toxicity and teratogenicity are observed. Whether this also would occur in human pregnancy is not known. The human pregnancy experience is limited to use in the 2nd and 3rd trimesters. No fetal or newborn toxicity have been reported following this use. Based on the animal data, the use of paclitaxel during organogenesis should be avoided if possible. Use after this period appears to be relatively low risk, but the fetus should be monitored appropriately. (See Carboplatin for additional data.)

FETAL RISK SUMMARY

Paclitaxel, an antineoplastic agent, is indicated for the treatment of advanced ovarian cancer but also is used in other malignancies. The drug is a natural product obtained by extraction from *Taxus brevifolia* (Pacific yew tree) (1,2). Paclitaxel is an antimicrotubule agent, an action that results in the inhibition of the normal reorganization of the microtubule network that is essential for vital interphase and mitotic cellular functions. It is in the same subclass of taxoids as docetaxel and cabazitaxel. The pharmacokinetics of paclitaxel are markedly affected by the dose and infusion rate with elimination half-lives varying from approximately 13 to 53 hours. Approximately 89%–98% of the agent is protein

bound (1). The free commercial form of paclitaxel contains the vehicle polyoxyethylated castor oil (also known as polyoxyl 35 castor oil) (1,2).

Reproduction studies in pregnant rabbits at doses about 0.2 times the maximum recommended human daily dose based on BSA (MRHDD) caused embryo and fetal toxicity (increased resorptions and intrauterine deaths). However, maternal toxicity was observed at this dose. No teratogenic effects were noted at a dose about 0.07 times the MRHDD, but the teratogenic potential of higher doses could not be assessed because of extensive fetal mortality (1).

The carcinogenic potential of paclitaxel has not been studied. The drug was not mutagenic in one test but was clastogenic in vitro (human lymphocytes) and in vivo (micronucleus test in mice). Fertility in male and female rats was impaired at doses about 0.04 times the MRHDD, and at this dose, increased embryo and fetal toxicity was observed (1).

Interestingly, a 1995 research report concluded that some, paclitaxel-induced, embryotoxicity in animals might be due to the polyoxyethylated castor oil vehicle (2). In an experiment with chick embryos, the researchers compared free paclitaxel containing the vehicle with liposome-encapsulated paclitaxel. At a dose of 1.5 mcg per egg, 60% of the embryos either died or were malformed. A 20-fold higher dose was required to produce the same degree of toxicity with the liposome-encapsulated product (2).

In a follow-up to the above study, the same group of researchers compared the developmental toxicity in rats of free and encapsulated paclitaxel (3). Free paclitaxel, at a dose of 10 mg/kg (approximately 0.4 times the MRHDD) given IV once on gestation day 8 (determined to be the most sensitive day for the production of paclitaxel-induced malformations), produced maternal toxicity and resorption of all embryos in surviving dams. At 2 mg/kg (about 0.08 times the MRHDD) of free paclitaxel, embryo–fetal toxicity (increased resorptions and reduced fetal weight) and anomalies (exencephaly, anencephaly, ventral wall defects, facial clefts, anophthalmia, diaphragmatic hernia, and malformations of the kidney, cardiovascular system, and tail) were observed (3). In contrast, no toxicity or anomalies were observed with a 2 mg/kg IV dose of encapsulated paclitaxel. At 10 mg/kg, toxicity and malformations were noted that were similar to those observed with the free drug at 2 mg/kg. Thus, encapsulation appeared to increase the dose needed to produce toxicity and malformations (3). However, encapsulation of paclitaxel could markedly increase or decrease the amount of drug crossing the placenta to the fetus. The authors of the study cited examples in perfused in vitro human placentas in which liposome

encapsulation reduced placental transfer. In contrast, they also cited studies in intact rats and rabbits that have shown that encapsulation enhanced placental transfer, possibly by a process involving placental intracellular sequestration and degradation of liposomes (3).

Although the molecular weight (about 854) suggests that paclitaxel will cross the placenta, the extensive protein binding might limit the exposure of the embryo or fetus. Of interest, in an in vitro model, paclitaxel slowly crossed the human placenta to the fetal side (4).

In a novel case report, a 21-year-old woman was diagnosed with metastatic ovarian cancer that was initially treated with surgery that left her uterus, right fallopian tube, and ovary in situ (5). She was then enrolled into a phase I transplant protocol and received three cycles of paclitaxel (225 mg/m²) and carboplatin (dose specified as AUC 6). Subsequent high-dose chemotherapy was then given (paclitaxel, carboplatin, and/or cyclophosphamide). After her chemotherapy, the woman received a successful transplant of autologous peripheral blood stem cells. Approximately 16 months after the transplant, she conceived but had a 1st trimester miscarriage. She conceived again several months later and eventually delivered a healthy full-term 3000-g female infant. The child was developing normally at 17 months of age (5).

A 33-year-old woman was diagnosed with ovarian carcinoma at 27 weeks' gestation (6). Six days after debulking surgery that preserved the pregnancy, she received the first cycle of paclitaxel (135 mg/m²) over 24 hours and cisplatin (75 mg/m²) over 4 hours. She received two more cycles of chemotherapy at 3-week intervals. Appropriate fetal growth was documented by ultrasound. Fetal lung maturity was demonstrated at 37 weeks' gestation and a cesarean section was performed to deliver a 2800-g female with Apgar scores of 9 and 10 at 1 and 5 minutes, respectively, and normal blood counts. The infant has had normal growth and development to 30 months of age (6).

A 2003 report described the pregnancy outcome of a 30-year-old woman treated with carboplatin and paclitaxel during the 2nd and 3rd trimesters (7). She was diagnosed with an advanced stage of serous papillary adenocarcinoma of the ovary in the 1st trimester. The woman underwent an exploratory laparotomy at 7.5 weeks' gestation and consented to chemotherapy beginning at 16–17 weeks. She received six cycles of carboplatin (dose specified as AUC 5) and paclitaxel (175 mg/m²) and was delivered by cesarean hysterectomy 3 weeks after the last cycle, at 35.5 weeks. The newborn (sex not specified) had Apgar scores of 9, 9, and 9 at 1, 5, and 10 minutes, respectively. Birth weight was 2500 g (44th percentile), and

the physical examination and laboratory tests were normal. In addition, the placenta appeared grossly normal. The infant was doing well at 15 months of age with no evidence of neurologic, renal, growth, or hematologic effects from the exposure (7).

In another 2003 report, a 36-year-old woman with breast cancer was treated with paclitaxel (175 mg/m^2 every 3 weeks for three cycles) and epirubicin (120 mg/m^2 every 3 weeks for four cycles) from the 14th to the 32nd week of pregnancy (8). At 36 weeks', she delivered by cesarean section a normal 2.280-kg female infant with a 5-minute Apgar score of 9. The child had normal development and growth at 36 months of age (8).

A 30-year-old woman became pregnant approximately 2 years after treatment of stage IIB fallopian tube carcinoma with paclitaxel and cisplatin (9). She was diagnosed with an asymptomatic intra-abdominal recurrence at 16 weeks' gestation but refused additional therapy. A 2888-g male infant was delivered by cesarean section at 37 weeks. No additional information about the infant was given (9).

A 38-year-old woman with breast cancer had been treated with a radical mastectomy followed by four cycles of doxorubicin and cyclophosphamide before pregnancy (10). Starting at about 21 weeks' gestation, she received 12 weekly cycles of paclitaxel (80 mg/m^2). At 37 weeks', she delivered by cesarean section a normal 2.45-kg male infant with Apgar scores of 9 at 1, 5, and 10 minutes. The infant's birth weight was at the 5th–10th percentile for gestational age. The infant had normal development and growth at 12 months of age (10).

A 2009 report described the use of paclitaxel (90 mg/m^2 on days 1, 8, and 15 of a 28-day cycle) for six cycles starting at 29 weeks' gestation for recurrent breast cancer (11). An elective cesarean section at 38 weeks' delivered a healthy infant (no other details were provided).

A 2007 report described the pregnancy outcome of 30-year-old woman with cervical cancer who was treated with paclitaxel (175 mg/m^2) and cisplatin (75 mg/m^2) at 19 weeks' gestation (12). Paclitaxel was discontinued after the first course because of a severe allergic reaction, but cisplatin was continued every 3 weeks until a cesarean section at 35 weeks'. The normal 2.400-kg female infant had Apgar scores of 7 and 9 at 1 and 5 minutes, respectively. The infant was doing well at 10 months of age (12).

Ovarian cancer was diagnosed in a 42-year-old woman at 18 weeks' gestation (13). Following surgery that preserved the pregnancy, she was treated with four courses of paclitaxel plus carboplatin (AUC 5) from 22 to 35

weeks'. A cesarean section delivered 2.600-kg male infant with Apgar scores of 9 at 1 and 5 minutes. The healthy infant was doing well at 6 months of age (13).

Another case involving the treatment of ovarian cancer with paclitaxel in pregnancy was reported in 2007 (14). Following diagnosis of the tumor at 25 weeks' gestation, the patient was treated with paclitaxel (175 mg/m²) and carboplatin (AUC 5) every 3 weeks for 3 cycles with the last cycle during the 32nd gestational week. At 35 weeks', a cesarean section delivered a healthy 2.450-kg male infant with Apgar scores of 9, 10, and 10. At 20 months, the child continued to show no abnormalities (14).

A third case of ovarian cancer in pregnancy was treated with paclitaxel (120 mg/m²) and carboplatin (AUC 3) in (bi-weekly cycles (15). Five cycles were given starting at) 24 weeks' gestation. An elective cesarean section at 36 weeks' delivered a 2.062-kg female infant with Apgar scores of 8 and 9 at 1 and 5 minutes, respectively. The child remained healthy at 40 months of age (15).

A 39-year-old woman in the 17th week of pregnancy was diagnosed with non-small-cell lung cancer (16). In the 21st week, paclitaxel (175 mg/m²) and cisplatin (75 mg/m²) every 21 days were started. Three cycles had been given when she presented in the 30th week with tonic-clonic seizures caused by brain metastases. An emergency cesarean section was performed to deliver a 1.720-kg male infant with Apgar scores of 3 and 4 at 1 and 5 minutes, respectively. Although the infant developed acute respiratory distress shortly after birth, no other abnormalities were found and he was doing well with normal development and growth after 15 months (16).

A second case of non-small-cell lung cancer occurring in pregnancy was reported in 2009 (17). Starting in the 19th week of pregnancy, the 33-year-old woman was treated with paclitaxel (60 mg/m²) weekly and carboplatin (AUC 5) every 3 weeks. The patient had received 5 weeks of treatment when brain metastases were discovered. Following corticosteroids for fetal lung maturity, she underwent a cesarean section to deliver a healthy male baby (no other details provided). At 5 months of age, the infant's development was normal (17).

BREASTFEEDING SUMMARY

Consistent with its molecular weight (about 854), paclitaxel is excreted into breast milk. In a 2012 case report, a 40-year-old woman at about 4 months

postpartum was exclusively breastfeeding when she began treatment with 6 weekly doses of IV paclitaxel and carboplatin for recurrent papillary thyroid cancer (18). Her infant was fed donor milk during treatment. After the 6th dose, milk samples were collected at 0, 4, 28, 172, and 316 hours. For paclitaxel, the level at 172 hours was 0.97 mg/L but was undetectable at 316 hours. Carboplatin levels remained detectable (0.16 mg/L) at 316 hours. The relative infant dose for paclitaxel was 16.7%, whereas the relative infant dose for carboplatin was 2.0%. The authors concluded that although these levels were probably too low to cause toxicity, potential toxicity could include myelosuppression (especially neutropenia and thrombocytopenia), severe hypersensitivity reactions, nephrotoxicity, and neurotoxicity (18). Because of the potential toxicity, women receiving these agents should not nurse (19).

PALIFERMIN

Keratinocyte Growth Factor

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of palifermin in human pregnancy have been located. The animal reproduction data suggest risk of developmental toxicity, but the embryo–fetal effects (growth restriction and death) might have been secondary to maternal toxicity. Importantly, the no-effect doses in two animal species were close to the human dose (based on body weight). A more informative dose comparison (BSA or AUC) was not provided by the manufacturer. The use of this agent by a pregnant patient implies that she also will receive or has received chemotherapy that is toxic to the bone marrow and oral mucosa, and possibly to her embryo or fetus as well. The addition of palifermin to decrease maternal oral mucosal toxicity and to allow a more rapid return to a normal intake of food and fluids appears to be an overall embryo–fetal benefit. In this context, although the absence of human pregnancy experience prevents an assessment of the potential for embryo–fetal harm, the maternal benefit appears to outweigh this unknown risk.

FETAL RISK SUMMARY

Palifermin, a water-soluble, 140 amino acid protein produced by recombinant DNA technology, is a human keratinocyte growth factor (KGF). It is indicated to decrease the incidence and duration of severe oral mucositis in patients with hematologic malignancies receiving myelotoxic therapy requiring hematopoietic stem cell support (1). KGF is an endogenous protein in the fibroblast growth factor family. It binds to the KGF receptor that is present on epithelial cells in many tissues (e.g., throughout the gastrointestinal tract), resulting in proliferation, differentiation, and migration of epithelial cells. Palifermin is given as a daily IV bolus dose for 3 days before and after myelotoxic therapy (total

of six doses). The elimination half-life is about 4.5 hours (range 3.3–5.7 hours) (1).

Reproduction studies have been conducted in rats and rabbits. In pregnant rats, IV doses 8 or more times the recommended human dose based on body weight (RHD) were associated with increased postimplantation loss, decreased fetal body weight, and/or increased skeletal variations. These doses also were maternal toxic (clinical signs and decreased body weight gain/food consumption). The no-effect dose for developmental toxicity was 4.8 times the RHD. Systemic toxicity in male and female rats was observed at a dose 5 times the RHD, and the fertility index was decreased at a dose about 16 times the RHD. In pregnant rabbits, increased postimplantation losses and decreased fetal body weights were observed at IV doses 2.5 times the RHD. This dose produced maternal toxicity similar to that observed in rats. The no-effect dose for developmental toxicity in the rabbit was equal to the RHD (1).

The carcinogenic potential of palifermin has not been studied in animals. Palifermin has been shown to enhance the growth of human epithelial tumor cell lines in vitro and to increase the rate of tumor cell line growth in a human xenograft model (1). No clastogenic or mutagenic effects were observed in assays (1).

It is not known if palifermin crosses the human placenta. The molecular weight of the protein (about 16,300) should preclude passive diffusion, but active transfer, such as occurs with immunoglobulins, is possible. Moreover, as an endogenous protein, KGF is present in the embryo and fetus.

BREASTFEEDING SUMMARY

No reports describing the use of palifermin during human lactation have been located. Although this protein has a high molecular weight (16,300), it might be excreted into breast milk, as are other proteins (e.g., antibodies). The effects of this exposure on a nursing infant are unknown, but palifermin would most likely be broken down to its constituent amino acids or fragments thereof in the infant's digestive tract. However, because it stimulates the proliferation, differentiation, and migration of epithelial cells, including epithelial tumor cell lines, the best course is to stop breastfeeding when the mother is being treated. Moreover, the use of palifermin implies that the mother also has received or is receiving myelotoxic chemotherapy, and exposure of a nursing infant to these agents should be avoided.

PALIPERIDONE

Antipsychotic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of paliperidone, the active metabolite of risperidone, in human pregnancy have been located. Developmental toxicity, in the absence of maternal toxicity, was not observed in two animal species. Risperidone was carcinogenic in rodents, but the relationship of this effect to humans has not been studied. Although there are no human pregnancy data with paliperidone, there are limited data for risperidone. (See Risperidone.) However, the absence of specific information for paliperidone prevents a complete assessment of the embryo–fetal risk. Nevertheless, if the mother’s disease requires the use of paliperidone, the benefits to her probably outweigh any fetal risk. Folic acid 4 mg/day has been recommended for women taking atypical antipsychotics because they may have a higher risk of neural tube defects due to inadequate folate intake and obesity (1). If paliperidone is used in pregnancy, health care professionals are encouraged to call the toll-free number 800-670-6126 for information about patient enrollment in the Motherisk study.

FETAL RISK SUMMARY

Paliperidone (9-hydroxyrisperidone), an atypical antipsychotic, is the major active metabolite of risperidone. (See also Risperidone.) It is a benzisoxazole derivative in the same antipsychotic subclass as iloperidone, risperidone, and ziprasidone. Paliperidone is indicated for the acute and maintenance treatment of schizophrenia. The plasma protein binding is 74%, and the metabolites are inactive. The terminal elimination half-life is about 23 hours (2).

Reproduction studies have been conducted in rats and rabbits. No increases in fetal abnormalities were observed in these species at oral doses that were 8

times the maximum recommended human dose based on BSA (MRHD) (2).

Carcinogenicity studies have not been performed with paliperidone. However, in mice and rats, the parent compound risperidone produced pituitary gland adenomas, endocrine pancreas adenomas, and mammary gland adenocarcinomas. This effect in rodents from risperidone and other antipsychotics is thought to be mediated by prolonged dopamine D₂ antagonism and hyperprolactinemia. The no-observed-effect-level (NOEL) for these tumors was equal to or less than the maximum recommended human dose of risperidone based on BSA (2).

Paliperidone was not mutagenic in three assays. Fertility of male and female rats was not affected by oral doses up to about 2 times the MRHD. However, preimplantation and postimplantation losses were increased at the maximum dose that also caused slight maternal toxicity. No decrease in live embryos was observed at a dose that was about 0.5 times the MRHD (2).

It is not known if paliperidone crosses the human placenta. The molecular weight (about 426), moderate plasma protein binding, and long elimination half-life suggest that the drug will cross to the embryo–fetus.

Antipsychotics, especially those classified as high potency, can cause extrapyramidal reactions (e.g., acute dystonia, akathisia, parkinsonism, and tardive dyskinesia) in those taking the drug and, if large doses are taken by the mother, also in the newborn. The American Academy of Pediatrics (AAP) classifies risperidone as high potency; its active metabolite should be classified similarly. However, the AAP did note that high-potency antipsychotics were preferred to minimize maternal anticholinergic, hypotensive, and antihistamine adverse effects (3).

BREASTFEEDING SUMMARY

No reports describing the use of paliperidone during human lactation have been located.

However, risperidone and its active metabolite, 9-hydroxyrisperidone (paliperidone), are excreted into breast milk (4–6). (See also Risperidone.)

A 21-year-old mother with a 2-year history of bipolar disorder stopped all medication when her pregnancy was diagnosed (4). She did well during pregnancy and delivered a healthy infant at 38 weeks' gestation. When her disease relapsed, she was admitted to the hospital 2.5 months after birth of her infant, stopped breastfeeding, and started on risperidone, eventually reaching a steady-state dose of 6 mg/day. Concentrations of risperidone and paliperidone were determined in the plasma and milk. The milk:plasma ratios,

based on AUC_{0-24} , were 0.42 and 0.24, respectively. Based on a daily milk intake of 150 mL/kg, a nursing infant would have received 0.84% of the mother's risperidone dose (mg/kg/day) and an additional 3.46% from the paliperidone (as risperidone equivalents), or about 4.3% of the weight-adjusted maternal dose. Although the combined amounts of risperidone and paliperidone measured in breast milk appear to be too low to cause extrapyramidal effects, concern was expressed for other effects, such as neuroleptic malignant syndrome, and effects on cognitive development (4).

A 2004 study measured the steady-state plasma and milk concentrations of risperidone and 9-hydroxyrisperidone in two breastfeeding women and one woman with risperidone-induced galactorrhea (5). A 29-year-old woman with galactorrhea was taking risperidone 3 mg at night (37.5 mcg/kg/day) for schizophrenia. The galactorrhea was attributed to elevated prolactin concentrations due to the D_2 antagonist effects of risperidone. Milk and plasma samples were collected 20 hours postdose, and then milk only on days 2 and 3, each at 21 hours postdose. The plasma concentrations of risperidone and the metabolite were <1 and 14 mcg/L, respectively. All milk risperidone concentrations were <1 mcg/L, whereas the mean concentration of the metabolite was 5.1 mcg/L (range 4.4–5.6 mcg/L). Although the woman was not nursing, the absolute and relative infant doses were 0.88 mcg/kg/day or 2.3% (as risperidone equivalents) (5).

The two women who were breastfeeding were treated for psychosis with risperidone doses of 42.1 (2 mg every 12 hours) and 23.1 mcg/kg/day (0.5 mg in the morning and 1 mg at night), respectively (5). The nursing infants were a 3.3-month-old female and a 6-week-old male, respectively. In the first woman, milk concentrations of the parent drug and metabolite were 49 and 142 mcg•hr/L (AUC), respectively, whereas the average concentrations were 2.1 and 6 mcg/L, respectively. The absolute infant doses were 0.32 and 0.9 mcg/kg/day, respectively. In the second woman, milk concentrations were 3.1 and 56.5 mcg•hr/L (AUC), respectively, whereas the average concentrations over 24 hours were 0.39 and 7.06 mcg/L, respectively. The absolute infant doses were 0.06 and 1.06 mcg/kg/day, respectively. The milk:plasma ratios were 0.1 and 0.5, respectively. Neither risperidone nor the metabolite was detected in the plasma of the infants and both were developing normally at 9 and 12 months, respectively (5).

A 23-year-old woman, nursing a 4.2-kg male infant 6 times daily, was diagnosed with paranoid schizophrenia 1 week after birth (6). She was hospitalized and started on risperidone 1 mg twice daily. The dose was
