changed to 2 mg every evening on day 7 and then to 3 mg every evening on day 10. Milk (fore and hind) and maternal plasma concentrations of risperidone and paliperidone were determined on days 6, 10, and 20. No drug accumulation was observed and the concentrations of paliperidone always exceeded those of risperidone. The ranges of risperidone and paliperidone milk concentrations were 0–3 and 1.2–11 ng/mL, respectively, whereas the plasma concentrations were 0.4–10 and 4–43 ng/mL, respectively. Moreover, the concentrations in fore- and hind-milk were comparable. On day 10, 15 hours after a 2 mg dose, the concentrations of risperidone and paliperidone in infant plasma were 0 and 0.1 ng/mL, respectively. The mother was discharged home on risperidone after 5 weeks. The psychomotor development of the infant during the mother's hospitalization was normal and no adverse effects or sedation in the infant were observed. The mother and infant were doing well 2 months after discharge (6).

The AAP classifies other antipsychotic drugs as agents for which the effect on nursing infants is unknown but may be of concern, especially when given for long periods (7). Neither risperidone nor paliperidone was mentioned, but the AAP noted that antipsychotics are excreted into breast milk and could conceivably alter both short-term and long-term CNS function (7). Although no adverse effects from exposure to risperidone and paliperidone have been observed, studies have not been conducted to determine if there are long-term effects.

PALIVIZUMAB

Respiratory Drug (Monoclonal Antibody)

PREGNANCY RECOMMENDATION: No Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of palivizumab in human pregnancy have been located. However, such reports are unlikely because the drug is indicated only for pediatric patients.

FETAL RISK SUMMARY

Palivizumab is a recombinant humanized monoclonal antibody antiviral that acts against respiratory syncytial virus (RSV). After IM injection, it acts by binding the RSV envelope fusion protein on the surface of the virus and blocking a critical step in the membrane fusion process. It also prevents cell-to-cell fusion of RSV-infected cells. Palivizumab is indicated for the prevention of serious lower respiratory tract disease caused by RSV in children at high risk for RSV disease. In children <24 months of age, the mean half-life was 20 days (1).

Animal reproduction studies and studies for carcinogenicity, mutagenicity, and fertility have not been conducted (1).

It is not known if palivizumab crosses the human placenta. The molecular weight (about 148,000) suggests that it will not cross, at least in the 1st and 2nd trimesters.

BREASTFEEDING SUMMARY

No reports describing the use of palivizumab during human lactation have been located. Such reports are unlikely because the drug is indicated only for pediatric patients. Moreover, after the colostrum phase, even if a lactating woman inadvertently received the drug, the high molecular weight (about 148,000) should prevent excretion of the monoclonal antibody into breast milk.

PALONOSETRON

Antiemetic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of palonosetron in human pregnancy have been located. The animal data suggest that the risk to the human embryo–fetus is low, but the lack of human pregnancy experience prevents a more complete assessment of the risk. Regarding other agents in this class, there is no human pregnancy experience with dolasetron and granisetron, but limited experience with ondansetron has not demonstrated embryo or fetal toxicity. Based on this experience and the lack of developmental toxicity in two animal species, palonosetron appears to represent a minimal risk to the human embryo or fetus.

FETAL RISK SUMMARY

Palonosetron is a selective serotonin (5-HT₃) receptor antagonist that is in the same pharmacologic class as dolasetron, granisetron, and ondansetron. IV doses of this agent are indicated for the prevention of acute nausea and vomiting associated with initial and repeat courses of moderately and highly emetogenic cancer chemotherapy, and for the prevention of delayed nausea and vomiting associated with initial and repeat courses of moderately emetogenic cancer chemotherapy. Only moderate amounts (about 62%) of palonosetron are bound to plasma proteins and about 50% is metabolized to two inactive compounds. The mean terminal elimination half-life is about 40 hours (1).

Reproduction studies have been conducted in pregnant rats and rabbits. In these species, oral doses up to 1894 and 3789 times, respectively, the recommended human IV dose based on BSA revealed no evidence of impaired fertility or harm to the fetus. In male and female rats, the highest dose had no

effect on fertility or reproductive performance (1).

In a 2-year study with mice, palonosetron was not tumorigenic at oral doses up to those producing systemic exposures about 150–289 times the human exposure based on AUC resulting from the recommended IV dose (HE). In a 2-year study with male and female rats, oral doses up to those producing systemic exposures 308 times the HE were carcinogenic. In other tests, palonosetron was not genotoxic but did have clastogenic effects (1).

It is not known if palonosetron crosses the human placenta. The molecular weight of the free base (about 297), the moderate protein binding and metabolism, and the extended plasma half-life suggest that substantial amounts of active drug will be at the maternal–fetal interface for prolonged periods.

BREASTFEEDING SUMMARY

No reports describing the use of palonosetron during human lactation have been located. The molecular weight of the free base (about 297), the moderate protein binding and metabolism, and the extended plasma half-life suggest that the drug will be excreted into breast milk. The effects of this exposure on a nursing infant are unknown. Because the use of palonosetron is normally for short periods, the risk of any toxicity in a nursing infant appears remote.

PAMIDRONATE

Bisphosphonate

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Although the dose comparisons in animal species were based on body weight, and maternal toxicity was evident, pamidronate, at doses close to those used in humans, did cause nonteratogenic toxicity in the embryo–fetus. The human data are limited to eight cases. In two of the cases, pamidronate was given during the 2nd trimester. Hypocalcemia was noted in one of the newborns but not the other. The amount of drug retained in bone and eventually released back into the systemic circulation is directly related to the dose and duration of treatment. Because pamidronate probably crosses the placenta, continuous exposure most likely occurred throughout gestation in six cases. However, these embryos were exposed during organogenesis to the low plasma concentrations resulting from the slow release of pamidronate from bone, not to the much higher concentrations obtained in the first few days after an IV dose. The use of pamidronate is not recommended in women who may become pregnant or during pregnancy. However, based solely on the limited human pregnancy experience, inadvertent exposure does not appear to represent a major risk to the embryo or fetus, but infants should be monitored for hypocalcemia during the first few days after birth.

FETAL RISK SUMMARY

Pamidronate, a hydrophilic bisphosphonate, is a synthetic analog of pyrophosphate that binds to the hydroxyapatite found in bone to inhibit bone resorption. Pamidronate has three indications: (a) for the treatment of moderate or severe hypercalcemia associated with malignancy, with or without bone metastases; (b) for the treatment of moderate to severe Paget's disease

of bone; and (c) in conjunction with standard antineoplastic therapy, for the treatment of osteolytic bone metastases of breast cancer and osteolytic lesions of multiple myeloma. Other agents in this pharmacologic class are alendronate, etidronate, ibandronate, risedronate, tiludronate, and zoledronic acid. Pamidronate is not metabolized. After IV infusion, about 46% of the dose is excreted as unchanged drug in the urine over 120 hours with a mean elimination half-life of 28 hours. The remainder of the dose is retained in the body. The amount bound to plasma proteins apparently has not been determined (1). Based on preclinical studies, the oral bioavailability is <2% (2).

Reproduction studies have been conducted in pregnant rats and rabbits. In these species, IV bolus doses 0.6–8.3 times the highest recommended human dose (based on body weight) produced toxicity in the mother (decreased body-weight gain and survival during parturition), embryo (death and general underdevelopment), and fetus (marked skeletal restriction) (1,2).

In 2-year carcinogenic studies with oral doses, male rats, but not females, had a significant increase in benign adrenal pheochromocytoma. After adjustment for the limited oral bioavailability, the lowest dose causing this effect was similar to the human IV dose. Pamidronate was not carcinogenic in mice. Tests for mutagenic effects have been negative (1).

It is not known if pamidronate crosses the human placenta. The molecular weight of the free acid (about 233), lack of metabolism, and prolonged elimination half-life suggest that the drug will cross the placenta to the embryo–fetus. The low lipid solubility may limit the exposure.

A 1990 report described a woman who received a 30-mg infusion of pamidronate at 34 weeks' for malignant hypercalcemia due to metastatic breast cancer (3). Two weeks later, she gave birth to healthy 3.06-kg male infant who developed transient hypocalcemia that resolved by 5 days of age. The infant's subsequent growth and development were normal.

A 42-year-old woman presented with newly diagnosed metastatic breast cancer at 24 weeks' gestation (4). Over the next 4 weeks, she was treated with oral dexamethasone (16 mg/day) and SC heroin (100 mg/day). At 28 weeks', she developed severe hypercalcemia that was treated with a single IV dose of pamidronate (90 mg over 8 hours). One week later, a 1412-g male infant was delivered by cesarean section. The Apgar score was 8 at 1 minute. The infant was treated for respiratory distress syndrome, narcotic withdrawal, and hypocalcemia. He was discharged home at 13 weeks of age weighing 3228 g. At 1 year, he was developing normally and his weight, length, and head circumference were at 50th percentile (4).

A 2004 report described two women with osteogenesis imperfecta who were treated with IV pamidronate before conception (5). The timing of the last IV dose in relation to conception was not provided in either case. The first case involved a 17-year-old woman who had received a cumulative IV dose of 49.5 mg/kg (9 mg/kg/year) over a 5-year period. Treatment was stopped when she became pregnant. Her only complication during pregnancy was hyperemesis gravidarum in the 1st trimester. She received daily doses of elemental calcium (1000 mg) and vitamin D (400 IU) throughout gestation. A 3600-g male infant was delivered vaginally at term. Apgar scores were 8 and 9 at 1 and 5 minutes, respectively. Blue sclera, but no dysmorphic features, fractures, or long bone deformities, were noted. The infant inherited osteogenesis imperfecta. Asymptomatic hypocalcemia (ionized calcium below the age-related reference range) was found at 24 hours of age but had resolved at 11 days of age without specific treatment. At that age, a skeletal survey found no evidence of fracture, abnormal bone development, modeling defect, or wormian bones (small irregular bones along the sutures of the cranium, particularly related to the parietal bone) in the skull. At 16 months, the baby's growth (weight and length) was normal, and he remained free of fracture (5).

In the second case, pregnancy occurred in a 17.8-year-old woman who had received a cumulative IV dose of 48 mg/kg (9 mg/kg/year) over 5.3 years (5). Treatment was stopped when she became pregnant. Similar to the above case, the woman received the same dose of calcium and vitamin D throughout gestation. Her pregnancy was uneventful, and she delivered a 2860-g female infant by cesarean section at 38 weeks' gestation. The infant inherited osteogenesis imperfecta and had bilateral talipes equinovarus but no fractures. Otherwise, the limbs were straight. Her plasma calcium was not measured in the first few days after birth. Blue sclera was noted at age 13 days, as were wormian bones on the skull radiograph. Otherwise, her physical examination was normal. At 14 months of age, her growth (weight and length) was normal and she remained free of fracture. The authors cited an incidence for talipes equinovarus of 0.93–6.8 per 1000 live births in the general population. Although the prevalence of the deformity in osteogenesis imperfecta is unknown, they had observed a second case among 400 children with the disorder. They concluded that an association between pamidronate and talipes equinovarus could not be excluded but that the possibility of such an association was unlikely (5). Another source thought the defect had a genetic component (6).

A 40-year-old woman with breast cancer was treated with doxorubicin and paclitaxel over a 3-week interval starting at 24 weeks' gestation (7). At 28

weeks', deteriorating renal function, uterine contractions, and hypercalcemia (17.6 mg/dL) were noted. When other therapies for the hypercalcemia failed, she was treated with IV pamidronate, 90 mg over 6 hours. At 48 hours posttreatment, her calcium concentration had decreased to 12.8 mg/dL and the uterine contractions had stopped. No effects were noted on the fetal heart rate. Her calcium level decreased to 9.9 mg/dL on day 3. At this time, preeclampsia developed and a cesarean section was conducted to give birth to a 1.147-kg female infant with a normal calcium concentration. The infant did well and was discharged from the neonatal intensive care unit at a gestational age of 36 weeks. The mother died 13 days after birth of her infant (7).

A 2006 report described the use of pamidronate before four uneventful pregnancies from three women (8). Treatment durations—interval between the last dose and conception (both in months) were: 46–3; 26–3 (first pregnancy) and 26–48 (second pregnancy); and 19–21. The four infants were healthy at birth and were developing normally. No evidence of biochemical or skeletal abnormality was found in the infants (8).

A woman with hereditary hyperphosphatasia was treated with pamidronate 1 mg/kg on 3 consecutive days every 4 months for 42 months (9). One month after the last cycle she conceived. The patient was given 1000 mg/day of elemental calcium but no vitamin D throughout pregnancy. The pregnancy was uneventful except for premature rupture of the membrane at 36 weeks' gestation, resulting in the birth of a 3130-g female infant with Apgar scores of 8 and 9. No structural anomalies, fractures or long bone deformities were noted in the infant. All laboratory tests were normal in the mother and infant shortly after birth and after 14 days of breastfeeding (9).

A 2008 review described 51 cases of exposure to bisphosphonates before or during pregnancy: alendronate (N = 32), pamidronate (N = 11), etidronate (N = 5), risedronate (N = 2), and zoledronic acid (N = 1) (10). The authors concluded that although these drugs may affect bone modeling and development in the fetus, no such toxicity has yet been reported.

BREASTFEEDING SUMMARY

Although the low molecular weight of the free acid (about 233), lack of metabolism, and prolonged elimination half-life suggest that pamidronate will be excreted into breast milk, a 2000 study was unable to detect the drug in milk. A 39-year-old woman with reflex sympathetic dystrophy delivered a healthy male infant at 40 weeks' gestation (11). She began breastfeeding, and several weeks later (exact time not stated), she began monthly treatments of IV

pamidronate 30 mg/infusion. After the infusion, she pumped and discarded her breast milk for 48 hours and then resumed nursing her infant. After the first dose, her breast milk was collected and separated into two pooled samples (0–24 and 25–48 hours). Pamidronate was not detected in either sample (detection limit 0.4 µmol/L) (11).

Breastfeeding during pamidronate treatment does not appear to place the nursing infant at risk.

Failure to detect the drug in milk in the above case might have been due to its low lipid solubility and acidic nature. Although the oral bioavailability of pamidronate in infants is not known, in adults it is very low, about 2% in the fasting state (2). Moreover, the drug is highly bound by calcium and should not be absorbable from milk. Based on these data, breastfeeding appears to be compatible with pamidronate therapy, but withholding nursing for 12–24 hours should ensure that the infant is exposed to little or no drug.

PANCURONIUM

Skeletal Muscle Relaxant

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Pancuronium has been administered directly to the fetus during the last half of pregnancy and to the mother at cesarean section without causing fetal harm. Although no teratogenicity was observed in two animal species, the use of pancuronium in early human pregnancy has not been reported. The drug is known to cross the human placenta to the fetus, at least near term. Placental transfer early in pregnancy has not been reported. Large or repetitive doses and/or prolonged dose-to-delivery intervals may potentially result in newborn depression, but the clinical significance of this appears to be low. Moreover, other anesthetic agents may contribute to the condition. In addition, transient fetal heart rate (FHR) changes, such as decreased accelerations and beat-to-beat variability, and an occasional sinusoidal-like pattern, have been observed after direct fetal administration, but apparently this does not indicate fetal compromise.

FETAL RISK SUMMARY

Pancuronium (pancuronium bromide) is a competitive (nondepolarizing) neuromuscular blocking agent. Structurally, it is a bisquaternary ammonium compound (i.e., contains two quaternary ammonium groups) and is commercially available as the dibromide. Pancuronium is used to induce skeletal muscle relaxation during anesthesia and other procedures and has been used to produce fetal muscle paralysis during intrauterine procedures.

Unpublished reproduction studies in rats and rabbits with pancuronium did not reveal any effect on the number of resorptions, litter size, birth weight and vitality, or the frequency of malformations (gross, skeletal, and internal organs) (1). Pregnant rats (average gestational length 21–22 days (2)) received

intraperitoneal doses of 0.16 mg/kg/day either from 7th to 14th day or from 1st to 20th day of gestation, whereas pregnant rabbits (average gestational length 31–34 days (2)) were given IV doses of 0.02 mg/kg/day from day 8 to day 16 of gestation.

Theoretically, the combination of relatively high molecular weight (about 733 for the dibromide) and the presence of two quaternary ammonium groups that are ionized at physiologic pH should limit the placental transfer of pancuronium. An animal study published in 1973 appeared to confirm the lack of significant transfer when cumulative IV doses up to 16.3 mg/kg administered to pregnant ferrets (neuromuscular blockade in the mother is complete at 0.015 mg/kg) did not cause neuromuscular blockade in the fetus during a 1-hour observation period (3). The fetus was responsive to pancuronium-induced blockade by direct administration. Further, the lack of adverse effects in newborns after mean doses of 0.0875 mg/kg at cesarean section led some authors to conclude that the drug did not cross the placenta (4). However, several human studies have demonstrated placental transfer, at least near term, when pancuronium was used during cesarean section (5–11).

Maternal IV bolus doses between 0.04 and 0.12 mg/kg (approximately 2.8–8.6 times the maternal ED₅₀, the dose producing a 50% depression of evoked twitch tension (12)) resulted in mean umbilical vein:maternal vein ratios ranging from 0.19 to 0.26. These ratios were higher than those measured with atracurium, fazadinium, pipecuronium, rocuronium, d-tubocurarine, and vecuronium (13). No clinical evidence of neuromuscular blockade was observed in five studies in which the neonatal condition was noted (5–9), but in one of the studies (9), the Neurological and Adaptive Capacity Scores (NACS) system indicated that neonatal depression was present. The NACS evaluates adaptive capacity, passive and active muscular tone, primary reflexes, and general assessment (13). The maximum score possible is 40 with a score of 35–40 denoting a normal, vigorous baby.

The NACS was measured at 15 minutes, 2 hours, and 24 hours in seven newborns whose mothers had been given IV doses of d-tubocurarine (3 mg), thiopental (4 mg/kg), succinylcholine (1.5 mg/kg), and pancuronium (0.04 mg/kg) immediately prior to cesarean section (9). Five newborns (71%) had an NACS value <35 at 15 minutes, three were <35 at 2 hours, and none were <35 at 24 hours (9). Although the NACS indicated depression, no neonatal adverse effects were actually observed (9). A 1998 review, commenting on this and other studies of neuromuscular relaxants in pregnancy, thought the low NACS values might have been caused by a contribution from the other anesthetic

agents (13).

The direct administration of pancuronium has been reported in animals and humans (14–38). A 1989 report compared the effects of pancuronium (0.5 mg/kg IV over 5 minutes) and d-tubocurarine (3.0 mg/kg IV over 5 minutes) on the heart rate and mean arterial pressure of fetal lambs (14). Whereas pancuronium significantly increased both rate and pressure, both measures were significantly decreased by d-tubocurarine. Only pancuronium affected fetal pH and Pco₂, increasing the former and decreasing the latter. The human studies, discussed below, all involve pancuronium administration during the second half of gestation.

In a study published in 1988, the baseline FHR, number of accelerations, and beat-to-beat variability were assessed before and after an IV bolus dose of pancuronium (0.05–0.10 mg/kg) was given to 17 fetuses before transfusion (15). Twenty minutes after transfusion, no changes were noted in the baseline FHR, although some heart rate patterns appeared “sinusoidal-like,” but significant decreases in accelerations ($p = 0.003$) and variability ($p = 0.0003$) were observed (15). The transient FHR changes were not indicative of fetal compromise and returned to normal when the fetus “awakened” (15). A 1991 abstract reported significantly less bradycardia with the use of pancuronium (0.3 mg/kg) compared with no muscle relaxant after cordocentesis (3.6% [8/224] vs. 8.2% [27/329], $p = 0.04$) and a near significant difference after intravascular transfusion (7.9% [9/114] vs. 40% [2/5], $p = 0.06$) (16).

Pancuronium (0.1 mg/kg IV) was administered to 20 fetuses immediately before blood transfusion at 28–34 weeks’ gestation (17). A control group of 20 fetuses matched for gestational age and hematocrit who did not receive pancuronium was used for comparison. After transfusion, compared with controls, fetuses receiving pancuronium had significantly fewer FHR accelerations (mean 0 vs. 3.0, $p < 0.0005$), less change in the baseline FHR (increase 1.5 beats/minute vs. decrease 4 beats/minute, $p < 0.0005$), lower mean minute range in FHR variation (17.3 vs. 34.7, $p < 0.0001$), and less short-term variation (3.4 vs. 7.35, $p = 0.0001$). Another study compared FHR changes after the use of pancuronium or vecuronium for intravascular transfusion, fetal thoracentesis, or paracentesis (18). Specific details were not provided for the pancuronium group, but the authors concluded that the pancuronium-induced increase in FHR and decrease in variability made it less desirable than vecuronium, which caused no FHR changes.

Fetal death at 25.5 weeks’ gestation, that was apparently the result of a cord hematoma, occurred 2 hours after an intravascular intrauterine transfusion

(19). The authors thought that the accident was related to the injection of pancuronium before confirmation of needle placement by aspiration of fetal blood. The results of an autopsy confirmed that the cause of death was compression of the umbilical vein by the hematoma with subsequent umbilical venous thrombosis.

Fetal administration of pancuronium immediately preceding magnetic resonance imaging has been described in a number of publications (20–28). Most used doses varying from 0.08 to 0.3 mg/kg (IV into the umbilical vein or IM) (20–25), two used 0.5 mg IM (26,27), and one reported 100 mg (sic) into the intrahepatic vein of each twin (28).

Direct fetal administration of pancuronium for intrauterine procedures, such as cordocentesis and intravascular transfusion, has been reported (29–38). The fetal dose ranged from 0.1 to 0.3 mg/kg IV or IM, but in one report, a single 0.5-mg IM dose was administered (29). In another study, pancuronium (0.15 mg/kg of the estimated total fetal body weights of twins) was administered in two cases to the smaller of a set of twins (38). The procedure was undertaken in an attempt to diagnose twin–twin transfusion syndrome. In the first case, the FHR patterns of both twins showed lack of accelerations and decreased variability and, in addition, the larger twin had a “sinusoidal-like” pattern. In the second case, absent accelerations and decreased variability occurred only in the smaller twin (38).

A continuous infusion of morphine, midazolam, and pancuronium was administered for 10 hours to allow mechanical ventilation in a seriously ill, pregnant (about 35 weeks) woman with pneumonia due to *Legionella pneumophila* (39). No evidence of fetal harm was observed during the infusion, but the fetus was noted to have a consistent pattern of “sleeping.” Approximately 3–4 weeks later, at 40 weeks’ gestation, the mother gave birth to a healthy female infant.

BREASTFEEDING SUMMARY

No reports describing the use of pancuronium in a lactating woman have been located. Because of the nature of the drug and its indications, such reports are unlikely to occur. Moreover, because pancuronium is a bisquaternary ammonium compound, it is ionized at physiologic pH. Only the nonionized form would be available for excretion into milk, and this would probably be only trace amounts (40). In addition, compounds of this type are poorly absorbed from the gastrointestinal tract (40).

PANITUMUMAB

Antineoplastic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of panitumumab in human pregnancy have been located. The animal reproduction data suggest risk, but the absence of human pregnancy experience prevents a more complete assessment of embryo and fetal risk. Until such data are available, the best course is to avoid the use of this antineoplastic in pregnancy. Women of reproductive age should use effective contraception. However, colorectal cancer can be fatal, so if a woman requires therapy with panitumumab and informed consent is obtained, treatment should not be withheld because of pregnancy. If an inadvertent pregnancy occurs, the woman should be advised of the potential risk for severe adverse effects in the embryo and fetus.

FETAL RISK SUMMARY

Panitumumab is a recombinant, human immunoglobulin G2 (IgG2) kappa monoclonal antibody. Panitumumab specifically binds to the human epidermal growth factor receptor (EGFR). It is indicated for the treatment of EGFR-expressing, metastatic colorectal carcinoma with disease progression on or following fluoropyrimidine-, oxaliplatin-, and irinotecan-containing chemotherapy regimens.

Panitumumab may cause severe, infusion-related toxicity, including hypotension and other adverse effects. The use of premedication before infusion was not standardized in clinical trials, so the efficacy of premedication to prevent infusion reactions is unknown (1). However, since premedication is recommended with other monoclonal antibodies, it is reasonable to use acetaminophen and an antihistamine (e.g., diphenhydramine) before each infusion of panitumumab. Moreover, hypotension in a pregnant woman could

have deleterious effects on placental perfusion resulting in embryo and fetal harm.

Reproduction studies have been conducted in cynomolgus monkeys. When panitumumab was given to monkeys during organogenesis (gestational days 20–50) in weekly doses that were 1.25–5 times the recommended human dose based on body weight (RHD), significant increases in embryolethal or abortifacient effects were observed. No structural anomalies in the offspring were observed (1).

The carcinogenic or mutagenic effects of panitumumab have not been studied. Panitumumab may adversely affect fertility. In female cynomolgus monkeys given weekly doses that were 1.25–5 times the RHD, prolonged menstrual cycles and/or amenorrhea were observed. The menstrual cycle irregularities were accompanied by both a decrease and delay in peak progesterone and 17β -estradiol levels. Normal menstrual cycles returned in most monkeys when panitumumab was stopped. A no-effect dose for menstrual cycle irregularities was not determined. No adverse effects were observed microscopically in reproductive organs of male cynomolgus monkeys given doses up to about 5 times the RHD for 26 weeks. However, the effects of this exposure on male fertility were not studied (1).

It is not known if panitumumab crosses the human placenta. The high molecular weight (about 147,000) suggests that it will not cross. As IgG does cross and, therefore, panitumumab may also cross. However, panitumumab was not detected in the serum of neonates from panitumumab-treated cynomolgus monkeys, but anti-panitumumab antibody titers were present in 14 of 27 offspring (1).

BREASTFEEDING SUMMARY

No reports describing the use of panitumumab during lactation have been located. The very high molecular weight (about 147,000) suggests that it will not be excreted into breast milk. However, human IgG is excreted into milk and, therefore, panitumumab may also be excreted (1). The effects of this potential exposure on a nursing infant are unknown, but immunosuppression and other severe adverse effects are potential complications.

PANTOPRAZOLE

Gastrointestinal Agent (Antisecretory)

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

The animal and limited human data suggest that pantoprazole represents a low risk in pregnancy. A study showing an association between in utero exposure to gastric acid-suppressing drugs and childhood allergy and asthma requires confirmation. Moreover, the human pregnancy experience with other proton pump inhibitors (PPIs) has not shown a causal relationship with congenital malformations. However, malformations may have been missed, because of the design and size of the studies. If pantoprazole is required or if inadvertent exposure does occur early in gestation, the known risk to the embryo–fetus appears to be low. Long-term follow-up of offspring exposed during gestation is warranted.

FETAL RISK SUMMARY

Pantoprazole is a PPI that blocks gastric acid secretion by a direct inhibitory effect on the gastric parietal cell. It is used for the short-term treatment of erosive esophagitis associated with gastroesophageal reflux disease (GERD). Pantoprazole is in the same class of PPIs as dexlansoprazole, esomeprazole, lansoprazole, omeprazole, and rabeprazole. It is extensively metabolized to inactive metabolites. The terminal elimination half-life is about 1 hour but is 3.5–10 hours in patients with altered metabolism (slow metabolizers). Serum protein binding, primarily to albumin, is about 98% (1).

Reproductive studies have been conducted in pregnant rats and rabbits at doses up to 88 and 16 times, respectively, the recommended human dose based on BSA. No evidence was found at these doses of impaired fertility or fetal harm (1).

Similar to other PPIs, pantoprazole is carcinogenic in mice and rats (gastrointestinal, liver, and thyroid) (1). The dose-related nature of the tumors

and the presumably limited in utero exposure to the drug during human gestation probably suggest a negligible risk. In addition, positive results were seen with pantoprazole in the in vitro human lymphocyte chromosomal aberration assays and in some mutagenic tests with mice, rats, and hamsters. In contrast, negative results were obtained in the in vitro Ames mutation assay, the mammalian cell-forward gene mutation assay, and in several other tests of mutagenicity (1).

It is not known if pantoprazole crosses the human placenta. The molecular weight (about 432 for the hydrated form) is low enough, but the short elimination half-life and high protein binding will limit the amount of drug available to cross at the maternal–fetal interface. Embryo–fetal exposure, however, may be higher in slow metabolizers because of the longer elimination half-life. Of interest, another PPI, omeprazole, has a similar molecular weight (about 345), elimination half-life (1 hour), and protein binding (about 95%), and is known to cross the human placenta. (See Omeprazole.)

A 2002 study conducted a meta-analysis involving the use of PPIs in pregnancy (2). In the 5 cohort studies analyzed, there were 593 infants, mostly exposed to omeprazole, but also including lansoprazole and pantoprazole. The relative risk (RR) for major malformations was 1.18, 95% confidence interval (CI) 0.72–1.94 (2).

A 2005 study by the European Network of Teratology Information Services reported the outcomes of pregnancies exposed to omeprazole (N = 295), lansoprazole (N = 62), or pantoprazole (N = 53) (3). In the pantoprazole group, the median duration of treatment was 14 days (range 7–23 days), and the dose used was 40 mg/day. The outcomes consisted of 1 spontaneous abortion (SAB), 3 elective abortions (EABs) (none for congenital anomalies), 1 stillbirth, and 48 live births. One infant exposed early in gestation (week 2 for 8 days) had congenital toxoplasmosis. Compared with a nonexposed control group, there was no difference in the rate of major malformations between the pantoprazole and control groups (RR 0.55, 95% CI 0.08–3.95). Similar results were observed for omeprazole and lansoprazole (3).

A population-based observational cohort study formed by linking data from three Swedish national health care registers over a 10-year period (1995–2004) was reported in 2009 (4). The main outcome measures were a diagnosis of allergic disease or a prescription for asthma or allergy medications. The drug types included in the study were gastric acid suppressors, including H₂-receptor antagonists, prostaglandins, PPIs, combinations for eradication of *Helicobacter pylori*, and drugs for peptic ulcer disease and GERD. Of 585,716 children,

29,490 (5.0%) met the diagnosis and 5645 (1%) had been exposed to gastric acid-suppression therapy in pregnancy. Of these children, 405 (0.07%) were treated for allergic disease. For developing allergy, the odds ratio (OR) was 1.43, 98% CI 1.29–1.59, irrespective of the drug, time of exposure during pregnancy, and maternal history of allergy. For developing childhood asthma, but not other allergic diseases, the OR was 1.51, 95% CI 1.35–1.69, irrespective of the type of acid-suppressive drug and the time of exposure in pregnancy. The authors proposed three possible mechanisms for their findings: (a) exposure to increased amounts of allergens could cause sensitization to digestion labile antigens in the fetus, (b) maternal Th2 cytokine pattern could promote an allergy-prone phenotype in the fetus, and (c) maternal allergen-specific immunoglobulin E could cross the placenta and sensitize fetal immune cells to food and airborne allergens. Several limitations of the study that might have affected their findings were identified, including a general increase in childhood asthma but not necessarily an increase in allergic asthma (4). The study requires confirmation.

A second meta-analysis of PPIs in pregnancy was reported in 2009 (5). Based on 1530 exposed compared with 133,410 not-exposed pregnancies, the OR for major malformations was 1.12, 95% CI 0.86–1.45. There also was no increased risk for SABs (OR 1.29, 95% CI 0.84–1.97) or preterm birth (OR 1.13, 95% CI 0.96–1.33) (5).

In a 2010 study from Denmark, covering the period 1996–2008, there were 840,968 live births among whom 5082 were exposed to PPIs between 4 weeks before conception to the end of the 1st trimester (6). In the exposed group there were 174 (3.4%) major malformations compared with 21,811 (2.6%) not exposed to PPIs (adjusted prevalence odds ratio [aPOR] 1.23, 95 CI 1.05–1.44). When the analysis was limited to exposure in the 1st trimester, there were 118 (3.2%) major malformations among 3651 exposed infants (aPOR 1.10, 95% CI 0.91–1.34). For exposure to pantoprazole in the 1st trimester, there were 21 (3.8%) major birth defects among 549 live births (aPOR 1.33, 95% CI 0.85–2.08) (see Esomeprazole, Lansoprazole, Omeprazole, and Rabeprazole for their data). The data showed that exposure to PPIs in the 1st trimester was not associated with a significantly increased risk of major birth defects (6). An accompanying editorial discussed the strengths and weaknesses of the study (7).

In a 2012 publication, the National Birth Defects Prevention study, a multisite population-based case-control study, examined whether nausea/vomiting of pregnancy (NVP) or its treatment were associated with the most common

noncardiac defects (nonsyndromic cleft lip with or without cleft palate [CL/P], cleft palate alone [CP], neural tube defects [NTDs], and hypospadias) (8). PPI exposure included esomeprazole, lansoprazole, and omeprazole. There were 4524 cases and 5859 controls. NVP was not associated with cleft palate or NTDs, but modest risk reductions were observed for CL/P and hypospadias. Increased risks were found for PPIs (N = 7) and hypospadias (adjusted OR [aOR] 4.36, 95% CI 1.21–15.81), steroids (N = 10) and hypospadias (aOR 2.87, 95% CI 1.03–7.97), and ondansetron (N = 11) and CP (aOR 2.37, 95% CI 1.18–4.76) (8).

Another 2012 study, using the Danish nationwide registries, evaluated the risk of hypospadias after exposure to PPIs during the 1st trimester and throughout gestation (9). The study period, 1997 through 2009, included all liveborn boys that totaled 430,569 of whom 2926 were exposed to maternal PPI use. Hypospadias was diagnosed in 20 (0.7%) exposed boys, whereas 2683 (0.6%) of the nonexposed had hypospadias (adjusted prevalence ratio [aPR] 1.1, 95% CI 0.7–1.7). For the 5227 boys exposed throughout pregnancy, 32 (0.6%) had hypospadias (PR 1.0, 95% CI 0.7–1.4). When the analysis was restricted to mothers with 2 or more PPI prescriptions, the aPR of overall hypospadias was 1.7 (95% CI 0.9–3.3), and 1.6 (95% CI 0.7–3.9) for omeprazole. The authors concluded that PPIs were not associated with hypospadias (9).

A large retrospective cohort study from Israel covering the period 1998–2009 was published in 2012 (10). Among 114,960 live births, there were 110,783 singletons and 1239 EABs. Major malformations were observed in 6037 (5.5%) singletons and in 468 abortuses. Exposure to a PPI (lansoprazole, omeprazole, or pantoprazole) during the 1st trimester occurred in 1186 (1159 infants and 27 abortuses). In the exposed infants and abortuses, 80 (6.7%) had a major malformation compared with 6425 (5.9%) not exposed (aOR 1.06, 95% CI 0.84–1.33). A separate analysis with pantoprazole was not possible because of the limited number of exposures. However, the overall data showed that exposure to PPIs during the 1st trimester was not associated with an increased risk of major defects. Moreover, additional analysis revealed that exposure during the 3rd trimester was not associated with increased risk of perinatal mortality, premature delivery, low birth weight, or low Apgar scores (10).

Five reviews on the treatment of GERD have concluded that PPIs can be used in pregnancy with relative safety (11–15). Because there is either very limited or no human pregnancy data for the three newest agents in this class (dexlansoprazole, esomeprazole, and rabeprazole), other drugs in the class are

preferred.

BREASTFEEDING SUMMARY

Small amounts of pantoprazole are excreted into breast milk. A 43-year-old mother, partially nursing a healthy 10-month-old, 8.2-kg, female infant was given a single 40-mg enteric-coated pantoprazole tablet (16). Breastfeeding was held while nine samples of maternal serum and six of breast milk were obtained over a 24-hour interval. The milk samples, about 10 mL each, were obtained at 0, 2, 4, 6, 8, and 24 hours postdose. Pantoprazole was detected only in the 2-hour (0.036 mg/L) and 4-hour (0.024 mg/L) samples, resulting in an estimated AUC of 0.103 mg·hr/L. The milk AUC was about 2.8% of the AUC for plasma. The peak maternal plasma concentration, 1.65 mg/L, occurred at 2 hours, but the levels were <0.025 mg/L at 8 and 24 hours postdose. If the infant had been nursing, the authors estimated that the infant dose would have been ≤0.14% of the weight-adjusted maternal dose (16).

The results of the above case are consistent with the relatively low molecular weight (about 432 for the hydrated form) that suggests pantoprazole will be excreted into breast milk. In addition, pantoprazole is unstable at acidic pH so the amount actually absorbed by the infant may have been less than estimated (16).

PANTOTHENIC ACID

Vitamin

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No reports of maternal or fetal complications associated with pantothenic acid have been located.

FETAL RISK SUMMARY

Pantothenic acid, a water-soluble B-complex vitamin, acts as a coenzyme in the metabolism or synthesis of a number of carbohydrates, proteins, lipids, and steroid hormones (1). The U.S. recommended daily allowance (RDA) for pantothenic acid or its derivatives (dexpantenol and calcium pantothenate) in pregnancy is 10.0 mg (2).

Deficiency of this vitamin was not found in two studies evaluating maternal vitamin levels during pregnancy (3,4). Like other B-complex vitamins, newborn pantothenic acid levels are significantly greater than maternal levels (3–6). At term, mean pantothenate levels in 174 mothers were 430 ng/mL (range 250–710 ng/mL) and in their newborns 780 ng/mL (range 400–1480 ng/mL) (3). Placental transfer of pantothenate to the fetus is by active transport, but it is slower than transfer of other B-complex vitamins (7,8). In one report, low-birth-weight infants had significantly lower levels of pantothenic acid than did normal-weight infants (6).

BREASTFEEDING SUMMARY

Pantothenic acid is excreted in breast milk with concentrations directly proportional to intake (9,10). With a dietary intake of 8–15 mg/day, mean milk concentrations average 1.93–2.35 mcg/mL (9). In a group of mothers who had delivered premature babies (28–34 weeks' gestational age), pantothenic acid milk levels were significantly greater than a comparable group with term babies (39–41 weeks) (10). Milk levels in the preterm group averaged 3.91 mcg/mL up to 40 weeks' gestational age and then fell to 3.16 mcg/mL. For the term group,

levels at 2 and 12 weeks postpartum were 2.57 and 2.55 mcg/mL, respectively. A 1983 English study measured pantothenic acid levels in pooled human milk obtained from preterm (26 mothers: 29–34 weeks) and term (35 mothers: ≥39 weeks) patients (11). Milk from mothers of preterm infants rose from 1.29 mcg/mL (colostrum) to 2.27 mcg/mL (16–196 days), whereas milk from mothers of term infants increased during the same period from 1.26 to 2.61 mcg/mL.

An RDA for pantothenic acid during lactation has not been established. However, because this vitamin is required for good health, amounts at least equal to the RDA recommendation for pregnancy are recommended. If the diet of the lactating woman adequately supplies this amount, maternal supplementation with pantothenic acid is probably not required. Supplementation with the pregnancy RDA recommendation for pantothenic acid is recommended for those women with inadequate nutritional intake.

PARAMETHADIONE

[Withdrawn from the market. See 8th edition.]

PAREGORIC

Antidiarrheal

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Paregoric is a mixture of opium powder, anise oil, benzoic acid, camphor, glycerin, and ethanol. Its action is mainly caused by morphine (see also Morphine). High or chronic use near term could result in neonatal depression and/or withdrawal. There also is concern that exposure to opioids during organogenesis, including morphine, results in a low absolute risk of congenital anomalies.

FETAL RISK SUMMARY

Paregoric is indicated for the treatment of diarrhea. Animal reproduction studies have not been conducted with paregoric or morphine. Although long-term animal studies have not been conducted, paregoric has no known carcinogenic or mutagenic potential (1).

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 90 of whom had 1st trimester exposure to paregoric (2, pp. 287–295). For use anytime during pregnancy, 562 exposures were recorded (2, p. 434). No evidence was found to suggest a relationship to large categories of major or minor malformations or to individual defects.

BREASTFEEDING SUMMARY

The active component of paregoric, morphine, is thought to be compatible with breastfeeding (see Morphine). However, high doses or chronic use might have long-term effects on a nursing infant.

PARGYLINE

[Withdrawn from the market. See 9th edition.]

PARICALCITOL

Vitamin

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of paricalcitol in human pregnancy have been located. The drug did not cause structural anomalies in animals, but high doses did cause toxicity that was thought to be secondary to hypercalcemia. Human pregnancy experience with vitamin D and calcitriol indicates that recommended doses are safe in pregnancy. There is no evidence that the effects of recommended doses of paricalcitol would be any different. However, if the mother is taking paricalcitol, she should not take pharmacologic doses of vitamin D and its derivatives (1).

FETAL RISK SUMMARY

Paricalcitol is a synthetic analog of calcitriol, the physiologically active form of vitamin D. (See also Calcitriol and Vitamin D.) Paricalcitol, oral or IV, is indicated for the prevention and treatment of secondary hyperparathyroidism associated with chronic kidney disease. The vitamin is well absorbed (72%) and is extensively bound to plasma proteins ($\geq 99.8\%$). Paricalcitol also is extensively metabolized. The plasma half-life in healthy individuals is 4–6 hours, but it is 17–20 hours in patients with chronic kidney disease (1).

Reproduction studies have been conducted in pregnant rabbits and rats. In these species, daily doses 0.5 and 2 times, respectively, the recommended human dose based on BSA (RHD) were associated with minimal decreases (5%) in fetal viability. In rats, a dose 13 times the RHD given 3 times weekly caused a significant increase in the mortality of newborn pups, but this dose also was maternally toxic. Long-term studies for carcinogenicity revealed an increased incidence of uterine leiomyoma and leiomyosarcoma in mice and uterine leiomyoma and benign adrenal pheochromocytoma in rats. Assays for

mutagenic or clastogenic effects were negative, as was impairment of fertility in male and female rats (1).

Paricalcitol crosses the rat placenta (1), but studies in humans have not been located. The molecular weight (about 417) and the elimination half-life suggest that paricalcitol will cross to the embryo and fetus. Moreover, both vitamin D and calcitriol cross the human placenta (see Vitamin D) but do so slowly. Therefore, paricalcitol probably crosses placenta, but the extensive metabolism and plasma protein binding should limit the amount reaching the embryo and/or fetus.

BREASTFEEDING SUMMARY

No reports describing the use of paricalcitol during human lactation have been located. The molecular weight (about 417) and the long elimination half-life in patients with chronic kidney disease (17–20 hours) suggest that the vitamin will be excreted into breast milk. However, the extensive metabolism and plasma protein binding should limit the amount in milk. Women who are nursing and taking paricalcitol should consider not taking vitamin supplements containing vitamin D. Whether such a woman does or does not, serum calcium levels in the nursing infant should be monitored.

PARNAPARIN

[Withdrawn from the market. See 9th edition.]

PAROMOMYCIN

Antibiotic (Aminoglycoside)/Amebicide

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Paromomycin is an aminoglycoside antibiotic used for intestinal amebiasis. No reports linking this agent with congenital malformations have been located. Because it is poorly absorbed, with almost 100% of an oral dose excreted unchanged in the feces, little if any of the drug will reach the fetus.

FETAL RISK SUMMARY

Two women, one at 13 weeks' and the other at 23 weeks' gestation, were treated for a symptomatic intestinal infection caused by *Giardia lamblia* (1). Both delivered normal female infants at term. A 1985 review of intestinal parasites and pregnancy concluded that treatment of the pregnant patient should only be considered if the "parasite is causing clinical disease or may cause public health problems" (2). When indicated, paromomycin has been recommended for the treatment of protozoan infections caused by *G. lamblia* and *Entamoeba histolytica* and for tapeworm infestations occurring during pregnancy (2).

BREASTFEEDING SUMMARY

Paromomycin excretion in human milk is not expected as the drug is not absorbed into the systemic circulation after oral dosing.

PAROXETINE

Antidepressant

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

A public health advisory was issued by the FDA regarding paroxetine on December 8, 2005 (1). The advisory cited evidence from two epidemiologic studies (2,3) that paroxetine use in the 1st trimester was associated with a 1.8-fold increased risk for congenital malformations overall and a 1.5- to 2.0-fold increased risk for cardiac defects (most were atrial or ventricular septal defects). The advisory noted that the pregnancy category for paroxetine had been changed from C to D and that paroxetine should be avoided, if possible, in the 1st trimester of pregnancy (1). The results of two 2007 case–control studies suggested that the absolute risk of any birth defect with paroxetine and other selective serotonin reuptake inhibitors (SSRIs) is low (4,5). One study found an increased risk from SSRIs (the highest risk was with paroxetine alone) for a group of three defects (anencephaly, craniosynostosis, and omphalocele) (5), but the other did not (3), and neither found a relationship with ventricular septal defects. In addition, one study found an association between paroxetine and four specific defects: anencephaly, gastroschisis, omphalocele, and right ventricular outflow tract obstruction lesions (4). The second study did not find an increased risk with the first three defects but did so for the cardiac defect (5). That study also reported that paroxetine was associated with neural tube defects and clubfoot. Although developmental toxicity is well known to be dose related, only one study has considered dosage, finding that doses >25 mg/day were related to major malformations and cardiac defects (6). An accompanying editorial highlighted the findings and limitations of these studies, concluding that the absolute risk of major malformations was likely to be low (7). For right ventricular outflow tract obstruction defects and all congenital heart defects, it was thought to be unlikely that the absolute risks would exceed 1% and 2%, respectively (7).

There also is evidence, but not conclusive, that SSRI antidepressants, including paroxetine, are associated with higher risks of other developmental toxicities, including spontaneous abortions (SABs), low birth weight, prematurity, neonatal serotonin syndrome, neonatal behavioral syndrome (withdrawal), possibly sustained abnormal neurobehavior beyond the neonatal period, respiratory distress, and persistent pulmonary hypertension of the newborn (PPHN).

Although more data have accumulated since publication of the above references, the issue whether or not paroxetine and other SSRIs cause structural anomalies is still being debated. One reason cited in a joint statement from the American Psychiatric Association and the American College of Obstetricians and Gynecologists (see reference 60) is the adequacy of the research that has not completely controlled for other factors that could influence birth outcomes, such as maternal illness or problematic health behaviors that could adversely affect pregnancy. Although avoiding the use of paroxetine in pregnancy, especially high doses, may be an option, the apparently low risk of embryo–fetal harm must be balanced against the risk of untreated or undertreated depression. The decision to use or not use paroxetine, or any other antidepressant, must be made on a case-by-case basis. If paroxetine is used in pregnancy, or if inadvertent exposure occurs, the woman should be counseled as to the potential, albeit low, risks for birth defects and the higher risks for complications in the newborn.

FETAL RISK SUMMARY

Paroxetine is an SSRI antidepressant. Its chemical structure is unrelated to other antidepressants, including those classified as SSRI agents. Paroxetine is metabolized to inactive metabolites. About 95% is bound to plasma protein and the mean plasma elimination half-life is about 21 hours (2).

All of the antidepressant agents in the SSRI class (citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline) share a similar mechanism of action but have different chemical structures. These differences could be construed as evidence against any conclusion that they share similar effects on the embryo, fetus, or newborn. In the mouse embryo, however, craniofacial morphogenesis appears to be regulated, at least in part, by serotonin. Interference with serotonin regulation by chemically different inhibitors produces similar craniofacial defects (8). Regardless of the structural differences,

therefore, some of the potential adverse effects on pregnancy outcome may also be similar.

In reproduction studies with rats and rabbits, paroxetine was not teratogenic at doses that were equivalent to 9.7 and 2.2 times, respectively, the maximum recommended human dose based on BSA (MRHD) for depression and social anxiety disorder (DSAD), and 8.1 and 1.9 times, respectively, the MRHD for obsessive-compulsive disorder (OCD). In rats dosed at 0.19 times the MRHD for DSAD and 0.16 times the MRHD for OCD, there was an increase in pup deaths when paroxetine was used during the last trimester and continued during lactation. The cause of the deaths was not known (2). In another study, no embryotoxic or teratogenic effects were observed in either of these species at doses similar to those used above (9).

The effects of paroxetine on behavioral changes in developing mice have been studied (10,11). The drug was administered for 2 weeks before conception and throughout gestation. A similar group of mice were administered placebo for comparison. The daily dose was known to achieve levels in the mouse serum equivalent to the upper human therapeutic level and to obtain levels in the fetal mouse brain equivalent to those in the adult mouse (11). No drug-induced facial abnormalities were seen nor were there any differences between the exposed and control groups in terms of pregnancy duration, litter size, and sex ratio. Body weights, however, were significantly lower for the exposed pups (both male and female) at least through postnatal day 5. Most of the behavioral tests showed no differences between the groups, but subtle differences in anxiety testing and adult male aggressiveness were noted. These effects may have resulted from the effect of paroxetine on the development of the postsynaptic serotonin (1A) receptors (11).

Consistent with the molecular weight (about 329 for the free base), paroxetine crosses the human placenta. A 2003 study of the placental transfer of SSRI antidepressants found cord blood:maternal serum ratios of 0.05–0.91 (12). The dose-to-delivery interval was 6–40 hours with the highest ratio occurring at 21 hours.

Congenital Malformations

By 1995, the FDA had received 10 reports of birth defects involving paroxetine, including 4 involving clubfoot and 2 cases of cutaneous hemangioma (F. Rosa, personal communication, FDA, 1995).

The results of a postmarketing survey of paroxetine, conducted in England between March 1991 and March 1992, were published in 1993 (13). A total of

137 pregnancies were identified, including 66 in which the drug was stopped before the last menstrual period. In this group, there were 12 deliveries, 9 SABs, 5 elective abortions (EABs), and 40 unknown outcomes. Among the remaining 71 pregnancies, 63 were known to be exposed during the 1st trimester, but the dates of exposure were uncertain in 8. The outcomes in the combined exposed group were 44 newborns (3 sets of twins; 1 twin stillborn [cause not specified]), 9 SABs, 12 EABs, and 9 unknown outcomes. There were no congenital anomalies in the liveborn infants (data not provided for the abortions or stillborn) (13).

A 1998 noninterventional observational cohort study described the outcomes of pregnancies in women who had been prescribed ≥ 1 of 34 newly marketed drugs by general practitioners in England (14). Data were obtained by questionnaires sent to the prescribing physicians 1 month after the expected or possible date of delivery. In 831 (78%) of the pregnancies, a newly marketed drug was thought to have been taken during the 1st trimester with birth defects noted in 14 (2.5%) singleton births of the 557 newborns (10 sets of twins). In addition, two birth defects were observed in aborted fetuses. However, few of the aborted fetuses were examined. Paroxetine was taken during the 1st trimester in 63 pregnancies. The outcomes of these pregnancies included 8 SABs, 11 EABs, 1 intrauterine death, 2 stillborns (twins), 3 cases lost to follow-up, 41 normal infants (3 premature plus 2 sets of full-term twins). No birth defects were noted in any of the outcomes (14).

In a 1996 descriptive case series, the European Network of the Teratology Information Services (ENTIS) prospectively examined the outcomes of 689 pregnancies exposed to antidepressants (15). Multiple drug therapy occurred in about two-thirds of the mothers. Paroxetine was used in three pregnancies, all with normal outcomes.

A prospective, multicenter, controlled cohort study published in 1998 evaluated the pregnancy outcomes of 267 women exposed to ≥ 1 of 3 SSRI antidepressants during the 1st trimester: fluvoxamine (N = 26); paroxetine (N = 97); and sertraline (N = 147) (16). The women were combined into a study group without differentiation as to the drug they had consumed. A randomly selected control group (N = 267) was formed from women who had exposures to nonteratogenic agents. In most cases, the pregnancy outcomes were determined 6–9 months after delivery. No significant differences were measured in the number of live births, SABs, EABs, stillbirths, major malformations, birth weight, or gestational age at birth. Nine major malformations were observed in each group. The relative risk (RR) for major

anomalies was 1.06 (95% confidence interval [CI] 0.43–2.62). No clustering of defects was apparent. The outcomes of women who took an antidepressant throughout gestation were similar to those who took an antidepressant only during the 1st trimester (16). All of the women in the study group had taken an antidepressant during embryogenesis (17).

A 2005 meta-analysis of 7 prospective comparative cohort studies involving 1774 patients was conducted to quantify the relationship between 7 newer antidepressants and major malformations (18). The antidepressants were bupropion, fluoxetine, fluvoxamine, nefazodone, paroxetine, sertraline, and trazodone. There was no statistical increase in the risk of major birth defects above the baseline of 1%–3% in the general population for the individual or combined studies (18).

A brief 2005 report described significant associations between the use of SSRIs in the 1st trimester and congenital defects (19). The data were collected by the CDC-sponsored National Birth Defects Prevention Study in an ongoing case–control study of birth defect risk factors. Case infants (N = 5357) with major birth defects were compared with 3366 normal controls. A positive association was found with omphalocele (161 cases; odds ratio [OR] 3.0, 95% CI 1.4–6.1). Paroxetine, which accounted for 36% of all SSRI exposures, had the strongest association with the defect (OR 6.3, 95% CI 2.0–19.6). The study also found a significant association between the use of any SSRI and craniosynostosis (372 cases; OR 1.8, 95% CI 1.0–3.2) (19).

In an expansion of the above CDC-sponsored study, 9622 case infants with major birth defects were compared with 4092 control infants selected randomly from the same geographic areas (4). The reported use of SSRIs in the period 1 month before to 3 months after conception was 2.4% (230 case mothers) and 2.1% (86 control mothers). Although the study found no significant associations between early gestational exposure to SSRIs overall and congenital heart defects (includes four types and eight subtypes), spina bifida, oral clefts, or nine other defects, significant associations were found with anencephaly (OR 2.4, 95% CI 1.1–5.1, p 0.02), craniosynostosis (OR 2.5, 95% CI 1.5–4.0, p <0.001), and omphalocele (OR 2.8, 95% CI 1.3–5.7, p 0.005). The use of paroxetine (OR 4.2, 95% CI 2.1–8.5) or citalopram (OR 4.0, 95% CI 1.3–11.9) significantly increased the risk for the combined three defects. For the three most commonly used SSRIs and individual defects, increased risks were found with fluoxetine (craniosynostosis N = 10, OR 2.8, 95% CI 1.3–6.1), sertraline (anencephaly N = 4, OR 3.2, 95% CI 1.1–9.3), and paroxetine (anencephaly N = 5, OR 5.1, 95% CI 1.7–15.3; right ventricular outflow tract obstruction N = 7,

OR 2.5, 95% CI 1.0–6.0; omphalocele N = 6, OR 8.1, 95% CI 3.1–20.8; and gastroschisis N = 5, OR 2.9, 95% CI 1.0–8.4). However, the absolute risks for these defects are small and require confirmation (4).

In a multicenter, prospective controlled study, the pregnancy outcomes of three groups of women were evaluated: (a) paroxetine 330 (286 in the 1st trimester); (b) fluoxetine 230 (206 in the 1st trimester); and (c) 1141 exposures not known to cause birth defects (20). Compared with controls, there was a higher rate of congenital defects among those exposed to 1st trimester paroxetine, 5.1% vs. 2.6%, RR 1.92, 95% CI 1.01–3.65. There also was a higher rate for cardiovascular anomalies, 1.9% vs. 0.6%, RR 3.46, 95% CI 1.06–11.42. In addition, perinatal complications were more prevalent in both SSRI groups than in controls (20).

A meta-analysis of clinical trials (1990–2005) with SSRIs was reported in 2006 (21). The SSRI agents included were citalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline. The specific outcomes analyzed were major, minor, cardiac malformations, and SABs. The OR with 95% CI for the four outcomes were 1.394 (0.906–2.145), 0.97 (0.13–6.93), 1.193 (0.531–2.677), and 1.70 (1.28–2.25), respectively. Only the risk of SABs was significantly increased (21).

In 1999, the Swedish Medical Birth Registry compared the use of antidepressants in early pregnancy and delivery outcomes for the years 1995–1997 (22). There were no significant differences for birth defects, infant survival, or risk of low birth weight (<2500 g) among singletons between those exposed to any antidepressant, SSRIs only, or non-SSRIs only, but a shorter gestational duration (<37 weeks) was observed for any antidepressant exposure (OR 1.43, 95% CI 1.14–1.80) (22). A second Registry report, published in 2006 covering the years 1995–2003, analyzed the relationship between antidepressants and major malformations or cardiac defects (3). There was no significant increase in the risk of major malformations with any antidepressant. The strongest effect among cardiac defects was with ventricular or atrial septum defects (VSDs-ASDs). Significant increases were found with paroxetine (OR 2.22, 95% CI 1.39–3.55) and clomipramine (OR 1.87, 95% CI 1.16–2.99) (3). In 2007, the analysis was expanded to include the years 1995–2004 (23). There were 6481 women (6555 infants) who had reported the use of SSRIs in early pregnancy. The number of women using a single SSRI during the 1st trimester was 2579 citalopram, 1807 sertraline, 908 paroxetine, 860 fluoxetine, 66 escitalopram, and 36 fluvoxamine. After adjustment, only paroxetine was significantly associated with an increased risk

of cardiac defects (N = 13, RR 2.62, 95% CI 1.40–4.50) or VSDs-ASDs (N = 8, RR 3.07, 95% CI 1.32–6.04). Analysis of the combined SSRI group, excluding paroxetine, revealed no associations with these defects. The study found no association with omphalocele or craniostenosis (23).

In 2006, the manufacturer reported the findings of a retrospective cohort study using United States United Healthcare data (2). There were 5956 infants of mothers dispensed paroxetine or other antidepressants during the 1st trimester, including 815 for paroxetine. Compared with other antidepressants, there was a trend for increased risk of cardiovascular defects with paroxetine (12 cases, OR 1.5, 95% CI 0.8–2.9). Nine of the paroxetine cases had VSDs. There also was an increased risk of overall major anomalies with paroxetine compared with other antidepressants (OR 1.8, 95% CI 1.2–2.8). The prevalence of all congenital defects was 4% for paroxetine vs. 2% for other antidepressants (2).

A cohort study from Denmark compared the number of infants with congenital malformations from mothers who either took or did not take an SSRI during the first 3 months of pregnancy (24). The 1051 women who filled a prescription for an SSRI from 30 days before conception to the end of the 1st trimester gave birth to 51 (4.9%) infants with a defect compared with 5112 (3.4%) infants from 150,780 control mothers (RR 1.34, 95% CI 1.00–1.79). For 453 women who filled such a prescription in the 2nd and 3rd months of pregnancy, 31 (6.8%) of whom had an infant with a defect, the RR was 1.84, 95% CI 1.25–2.71 (24).

A 2007 study evaluated the association between 1st trimester exposure to paroxetine and cardiac defects by quantifying the dose–response relationship (6). A population-based pregnancy registry was used by linking three administrative databases so that it included all pregnancies in Quebec between 1997 and 2003. There were 101 infants with major congenital defects, 24 involving the heart, among the 1403 women using only one type of antidepressant during the 1st trimester. The use of paroxetine or other SSRIs did not significantly increase the risk of major defects or cardiac defects compared with non-SSRI antidepressants. However, a paroxetine dose >25 mg/day during the 1st trimester was significantly associated with an increased risk of major defects (OR 2.23, 95% CI 1.19–4.17) and of cardiac defects (OR 3.07, 95% CI 1.00–9.42) (6).

A study published in 2007 was conducted to determine if paroxetine exposure in the 1st trimester was associated with congenital malformations (25). Exposure to the antidepressants was based on drug dispensing and

timing was based on estimated dates of conception for singleton and multi-gestations. Using data collected in 1995–2004, the study cohorts included 1020 infants exposed to paroxetine monotherapy or polytherapy in the 1st trimester, and a subset of 815 infants exposed only to paroxetine monotherapy in the 1st trimester. The comparison cohorts, exposed to other antidepressants, were 4936 exposed to monotherapy or polytherapy, and a subset of 4198 infants exposed only to monotherapy in the 1st trimester. The adjusted odds ratios (AORs) for all paroxetine-associated congenital malformations were 1.89 (95% CI 1.20–2.98) for monotherapy, and 1.76 (95% CI 1.18–2.64) for monotherapy or polytherapy. For cardiovascular malformations, the AORs for the two groups were 1.46 (95% CI 0.74–2.88) and 1.68 (95% CI 0.95–2.97), respectively. A number of study limitations were discussed, such as missing data from charts that could not be assessed and the inability to document actual consumption of the antidepressants. The investigators concluded that the findings suggested a possible modest increased occurrence of congenital defects compared with other antidepressants (25).

A 2007 review conducted a literature search to determine the risk of major congenital malformations after 1st trimester exposure to SSRIs and SNRIs (26). Fifteen controlled studies were analyzed. The data were adequate to suggest that citalopram, fluoxetine, sertraline, and venlafaxine were not associated with an increased risk of congenital defects. In contrast, the analysis did suggest an increased risk with paroxetine. The data were inadequate to determine the risk for the other SSRIs and SNRIs (26).

Data collected in the period 1993–2004 by the Slone Epidemiology Center Birth Defects Study and reported in 2007 evaluated associations between 1st trimester use of SSRIs (defined as exposure 28 days before to 112 days after the last menstrual period) and the risk of major birth defects (5). There were 9849 case infants with major malformations and 5860 control infants without malformations. Two analyses were conducted: one on defects previously associated with SSRIs (craniosynostosis, omphalocele, and cardiac defects) and the other on some defects not previously reported to be associated with SSRI exposure. For outcomes previously reported, only the cardiac anomaly, right ventricular outflow tract obstruction defect, was associated with the use of any SSRI (OR 2.0, 95% CI 1.1–3.6). Paroxetine also was associated with that defect (OR 3.3, 95% CI 1.3–8.8). Sertraline was associated with an increased risk of omphalocele (OR 5.7, 95% CI 1.6–20.7) and septal defects (OR 2.0, 95% CI 1.2–4.0). For defects not previously associated with SSRIs, increased risks were found with sertraline (anal atresia, OR 4.4, 95% CI 1.2–16.4; and

limb reduction defects, OR 3.9, 95% CI 1.1–13.5) and paroxetine (neural tube defects, OR 3.3, 95% CI 1.1–10.4; and clubfoot, OR 5.8, 95% CI 2.6–12.8). The use of any SSRI also was associated with clubfoot (OR 2.2, 95% CI 1.4–3.6). Additional studies are required but, even if confirmed, the absolute risks are small because the estimated prevalence of the defects also is small (e.g., the prevalence of anal atresia and right ventricular outflow tract obstruction defect are both thought to be 5.5 cases per 10,000 live births). Thus, an increased risk of four would mean an absolute risk of 0.2% (5).

A 2003 prospective study evaluated the pregnancy outcomes of 138 women treated with SSRIs antidepressants during gestation (27). The number of women using each agent was 73 fluoxetine, 36 sertraline, 19 paroxetine, 7 citalopram, and 3 fluvoxamine. Most (62%) took an SSRI throughout pregnancy and 95% were taking an SSRI at delivery. Birth complications were observed in 28 infants, including preterm birth (9 cases), meconium aspiration, nuchal cord, floppy at birth, and low birth weight. Four infants (2.9%) had low birth weight, all exposed to fluoxetine (40–80 mg/day) throughout pregnancy, including two of the three infants of mothers taking 80 mg/day. One infant had Hirschsprung disease, a major defect, and another had cavum septi pellucidi (neither the size of the cavum nor the SSRI agents were specified) (27). The clinical significance of cavum septi pellucidi is doubtful as it is nearly always present at birth but resolves in the first several months (28).

A 2008 retrospective case–control study from the province of Quebec involved 2329 women who had used antidepressants, 189 (8.1%) of whom had a baby with a major defect (29). The antidepressants were SSRIs, tricyclics, and newer classes of antidepressants. No association was found between the duration of antidepressant use during the 1st trimester and major congenital defects (29).

In 2008, Teratogen Information Services (TISs) in Jerusalem, Italy, and Germany reported a prospective, case–controlled, multicenter, observational study for major congenital anomalies (30). Women taking paroxetine (N = 348) or fluoxetine (N = 253) in the 1st trimester were compared with women exposed to nonteratogens (N = 1467). Significant increases in major anomalies were found for paroxetine (5.5%) and fluoxetine (5.9%) compared with controls (2.9%). After logistic regression analysis, cigarette smoking of ≥ 10 cigarettes/day (OR 5.4, 95% CI 1.76–16.54) and fluoxetine (OR 4.47, 95% CI 1.31–15.27) were significant variables for cardiovascular anomalies but not paroxetine (2.66, 95% CI 0.80–8.90) (30).

In a 2008 report, investigators gathered unpublished data from eight TISs on

1174 infants exposed in utero to paroxetine during the 1st trimester (31). In addition, information was obtained from five published database studies regarding 2061 cases of 1st trimester exposure to paroxetine. The control group consisted of pregnancy outcomes of women who had called a TIS inquiring about exposures to drugs thought to be safe in pregnancy. The rate of cardiovascular anomalies in the exposed TISs group was 0.7% compared with 0.7% in controls. In the database, the rate was 1.5%. When the TISs and database groups were combined, the mean rate of cardiovascular defects was 1.2% (95% CI 1.1–2.1). Although the investigators did not categorize the data by dose because there was insufficient variability to conduct a dose–response analysis, most of the women were taking ≤ 20 mg/day (31).

A 2009 study from Israel investigated the prevalence of nonsyndromic congenital heart defects in infants exposed in utero to SSRIs (32). The prospective case–control study involved 235 women who took the agents during the 1st trimester and who gave birth in the years 2000–2007 at one center. Controls (N = 67,636) were infants not exposed in utero to SSRIs. All infants with a persistent cardiac murmur were evaluated by echocardiography. In the cases, nonsyndromic heart defects (6 VSDs, 1 bicuspid aortic valve, and 1 right superior vena cava to coronary sinus) were found in 8 (3.40%) compared with 1083 (1.60%) controls. The difference was significant (RR 2.17, 95% CI 1.07–4.39). The prevalence rates for paroxetine and fluoxetine were 4.3% and 3.0%, respectively. Although there was a twofold higher risk for cardiac defects, all of the defects in the exposed group were considered mild (32).

A 2010 case report described abnormalities in naturally conceived, monozygotic twin females born at 33 weeks' gestation from a pregnancy complicated by gestational diabetes, polyhydramnios, and preterm premature rupture of the membranes (33). The birth weights were 1420 g (10–25th percentile) and 1250 g (<3rd percentile). Their mother had used paroxetine 5 mg/day during the first 2 months of pregnancy and 20 mg/day in the last 3 weeks. Ultrasound at 20 weeks' had shown right aortic arch in the first twin and a single umbilical artery in the second twin. At birth, facial dysmorphism, consisting of hypertelorism, proptosis, hypoplastic nasal pyramid, and wide nostrils were noted. Neurobehavioral and motor signs were noted on the 2nd day of life (hyperactivity, irritability, jitteriness, hyperextension of the trunk and limbs with worsening dyspnea during handling). At 6 months of life, the twins had adequate psychomotor development with no neurobehavioral or respiratory symptoms (33).

In a population-based case–control study from the Netherlands, 678 cases (fetuses and children with isolated heart defects) were compared with 615 controls (fetuses and children with a genetic disorder with no heart defect) (34). Exposure to paroxetine only in the 1st trimester was not associated with a significantly increased risk for heart defects overall (10 cases) (adjusted OR 1.5, 95% CI 0.5–4.0) but, based on three cases, was for atrium septum defects (adjusted OR 5.7, 95% CI 1.4–23.7) (34).

A 2010 meta-analysis of epidemiological studies evaluated 1st trimester exposures to paroxetine and congenital defects, particularly cardiac defects (35). The investigators analyzed published data from 1992 to 2008 and, in some instances, involved additional information that was requested and received from the original authors. The meta-analysis found little evidence of publication bias or overall statistical heterogeneity. The prevalence OR for 1st trimester paroxetine use and combined cardiac defects was 1.46, 95% CI 1.17–1.82, whereas for aggregated congenital defects it was 1.24, 95% CI 1.08–1.43. However, the increased prevalence of aggregated defects may have resulted, in part, from the increased prevalence of cardiac defects (35). Immediately following this meta-analysis were two sophisticated commentaries, one supporting an association between paroxetine and cardiac defects (36) and one opposing such an association (37).

A prospective cohort study evaluated a large group of pregnancies exposed to antidepressants in the 1st trimester to determine if there was an association with major malformations (38). The patient population came from the Motherisk database and involved 928 cases that met their criteria. The 928 matched (for age, smoking, and alcohol use) controls were pregnancies not exposed to antidepressants or known teratogens. In addition to the 149 paroxetine cases, the other cases were 113 bupropion, 184 citalopram, 21 escitalopram, 61 fluoxetine, 52 fluvoxamine, 68 mirtazapine, 39 nefazodone, 61 sertraline, 17 trazodone, and 154 venlafaxine. In the antidepressant group, there were 24 (2.5%) major defects compared with 25 (2.6%) in controls (odds ratio 0.9, 95% CI 0.5–1.61). There were five major anomalies in the paroxetine group: bilateral pulmonary hypoplasia, ventricular septal defect, clinodactyly, cleft lip and palate, and an omphalocele. There were no major defects in the pregnancies exposed to bupropion, escitalopram, or trazodone (38).

Complications in Neonates

(Includes references 22 and 27 above.)

A 2001 case report described complications consistent with neonatal

withdrawal in four neonates exposed to paroxetine during pregnancy (39). The infants were delivered at 37–38 weeks' gestation and one mother breastfed her infant. The maternal doses were 10–120 mg/day. The symptoms in the four infants included jitteriness, irritability, lethargy, myoclonus, vomiting, and hypothermia. In one infant, serum levels of paroxetine and desipramine on days 5 and 15 of age were 48 and 70 ng/mL, respectively, and <10 and <10 ng/mL, respectively. In a second infant, the serum paroxetine concentration on day 2 was 66 ng/mL, whereas trazodone was undetectable. Two infants were hypoglycemic (one shortly after birth and one at 40 hours of age), but both mothers had gestational diabetes mellitus. Necrotizing enterocolitis was also observed in two infants. The withdrawal symptoms in one infant resolved over a few days, but some symptoms in the other three were still apparent at discharge on days 5, 22, and 24 of age, respectively (39).

Another 2001 report described withdrawal symptoms in newborn infants exposed in utero to SSRIs (40). Male infants exposed to paroxetine (N = 3; 10–40 mg/day), citalopram (N = 1; 30 mg/day), or fluoxetine (N = 1; 20 mg/day) during gestation exhibited withdrawal symptoms at or within a few days of birth and lasting up to 1 month. Symptoms included irritability, constant crying, shivering, increased tonus, eating and sleeping problems, and convulsions (40).

Paroxetine withdrawal was suspected in a third 2001 case report (41). The mother had taken paroxetine (40 mg/day) throughout pregnancy and delivered a 2690-g female infant at 35 weeks' gestation. Apgar scores were 9, 10, and 10 at 1, 5, and 10 minutes, respectively. The premature infant was bottle-fed and did well during the first few days, but then became irritable, lethargic, hypertonic, apathetic, and jittery. Tube feeding was required. The infant improved without therapy and was discharged home at 18 days of age. After delivery, the mother's serum paroxetine concentration was 126 mcg/L (therapeutic levels 10–150 mcg/L) (41).

The pregnancy outcomes of 55 women taking paroxetine (median dose 20 mg/day) in the 3rd trimester were reported in 2002 (42). Twelve neonates had complications requiring short-term intensive treatment and prolonged hospitalization. The complications, all resolving within 1–2 weeks, included respiratory distress (N = 9; 3 preterm infants), hypoglycemia (N = 2), and jaundice (N = 1). Compared with controls, significantly more infants were premature. In contrast, only three complications were observed in 54 matched controls. Twenty-seven women in the comparison group had used paroxetine (median dose 20 mg/day) in the 1st and 2nd trimesters, but not in the 3rd trimester. Only 3rd trimester exposure was associated with respiratory distress

(OR 9.53, 95% CI 1.14–79.30) (42).

The effect of SSRIs on birth outcomes and postnatal neurodevelopment of children exposed prenatally was reported in 2003 (43). Thirty-one children (mean age 12.9 months) exposed during pregnancy to SSRIs (15 sertraline, 8 paroxetine, 7 fluoxetine, and 1 fluvoxamine) were compared with 13 children (mean age 17.7 months) of mothers with depression who elected not to take medications during pregnancy. All of the mothers had healthy lifestyles. The timing of the exposures was 71% in the 1st trimester, 74% in the 3rd trimester, and 45% throughout. The average duration of breastfeeding in the subjects and controls was 6.4 and 8.5 months. Twenty-eight (90%) subjects nursed their infants, 17 of who took SSRIs (10 sertraline, 4 paroxetine, and 3 fluoxetine) compared with 11 (85%) controls, 3 of whom took sertraline. There were no significant differences between the groups in terms of gestational age at birth, premature births, birth weight and length or, at follow-up, in sex distribution or gain in weight and length (expressed at percentage). Seven (23%) of the exposed infants were admitted to a neonatal intensive care unit (NICU) (six respiratory distress, four meconium aspiration, and one cardiac murmur) compared with none of the controls (ns). Follow-up examinations were conducted by a pediatric neurologist, psychologist, and a dysmorphologist who were blinded as to the mother's mediations status. The mean Apgar scores at 1 and 5 minutes were lower in the exposed group than in controls, 7.0 vs. 8.2, and 8.4 vs. 9.0, respectively. There was one major defect in each group: small asymptomatic ventricular septal defect (exposed); bilateral lacrimal duct stenosis that required surgery (control). The test outcomes for mental development were similar in the groups, but significant differences in the subjects included a slight delay in psychomotor development and lower behavior motor quality (tremulousness and fine motor movements) (43).

A 2004 case report described a term 3750-g male newborn who had a normal examination at birth except that he did not cry in the delivery room or afterward (44). The mother had taken paroxetine 20 mg/day throughout the pregnancy. The infant was bottle-fed and had a normal appetite. He was discharged home at 48 hours of age, but was readmitted 2 days later because of lethargy and the absence of cry. The only abnormality detected on examination was the lack of reaction to pain stimulation. On the day 6 of life, an electroencephalogram (EEG) was abnormal (“...depressed background activity with trace alternance and independent spike and wave activity; somatosensory-evoked potentials on the posterior tibial were impossible to elicit”). The infant began crying and responded to pain stimulation on day 13 of life and an EEG

on day 14 showed marked improvement. Physical examination at 6 weeks of age was normal (44).

A 2004 prospective study examined the effect of four SSRIs (citalopram, fluoxetine, paroxetine, and sertraline) on newborn neurobehavior, including behavioral state, sleep organization, motor activity, heart rate variability, tremulousness, and startles (45). Seventeen SSRI-exposed, healthy, full-birth-weight newborns and 17 nonexposed, matched controls were studied. A wide range of disrupted neurobehavioral outcomes were shown in the subject infants. After adjustment for gestational age, the exposed infants were found to differ significantly from controls in terms of tremulousness, behavioral states, and sleep organization. The effects observed on motor activity, startles, and heart rate variability were not significant after adjustment (45).

A 37-year-old woman with depression was treated with paroxetine 30 mg/day and chlorpromazine 100 mg/day throughout gestation (46). The woman delivered a 4.46-kg female infant at 39 weeks' gestation with Apgar scores of 6 and 9 at 1 and 5 minutes, respectively. Both the birth weight and head circumference (38 cm) were >97th percentile. The infant was not breastfed. At 12 hours of age, the infant developed a mild fever and respiratory distress (tachypnea, respiratory rate 80/minute, and intercostal recession). At 60 hours of age, rhythmical jerking of the left arm and leg was observed. Investigations for infectious and metabolic causes were negative. On day 6, a blood sample for paroxetine was negative (detection level 5 mcg/L). The infant continued to display jitteriness, tremor, focal jerking movements of all four limbs with hypertonia, opisthotonus posturing, hyper-reflexia, and a hyperactive Moro reflex. Abnormal posture with neck retraction and generalized hypertonia persisted until day 8, but by day 11, the infant was feeding well and all symptoms had resolved (46).

A 2004 case report described severe symptoms in a newborn consisting of tremor, rigidity, and diarrhea during the first 4 days after birth (47). The mother had taken chlorpromazine 20 mg/day up to 32 weeks' gestation, at which time she began paroxetine 30 mg/day. The 4080-g female was delivered by cesarean section at 42 weeks' with Apgar scores of 7, 8, and 9 presumably at 1, 5, and 10 minutes, respectively. The symptoms began 1.5 hours after birth. Paroxetine levels in the infant and mother 17 hours after birth were 30 and 94 nmol/L (trough), respectively. Genetic analysis of the infant revealed that she had two defective CYP2D6 alleles, the enzyme responsible for metabolizing paroxetine, thus classifying her as a poor metabolizer. Nevertheless, the mother breastfed the infant while taking paroxetine 30 mg/day and at 4 months

of age, the infant's growth and development were normal (47).

The database of the World Health Organization (WHO) was used in a 2005 report on neonatal SSRI withdrawal syndrome (48). Ninety-three suspected cases with either neonatal convulsions or withdrawal syndrome were identified in the WHO database. Mothers had taken paroxetine in 64 of the cases. The analysis suggested that paroxetine might have an increased risk of convulsions or withdrawal compared with other SSRIs (48).

Evidence for a neonatal behavioral syndrome associated with in utero exposure to SSRIs and serotonin and norepinephrine reuptake inhibitors (SNRIs) (collectively called serotonin reuptake inhibitors [SRIs]) in late pregnancy was reviewed in 2005 (49). The report followed a recent agreement by the FDA and manufacturers for a class labeling change about the neonatal syndrome. Analysis of case reports, case series, and cohort studies revealed that late exposure to SRIs carried an overall risk ratio of 3.0 (95% CI 2.0–4.4) for the syndrome compared with early exposure. The case reports (N = 18) and case series (N = 131) involved 97 cases of paroxetine, 18 fluoxetine, 16 sertraline, 12 citalopram, 4 venlafaxine, and 2 fluvoxamine. There were nine cohort studies analyzed. The typical neonatal syndrome consisted of central nervous system (CNS), motor, respiratory, and gastrointestinal signs that were mild and usually resolved within 2 weeks. Only 1 of 313 quantifiable cases involved a severe syndrome consisting of seizures, dehydration, excessive weight loss, hyperpyrexia, and intubation. There were no neonatal deaths attributable to the syndrome (49).

Possible sustained neurobehavioral outcomes beyond the neonatal period were reported in 2005 (50). Based on previous findings that prenatally exposed newborns had reduced pain responses, biobehavioral responses to acute pain (heel lance) were prospectively studied in 2-month-old infants. The responses included facial action (Neonatal Facial Coding System) and cardiac autonomic reactivity (derived from respiratory activity and heart rate variability). Three groups of infants were formed: 11 infants with prenatal SSRI exposure alone (2 fluoxetine and 9 paroxetine); 30 infants with prenatal and postnatal (from breast milk) SSRI exposure (6 fluoxetine, 20 paroxetine, and 4 sertraline); and 22 nonexposed controls (mothers not depressed). The exposure during breastfeeding was considered to be very low. Heel lance–induced facial action increased in all three groups but was significantly lowered (blunted) in the first group. Heart rate was significantly lower in the exposed infants during recovery. Moreover, exposed infants had a greater return of parasympathetic cardiac modulation, whereas controls had a sustained sympathetic response. The

findings were consistent with the patterns of pain reactivity observed in exposed newborns and suggested sustained neurobehavioral outcomes (50).

A 2006 case report described serotonin toxicity in a newborn that was correlated with serum levels of paroxetine (51). The 29-year-old mother had taken paroxetine, 15 mg/day, from 28 weeks' gestation to delivery at 40 weeks'. The 3-kg male infant had Apgar scores of 9 and 9 at 1 and 5 minutes, respectively. At birth, the infant was pale and flaccid, with an irregular heartbeat (premature atrial contractions), and had signs of respiratory distress. Subsequent examinations revealed a pneumomediastinum and pneumothorax. The hypotonicity was replaced by hypertonicity at about 5 hours of age. Most of the symptoms had resolved within about 24 hours and the infant began breastfeeding at 52 hours of age. A cord blood paroxetine level, about 23 hours after the last dose, was 368 nmol/L (therapeutic range for adults at the author's institution 12–155 nmol/L). Serial drug levels in the infant during the first 24 hours decreased from about 400 nmol/L at birth to 125 nmol/L at 24 hours. The decrease paralleled the decrease in hypertonicity (51).

A significant increase in the risk of low birth weight (<10th percentile) and respiratory distress after prenatal exposure to SSRIs was reported in 2006 (52). The population-based study, representing all live births (N = 119,547) during a 39-month period in British Columbia, Canada, compared pregnancy outcomes of depressed mothers treated with SSRIs with outcomes in depressed mothers not treated with medication and in nonexposed controls. The severity of depression in the depressed groups was accounted for by propensity score matching (52).

A 30% incidence of SSRI-induced neonatal abstinence syndrome was found in a 2006 cohort study (53). Sixty neonates with prolonged in utero exposure to SSRIs were compared with nonexposed controls. The agents used were paroxetine (62%), fluoxetine (20%), citalopram (13%), venlafaxine (3%), and sertraline (2%). Assessment was conducted by the Finnegan score. Ten of the infants had mild and eight had severe symptoms of the syndrome. The maximum mean score in infants with severe symptoms occurred within 2 days of birth, but some occurred as long as 4 days after birth. Because of the small numbers, a dose–response analysis could only be conducted with paroxetine. Infants exposed to mean maternal doses that were <19 mg/day had no symptoms, <23 mg/day had mild symptoms, and 27 mg/day had severe symptoms (53).

A 2007 case report described seizures in a newborn infant whose mother had taken paroxetine 30 mg/day throughout pregnancy (54). At birth, the infant

was floppy with respiratory distress. Tonic seizures were noted 5 minutes after vaginal birth and continued intermittently, in spite of treatment, until about 48 hours. Other symptoms included hypertonia, fluctuating temperature, and hypoglycemia. He was weaned off of phenobarbital by 2 months of age. His growth and neurodevelopment at 15 months were appropriate (54).

A 2007 retrospective cohort study examined the effects of exposure to SSRIs or venlafaxine in the 3rd trimester on 21 premature and 55 term newborns (55). The randomly selected unexposed control group consisted of 90 neonates of mothers not taking antidepressants, psychotropic agents, or benzodiazepines at the time of delivery. There were significantly more premature infants among the subjects (27.6%) than in controls (8.9%), but the groups were not matched. The antidepressants, number of subjects, and daily doses in the exposed group were paroxetine (46; 5–40 mg), fluoxetine (10; 10–40 mg), venlafaxine (9; 74–150 mg), citalopram (6; 10–30 mg), sertraline (3; 125–150 mg), and fluvoxamine (2; 50–150 mg). The behavioral signs that were significantly increased in exposed compared with nonexposed infants were: CNS—abnormal movements, shaking, spasms, agitation, hypotonia, hypertonia, irritability, and insomnia; respiratory system—indrawing, apnea/bradycardia, and tachypnea; and other—vomiting, tachycardia, and jaundice. In exposed infants, CNS (63.2%) and respiratory system (40.8%) signs were most common, appearing during the first day of life and lasting for a median duration of 3 days. All of the exposed premature infants exhibited behavioral signs compared with 69.1% of exposed term infants. The duration of hospitalization was significantly longer in exposed premature compared with nonexposed premature infants, 14.5 vs. 3.7 days, respectively. In 75% of the term and premature infants, the signs resolved within 3 and 5 days, respectively. There were six infants in each group with congenital malformations, but the drugs involved were not specified (55).

A case–control study, published in 2006, was conducted to test the hypothesis that exposure to SSRIs in late pregnancy was associated with persistent pulmonary hypertension of the newborn (56). A total of 1213 women were enrolled in the study, 377 cases whose infants had PPHN and 836 matched controls and their infants. Mothers were interviewed by nurses that were blinded to the hypothesis. Fourteen case infants had been exposed to an SSRI after the 20th week of gestation compared with six control infants (adjusted OR 6.1, 95% CI 2.2–16.8). The numbers were too small to analyze the effects of dosage, SSRI used, or reduction of the length of exposure before delivery. No increased risk of PPHN was found with the use of SSRIs before

the 20th week or with the use of non-SSRI antidepressants at any time in pregnancy. If the relationship was causal, the absolute risk was estimated to be about 1% (56).

A 2008 reference found that, after controlling for maternal illness, longer prenatal exposure to SSRIs significantly increased the risks of lower birth weight, respiratory distress, and reduced gestational age (57).

In a 2009 retrospective study, the medical records of 25,214 births that occurred at the Mayo Clinic from 1993 to 2005 were reviewed for use of SSRIs during pregnancy (58). A total of 808 mothers took an SSRI (122 citalopram, 8 escitalopram, 184 fluoxetine, 134 paroxetine, 296 sertraline, 53 venlafaxine, and 1 to more than 1 SSRI) and 24,406 did not. The prevalence of congenital heart disease in the two groups was 3 (0.4%) and 205 (0.8%). There were 16 infants with PPHN, none of whom had been exposed to SSRIs (58).

A prospective cohort study from Denmark evaluated the effects of SSRIs on pregnancy outcomes (59). Three groups of women that gave birth at a single hospital in 1989–2006 were identified: 329 exposed to SSRIs during pregnancy, 4902 with a history of psychiatric illness but not treated with SSRIs, and 51,770 reported no history of psychiatric illness. Compared with the other groups, SSRI exposure was significantly associated with an increased risk of preterm birth, a low 5-minute Apgar score, and admission to an NICU. The NICU admissions were not explained by the lower Apgar score or gestational age (59).

Representatives of the American Psychiatric Association and the American College of Obstetricians and Gynecologists issued a joint statement on the management of depression during pregnancy in 2009 (60). The objective of the statement was to analyze the maternal and neonatal risks of depression and antidepressant exposure and to develop algorithms for periconceptional and antenatal management. Three algorithms were developed: (i) patients considering pregnancy who were currently being treated; (ii) pregnant patients having a recurrent major depressive disorder (MDD) who were not taking an antidepressant; and (iii) pregnant patients with MDD who were taking an antidepressant. The conclusion of the joint statement was that research had not adequately controlled for other factors that could influence birth outcomes such as maternal illness or problematic health behaviors that could adversely affect pregnancy (60).

A large 2009 review of SSRIs and SNRIs in pregnancy concluded that use of these agents was associated with adverse effects and such use required careful follow-up of infants exposed in utero (61).

Spontaneous Abortions

A nested case–control study in Quebec found that the use of antidepressants during pregnancy were significantly associated with SABs (62). Significant increases were observed for SSRIs alone, SNRIs alone, combined use of different classes of antidepressants, paroxetine, and venlafaxine. The ranges for the OR were 1.68–3.51, with the highest in the combined use group. Because of the smaller number of exposures among other SSRIs and in other antidepressant classes, the authors thought that their data suggested a class effect of SSRIs, rather than a specific drug effect (62). An accompanying commentary discussed the difficulties of measuring the effects of antidepressants in pregnancy and concluded that if a risk of SAB existed, it was small (63).

A 2010 review evaluated 15 prospective studies involving antidepressants that had been published in 1975–2009 to determine if there was an association between specific agents and SAB (64). The majority of the studies involved tricyclic antidepressants or SSRIs. After adjustment, only paroxetine (OR 1.7, 95% CI 1.3–2.3) and venlafaxine (OR 2.1, 95% CI 1.3–3.3) were significantly associated with the risk of SABs (64).

BREASTFEEDING SUMMARY

Paroxetine is excreted into breast milk. A brief 1996 correspondence described a 39-year-old, 60-kg woman with a recurrent depressive and obsessive disorder who was started on paroxetine 20 mg/day (333 mcg/kg/day) 3 days after delivery (65). One week later, analysis of a milk sample for paroxetine revealed a concentration of 7.6 ng/mL. Assuming that the infant ingested 0.15 L/kg of milk per day, the estimated daily weight-adjusted dose was 0.34% of the mother's dose. The minimum milk:plasma ratio (obtained 4 hours after a dose) was estimated to be 0.09. No data were available on the effects of this exposure on the nursing infant (65).

Breast milk concentrations of paroxetine in seven lactating women were reported in a 1999 publication (66). In six women receiving a paroxetine dose of 10–40 mg/day, milk and maternal serum samples were obtained 4–7 and 24 hours after a dose. The samples corresponded to either close to peak milk concentrations or trough levels. Based on AUC calculations, the mean estimated daily infant dose was 1.4% (range 0.7%–2.9%) of the weight-adjusted maternal dose. The mean milk:serum ratio was 0.69 (range 0.39–1.11). In a seventh woman, frequent sampling during two 24-hour periods (one at 20 mg/day and one at 40 mg/day, 7 weeks apart) resulted in estimated daily

infant doses of 1.0% and 2.0%, respectively, of the weight-adjusted maternal dose. The milk:serum ratios were 0.69 and 0.72, respectively. The study also measured paroxetine concentrations in fore-milk and hind-milk at two steady-state doses (20 and 40 mg/day) in one subject. Drug levels in hind-milk were a mean 78% (range 16%–169%) higher than those in fore-milk. The increase paralleled the increase in milk triglycerides and was thought to be consistent with the lipophilic properties of the drug. No adverse effects of the exposure were observed in the seven nursing infants (66).

In a two-phase study published in 1999, the dose of paroxetine received by 10 nursing infants from breast milk was estimated (67). In six subjects sampled over 24 hours, the mean daily estimated infant dose was 1.13% (range 0.5%–1.7%) of the weight-adjusted maternal dose (based on AUC). The mean milk:plasma ratio was 0.39 (range 0.32–0.51). In the second phase, milk and serum samples were obtained from four subjects around a normal infant feeding time. In this case, the mean infant dose was 1.25% (range 0.38%–2.24%) of the maternal dose and the mean milk:plasma ratio was 0.96 (range 0.31–3.33). The milk:plasma ratio was similar for fore- and hind-milk. Paroxetine was detected (limit 2 ng/mL) in the plasma of one of the eight infants tested, but the concentration was below the level of quantification for the assay (4 ng/mL). No adverse effects were noted in any of the infants (67).

A 2000 study described the excretion of paroxetine into breast milk (68). Sixteen women on a stable paroxetine dose (mean 23.1 mg/day; range 10–50 mg/day) were studied during the postpartum period (4–55.2 weeks). Seven of the women had continued their prenatal paroxetine, four had started the antidepressant postpartum, and data were not available for five subjects. Milk samples were collected after a dose at 4- to 6-hour intervals over a 24-hour period. The mean milk concentration was 41.6 ng/mL (range 2–101 ng/mL). Paroxetine concentrations were higher in hind-milk than in fore-milk. No detectable levels of paroxetine (all <2 ng/mL) were found in the infants serum, including the 10 infants who were exclusively breastfed. No adverse effects in the nursing infants were reported by the mothers upon direct interview (68).

In another 2000 report, maternal serum, breast milk, and infant serum samples were obtained from 24 mother–infant pairs (mean infant age 4.5 months) 6 hours after a paroxetine dose (69). In 13 of the pairs, the infants were exclusively breastfed. All of the mothers were on a stable dose of paroxetine (10–40 mg/day for at least 30 days). One mother–infant pair was tested twice; once at 10 mg/day and again at 40 mg/day. The mean maternal serum, breast milk, and infant serum concentrations (ng/mL) were 45.2, 19.2,

and not detectable (<0.1 ng/mL), respectively. The mean milk:plasma ratio, infant dose, and percent of maternal dose were 0.53, 2.88 mcg/kg/day, and 1.1%, respectively. No adverse effects of the drug exposure were noted in the nursing infants (69).

In a 2002 report, the pregnancy outcomes of 55 women who had taken paroxetine during the 3rd trimester were reported (see Fetal Risk Summary) (42). Thirty-six of the women breastfed their infants. Eight of the women reported adverse symptoms in their infants: alertness (N = 6), constipation (N = 3), sleepiness (N = 1), and irritability (N = 1). No adverse events were reported in 44 breastfed infants in the comparison group (42).

A 2004 study was conducted in 25 women (nursing 26 infants) to quantify the concentration of the SSRI or SNRI in their breast milk (70). The antidepressants taken by the women were citalopram (nine), paroxetine (six), sertraline (six), fluoxetine (one), and venlafaxine (three). The maternal mean dose of paroxetine was 20 mg/day (10–30 mg/day). The mean milk concentration was 88 nmol/L (18–152 nmol/L), resulting in a theoretical maximum infant dose that was 1.4% of the mother's weight-adjusted dose. Paroxetine was not detected in the infant's serum, even though one mother–infant pair was identified as CYP2D6 poor metabolizers. There was no evidence of adverse effects in the breastfeeding infants (70).

A 1999 review of SSRI agents concluded that if there were compelling reasons to treat a mother for postpartum depression, a condition in which a rapid antidepressant effect is important, the benefits of therapy with SSRIs would most likely outweigh the risks (71). However, because the long-term effects of exposure to SSRI antidepressants in breast milk on the infant's neurobehavioral development are unknown, stopping or reducing the frequency of breastfeeding should be considered if therapy with these agents is required. Avoiding nursing around the time of peak maternal concentration (about 4 hours after a dose) may limit infant exposure. However, the long elimination half-lives of all SSRIs and their weakly basic properties, which are conducive to ion trapping in the relatively acidic milk, probably will lessen the effectiveness of this strategy. The American Academy of Pediatrics classifies paroxetine as a drug for which the effect on nursing infants is unknown but may be of concern (72).

A 2010 study, using human and animal models, found that drugs that disturb serotonin balance such as SSRIs and SNRIs can impair lactation (73). The authors concluded that mothers taking these drugs may need additional support to achieve breastfeeding goals.

PASIREOTIDE

Endocrine/Metabolic (Somatostatin Analog)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of pasireotide in human pregnancy have been located. The animal data suggest risk, but the absence of human pregnancy experience prevents a full assessment of the embryo–fetal risk. If a woman becomes pregnant while receiving the drug, she should be informed of the potential risk, including abortion, to her embryo and/or fetus.

FETAL RISK SUMMARY

Pasireotide is a cyclohexapeptide somatostatin analog that is given as an SC injection. It is in the same subclass as octreotide. Pasireotide is indicated for the treatment of adult patients with Cushing’s disease for whom pituitary surgery is not an option or has not been curative. The drug is not metabolized. Plasma protein binding is moderate (88%) and the calculated effective half-life is about 12 hours (1).

Reproduction studies have been conducted in rats and rabbits. In rats throughout organogenesis, doses resulting in exposures that were 4 times or higher than the maximum therapeutic dose based on AUC (MHD) caused maternal toxicity. Exposures less than the human clinical exposure based on BSA caused a significant increase in implantation loss and decreased viable fetuses, corpora lutea, and implantation sites. In addition, restricted growth was noted in rat pups exposed during prenatal and postnatal studies but was reversible after weaning. In rabbits through organogenesis, an exposure that was 7 times the MHD caused maternal toxicity. At exposures less than the MHD, an increased incidence of skeletal malformations was observed in offspring (1).

Long-term studies for carcinogenesis were negative in rats and mice. Pasireotide was not mutagenic or genotoxic in several assays. As noted above, fertility studies in rats caused harm. In addition, abnormal cycles or acyclicity were observed (1).

It is not known if pasireotide crosses the human placenta. The molecular weight (about 1313) suggests that passage would be limited, but the moderate plasma protein binding and long effective half-life could increase the possibility for crossing to the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use of pasireotide during human breastfeeding have been located. The molecular weight (about 1313) suggests that excretion into breast milk will be limited, but the moderate plasma protein binding (88%) and long effective half-life (12 hours) could increase the possibility for excretion. The effect of this exposure on a nursing infant is unknown. The most common ($\geq 20\%$) adverse reactions in adults were diarrhea, nausea, hyperglycemia, cholelithiasis, headache, abdominal pain, fatigue, and diabetes mellitus (1). Because of these potential risks, the best course is to not breastfeed.

PASSION FLOWER

Herb

PREGNANCY RECOMMENDATION: No Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of passion flower during human pregnancy have been located. As with most herbal products, a large number of chemicals have been identified in this herb and none has undergone reproductive testing. Since passion flower has been used for hundreds of years or longer, it is doubtful that a major teratogenic effect or other significant reproductive toxicity would have escaped notice. More subtle or low-incidence effects, however, including structural and behavioral teratogenicity, the induction of abortions due to its uterine stimulant properties, and infertility, may have escaped detection, and further study is required before human reproductive risk or safety can be assessed. In addition to the above concerns, standardization of any herbal product is often questionable (1). As such, the presence of therapeutic or subtherapeutic amounts of active ingredients, or their complete absence, in a given preparation cannot be predicted. Commercial herbal products may also be adulterated with unlabeled ingredients (1). Because of these uncertainties, the consumption of passion flower during gestation should be avoided.

FETAL RISK SUMMARY

The herbal product used for medicinal purposes usually refers to the plant, *Passiflora incarnata*, but the common name, passion flower, may refer to many of the approximately 400 species of the genus *Passiflora*. Some species are grown for their flowers. In addition, some species produce edible fruit, such as *P. incarnata*, *P. edulis*, and *P. quadrangularis*. The plant is a perennial vine that may reach 10 meters in length. It is indigenous to the southeastern United

States to South America. The medicinal parts include the whole or cut dried herb and the fresh aerial parts (2,3). In this review, the term passion flower will only refer to *P. incarnata*, the product used in herbal medicine.

Commercial products of passion flower are available for both oral and topical administration. A number of indications have been claimed for passion flower, including nervousness (e.g., hysteria, nervous exhaustion, pediatric nervousness, and excitability), neuralgia, insomnia, pain, asthma and other bronchial disorders, generalized seizures, compresses for burns, hemorrhoids (externally), and for menopausal complaints (2–5).

As with most herbs, a relatively large number of chemical compounds are contained in the commercial product: flavonoids (content 2.5%; includes flavone di-C-glycosides shaftoside, isoshaftoside, isovitexin, iso-orientin, vicenin, lucenin, saponarin, and passiflorine), maltol (0.05%), cyanogenic glycosides (gynocardine [$<0.1\%$]), and indole alkaloids (harman, harmine, harmaline, harmalol, and harmin) are the primary constituents (2–5). The alkaloids, however, are reportedly present in subtherapeutic amounts (6). Other constituents include free flavonoids (apigenin, luteolin, quercetin, and campherol), several acid compounds (phenolic, linoleic, linolenic, palmitic, oleic, myristic, formic, and butyric acids), coumarins, phytosterols, and essential oil (2).

The pharmacologic activity of passion flower apparently derives from the flavonoids and alkaloids (2,4). A few studies have apparently documented the sedative action of passion flower in animals and humans. The FDA prohibited the use of passion flower in over-the-counter (OTC) products in 1978 because it had not been proven to be safe and effective (6), but the product is apparently available as a herbal remedy.

No reports have been located describing the use of passion flower in human pregnancy. However, two sources have cited reports that the herb is contraindicated during pregnancy because of the uterine stimulant action of the harman (harmala) alkaloids (harman, harmaline) shown in animals and because of the presence of cyanogenic glycoside gynocardine (2,4). In contrast, the German Commission E monographs state that there are no contraindications (5).

BREASTFEEDING SUMMARY

No reports describing the use of passion flower during lactation have been located. Because of the large number of chemical compounds in the herb, the lack of standardization of commercial products, and the complete lack of

information on the effects of exposure to these substances in a nursing infant, the use of passion flower during breastfeeding should be avoided.

PAZOPANIB

Antineoplastic (Tyrosine Kinase Inhibitor)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of pazopanib in human pregnancy have been located. The animal reproduction data suggest risk because developmental toxicity (growth restriction, structural anomalies, and death) was observed in two species at systemic exposures that were much lower than those in humans. The absence of human pregnancy experience prevents a full assessment of the embryo–fetal risk. The manufacturer advises women to avoid becoming pregnant while taking pazopanib (1). However, renal cell carcinoma may be fatal without appropriate treatment. If a woman becomes pregnant while receiving everolimus she should be advised of the potential for embryo–fetal harm. If possible, avoiding the 1st trimester should be considered.

FETAL RISK SUMMARY

Pazopanib is a tyrosine kinase inhibitor antineoplastic that is available as oral tablets. It is indicated for the treatment of advanced renal cell carcinoma. Pazopanib is in the same subclass as several other agents (see Appendix). The drug is metabolized, but the activity of the metabolites (assumed to be inactive) was not stated. Plasma protein binding is >99% and the mean elimination half-life is about 31 hours (1).

Reproduction studies have been conducted in rats and rabbits. In rats, doses given during organogenesis that resulted in exposures that were about 0.1 times the human clinical exposure based on AUC (HCE) caused cardiovascular malformations (retroesophageal subclavian artery, missing innominate artery, changes in the aortic arch) and incomplete or absent ossification. Other toxicities were reduced fetal body weight, and pre- and postimplantation embryoletality. In rabbits, doses resulting in exposures that were about 0.007 times the HCE caused maternal toxicity (reduced food consumption, increased

postimplantation loss, and abortion). At 0.02 times the HCE, severe maternal body weight loss and 100% litter loss were observed. Fetal body weight was reduced at a dose 1% (AUC not calculated) of the dose causing 100% litter loss (1).

Carcinogenicity studies have not been conducted, but in a 13-week mouse study, proliferative lesions in the liver including eosinophilic foci in two females and a single case of adenoma in another female were noted. The drug was not mutagenic or clastogenic in various assays. In female rats, various doses all resulting in exposures less than the HCE, caused decreased fertility, increased pre- and postimplantation losses, and decreased fetal body weight. Decreased corpora lutea and increased cysts were noted in mice given a dose that was about 1.3 times the HCE for 13 weeks, and in a 26-week study, ovarian atrophy was seen in rats at a dose that was about 0.85 times the HCE. Decreased corpora lutea were also noted in monkeys given a dose that was about 0.4 times the HCE for up to 34 weeks. The drug did not affect mating or fertility in male rats, but did cause decreases in sperm production and concentrations, as well as decreased testicular and epididymal weights. In a 6-month toxicity study with male rats, atrophy and degeneration of the testes with aspermia, hypospermia, and cribiform change in the epididymis were observed (1).

It is not known if pazopanib crosses the human placenta. The molecular weight (about 438 for the free base) and long elimination half-life suggest that the drug will cross, but the high plasma protein binding might limit the amount crossing.

BREASTFEEDING SUMMARY

No reports describing the use of pazopanib during human lactation have been located. The molecular weight (about 438 for the free base) and long elimination half-life (about 31 hours) suggest that the drug will be excreted into breast milk, but the high plasma protein binding (>99%) might limit the amount. The effect of this exposure on a nursing infant is unknown. In adults, adverse reactions occurring in $\geq 10\%$ of patients were diarrhea, hypertension, hair color changes, nausea and vomiting, anorexia, fatigue, asthenia, abdominal pain, and headache. Other serious toxicities, such as hepatotoxicity, were also observed (1). Because the potential for severe toxicity in a nursing infant is a concern, women receiving pazopanib should not breastfeed.

PEGAPTANIB

Ophthalmic

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of pegaptanib in human pregnancy have been located. The animal data suggest low risk, but the absence of human pregnancy experience prevents a more complete assessment. However, the very low plasma levels probably prevent clinically significant amounts of the drug from reaching the embryo or fetus. Thus, if a woman requires pegaptanib, it should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Pegaptanib is an aptamer—a pegylated modified oligonucleotide that is a selective vascular endothelial growth factor (VEGF) antagonist. It is in the same class as ranibizumab. Pegaptanib is indicated for the treatment of neovascular (wet) age-related macular degeneration. It is administered as a 0.3-mg intravitreal injection every 6 weeks. When a 3-mg dose (10 times the recommended dose) was given, the mean maximum plasma concentration, about 80 ng/mL, occurred within 1–4 days. The mean AUC was about 25 mcg·hr/mL and the plasma elimination half-life was about 10 days. Pegaptanib is metabolized but the amount of metabolism apparently has not been determined (1).

Reproduction studies have been conducted in mice. In pregnant mice, no evidence of maternal toxicity, teratogenicity, or fetal mortality was observed with daily IV doses up to about 7000 times the recommended human monocular ophthalmic dose of 0.3 mg based on body weight (1).

Studies for carcinogenicity and fertility have not been conducted with pegaptanib. Mutagenicity and clastogenicity assays with pegaptanib and its monomer component nucleotides have been negative (1).

It is not known if pegaptanib crosses the human placenta. The molecular weight (about 50,000) suggests that exposure of the embryo and/or fetus is unlikely. The drug does cross the mouse placenta after IV administration (1). Moreover, the plasma elimination half-life is very long. Nevertheless, if the drug does cross the human placenta, the very low plasma levels will limit the amount reaching the embryo and/or fetus.

BREASTFEEDING SUMMARY

No reports describing the use of pegaptanib during human lactation have been located. Although the long plasma elimination half-life (about 10 days) favors excretion, the molecular weight (about 50,000) and very low plasma concentrations suggest that the drug will not be excreted into breast milk. The effects of any exposure on a nursing infant are unknown, but probably are clinically insignificant. Thus, if a lactating woman requires pegaptanib, it should not be withheld because she is breastfeeding.

PEGFILGRASTIM

Hematopoietic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of pegfilgrastim in human pregnancy have been located. Although the animal data do not suggest fetal risk, the absence of human pregnancy experience prevents an assessment of the embryo–fetal risk. Filgrastim has been used in the pregnancy without apparent fetal harm. (See Filgrastim.) Therefore, until human data are available, filgrastim would be preferred over pegfilgrastim in pregnancy.

FETAL RISK SUMMARY

Pegfilgrastim is a covalent conjugate of monomethoxypolyethylene glycol and filgrastim that results in reduced renal elimination and prolonged persistence in the serum. (See also Filgrastim.) Pegfilgrastim is indicated to decrease the incidence of infection, as manifested by febrile neutropenia, in patients with nonmyeloid malignancies receiving myelosuppressive chemotherapy associated with a clinically significant incidence of febrile neutropenia. The serum half-life depends on the dose and the number of neutrophils, ranging from 15 to 80 hours after SC injection (1).

Reproduction studies have been conducted in rats and rabbits. In rats, pegfilgrastim given SC in doses up to 1000 mcg/kg/dose every other day during organogenesis caused no embryotoxic or fetotoxic outcome. However, an increased incidence of wavy ribs was observed at the maximum dose. When doses up to 1000 mcg/kg/dose were given once weekly from gestation day 6 through lactation day 18, no maternal toxicity or adverse effects on the growth or development of offspring were observed. The highest dose was about 23 times the recommended human dose (RHD). In addition, the once-weekly dose in male and nonpregnant female rats had no effect on reproductive

performance, fertility, or sperm parameters. In rabbits, SC doses as low as 4 times the RHD given every other day were maternally toxic (decreased food consumption and maternal weight gain) and fetotoxic (decreased body weights). At about 16 times the RHD or higher, there was an increased incidence of resorptions and abortions with a corresponding decrease in the number of live fetuses (1).

It is not known if pegfilgrastim crosses the human placenta, but filgrastim apparently reaches the fetus late in gestation in amounts sufficient to produce a biologic effect. (See Filgrastim.) The molecular weight of pegfilgrastim (about 39,000) is twice that of filgrastim (about 19,000) because of the polyethylene glycol. The addition of this nonamino acid moiety may prevent the transfer of pegfilgrastim in amounts sufficient to produce a biologic effect in the fetus.

BREASTFEEDING SUMMARY

No reports describing the use of pegfilgrastim during human lactation have been located. Pegfilgrastim is composed of monomethoxypolyethylene glycol and filgrastim that are chemically bound together. This produces a compound with a very long half-life (15–80 hours) and a very high molecular weight (about 39,000). Excretion into breast milk is doubtful, but even if the drug were excreted, it probably would be digested in a nursing infant's stomach. The risk to a nursing infant is unknown but appears to be low to nonexistent. Therefore, treatment with pegfilgrastim should not be withheld because of breastfeeding.

PEGINESATIDE

Hematologic Agent (Hematopoietic)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of peginesatide in human pregnancy have been located. Animal reproduction tests suggest risk, but the absence of human pregnancy experience prevents a more complete assessment of embryo–fetal risk.

FETAL RISK SUMMARY

Peginesatide is given as an IV or SC injection. It is a dimeric peptide that is covalently linked to a PEG chain. Peginesatide is indicated for the treatment of anemia due to chronic kidney disease in adult patients on dialysis. The agent binds to and activates the human erythropoietin receptor and stimulates erythropoiesis in human red blood cell precursors. Peginesatide is not metabolized. The mean half-life in dialysis patients is 47.9 ± 17.7 hours (1).

Reproduction studies have been conducted in rats and rabbits. In rats given an IV every 3 days for a total of five doses, and every 5th day in rabbits for a total of three doses, adverse embryo–fetal effects included reduced fetal weights, increased resorption, embryo–fetal death, cleft palate (rats only), sternoschisis (rats only), variations in blood vessels (rats only), sternum anomalies, fused sternebrae (rabbits only), unossification of sternebrae and metatarsals, and reduced ossification of some bones. In rats, embryo–fetal toxicity was evident at doses of ≥ 1 mg/kg resulting in exposures (AUC) comparable to or higher than those in humans after IV administration at a dose of 0.35 mg/kg in patients on dialysis. In rabbits, adverse effects were observed at doses lower (5%–50%) than the dose of 0.35 mg/kg in patients (1).

Long-term carcinogenicity studies in rats were negative as were assays for mutagenic or clastogenic effects. In males and females given IV doses,

peginesatide produced adverse effects in males including reduced weight of seminal vesicles and prostate. In females, decreased viable fetuses appeared to be due to preimplantation and postimplantation losses. There were no apparent drug-related effects on estrous cycles or the number of corpora lutea (1).

It is not known if peginesatide crosses the human placenta. The molecular weight (about 4900 for the dimeric peptide alone) suggests that the drug will not cross the placenta in spite of a relative long mean half-life. However, exposure during the 3rd trimester might still occur.

BREASTFEEDING SUMMARY

No reports describing the use of peginesatide during human lactation have been located. The molecular weight (about 4900 for the dimeric peptide alone) suggests that clinically significant amounts of the drug will not be excreted into breast milk in spite of a relative long (about 48 hours) mean half-life. Moreover, even if small amounts were excreted, they probably would be digested in the infant's gut. Nonetheless, if the drug is used during lactation, the nursing infant should be monitored for the most common ($\geq 10\%$) adverse effects in patients. These effects were dyspnea, diarrhea, nausea, and cough (1).

PEGLOTICASE

Antigout (Uricosuric)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of pegloticase in human pregnancy have been located. Although animal data suggest low risk, the absence of human pregnancy experience prevents a more complete assessment of the embryo–fetal risk. If the drug is used in a pregnancy, the woman should be informed of the lack of data.

FETAL RISK SUMMARY

Pegloticase is a PEGylated, recombinant, mammalian urate oxidase enzyme given as an IV infusion every 2 weeks. It is indicated for the treatment of chronic gout in adult patients who are refractory to conventional therapy. No information was provided by the manufacturer on plasma protein binding, metabolism, or elimination half-life (1). However, in two studies, the mean elimination half-life was 12.5 (range 3.5–21.5 days) and 14 days (range 7–44 days) (2,3).

Reproduction studies have been conducted in rats. In this species, doses given on gestation days 6–16 that were 6–50 times higher than the maximum recommended human dose based on BSA were not teratogenic (1).

Pegloticase has not been evaluated for carcinogenesis, mutagenesis, or impairment of fertility.

It is not known if pegloticase crosses the human placenta. The high molecular weight (about 540,000) suggests that exposure of the embryo–fetus is unlikely to occur.

BREASTFEEDING SUMMARY

No reports describing the use of pegloticase during human lactation have been

located.

The high molecular weight (about 540,000) suggests that the enzyme will not be excreted into breast milk. If excretion does occur, the enzyme most likely would be digested in the infant's gut. Consequently, although the risk to a nursing infant is unknown, it appears to be negligible.

PEGVISOMANT

Metabolic Agent (Growth Hormone Receptor Antagonist)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

The limited human data, as well as the animal data, suggest that use of pegvisomant during human pregnancy represents a low risk of embryo–fetal harm.

FETAL RISK SUMMARY

Pegvisomant, an analog of human growth hormone (GH) that has been structurally altered to act as a GH antagonist, is given as a daily SC injection. The protein is covalently bound to various amounts of polyethylene glycol (PEG) polymers to reduce its clearance rate. Pegvisomant is indicated for the treatment of acromegaly in patients who have had an inadequate response to surgery and/or radiation therapy and/or other medical therapies, or for whom these therapies are not appropriate. The goal of treatment is to normalize serum insulin-like growth factor-1 (IGF-1). The mean serum elimination half-life is about 6 days (1).

Reproduction studies have been conducted in rabbits. No evidence of teratogenic effects was observed with SC doses up to 10 times the maximum human therapeutic dose based on BSA (MHTD) during organogenesis. However, at the highest dose, a slight increase in postimplantation loss was observed (1).

In long-term studies for carcinogenic potential in rats, an increase in malignant fibrous histiocytoma at injection sites in male rats but not in female rats was observed. The tumors were thought to have been caused by irritation and the high sensitivity of the rat to repeated SC injections. Multiple assays for mutagenicity were negative. There was no effect on fertility or reproductive performance of female rabbits at SC doses up to 10 times the MHTD (1).

It is not known if pegvisomant crosses the human placenta. Although the elimination half-life is prolonged, the protein is bound to various amounts of PEG polymers yielding predominant molecular weights of 42,000–52,000. This suggests that little if any of the drug will cross to the embryo–fetus. In a case discussed below, analysis of a cord blood sample at term revealed a minimal concentration of the protein.

A 2006 case report described the use of pegvisomant (20 mg SC daily) in a 29-year-old woman with active acromegaly who underwent in vitro fertilization (2). A positive pregnancy test was documented 2 weeks later and pegvisomant was discontinued. She eventually gave birth to a healthy, 3.5-kg male infant who was physically and developmentally normal at 1 year of age (2).

Another case report described the use of pegvisomant throughout the pregnancy of a 26-year-old woman with acromegaly (3). The woman conceived during the 13th month of pegvisomant therapy while receiving 15 mg/day. The dose was increased to 20 mg/day at 1 month and to 25 mg/day at 3 months for the remainder of the pregnancy. At 40 weeks' gestation, she underwent a cesarean section to give birth to 3.8 kg female infant with Apgar scores of 9 and 9. The infant's weight, length, and head circumference were at the 75th percentile. GH and IGF-1 concentrations in cord blood were within the normal range and a pegvisomant concentration was minimal (112 ng/mL). These findings suggested that pegvisomant had no effect on fetal GH or IGF-1 interactions. At 6 months of age, the infant was healthy and achieving normal developmental milestones (3).

A 2005 review of acromegaly pharmacotherapy stated that pegvisomant should not be used in pregnancy (4). However, no studies of the drug in pregnancy were cited. In contrast, a 2012 review of acromegaly concluded that treatment of the disease in pregnancy does not cause teratogenicity or significant complications (5).

BREASTFEEDING SUMMARY

No reports describing the use of pegvisomant during human breastfeeding have been located. However, in a case report discussed earlier, a mother receiving 25 mg/day of the protein had undetectable concentrations (<50 ng/mL) in her milk (4). The timing of the sample relative to the last dose or the time after birth was not reported. The concentration of GH in her breast milk was 0.6 ng/mL, whereas the GH concentration in three milk samples from normal healthy mothers was consistently <0.1 ng/mL (4).

In the above study, the undetectable pegvisomant concentration in milk is

consistent with the high molecular weights (42,000–52,000) of PEG-bound pegvisomant. Moreover, even if some of the protein is excreted into milk, it would most likely be digested in the infant's gut and not absorbed.

PEMETREXED

Antineoplastic (Antimetabolite)

PREGNANCY RECOMMENDATION: Contraindicated—1st Trimester
Contraindicated (If Combined with Cisplatin)

BREASTFEEDING RECOMMENDATION: Hold Breastfeeding
Contraindicated (If Combined with Cisplatin)

PREGNANCY SUMMARY

No reports describing the use of pemetrexed in human pregnancy have been located. The animal data suggest risk based on the only animal species tested. The drug is often combined with cisplatin, another antineoplastic. The drug should be avoided in pregnancy, especially during the 1st trimester. Use after that period may be appropriate if the mother's condition requires use of the drug, but severe fetal toxicity (e.g., bone marrow suppression observed in adults) is a potential risk.

FETAL RISK SUMMARY

Pemetrexed is a folate analog metabolic inhibitor that is given as a 10-minute IV infusion on day 1 of each 21-day cycle. It is in the same antineoplastic subclass of folic acid antagonists (antimetabolites) as aminopterin, methotrexate, and pralatrexate. Pemetrexed is indicated for nonsquamous non-small-cell lung cancer and mesothelioma either alone or in combination with cisplatin. (See also Cisplatin.) Pemetrexed is not metabolized to an appreciable extent and is primarily eliminated unchanged in the urine. Plasma protein binding is about 81%. In patients with normal renal function, the elimination half-life is 3.5 hours (1).

Reproduction studies have been conducted in mice. Repeated intraperitoneal doses given to mice during organogenesis caused dose-related fetal malformations: incomplete ossification of talus and skull bone at about 1/833rd the recommended IV human dose based on BSA (RHD) and cleft palate at about 1/33rd the RHD. Embryo-fetal deaths and reduced litter sizes also were observed (1).

Carcinogenicity studies have not been conducted with pemetrexed. The drug

was clastogenic in an in vivo mouse assay, but was not mutagenic in multiple in vivo tests. IV doses administered to male mice that were about $\geq 1/1666$ th the RHD resulted in reduced fertility, hypospermia, and testicular atrophy (1).

It is not known if pemetrexed crosses the human placenta. The molecular weight (about 471 for the nonhydrated form), moderate plasma protein binding, and the elimination half-life suggest that the drug will cross to the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use of pemetrexed during human lactation have been located. The molecular weight (about 471 for the nonhydrated form), moderate (81%) plasma protein binding, and the elimination half-life (3.5 hours) suggest that the drug will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown, but severe toxicity such as that observed in patients receiving the drug (e.g., bone marrow suppression, hepatic and renal toxicities, and gastrointestinal disturbances) is a potential complication. Holding breastfeeding for 18–24 hours while “pumping and dumping,” would allow the drug to be nearly eliminated from the mother’s circulation and lessen the risk to a nursing infant. However, breastfeeding is not recommended if the therapy includes cisplatin (see Cisplatin).

PEMOLINE

[Withdrawn from the market. See 9th edition.]

PENBUTOLOL

Sympatholytic (Antihypertensive)

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of penbutolol in human pregnancy have been located. If used near delivery, the newborn infant should be closely observed for 24–48 hours for signs and symptoms of β -blockade. Long-term effects of in utero exposure to β -blockers have not been studied but warrant evaluation.

Some β -blockers may cause intrauterine growth restriction (IUGR) and reduced placental weight, especially those lacking intrinsic sympathomimetic activity (ISA) (i.e., partial agonist). Treatment beginning early in the 2nd trimester results in the greatest weight reductions, whereas treatment restricted to the 3rd trimester primarily affects only placental weight. Penbutolol does possess ISA. However, IUGR and reduced placental weight may potentially occur with all agents within this class. Although growth restriction is a serious concern, the benefits of maternal therapy with β -blockers, in some cases, might outweigh the risks to the fetus and must be judged on a case-by-case basis.

FETAL RISK SUMMARY

Penbutolol is a nonselective β_1 , β_2 -adrenergic blocking agent used in the treatment of hypertension. No teratogenic effects were noted in mice, rats, and rabbits treated with doses up to 250 times the maximum recommended human dose (MRHD) (1,2). A slight increase in fetal and newborn mortality was observed in rabbits given 156 times the MRHD (2). In rats dosed at 200 times the MRHD, decreased pup body weight and survival were observed (2). In mice, the drug produced no behavioral changes in the exposed offspring (1).

BREASTFEEDING SUMMARY

No reports describing the use of penbutolol during human lactation have been located. If penbutolol is used during nursing, the infant should be closely monitored for hypotension, bradycardia, and other signs or symptoms of β -blockade. Long-term effects of exposure to β -blockers from milk have not been studied but warrant evaluation.

PENCICLOVIR

Antiviral

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

One study reported the use of penciclovir in human pregnancy and found no statistically significant association with major birth defects (1). Penciclovir is the active metabolite of the prodrug famciclovir (see also Famciclovir). Animal reproductive data suggest low risk. In addition, the drug has not been detected in the plasma or urine after single or repeated topical doses in healthy males. Thus, the risk to an embryo or fetus from maternal use of the agent appears to be nil.

FETAL RISK SUMMARY

Penciclovir is an antiviral agent indicated for the treatment of recurrent herpes labialis (cold sores) in adults and children 12 years of age and older. Penciclovir is available for topical administration as a 1% cream that is active against herpes simplex types 1 and 2. The agent was not detected in the plasma (detection level 0.1 mcg/mL) or urine (detection level 10 mcg/mL) of healthy male adults following single or repeat applications of the cream (2).

Reproduction studies with penciclovir have been conducted in rats and rabbits. In these species, IV doses that were 260 and 355 times, respectively, the maximum recommended human topical dose caused no adverse effects on the course and outcome of pregnancy or on fetal development (2).

Two-year carcinogenicity studies have been conducted with famciclovir (the prodrug) in rats and mice. At a dose about 395 times the maximum theoretical human exposure from topical penciclovir based on AUC (M_{THE}), an increase in the incidence of mammary adenocarcinoma was observed in female rats. This tumor is common in female rats of the strain used. No increases in tumor incidence were observed in male rats or in male and female mice at doses

producing exposures that were about 190 and 100 times, respectively, the MTHE. High doses of penciclovir produced mixed results in mutagenic assays. In fertility studies with rats and dogs, high IV doses that were about 1155 and 3255 times, respectively, the MTHE caused testicular toxicity that included atrophy of the seminiferous tubules and decreased sperm counts. These effects were not observed with lower doses, nor have they been observed in clinical trials in immunocompetent men treated with famciclovir for recurrent genital herpes (2).

It is not known if penciclovir crosses the human placenta. The molecular weight (about 253) is low enough, but the systemic concentration is below the limit of detection. Consequently, clinically significant exposure of the embryo or fetus is not expected.

A 2010 study compared the pregnancy outcomes of 118 women exposed to penciclovir topical cream in the 1st trimester with 837,677 unexposed cases (1). The number of infants with birth defects in the two groups were 5 (4.2%) and 19,965 (2.4%), respectively. There was no significant association between exposure to penciclovir and the risk of major birth defects (prevalence odds ratio 1.88, 95% confidence interval 0.76–4.62) (1).

BREASTFEEDING SUMMARY

No reports describing the use of penciclovir during lactation have been located. The molecular weight (about 253) is low enough for excretion into breast milk, but the systemic concentration is below the limit of detection. Consequently, the effects on a nursing infant are probably nil.

PENICILLAMINE

Chelating Agent

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although the evidence is incomplete, maintaining the daily dose at ≤ 500 mg may reduce the incidence of penicillamine-induced toxicity in the newborn (1,2). The manufacturer recommends that the dose should be limited to 1 g/day and, if a cesarean section is planned, to 250 mg/day for 6 weeks before delivery and postoperatively until wound healing is complete (3).

FETAL RISK SUMMARY

Penicillamine is a chelating agent used in the treatment of Wilson's disease, cystinuria, and severe rheumatoid arthritis. Reproductive studies in rats at doses 6 times higher than the maximum recommended human dose revealed fetal anomalies consisting of skeletal defects, cleft palates, and fetal resorptions (3).

The use of penicillamine during pregnancy has been observed in >100 pregnancies (1,2,4–20). The mothers were treated for rheumatoid arthritis, cystinuria, or Wilson's disease. Most of the pregnancies resulted in healthy newborns who developed normally, but anomalies were observed in 10 infants:

Cutis laxa, hypotonia, hyperflexion of hips and shoulders, pyloric stenosis, vein fragility, varicosities, impaired wound healing, death (5)

Cutis laxa, growth restriction, inguinal hernia, simian crease, perforated bowel, death (8)

Cutis laxa (6)

Cutis laxa, mild micrognathia, low-set ears, inguinal hernia (12)

Cutis laxa, inguinal hernia (13)

Marked flexion deformities of extremities, dislocated hips, hydrocephalus, intraventricular hemorrhage, death (14)

Cerebral palsy, blindness, bilateral talipes, sudden infant death at 3 months

(14)

Hydrocephalus (14)

Ventricular septal defect (small) (9)

Bilateral cleft lip with totally cleft palate (19)

The relationship of the last five cases listed above to penicillamine is controversial because they did not include connective tissue anomalies. The drug may be partially responsible, but other factors, such as maternal infections and surgery, may have a stronger association with the defects (14).

A 2000 review cited data from the literature involving 111 women with Wilson's disease who had 153 pregnancies (20). The outcomes included 144 normal neonates (1 premature), 4 elective abortions, 1 spontaneous abortion, and 4 cases of birth defects (mannosidosis; cleft lip and palate; 2 transient cutis laxa).

Penicillamine crosses the placenta to the fetus. A mother was treated for cystinuria throughout gestation with penicillamine hydrochloride 1050 mg/day (843 mg of penicillamine base) (4). The drug was found in the urine of her newborn infant. The baby's physical and mental development was normal at 3 months.

A 1993 report described the effects of untreated Wilson's disease on a fetus (21). A 23-year-old woman, diagnosed with Wilson's disease at 12 years of age, had been treated with penicillamine but she had stopped the therapy when she was 15 years old. Liver cirrhosis, thrombocytopenia, and low serum proteins developed during the 2nd trimester and, when the diagnosis of Wilson's disease was remade (the patient had withheld information about her past history), an elective cesarean section was performed at 36 weeks' gestation. The 2380-g male infant had hepatomegaly, elevated liver enzymes, slightly low serum ceruloplasmin, and high excretion of urinary copper. His development during the first year was normal, as was his current serum ceruloplasmin concentration, but his liver enzymes remained elevated, possibly because of copper accumulation in the fetal liver (21).

Several conflicting recommendations have appeared in the literature concerning the use of penicillamine during pregnancy. The authors of one review believe the drug should be avoided during pregnancy (22). Another suggests that therapy with penicillamine should be continued during pregnancy in women with Wilson's disease, but stopped in those with rheumatoid arthritis (23). Still others recommend continuing therapy during the treatment of Wilson's disease, except during the 1st trimester (24).

BREASTFEEDING SUMMARY

No reports describing the use of penicillamine during lactation have been located. Authors of one review recommend avoiding penicillamine during lactation (21). However, a 2000 review stated that no adverse effects in nursing infants have been reported by mothers taking penicillamine, even though one study did find lower amounts of zinc and copper in milk (20).

PENICILLIN G

Antibiotic (Penicillin)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Penicillin G is used routinely for maternal infections during pregnancy. Reproduction studies in mice, rats, and rabbits revealed no evidence of impaired fertility or fetal harm (1). The antibiotic is considered low risk in pregnancy.

FETAL RISK SUMMARY

Several investigators have documented the rapid passage of penicillin G into the fetal circulation and amniotic fluid (2–6). Therapeutic levels are reached in both sites except for the amniotic fluid during the 1st trimester (6). At term, maternal serum and amniotic fluid concentrations are equal 60–90 minutes after IV administration (3). Continuous IV infusions (10,000 U/hr) produce equal concentrations of penicillin G at 20 hours in maternal serum, cord serum, and amniotic fluid (3).

The early use of penicillin G was linked to increased uterine activity and abortion (7–11). It is not known whether this was related to impurities in the drug or to penicillin itself. No reports of this effect have appeared since a report published in 1950 (11). An anaphylactic reaction in a pregnant patient reportedly led to the death of her fetus in utero (12).

Only one reference has linked the use of penicillin G with congenital abnormalities (13). An examination of hospital records indicated that in three of four cases the administration of penicillin G had been followed by the birth of a malformed baby. A retrospective review of additional patients exposed to antibiotics in the 1st trimester indicated an increase in congenital defects. Unfortunately, the authors did not analyze their data for each antibiotic, so no causal relationship to penicillin G could be shown (13,14).

In another case, a patient was treated in early pregnancy with high doses of penicillin G procaine IV,* cortisone, and sodium salicylate (15). A cyclopic male

was delivered at term but died 5 minutes later. The defect was attributed to salicylates, cortisone, or maternal viremia. In a controlled study, 110 patients received one to three antibiotics during the 1st trimester for a total of 589 weeks (16). Penicillin G was given for a total of 107 weeks. The incidence of birth defects was no different from that in a nontreated control group. (*Penicillin G procaine should not be given IV. Presumably, the drug was either given IM or the procaine form was not used. Attempts to clarify this with the authors have been unsuccessful.)

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 3546 of whom had 1st trimester exposure to penicillin derivatives (17, pp. 297–313). For use anytime during pregnancy, 7171 exposures were recorded (17, p. 435). In neither group was evidence found to suggest a relationship to large categories of major or minor malformations or to individual defects. From these data, it is unlikely that penicillin G is teratogenic.

BREASTFEEDING SUMMARY

Penicillin G is excreted into breast milk in low concentrations. Milk:plasma ratios following IM doses of 100,000 U in 11 patients varied between 0.02 and 0.13 (18). The maximum concentration measured in milk was 0.6 U/mL after this dose. Although no adverse effects were reported, three potential problems exist for the nursing infant: modification of bowel flora, direct effects on the infant (e.g., allergic response), and interference with the interpretation of culture results if a fever workup is required.

PENICILLIN G, BENZATHINE

Antibiotic (Penicillin)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Benzathine penicillin G is a combination of an ammonium base and penicillin G suspended in water (see also Penicillin G). Reproduction studies in mice, rats, and rabbits have revealed no evidence of impaired fertility or fetal harm (1). The antibiotic is considered low risk in pregnancy.

FETAL RISK SUMMARY

The pharmacokinetics of benzathine penicillin G in healthy women at 38–39 weeks' gestation, 1–7 days before delivery, have been described (2). Penicillin concentrations were measured in maternal serum, maternal cerebrospinal fluid, cord serum, and amniotic fluid. Because of the wide range of concentrations measured, the authors concluded that the altered pharmacokinetics occurring at this time may adversely affect the efficacy of the drug to prevent congenital syphilis.

BREASTFEEDING SUMMARY

See Penicillin G.

PENICILLIN G, PROCAINE

Antibiotic (Penicillin)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Procaine penicillin G is an equimolar combination of procaine and penicillin G suspended in water (1). The combination is broken down in vivo into the two components. Reproduction studies in mice, rats, and rabbits have revealed no evidence of impaired fertility or fetal harm (2) (see also Penicillin G). The antibiotic is considered low risk in pregnancy.

FETAL RISK SUMMARY

A case report described the use of high doses of penicillin G procaine IV,* cortisone, and sodium salicylate in early pregnancy followed by the delivery at term of a cyclopic male infant (3). The lethal defect was attributed to salicylates, cortisone, or maternal viremia. (*Penicillin G procaine should not be given IV. Presumably, the drug was either given IM or the procaine form was not used. Attempts to clarify this with the authors have been unsuccessful.)”

BREASTFEEDING SUMMARY

See Penicillin G.

PENICILLIN V

Antibiotic (Penicillin)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No reports linking the use of penicillin V with congenital defects have been located. The antibiotic is considered low risk in pregnancy.

FETAL RISK SUMMARY

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 3546 of whom had 1st trimester exposure to penicillin derivatives (1, pp. 297–313). For use anytime during pregnancy, 7171 exposures were recorded (1, p. 435). In neither group was evidence found to suggest a relationship to large categories of major or minor malformations or to individual defects.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 4597 newborns had been exposed to penicillin V during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 202 (4.4%) major birth defects were observed (195 expected). Specific data were available for six defect categories, including (observed/expected) 46/56 cardiovascular defects, 5/7 oral clefts, 3/2 spina bifida, 17/13 polydactyly, 7/8 limb reduction defects, and 8/11 hypospadias. These data do not support an association between the drug and congenital defects.

Penicillin V depresses both plasma-bound and urinary excreted estriol (2). Urinary estriol was formerly used to assess the condition of the fetoplacental unit, with depressed levels being associated with fetal distress. This assessment is now made by measuring plasma-unconjugated estriol, which is not usually affected by penicillin V.

The pharmacokinetics of penicillin V during the 2nd and 3rd trimesters have been reported (3). Elimination of the drug is enhanced at these stages of pregnancy.

BREASTFEEDING SUMMARY

No reports describing the use of penicillin V during human lactation have been located. (See also Penicillin G.)

PENTAERYTHRITOL TETRANITRATE

[Withdrawn from the market. See 9th edition.]

PENTAMIDINE

Antiprotozoal

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Pentamidine is an antiprotozoal agent indicated for the treatment of pneumonia caused by *Pneumocystis carinii*, a common opportunistic infection in patients suffering from HIV disease. Although no developmental toxicity has been observed with this agent, some sources consider it contraindicated in pregnancy. Nevertheless, the maternal benefit appears to outweigh the unknown embryo–fetal risk.

FETAL RISK SUMMARY

The mechanism of action of pentamidine is not fully known. In vitro tests have indicated that pentamidine inhibits the synthesis of DNA, RNA, phospholipids, and proteins, and may be a folic acid antagonist by inhibiting dihydrofolate reductase (1,2).

Pentamidine was not teratogenic in pregnant rats treated with doses similar to those used in humans (3). However, these doses were embryocidal when administered during embryogenesis (3). Significant placental transfer was observed in rats administered pentamidine in late pregnancy (4). By the 12th hour, fetal brain tissue concentrations of pentamidine were statistically similar to the maternal serum levels achieved 2 hours after the dose.

In an experiment using in vitro–perfused human placentas, the placental transfer of pentamidine in humans was undetectable with therapeutic maternal concentrations of approximately 2 mcg/mL (5). The level of sensitivity of the high-performance liquid chromatography method was 0.05 mcg/mL. When peak concentrations of pentamidine on the maternal side were increased to approximately 14 mcg/mL, fetal levels were consistently 0.2 mcg/mL at 30 minutes. Pentamidine did concentrate in placental tissue at all drug levels studied, but the clinical significance of this to placental function is unknown (5).

In contrast to the above, a study published in 1995 used a more sensitive test to document the placental transfer of pentamidine at about 33 weeks' gestation (6). A 21-year-old HIV-infected woman received pentamidine, 200 mg (3.4 mg/kg) IV daily, for 7 days before a cesarean section. A maternal serum sample, drawn 8 hours after her seventh dose, was 0.0813 mcg/mL (free base). The pentamidine concentration in the cord blood sample, obtained 16.5 hours after the dose, was 0.0132 mcg/mL.

The CDC recommends aerosolized pentamidine as one of two treatment regimens for prophylaxis against *P. carinii* in persons infected with HIV (7,8). However, because the safety of this treatment has not been established in human pregnancies, the CDC advises against this use in pregnant women (7,8). Others have cited information from the manufacturer that the use of aerosolized pentamidine is contraindicated in pregnancy (9).

A 1988 reference cited a concern that pregnant health care workers involved in the care of patients treated with aerosolized pentamidine might be at risk for fetal harm (10). An estimation of this risk, based on a pharmacokinetic model, was published in 1994 (11). The maximum exposure of health care workers, at two different hospitals, to aerosolized pentamidine was estimated to be 1.7 and 9.8 mcg/kg/day (IV equivalent). The authors then calculated the embryo-lethal and teratogenic IV-equivalent reference doses, based on pregnant rat data, to be 0.08 and 4 mcg/kg/day, respectively. Comparison of the estimated actual exposures to the predicted toxic levels led to the conclusion that improvement was needed in the methods used to reduce pentamidine exposure of health care workers (11).

An argument favoring the use of pentamidine in the pregnant patient with active *P. carinii* pneumonia, when other treatment regimens had failed, was put forth in a 1987 article (12). Moreover, this same source, in a 1990 reference, argued that the availability of aerosolized pentamidine for prophylaxis should be disclosed to the pregnant HIV-seropositive patient "as part of the informed consent process" (13). This latter position is strengthened by the *in vitro* data cited above relating to the placental transfer of the agent. Because aerosolized pentamidine results in very low systemic concentrations, fetal exposure to the drug by this route is probably minimal and below the level of detection.

The use of aerosolized and IV pentamidine during gestation in women with HIV infection has been described (14–17). A 1992 abstract described the use of aerosolized pentamidine, 300 mg/month, in 15 women during the 2nd and 3rd trimesters (14). No significant effects on the course of pregnancy or on the fetus or newborn were observed. The second reference reported five

pregnancies (six fetuses, one set of twins) that were treated with aerosolized pentamidine, zidovudine, and other drugs (15). One woman was treated throughout her 39-week gestation, one from 10 to 39 weeks' gestation, and three during the 2nd and 3rd trimesters. The outcomes of the exposed pregnancies included one growth-restricted infant, one with albinism, one with congenital cytomegalovirus infection, and three normal infants. The latter two references described IV pentamidine in five women (16) and aerosolized drug in nine (16,17). No adverse fetal effects of the drug were reported.

BREASTFEEDING SUMMARY

Because systemic concentrations achieved with aerosolized pentamidine are very low, breast milk levels of the drug after administration via this route are probably nil. No reports of lactating women administered pentamidine by any route (IM, IV, or by inhalation) have been located.

PENTAZOCINE

Narcotic Agonist–Antagonist Analgesic

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The National Birth Defects Prevention Study discussed below found evidence that opioid use during organogenesis is associated with a low absolute risk of congenital birth defects. In addition, pentazocine is associated with behavioral teratogenicity, either from the drug itself, the mother's lifestyle, other drug abuse, or a combination of these factors. Moreover, its abuse during pregnancy is associated with intrauterine growth restriction and withdrawal in the newborn.

FETAL RISK SUMMARY

Oral pentazocine is only available in the United States in combination with naloxone or acetaminophen. However, an injectable form of the drug is available. Reproductive studies in animals did not find embryotoxic or teratogenic effects (1). In a 1975 reference, however, increasing single SC doses of pentazocine (98–570 mg/kg) administered to hamsters during the critical period of CNS organogenesis resulted in a significant increase in the number of offspring with malformations (exencephaly, cranioschisis, and various other CNS lesions). Maternal death was observed in 10% of the mothers at the highest dose, but not with the lower doses (2).

The drug rapidly crosses the placenta, resulting in cord blood levels of 40%–70% of maternal serum (3). Withdrawal has been reported in infants exposed in utero to chronic maternal ingestion of pentazocine (4–8). Symptoms, presenting within 24–48 hours of birth, consist of trembling and jitteriness, marked hyperirritability, hyperactivity with hypertonia, high-pitched cry, diaphoresis, diarrhea, vomiting, and opisthotonic posturing.

During labor, increased overall uterine activity has been observed after pentazocine, but without changes in fetal heart rate (9). In equianalgesic doses,

most studies report no significant differences between meperidine and pentazocine in pain relief, length of labor, or Apgar scores (10–15). However, meperidine in one study was observed to produce significantly lower Apgar scores than pentazocine, especially in repeated doses (16). Severe neonatal respiratory depression may also occur with pentazocine (10,16).

A 1982 report from New Orleans described 24 infants born of mothers using the IV combination of pentazocine/tripelennamine (T's and blue's) (17). Doses were unknown but probably ranged from 200 to 600 mg of pentazocine and 100 to 250 mg of tripelennamine. Six of the newborns were exposed early in pregnancy. Birth weights for 11 of the infants were <2500 g; 9 of these were premature (<37 weeks) and 2 were small for gestational age. Daily or weekly exposure throughout pregnancy produced withdrawal symptoms, occurring ≤7 days of birth, in 15 of 16 infants. Withdrawal was thought to be related to pentazocine, but antihistamine withdrawal has been reported (see Diphenhydramine). Thirteen of 15 infants became asymptomatic 3–11 days following onset of withdrawal, but symptoms persisted for up to 6 months in 2 (17).

Three cases of maternal bacterial endocarditis were observed following IV drug abuse, one of which involved the injection of pentazocine/tripelennamine intermittently throughout pregnancy (18). Following satisfactory antibiotic treatment for the infection, the mother gave birth at term to a healthy, male infant.

In a study published in 1983, three groups of pregnant women were evaluated in a perinatal addiction program in the Chicago area (19). One group (N = 13) was composed of women addicted to pentazocine/tripelennamine. A second group consisted of women who conceived while self-administering heroin, and who were then converted to low-dose (5–40 mg/day) methadone (N = 46). The third group consisted of drug-free controls (N = 27). The three groups were statistically similar as to mean maternal age, educational level, gravidity, cigarette smoking, and mean weight gain during pregnancy. Heavy alcohol users were excluded. All infants were delivered at term. Apgar scores were similar among the three groups of newborns, and no significant perinatal complications were observed. Mean birth weight, length, and head circumference were similar between the two drug groups. Compared with the drug-free controls, the pentazocine/tripelennamine-exposed infants had significantly lower weights (2799 vs. 3479 g), lengths (48.1 vs. 51.1 cm), and head circumferences (32.9 vs. 34.7 cm). Neonatal withdrawal was observed in both drug-exposed infant groups. Withdrawal characteristics observed in the

pentazocine/tripelennamine infants were similar to those seen in the methadone group, consisting of irritability, voracious sucking, and feeding difficulties (19). However, none of these infants required therapy for their symptoms. Neonatal behavior was evaluated using the Brazelton Neonatal Behavioral Assessment Scale. Results of these tests indicated that the infants exposed to the drug combination had interactive deficits and withdrawal similar to the methadone-addicted babies (19).

In 1986, nearly the same data as above were published but with the addition of a group exposed to mixed sedative/stimulant (N = 22) and a group exposed to phencyclidine (N = 9) (20). The outcomes of the pentazocine/tripelennamine group were the same as above.

Another study described the effects of pentazocine/tripelennamine abuse in 50 pregnancies identified retrospectively from 23,779 deliveries occurring between 1981 and 1983 (21). Compared with matched controls, users of the combination were significantly more likely to have no prenatal care; to be anemic; and to have syphilis, gonorrhea, or hepatitis. Moreover, their infants were significantly more likely to be small for gestational age, to have lower birth weights (3260 vs. 2592 g), to have a 1-minute Apgar score <7, and to have neonatal withdrawal. No congenital abnormalities were observed in the infants exposed to the drug combination.

A study published in 1993 examined the effects on the fetus and newborn of IV pentazocine and methylphenidate abuse during pregnancy (22). During a 2-year (1987–1988) period, 39 infants (38 pregnancies, 1 set of twins) were identified in the study population as being subjected to the drug abuse during gestation, a minimum incidence of 5 cases per 1000 live births. Many of the mothers had used cigarettes (34%) or alcohol (71%) or abused other drugs (26%). The median duration of IV pentazocine and methylphenidate abuse was 3 years (range 1–9 years) with a median frequency of 14 injections/week (range 1–70 injections/week). Among the infants, 8 were delivered prematurely, 12 were growth restricted, and 11 had withdrawal symptoms. Four of the infants had birth defects, including twins with fetal alcohol syndrome, one with a ventricular septal defect, and one case of polydactyly. Of the 21 infants who had formal developmental testing, 17 had normal development and 4 had low-normal developmental quotients (22).

Results of a National Birth Defects Prevention Study (1997–2005) were published in 2011 (23). This population-based case–control study examined the association between maternal use of opioid analgesics and >30 types of major structural birth defects. In 17,449 case mothers, therapeutic opioid use was

reported by 454 (2.6%) compared with 134 (2.0%) of 6701 control mothers. Indications for use of opioid analgesics were surgical procedures (41%), infections (34%), chronic diseases (20%), and injuries (18%). Dose, duration, or frequency were not evaluated. The exposure period evaluated was from 1 month before to 3 months after conception. Limiting the exposure period to the first 2 months after conception produced similar results. Infants with >1 defect were included in multiple birth defect categories. The following opioids were included (number of cases for each agent not specified): codeine, hydrocodone, hydromorphone, fentanyl, meperidine, methadone, morphine, oxycodone, pentazocine, propoxyphene, and tramadol. The birth defect, total number, number exposed, and the adjusted odds ratio (aOR) with 95% confidence interval (CI) were as follows:

| Birth Defect | Total | Cases | aOR (95% CI) |
|--|-------|-------|---------------|
| Spina bifida | 718 | 26 | 2.0 (1.3–3.2) |
| <i>Any heart defect (20 types)</i> | 7724 | 211 | 1.4 (1.1–1.7) |
| Atrioventricular septal defect | 175 | 9 | 2.4 (1.2–4.8) |
| Teratology of Fallot | 672 | 21 | 1.7 (1.1–2.8) |
| Conotruncal defect | 1481 | 41 | 1.5 (1.0–2.1) |
| Conoventricular septal defect | 110 | 6 | 2.7 (1.1–6.3) |
| Left ventricular outflow tract obstruction defect | 1195 | 36 | 1.5 (1.0–2.2) |
| Hypoplastic left heart syndrome | 357 | 17 | 2.4 (1.4–4.1) |
| Right ventricular outflow tract obstruction defect | 1175 | 40 | 1.6 (1.1–2.3) |
| Pulmonary valve stenosis | 867 | 34 | 1.7 (1.2–2.6) |
| Atrial septal defect (ASD) | 511 | 17 | 2.0 (1.2–3.6) |
| Ventricular septal defect + ASD | 528 | 17 | 1.7 (1.0–2.9) |
| Hydrocephaly | 301 | 11 | 2.0 (1.0–3.7) |
| Glaucoma/anterior chamber defects | 103 | 5 | 2.6 (1.0–6.6) |
| Gastroschisis | 726 | 26 | 1.8 (1.1–2.9) |

The authors speculated that the activity of opioids and their receptors as

growth regulators during development of the embryo might be a mechanism to explain the above findings. The exposure data were obtained by retrospective maternal self-report; the authors acknowledged that recall bias and misclassification might have affected their results. They concluded that the absolute risk was a modest absolute increase above the baseline risk for birth defects (23).

BREASTFEEDING SUMMARY

No reports describing the use of pentazocine during lactation have been located. The molecular weight (about 285) suggests that the drug will be excreted into breast milk. The effects of this exposure on a nursing infant are unknown, but small, infrequent doses most likely present a minimal risk.

PENTOBARBITAL

Sedative/Hypnotic

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports linking the use of pentobarbital with congenital defects have been located. However, the data are limited and there are no relevant animal reproduction studies.

FETAL RISK SUMMARY

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 250 of whom had 1st trimester exposure to pentobarbital (1). No evidence was found to suggest a relationship to large categories of major or minor malformations or to individual defects. Hemorrhagic disease and barbiturate withdrawal in the newborn are theoretical possibilities (see also Phenobarbital).

BREASTFEEDING SUMMARY

Pentobarbital is excreted into breast milk (2). Breast milk levels of 0.17 mcg/mL have been detected 19 hours after a dose of 100 mg daily for 32 days. The effect on the nursing infant is not known.

PENTOSAN

Urinary Tract Agent (Analgesic)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Except for the one case (discussed below), no reports describing the use of pentosan in human pregnancy have been located. The animal data suggest low risk but the absence of human pregnancy experience prevents a more complete assessment. The drug does not appear to cross the placenta, at least in amounts that could affect fetal coagulation. The prevalence of interstitial cystitis in pregnancy is unknown. Studies have found that nearly one in four women in the general population has the disease (1). Thus, the prevalence in pregnancy may be higher than suggested by the lack of reported exposures. Based only on the animal data and the pharmacokinetics of the drug, inadvertent or planned exposure during gestation appears to represent a low risk to the embryo–fetus.

FETAL RISK SUMMARY

Pentosan polysulfate is an oral semi-synthetic heparin-like macromolecular carbohydrate derivative that chemically and structurally resembles glycosaminoglycans. It is a low-molecular-weight heparinoid compound with anticoagulant and fibrinolytic effects. Pentosan is indicated for the relief of bladder pain or discomfort associated with interstitial cystitis. The oral absorption is low, about 3%, and drug reaching the systemic circulation is partly metabolized in the liver, spleen, and kidney. The elimination half-life from urine following oral administration is 4.8 hours (2).

Reproduction studies have been conducted in mice, rats, and rabbits. In mice and rats, daily IV doses 0.42 times the daily oral human dose based on BSA (DOHD) revealed no evidence of impaired fertility or fetal harm. A similar

negative result was observed in rabbits given daily IV doses 0.14 times the DOHD. Bathing of in vitro–cultured mouse embryos with a concentration of 1 mg/mL caused reversible limb bud abnormalities (2). However, this finding has no clinical significance because the concentration was far in excess of the potential human embryo exposure.

Animal studies for carcinogenicity have not been conducted. However, assays for mutagenic and clastogenic effects were negative (2).

The high molecular weight (4000–6000) and low oral absorption suggest that pentosan does not reach the embryo or the fetus. A 1986 study found no evidence of placental transfer in eight women undergoing elective abortions between the 18th and 23rd week of gestation for chromosomal abnormalities (3). All women were given a single 50-mg IV dose of pentosan polysulfate. Blood samples drawn 30 minutes later showed a marked change in the mean activated partial thromboplastin time (APTT), which increased from 35 to 88 seconds, and factor V level, decreasing from 87% to 33%. Fetal samples, drawn from the umbilical cord before abortion in controls and at the same time as the maternal samples in exposed fetuses, showed no differences in these parameters (93 vs. 91 seconds and 42% vs. 48%, respectively) (3).

BREASTFEEDING SUMMARY

No reports describing the use of pentosan polysulfate during human lactation have been located. The high molecular weight (4000–6000) and low oral bioavailability suggest that the drug will not be detected in breast milk. Moreover, at least in adults, the oral absorption is only about 3%. Thus, the risk to a nursing infant from the drug probably is nil.

PENTOSTATIN

Antineoplastic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of pentostatin in human pregnancy have been located. The animal reproduction data suggest risk, but the absence of human pregnancy experiences prevents a complete assessment of the embryo–fetal risk. However, pentostatin inhibits the synthesis of DNA and RNA, and increases DNA damage. Because hairy cell leukemia usually has an indolent course, deferring treatment until after delivery may be appropriate (1).

FETAL RISK SUMMARY

Pentostatin is a hydrophilic, cytotoxic agent that is classified as an antimetabolite. It is in the same antineoplastic subclass of purine analogs and related agents as cladribine, clofarabine, fludarabine, mercaptopurine, and thioguanine. Pentostatin is indicated as single-agent treatment for both untreated and alpha-interferon-refractory hairy cell leukemia patients with active disease as defined by clinically significant anemia, neutropenia, thrombocytopenia, or disease-related symptoms. It inhibits DNA and RNA synthesis and causes increased DNA damage. The agent is partially metabolized before urinary excretion, but the activity of the metabolites (assumed to be inactive) has not been stated. Plasma protein binding is very low (about 4%) and the terminal elimination half-life is 5.7 hours (2).

Reproduction studies have been conducted in rats, mice, and rabbits. In rats, daily IV doses (days 6–15) that were about (based on total dose) 1.5 and 11 times the recommended human dose given every 2 weeks based on BSA (RHD) caused maternal toxicity and the highest dose was associated with various fetal skeletal malformations. Other defects observed in rats were

omphalocele at about 0.75 times the RHD, gastroschisis at about 11 and 15 times the RHD, and flexure defect of the hindlimbs at about 11 times the RHD. The drug was teratogenic (defects not specified) in mice given a single intraperitoneal dose that was about 1.5 times the RHD. No teratogenicity was observed in rabbits with daily IV doses (days 6–18) that were about (based on total dose) 0.05–0.2 times the RHD. However, maternal toxicity, abortions, early deliveries, and deaths occurred in all dose groups (2).

Carcinogenic studies have not been conducted. Pentostatin was mutagenic in some assays but not others, and was clastogenic in one test. Fertility studies have not been conducted, but in a 5-day IV toxicity study in dogs, mild seminiferous tubular degeneration was observed (2).

It is not known if pentostatin crosses the human placenta. The molecular weight (about 268), low plasma protein binding, and moderate elimination half-life suggest that exposure of the embryo–fetus will occur.

BREASTFEEDING SUMMARY

No reports describing the use of pentostatin during human lactation have been located. The molecular weight (about 268), low plasma protein binding (about 4%), and moderate elimination half-life (5.7 hours) suggest that the drug will be excreted into breast milk. However, the hydrophilic properties of the drug may limit excretion. The effect of this exposure on a nursing infant is unknown, but the drug has caused severe toxicity in treated patients, such as gastrointestinal upset, rash, fever, and fatigue. If a woman elects to breastfeed in spite of this potential risk, pumping and dumping for about 30 hours after a dose should significantly reduce the exposure.

PENTOXIFYLLINE

Hemorrhheologic Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Pentoxifylline is a synthetic xanthine derivative used to lower blood viscosity in peripheral vascular and cerebrovascular diseases. No published reports of its use in human pregnancy have been located. The drug caused embryo death in rats at a dose near the human therapeutic dose.

FETAL RISK SUMMARY

Reproduction studies in rats and rabbits at oral doses up to 4.2 and 3.5 times the maximum recommended human dose based on BSA revealed no evidence of teratogenicity. In rats, however, an increased incidence of resorptions was seen at the maximum dose (1).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 34 newborns had been exposed to pentoxifylline during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Five (14.7%) major birth defects were observed (one expected), including (observed/expected) 2/0 cardiovascular defects and 1/0 spina bifida. No anomalies were observed in four other defect categories (oral clefts, polydactyly, limb reduction defects, and hypospadias) for which specific data were available. Although the number of exposures is small, the total number of defects and both specific defects are suggestive of possible associations, but other factors, including the mother's disease, concurrent drug use, and chance, may be involved.

Pentoxifylline causes a significant increase in sperm motility, but not concentration, and may be useful in patients with normogonadotrophic asthenozoospermia (2).

BREASTFEEDING SUMMARY

Pentoxifylline is excreted into human milk. Five healthy women who had been breastfeeding for at least 6 weeks were given a single 400-mg sustained-release tablet of pentoxifylline after a 4-hour fast (3). The mean milk:plasma ratio of unmetabolized pentoxifylline at 4 hours was 0.87. Mean milk:plasma ratios for the three major metabolites at 4 hours were 0.76, 0.54, and 1.13. Mean milk concentration of pentoxifylline at 2 hours (73.9 ng/mL) was approximately twice as much as that occurring at 4 hours (35.7 ng/mL) (3). Pentoxifylline and its metabolites are stable in breast milk for 3 weeks when stored at -15°C (4).

PEPPERMINT

Herb

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Peppermint and its oil have been used for hundreds of years. These products are available as teas, liquid extract, capsules, lozenges, throat sprays, flavorings, liniments, and inhalants. Several sources state that ingestion of large doses of peppermint/peppermint oil is unsafe in pregnancy because of possible emmenagogue and abortifacient effects. Although scientific documentation of increased uterine bleeding and abortion associated with peppermint/peppermint oil has not been located, high oral doses of menthol (e.g., 2–9 g) are considered lethal (1). However, this should not be concern for topical preparations and ingesting recommended doses of oral products. The absence in the medical literature of adverse reports involving a commonly used substance suggests that there is little risk from the typical use of this herb in pregnancy.

FETAL RISK SUMMARY

A variety of peppermint plants are cultivated in Europe and North America. Peppermint (*Mentha x piperita*) and its essential oil, first described in England in 1696, have been used in the treatment of cancers, colds, cramps, indigestion, nausea, sore throat, and toothaches (2). The plants contain 0.1%–1.5% essential oil (2,3). More than 100 compounds have been isolated from peppermint oil, but the primary pharmacologically active agents are menthol (29%–48%), menthone (20%–31%), and menthyl acetate (3%–10%), and lesser amounts of caffeic acid, flavonoids, and tannins (2). Menthol is a common ingredient in over-the-counter mouth and throat products and liniments.

The ingestion of large doses of peppermint or peppermint oil in pregnancy is

considered by some reviewers to be unsafe because of a possible emmenagogue and abortifacient properties (1,2,4–6), but another source does not mention these effects (7). No original reports describing this toxicity have been located.

A 2000 review conducted an extensive search of the literature regarding the use of herbal products for nausea/vomiting of pregnancy (8). Finding little information in scientific and medical databases, the author continued the search in Web sites and the lay literature. From this source, the most commonly recommended herbs, all in the form of teas, were red raspberry leaf, ginger, peppermint, and chamomile (Roman and/or German). There were 33 sources recommending peppermint and 6 stating that it was unsafe in pregnancy. However, none of the sources provided scientific or clinical evidence to support their recommendations or warnings (8).

In a 2004 nonrandomized study conducted in Canada, 20 of 27 women (74%) experienced pregnancy-induced nausea/vomiting 10 of whom were being treated with herbal remedies (9). The herbal remedies were ginger (N = 3), ginger plus peppermint (N = 3), peppermint (N = 3), and cannabis (N = 1). Although the peak incidence of nausea/vomiting of pregnancy is usually in the 1st trimester, no information was given on the timing or quantity of the exposures or the outcomes of the pregnancies (9).

BREASTFEEDING SUMMARY

No reports describing the use of peppermint, peppermint oil, or menthol during lactation have been located. Peppermint and its oil have been used for hundreds of years. These products are available as teas, liquid extract, capsules, lozenges, throat sprays, flavorings, liniments, and inhalants. The absence in the medical literature of adverse reports involving a commonly used substance suggests that there is little risk to a nursing infant from the mother's use of this herb during breastfeeding. Because infants may be sensitive to menthol (1,2), rubs and liniments containing menthol should not be applied to the mother's breast or nipples.

PERAMPANEL

Anticonvulsant

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of perampanel in human pregnancy have been located. The animal data suggest risk, but the absence of human pregnancy experience prevents a more complete assessment of the embryo–fetal risk. If the drug is used in pregnancy, physicians are encouraged to recommend that their patient enroll in the North American Antiepileptic Drug Pregnancy Registry by calling the toll free number 1-888-233-2334. Information on the Registry can also be found at the website: <http://www.aedpregnancyregistry.com>.

FETAL RISK SUMMARY

Perampanel is a noncompetitive antagonist of a glutamate receptor on postsynaptic neurons. It is indicated as adjunctive therapy for the treatment of partial-onset seizures with or without secondarily generalized seizures in patients with epilepsy 12 years or older. It is extensively metabolized to apparently inactive metabolites. Plasma protein binding, mainly to albumin and α 1-acid glycoprotein, is about 95%–96% and the half-life is about 105 hours (1).

Reproduction studies have been conducted in rats and rabbits. In pregnant rats during organogenesis, all doses (1, 3, or 10 mg/kg/day) tested resulted in visceral abnormalities (diverticulum of the intestine). The lowest dose was similar to the human dose of 8 mg/day based on BSA (HD). Embryo lethality and reduced fetal body weight were observed at the mid and high doses. When all doses tested were given throughout gestation and lactation, fetal and pup deaths were observed at the mid and high doses and delayed sexual maturation in males and females at the highest dose. No effects were observed

on measures of neurobehavioral or reproductive function in the offspring. The no-effect dose for prenatal and postnatal developmental toxicity was similar to the HD. In pregnant rabbits given the drug throughout organogenesis at the same three doses as above, embryo lethality was observed at the mid to high doses; the no-effect dose was about 2 times the HD (1).

Long-term studies for carcinogenicity in mice and rats were negative as were the assays for mutagenicity. No clear effects on fertility were observed in male and female rats given perampanel (1, 10, or 30 mg/kg/day) before and throughout mating and continuing in females to gestation day 6. Prolonged and/or irregular estrus cycles were observed at all doses tested, but especially at the highest dose (1).

It is not known if perampanel crosses the human placenta. The molecular weight (about 349 for the nonhydrated form) and the long half-life suggest that the drug will cross to the embryo and fetus in spite of the high plasma protein binding.

BREASTFEEDING SUMMARY

No reports describing the use of perampanel during human lactation have been located.

The molecular weight (about 349 for the nonhydrated form) and the long half-life (105 hours) suggest that the drug will be excreted into breast milk in spite of the high (95%–96%) plasma protein binding. The effect of this exposure on a nursing infant is unknown. If the drug is used during breastfeeding, the infant should be monitored for some of the most common adverse reactions observed in adults, such as dizziness, somnolence, fatigue, irritability, and nausea.

PERGOLIDE

[Withdrawn from the market. See 9th edition.]

PERINDOPRIL

Antihypertensive

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The fetal toxicity of perindopril in the 2nd and 3rd trimesters is similar to other angiotensin-converting enzyme (ACE) inhibitors. The use of this drug during the 2nd and 3rd trimesters may cause teratogenicity and severe fetal and neonatal toxicity. Fetal toxic effects may include anuria, oligohydramnios, fetal hypocalvaria, intrauterine growth restriction (IUGR), prematurity, and patent ductus arteriosus. Stillbirth or neonatal death may occur. Anuria-associated oligohydramnios may produce fetal limb contractures, craniofacial deformation, and pulmonary hypoplasia. Severe anuria and hypotension, which is resistant to both pressor agents and volume expansion, may occur in the newborn following in utero exposure. Newborn renal function and blood pressure should be closely monitored.

FETAL RISK SUMMARY

Perindopril, an ACE inhibitor, is a prodrug that is hydrolyzed in vivo to the active agent, perindoprilat. The agent is used in the management of essential hypertension.

Reproduction studies have been conducted with perindopril in mice, rats, rabbits, and cynomolgus monkeys (1). No evidence of teratogenicity was observed in these species at doses 6, 670, 50, and 17 times, respectively, the maximum recommended human dose based on BSA for a 50-kg adult (MRHD). At 6 times the MRHD in rats, no adverse effects on reproductive performance or fertility were observed in male and female rats (1).

It is not known if either perindopril or its metabolite, perindoprilat, crosses the human placenta to the fetus. The molecular weights of perindopril (about 368 for the free acid or 442 for the salt form) and perindoprilat (less than the

prodrug) suggest that transfer to the embryo and fetus will occur.

A retrospective study using pharmacy-based data from the Tennessee Medicaid program identified 209 infants, born between 1985 and 2000, who had 1st trimester exposure to ACE inhibitors (2). Infants of mothers with evidence of diabetes, either before or during pregnancy, were excluded, as were those exposed to angiotensin-receptor antagonists (ARBs), ACE inhibitors, or other antihypertensives beyond the 1st trimester, and exposure to known teratogens. Two comparison groups, other antihypertensives (N = 202) and no antihypertensives (N = 29,096), were formed. The number of major birth defects in each of the three groups was 18 (8.6%), 4 (2%), and 834 (2.9%), respectively. Compared with the no antihypertensives group, exposure to ACE inhibitors was associated with a significantly increased risk of major defects (relative risk [RR] 2.71, 95% confidence interval [CI] 1.72–4.27). When the analysis was conducted by the type of defect, the highest rates were with cardiovascular defects, 9, 2, and 294, respectively, RR 3.72, 95% CI 1.89–7.30, and with CNS defects, 3, 0, and 80, respectively, RR 4.39, 95% CI 1.37–14.02. The major defects observed in the subject group were atrial septal defect (N = 6, includes three with pulmonic stenosis and/or three with ductus arteriosus [PDA]), renal dysplasia (N = 2), PDA alone (N = 2), and one each of ventricular septal defect, spina bifida, microcephaly with eye anomaly, coloboma, hypospadias, intestinal and choanal atresia, Hirschsprung disease, and diaphragmatic hernia (2). In an accompanying editorial, it was noted that neither previous reports of 1st trimester exposure to ACE inhibitors nor the animal studies had observed an increased risk of birth defects (3). It also was noted that no mechanism for ACE inhibitor–induced teratogenicity was known. A subsequent communication raising concerns about the validity of the study in terms of adequate exclusion of diabetes, charting and coding errors in busy medical practices, and the effects of maternal obesity (4) was addressed by the investigators (5).

Perindopril and other ACE inhibitors are human teratogens when used in the 2nd and 3rd trimesters, producing fetal hypocalvaria and renal defects. The cause of the defects and other toxicity is probably related to fetal hypotension and decreased renal blood flow. The compromise of the fetal renal system may result in severe, and at times fatal, anuria, both in the fetus and in the newborn. Anuria-associated oligohydramnios may produce pulmonary hypoplasia, limb contractures, persistent PDA, craniofacial deformation, and neonatal death (6,7). IUGR, prematurity, and severe neonatal hypotension may also be observed. Two reviews of fetal and newborn renal function indicated that both

renal perfusion and glomerular plasma flow are low during gestation and that high levels of angiotensin II may be physiologically necessary to maintain glomerular filtration at low perfusion pressures (8,9). Perindopril prevents the conversion of angiotensin I to angiotensin II and, thus, may lead to in utero renal failure. Since the primary means of removal of the drug is renal, the impairment of this system in the newborn prevents elimination of the drug resulting in prolonged hypotension. Newborn renal function and blood pressure should be closely monitored. If oligohydramnios occurs, stopping perindopril may resolve the problem but may not improve infant outcome because of irreversible fetal damage (6). In those cases in which perindopril must be used to treat the mother's disease, the lowest possible dose should be used combined with close monitoring of amniotic fluid levels and fetal well-being. Guidelines for counseling exposed pregnant patients have been published and should be of benefit to health professionals faced with this task (6,10).

The observation in Tennessee Medicaid data of an increased risk of major congenital defects after 1st trimester exposure to ACE inhibitors raises concerns about teratogenicity that have not been seen in other studies (3). Medicaid data are a valuable tool for identifying early signals of teratogenicity, but are subject to a number of shortcomings and their findings must be considered hypotheses until confirmed by independent studies.

A 2012 review of the use of ACE inhibitors and ARBs in the 1st trimester concluded that there may be an elevated teratogenic risk, but the risk appeared to be related to other factors (11). The factors, that typically coexist with hypertension in pregnancy, included diabetes, advanced maternal age, and obesity.

BREASTFEEDING SUMMARY

No reports describing the use of the prodrug perindopril during human lactation have been located. The molecular weights of perindopril (about 368 for the free acid and 442 for the salt form) and its active metabolite, perindoprilat (molecular weight less than perindopril), suggest that both will be excreted into breast milk. The effects on a nursing infant from exposure to perindopril or perindoprilat in milk are unknown. However, other agents in this class are excreted into milk and, because the amounts are low and no adverse effects have been observed in nursing infants, are classified as compatible with breastfeeding by the American Academy of Pediatrics (see also Captopril and Enalapril).

PERMETHRIN

Scabicide

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Neither the animal data nor the limited human pregnancy data suggest risk for the embryo or fetus. The CDC considers permethrin or pyrethrins with piperonyl butoxide to be the treatments of choice for pubic lice in pregnant women (1). Although not specifically mentioned, permethrin or pyrethrins with piperonyl butoxide should also be used if other body areas of a pregnant woman, such as the head, are infested with lice. For pregnant women with scabies, permethrin is considered the treatment of choice in the United States and the United Kingdom (1,2).

FETAL RISK SUMMARY

Permethrin, a pyrethroid, is indicated for the topical treatment of *Sarcoptes scabiei* (scabies) infestations. The drug is also active against lice, ticks, fleas, mites, and other arthropods. In patients with moderate to severe scabies, systemic absorption was estimated to be $\leq 2\%$ of the dose (3,4).

Oral reproduction studies with permethrin have been conducted in mice, rats, and rabbits at doses of 200–400 mg/kg/day (3,4). No adverse effects on fertility or evidence of fetal harm were observed in these studies. Species-specific carcinogenesis was observed in mouse studies but negative results were seen in rats. Genetic toxic studies revealed no evidence of mutagenicity (3,4). Only the highest oral concentrations (2500–4000 ppm) of permethrin administered after implantation were found to lower significantly the protein and glycogen contents of rat placentas, but this had no statistical effect on the number of live fetuses (5).

Although no studies of permethrin placental transfer have been located, the molecular weight (about 391) is low enough that transfer should occur. However, because only small amounts are absorbed systemically and these are rapidly metabolized by ester hydrolysis to inactive metabolites, the

opportunity for fetal exposure to permethrin appears to be minimal, if it occurs at all.

A 1995 case report described the use of multiple courses of permethrin and other agents in a pregnant woman who had developed crusted scabies (6). She was initially treated at 2 months' gestation with monosulfiram (a pesticide not available in the United States). Relapse occurred at 5 months' gestation and she was treated with two total-body (24-hour) applications of malathion 0.5% liquid and one total-body (24-hour) application of monosulfiram 25% solution. Three weeks later another relapse occurred and she was treated with permethrin 5% cream to the whole body for 12 hours. Because live mites were found the next day, a sulfur/tar/coconut oil soak to the scalp was used 3 times daily followed by two total-body benzyl benzoate 25% treatments within 24 hours. Then permethrin cream was used weekly for 3 weeks. A healthy male infant was delivered at term (6).

A 2005 observational study compared 113 pregnancies exposed to permethrin sometime in gestation with 113 matched controls (7). There were no differences between the groups in pregnancy outcomes in terms of live births, spontaneous abortions, therapeutic abortions, major malformations, birth weight, and gestational age at delivery.

BREASTFEEDING SUMMARY

No reports describing the use of topical permethrin during lactation have been located. Although the molecular weight (about 391) is low enough for excretion into breast milk, the minimal systemic absorption and rapid metabolism suggests that little, if any, of the drug will be found in milk. The CDC considers permethrin or pyrethrins with piperonyl butoxide to be the treatment of choice for pubic lice during lactation (1). For lactating women with scabies, permethrin is considered the treatment of choice in the United States and the United Kingdom (1,2).

PERPHENAZINE

Antipsychotic

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although occasional published reports have attempted to link various phenothiazine compounds with congenital defects, the bulk of the evidence suggests that the therapeutic use of these drugs are safe for the mother and fetus (see also Chlorpromazine). A possible association between perphenazine, amitriptyline, or both and congenital defects is suggested by a single case, but without confirming evidence no conclusions can be reached.

FETAL RISK SUMMARY

Perphenazine is a piperazine phenothiazine in the same group as prochlorperazine (see Prochlorperazine). The phenothiazines readily cross the placenta to the fetus (1).

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 63 of whom had 1st trimester exposure to perphenazine (2). For use anytime during pregnancy, 166 exposures were recorded. No evidence was found in either group to suggest either a relationship to malformations, or an effect on perinatal mortality rates, birth weight, or IQ scores at 4 years of age.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 140 newborns had been exposed to perphenazine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Five (3.6%) major birth defects were observed (six expected), four of which were cardiovascular defects (one expected). No anomalies were observed in five other defect categories (oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available. The number of cardiovascular defects is suggestive of a

possible association, but other factors, including the mother's disease, concurrent drug use, and chance, may be involved.

A case of maternal suicide attempt with a combination of amitriptyline (725 mg) and perphenazine (58 mg) at 8 days' gestation was described in a 1980 abstract (3). An infant was eventually delivered with multiple congenital defects. The abnormalities included microcephaly, "cotton-like" hair with pronounced shedding, cleft palate, micrognathia, ambiguous genitalia, foot deformities, and undetectable dermal ridges (3).

Perphenazine has been used as an antiemetic during normal labor without producing any observable effect on the newborn (4).

BREASTFEEDING SUMMARY

Perphenazine is excreted into human milk (5). A 50-kg, lactating 22-year-old woman was taking perphenazine 12 mg twice daily (480 mcg/kg) for postpartum psychosis. She had a 1-month-old child. During a 24-hour interval, she produced 510 mL of milk that contained 3.2 ng/mL (7.8 nmol/L) of perphenazine. Because of toxicity, her dose was decreased to 8 mg twice daily, with a proportionate decrease in the concentration in milk to 2.1 ng/mL. The mean milk:plasma ratio from samples drawn at various times during the day was approximately 1. Calculated on the infant's weight of 3.5 kg, the authors estimated that the infant would consume about 0.1% of the weight-adjusted maternal dose. Because they did not consider this exposure to be clinically significant, breastfeeding was started. For the next 3.5 months while the mother was on perphenazine, the infant's growth and development were normal. Although no adverse effects were observed in this single case, the American Academy of Pediatrics classifies perphenazine as a drug for which the effect on nursing infants is unknown but may be of concern (6).

PERTUZUMAB

Antineoplastic (Monoclonal Antibody)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of pertuzumab in human pregnancy have been located. The animal data suggest risk, but the absence of human pregnancy experience prevents a more complete assessment of embryo–fetal risk. However, the drug is given in combination with two other antineoplastics, so the embryo–fetus could potentially be exposed to three agents. The manufacturer recommends that women of reproductive potential should use effective contraception while receiving therapy and for 6 months after the last dose. If the drug is given during pregnancy or a woman becomes pregnant during therapy, the manufacturer encourages enrollment in the MoTHER Pregnancy Registry by calling 1-800-690-6720 (1).

FETAL RISK SUMMARY

Pertuzumab is a recombinant humanized monoclonal antibody. It is indicated for use in combination with trastuzumab and docetaxel (see also Trastuzumab and Docetaxel) for the treatment of patients with HER2-positive metastatic breast cancer who have not received prior anti-HER2 therapy or chemotherapy for metastatic disease. Pertuzumab is given as an IV infusion every 3 weeks. The median half-life is 18 days. Metabolism and plasma protein binding were not specified in the product information (1).

Reproduction studies have been conducted in cynomolgus monkeys. In this species, IV bi-weekly doses that were 2.5–20 times the recommended human dose based on C_{max} (RHD) during organogenesis (gestational days 19–50) were embryotoxic with dose-dependent increases (33%–85%) in embryo–fetal death occurring in gestational days 25–70. At cesarean section on gestational day 100, oligohydramnios, decreased relative lung and kidney weights, and microscopic evidence of renal hypoplasia consistent with delayed renal

development were seen in all dose groups (1).

Studies for carcinogenic and mutagenic potential have not been conducted. Although specific fertility studies have not been performed, no adverse effects on male and female reproductive organs were observed in repeat-dose toxicity studies up to 6 months duration in cynomolgus monkeys (1).

It is not known if pertuzumab crosses the human placenta. Even though the half-life is long, the high molecular weight (about 148,000) probably precludes passage to the embryo–fetus, at least during early pregnancy. However, the monkey and human placentas are similar (both are hemomonochorial) and the drug did cause embryo–fetal toxicity in monkeys.

BREASTFEEDING SUMMARY

No reports describing the use of pertuzumab during human lactation have been located. The molecular weight (about 148,000) suggests that the drug will not be excreted into mature breast milk. However, immunoglobulins, such as IgG, readily pass into milk during the colostrum phase (first 48 hours) and, because pertuzumab has a long half-life (18 days), doses received late in pregnancy will be excreted into colostrum and possibly into early milk. Moreover, the drug is given in combination with trastuzumab and docetaxel, so a nursing infant might be exposed to three antineoplastics. Consequently, the safest course for the infant is to not breastfeed if the mother is receiving this therapy.

PEYOTE

Hallucinogen

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible (Low Dose) Contraindicated (Recreational Use)

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity (Low Dose) Contraindicated (Recreational Use)

PREGNANCY SUMMARY

Peyote is a hallucinogenic agent that is used legally in certain religious ceremonies. An active alkaloid in peyote is mescaline, an agent that causes developmental toxicity in animals. The use of peyote for religious rituals by certain Indian populations involves low doses and does not appear, based on limited data, to cause developmental toxicity. If true, this would be consistent with the principle that developmental toxicity is dose related. However, the apparent low risk of developmental toxicity in Native American populations using carefully monitored amounts of peyote probably is not transferable to the recreational use of peyote, and certainly not to the use of mescaline. Although the recreational use of peyote or mescaline in pregnancy has not been studied, the presumed higher doses might represent a risk to the embryo or fetus. In addition, the lifestyle of recreational users and the probable use of other hallucinogenic or abuse drugs might not be conducive to a healthy pregnancy. Therefore, such use should be discouraged in pregnancy and is classified as contraindicated.

FETAL RISK SUMMARY

The aboveground parts of peyote (*Lophophora williamsii*) are used primarily for their hallucinogenic properties. Other uses include orally for the treatment of fever, rheumatism, and paralysis, and topically for treating fractures, wounds, and snakebite (1). Scientific documentation of these uses has not been located. The active ingredient in peyote is mescaline, a chemical structurally related to amphetamines. It causes CNS and sympathetic stimulation. The effect on the CNS is similar to that of lysergic acid diethylamide (LSD) (1). (See also Lysergic Acid Diethylamide.)

A 1967 study used a single SC dose of mescaline (0.45, 1.33, or 3.25 mg/kg) in pregnant hamsters on day 8 (organogenesis) (2). Congenital malformations of the brain, spinal cord, liver, and other viscera were increased. The incidence of defects, however, was not dose-related as the lowest dose caused the greatest number of defects (28%), whereas the highest dose caused the fewest (9%). Resorptions (7%–25%), dead fetuses (5%–10%), and runts (5%–12%) were dose related (2).

A 1981 reproduction study with mescaline was conducted in hamsters (3). Oral doses of 16 and 32 mg/kg on the 7th through the 10th day of gestation resulted in dose-dependent increases in resorptions and corresponding decreases in litter size. The number of resorptions in controls and the two doses were 6.4%, 12.0%, and 48.8%, respectively. There also was a dose-related increased delay in the ossification of the skull, sternum, and metatarsals. No gross abnormalities were observed at necropsy (3).

Using an IV combination of carbon-14 labeled and unlabeled mescaline, investigators found that the drug crossed the placenta to the fetus in monkeys (4). Although the passage was limited by the high ionization at physiologic pH (99.3%) (pK_a 9.56) and the low lipid solubility of nonionized mescaline, the drug crossed the placenta and concentrated, at various postinjection times, in the fetal organs. Low concentrations were found in fetal blood, brain, and cerebrospinal fluid (4). A similar study in mice, using only labeled mescaline given intraperitoneally, found that the drug crossed the placenta and concentrated in fetal organs with the lowest concentrations in fetal brain (5). Although one author stated that mescaline is known to cross the human placenta (6), such studies have not been located. The molecular weight (about 211) is low enough that exposure of the embryo and fetus should be expected. Passage across the human placenta should be limited by the ionization at physiologic pH and the low solubility of unionized mescaline found in the above monkey study.

A 1979 case report described a pregnancy in which the mother and father regularly used LSD, peyote, and marijuana during the first 4 months of gestation (7). The woman delivered a healthy 2951-g male infant without any abnormalities at about 38 weeks' gestation. The infant was doing well at 8 months of age.

A brief 1970 review summarized the history, dosage, effects, and adverse effects of mescaline (8). Mescaline was only one of the then-known eight alkaloids present in peyote. Peyote has been used by some Mexican and American Indian tribes for hundreds of years and still is being used legally for

religious rituals by the Native American Church. The author thought that mescaline, based on dosage, was the least potent of the commonly used hallucinogens (other hallucinogens not specified). The author also thought that mescaline might be teratogenic based on animal studies (8).

A 2001 review provided more information on the legal use of peyote and its pharmacology (6). Although *L. williamsii* is the cactus legally available and cultivated by the Native American Church, other members of the cactaceae family including *Trichocereus pachanoi* (San Pedro cactus) and *Opuntia cylindrical* also contain mescaline and other alkaloids. In addition to mescaline, about 50 alkaloids have been identified in these cacti. When peyote is used according to recommendations of the Native American Church, the risk for developmental toxicity was not thought to be increased. No increase in malformations was observed in Huichol Indians, a tribe that has used peyote as part of its religious rituals for centuries. However, based on the 1967 animal study cited above, the author concluded that risk of human developmental toxicity was associated with the recreational use of peyote and/or mescaline in which much higher doses than those in religious rituals are used. In addition, mescaline obtained on the street is often mislabeled and may not contain any mescaline at all. For example, phencyclidine (PCP), a much more potent and longer-lasting hallucinogen, is often labeled as mescaline (6). (See also Phencyclidine.)

BREASTFEEDING SUMMARY

No reports describing the use of peyote or its active alkaloid mescaline during human lactation have been located. The molecular weight of mescaline (about 211) is low enough that excretion into breast milk should be expected. The effect of this exposure on a nursing infant is unknown. However, the use of low doses of peyote by adults in religious rituals often is associated with adverse effects, such as nausea, vomiting, and sympathomimetic effects (mydriasis, mild tachycardia, mild hypertension, diaphoresis, ataxia, and hyperreflexia) (6). Higher maternal doses that may be associated with recreational use of peyote, and certainly with mescaline, could cause these effects in a nursing infant. Thus, the recreational use of peyote or mescaline should be considered contraindicated.

PHENACETIN

[Withdrawn from the market. See 9th edition.]

PHENAZOPYRIDINE

Urinary Tract Agent (Analgesic)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports linking the use of phenazopyridine with congenital defects have been located. There are no relevant animal reproduction data. However, the human pregnancy experience suggest low risk for the embryo–fetus.

FETAL RISK SUMMARY

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 219 of whom had 1st trimester exposure to phenazopyridine (1, pp. 299–308). For use anytime during pregnancy, 1109 exposures were recorded (1, p. 435). In neither group was evidence found to suggest a relationship to large categories of major or minor malformations or to individual defects. A brief 2008 review of urinary tract infections in pregnancy also cited the above data (2).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 496 newborns had been exposed to phenazopyridine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 27 (5.4%) major birth defects were observed (21 expected), including (observed/expected) 7/5 cardiovascular defects and 1/1 oral cleft. No anomalies were observed in four other defect categories (spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available. These data do not support an association between the drug and congenital defects.

It is not known if phenazopyridine crosses the human placenta. The molecular weight (about 214 for the free base) suggests that the drug will cross to the embryo–fetus.

In a large 1985 study involving 6509 women with live births, 217 were exposed to phenazopyridine in the 1st trimester (3). One infant had a congenital disorder. Although the defect was not described, the incidence (0.5%) was very low.

BREASTFEEDING SUMMARY

No reports describing the use of phenazopyridine during human lactation have been located. The molecular weight (about 214 for the free base) suggests that the drug will be excreted into breast milk. Because phenazopyridine can cause methemoglobinemia, sulfhemoglobinemia, and hemolytic anemia, it should not be used during breastfeeding, especially with an infant under 1 month of age or with G-6-PD deficiency (4).

PHENCYCLIDINE

Hallucinogen

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Phencyclidine (PCP) is an illicit drug used for its hallucinogenic effects. Although the drug does not appear to cause structural anomalies, its use in pregnancy has been associated with functional/neurobehavioral defects.

FETAL RISK SUMMARY

Exposure of the fetus to PCP has been demonstrated in humans with placental metabolism of the drug (1–7). Qualitative analysis of the urine from two newborns revealed phencyclidine levels of 75 ng/mL or greater up to 3 days after birth (2). In 24 (12%) of 200 women evaluated at a Los Angeles hospital, cord blood PCP levels ranged from 0.10 to 5.80 ng/mL (3). Cord blood concentrations were twice as high as maternal serum—1215 vs. 514 pg/mL in one woman who allegedly consumed her last dose approximately 53 days before delivery (4). PCP in the newborn's urine was found to be 5841 pg/mL (4).

Relatively few studies have appeared on the use of PCP during pregnancy, but fetal exposure may be more common than this lack of reporting indicates. During a 9-month period in 1980–1981 at a Cleveland hospital, 30 of 519 (5.8%) consecutively screened pregnant patients were discovered to have PCP exposure (8). In a subsequent report from this same hospital, 2327 pregnant patients were screened for PCP exposure between 1981 and 1982 (6). Only 19 patients (0.8%) had positive urine samples, but up to 256 (11%) or more may have tested positive with more frequent checking (6). In the Los Angeles study cited above, 12% were exposed (3). However, the specificity of the chemical screening methods used in this latter report has been questioned (7).

Most pregnancies in which the mother used PCP apparently end with healthy newborns (3,4,9). However, case reports involving four newborns indicate that the use of this agent may result in long-term damage (2,9,10):

Depressed at birth, jittery, hypertonic, poor feeding (2) (two infants)

Irritable, poor feeding and sucking reflex (9) (one infant)

Triangular-shaped face with pointed chin, narrow mandibular angle, antimongoloid slanted eyes, poor head control, nystagmus, inability to track visually, respiratory distress, hypertonic, jitteriness (10) (one infant)

Irritability, jitteriness, hypertonicity, and poor feeding were common features in the affected infants. In three of the neonates, most of the symptoms had persisted at the time of the report. In the case with the malformed child, no causal relationship with PCP could be established. Marijuana was also taken, which is a known teratogen in some animal species (11). However, marijuana is not considered to be a human teratogen (see Marijuana).

A study published in 1992 described the effects of PCP on human fetal cerebral cortical neurons in culture (12). High levels of the drug caused progressive degeneration and death of the neurons, whereas sublethal concentrations inhibited axonal outgrowth. Because the fetal CNS can concentrate and retain PCP, these results suggested that PCP exposure during pregnancy could produce profound functional impairments (12).

Abnormal neurobehavior in the newborn period was observed in nine infants delivered from mothers who had used PCP during pregnancy (13). The abnormality was significantly more than that observed in control infants and those exposed in utero to opiates, sedative/stimulants, or the combination of pentazocine and tripeleminamine (i.e., T's and blue's). However, by 2 years of age, the mental and psychomotor development of all drug-exposed infants, including those exposed to PCP, were similar to controls.

BREASTFEEDING SUMMARY

PCP is excreted into breast milk (14). One lactating mother, who took her last dose 40 days previously, excreted 3.90 ng/mL in her milk. Women consuming PCP should not breastfeed. The American Academy of Pediatrics considers the drug to be contraindicated during breastfeeding (15).

PHENDIMETRAZINE

Central Stimulant/Anorexiant

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

It is doubtful if any real benefit is derived from the use of phendimetrazine for weight control during pregnancy, and its use during gestation, especially during the 1st trimester, should be considered contraindicated. (See also Phentermine or Amphetamine.)

FETAL RISK SUMMARY

Phendimetrazine is a sympathomimetic amine that has pharmacologic activity similar to the amphetamines. No animal or human reproductive data are available. It is indicated for the management of exogenous obesity as a short-term adjunct (a few weeks) in a regimen of weight reduction based on caloric restriction. Its activity is similar to amphetamines. Animal reproduction studies have not been conducted (1).

It is not known if phendimetrazine crosses the human placenta. The molecular weight (about 191 for the free base) is low enough, but its hydrophilic nature should limit the exposure of the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use phendimetrazine during lactation have been located. The molecular weight (191 for the free base) is low enough for excretion into breast milk. Milk is slightly acidic compared with plasma and ion trapping could result in milk:plasma ratios >1 . Because CNS stimulation and other adverse reactions may occur in a nursing infant exposed to this drug in milk, breastfeeding should be considered a contraindication if the mother is taking phendimetrazine.

PHENELZINE

Antidepressant

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Phenelzine is a monoamine oxidase (MAO) inhibitor used in the treatment of depression. Other agents in this subclass are iproniazid, isocarboxazid, nialamide, and tranylcypromine. The human pregnancy experience is too limited to assess the embryo–fetal risk. (See also Tranylcypromine.)

FETAL RISK SUMMARY

Phenelzine has been found to be effective in depressed patients clinically characterized as atypical, nonendogenous, or neurotic. It is extensively metabolized to apparently inactive metabolites. Plasma protein binding was not reported by the manufacturer, but the mean elimination half-life after a single 30-mg dose was 11.6 hours (1).

In reproduction studies with mice at doses above the maximum recommended human dose, a significant decrease in the number of viable offspring per mouse was observed (1).

It is not known if phenelzine crosses the human placenta. The molecular weight of the sulfate form (about 234) and elimination half-life suggest that exposure of the embryo–fetus should be expected.

The Collaborative Perinatal Project monitored 21 mother–child pairs exposed to MAO inhibitors during the 1st trimester, 3 of which were exposed to phenelzine (2). Three of the 21 infants had malformations (relative risk 2.26). Details of the three cases with phenelzine exposure were not specified (2).

A 1995 report described a 25-year-old woman who had been treated for depression with phenelzine (45 mg/day) for 6 years before becoming pregnant (3). The drug was continued throughout gestation. Because labor failed to progress, a cesarean section was performed to give birth to a healthy male

infant with Apgar scores of 9 at 1 and 5 minutes (3).

A 31-year-old white female with severe recurrent major depression took phenelzine 45 mg/day before and throughout her pregnancy (4). Attempts to taper her dose were unsuccessful and the patient declined to change to other depression therapy. An ultrasound at 10 weeks' gestation revealed nonidentical twins. A repeat examination at 16 weeks' showed resorption of one fetus, an event that was considered spontaneous and not related to the patient's drug therapy. Because of worsening depression in the 2nd trimester, her daily dose was increased to 52.5 mg. At 37 weeks', she gave birth to a normal healthy 2.651-kg male infant with Apgar scores of 6, 8, and 9 at 1, 5, and 10 minutes, respectively. The infant was discharged home on day 3 and growth and development were normally at 16 months of age (4).

A 2014 case study described the use of phenelzine (105 mg/day), lithium (900 mg/day), and quetiapine (600mg/ day) in a 31-year-old woman with bipolar affective disorder (5). She was also taking metformin (1 g/day) for polycystic ovarian syndrome with oligomenorrhea. Despite her oligomenorrhea, a pregnancy was confirmed at 17 weeks' gestation. A glucose tolerance test was negative at 26 weeks'. Lithium was suspended 24–48 hours before induction of labor at 39 weeks' Because of obstructed labor, a cesarean section was performed to give birth to a 4.2-kg male infant with Apgar scores of 5 and 9 at 1 and 5 minutes, respectively. The baby required initial resuscitation during the first 10 minutes. The baby was discharged home with the mother at 5 days. At 10 weeks of age, the baby's growth and development were normal (5).

BREASTFEEDING SUMMARY

No reports describing the use of phenelzine during breastfeeding have been located. The molecular weight (about 234) and moderately long elimination half-life (11.6 hours) suggest that the drug will be excreted into breast milk. If the drug is used during breastfeeding, the infant should be monitored for the most common adverse reactions observed in adults (dizziness, headache, drowsiness, sleep disturbances, fatigue, weakness, tremors, twitching, myoclonic movements, hyperreflexia, constipation, dry mouth, and edema).

PHENINDIONE

Anticoagulant

See Coumarin Derivatives.

PHENIRAMINE

Antihistamine

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

In general, antihistamines are considered low risk in pregnancy. However, exposure near birth of premature infants has been associated with an increased risk of retrolental fibroplasia.

FETAL RISK SUMMARY

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 831 of whom were exposed to pheniramine during the 1st trimester (1, pp. 322–334). A possible relationship between this use and respiratory malformations and eye/ear defects was found, but independent confirmation is required. For use anytime during pregnancy, 2442 exposures were recorded (1, pp. 436–437). No evidence was found in this group to suggest a relationship to congenital anomalies.

It is not known if pheniramine crosses the human placenta. The molecular weight (about 240) is low enough that exposure of the embryo–fetus should be expected.

An association between exposure during the last 2 weeks of pregnancy to antihistamines in general and retrolental fibroplasia in premature infants has been reported. See Brompheniramine for details.

BREASTFEEDING SUMMARY

No reports describing the use of pheniramine during human lactation have been located. The molecular weight (about 240) is low enough for excretion into breast milk.

PHENOBARBITAL

Sedative/Anticonvulsant

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Phenobarbital therapy in the epileptic pregnant woman presents a risk to the fetus in terms of major and minor congenital defects, hemorrhage at birth, and addiction. Adverse effects on neurobehavioral development have also been reported. The risk to the mother, however, is greater if the drug is withheld and seizure control is lost. The risk:benefit ratio, in this case, favors continued use of the drug during pregnancy at the lowest possible level to control seizures. Use of the drug in nonepileptic patients does not seem to pose a significant risk for structural defects, but neurodevelopment, hemorrhage, and addiction in the newborn are still concerns.

FETAL RISK SUMMARY

Phenobarbital has been used widely in clinical practice as a sedative and anticonvulsant since 1912 (1). The drug crosses the placenta to the fetus at birth (2). Factors significantly influencing placental transfer were duration of maternal treatment, gestational age, and arterial cord pH (2).

The potential teratogenic effects of phenobarbital were recognized in 1964 along with phenytoin (3). Since this report, there have been numerous reviews and studies on the teratogenic effects of phenobarbital either alone or in combination with phenytoin and other anticonvulsants. Based on this literature, the epileptic pregnant woman taking phenobarbital in combination with other antiepileptics has a two- to threefold greater risk for delivering a child with congenital defects over the general population (4–11).

It has not always been known if the increased risk of congenital anomalies was caused by antiepileptic drugs, the disease itself, genetic factors, or a combination of these factors. A 1991 study of epileptic mothers who had been

treated with either phenobarbital or carbamazepine, or the two agents in combination during pregnancy concluded that major and minor anomalies appeared to be more related to the mother's disease than to the drugs (11). An exception to this was the smaller head circumference observed in infants exposed in utero to either phenobarbital alone or in combination with carbamazepine. However, an earlier publication thought there was evidence that drugs were the causative factor (12).

A prospective study published in 1999 described the outcomes of 517 pregnancies of epileptic mothers identified at one Italian center from 1977 (13). Excluding genetic and chromosomal defects, malformations were classified as severe structural defects, mild structural defects, and deformations. Minor anomalies were not considered. Spontaneous (N = 38) and early (N = 20) voluntary abortions were excluded from the analysis, as were seven pregnancies that delivered at other hospitals. Of the remaining 452 outcomes, 427 were exposed to anticonvulsants of which 313 involved monotherapy: phenobarbital (N = 83), carbamazepine (N = 113), valproate (N = 44), primidone (N = 35), phenytoin (N = 31), clonazepam (N = 6), and other (N = 1). There were no defects in the 25 pregnancies not exposed to anticonvulsants. Of the 42 (9.3%) outcomes with malformations, 24 (5.3%) were severe, 10 (2.2%) were mild, and 8 (1.8%) were deformities. There were four malformations with phenobarbital monotherapy: two (2.4%) severe (Fallot's tetralogy, hydronephrosis), one (1.2%) mild (umbilical and inguinal hernia), and one (1.2%) deformation (hip dislocation). The investigators concluded that the anticonvulsants were the primary risk factor for an increased incidence of congenital malformations (see also Carbamazepine, Clonazepam, Phenytoin, Primidone, and Valproic Acid) (13).

A 2001 prospective study provides further evidence that the congenital defects observed in the offspring of epileptic mothers treated with anticonvulsants are caused by drugs (14). The prospective cohort study, conducted from 1986 to 1993 at five maternity hospitals, was designed to determine if anticonvulsant agents or other factors (e.g., genetic) were responsible for the constellation of abnormalities seen in infants of mothers treated with anticonvulsants during pregnancy. A total of 128,049 pregnant women were screened at delivery for exposure to anticonvulsant drugs. Three groups of singleton infants were identified: (a) exposed to anticonvulsant drugs, (b) not exposed to anticonvulsant drugs but with a maternal history of seizures, and (c) not exposed to anticonvulsant drugs and with no maternal history of seizures (control group). For a variety of reasons, including exposure to other

teratogens, many identified infants were excluded, leaving 316, 98, and 508 infants, respectively, in the three groups for analysis. Anticonvulsant monotherapy occurred in 223 women: phenytoin (N = 87), phenobarbital (N = 64), carbamazepine (N = 58), and too few cases for analysis with valproic acid, clonazepam, diazepam, and lorazepam. Ninety-three infants were exposed to two or more anticonvulsant drugs. All infants were examined systematically (blinded as to group in 93% of the cases) for embryopathy associated with anticonvulsant exposure (major malformations, hypoplasia of the midface and fingers, microcephaly, and intrauterine growth restriction). Compared with controls, statistically significant associations between anticonvulsants and anticonvulsant embryopathy were phenobarbital monotherapy, 26.6% (17/64); phenytoin monotherapy, 20.7% (18/87); all infants exposed to anticonvulsant monotherapy, 20.6% (46/223); those exposed to two or more anticonvulsants, 28.0% (26/93); and all infants exposed to anticonvulsants (monotherapy and polytherapy), 22.8% (72/316). Nonsignificant associations were found for carbamazepine monotherapy, 13.8% (8/58); nonexposed infants with a maternal history of seizures, 6.1% (6/98); and controls, 8.5% (43/508). The investigators concluded that the distinctive pattern of physical abnormalities observed in infants exposed to anticonvulsants during gestation was due to the drugs rather than to epilepsy itself (14).

A phenotype, as described for phenytoin in the fetal hydantoin syndrome (FHS), apparently does not occur with phenobarbital. (See Phenytoin for details of FHS.) However, as summarized by Janz (15), some of the minor malformations composing the FHS have been occasionally observed in infants of epileptic mothers treated only with phenobarbital.

The effects of prenatal exposure to phenobarbital on CNS development of offspring have been studied in both animals (16–18) and humans (11,19–22). The neural development in 90-day-old offspring of female rats given phenobarbital in doses of 0, 20, 40, or 60 mg/kg/day before and throughout gestation were described in a 1992 study (16). The drug produced dose- and sex-dependent changes in the electroencephalograms of the offspring. Lower doses resulted in adverse changes in learning and attentional focus, whereas higher doses also adversely affected neural function related to slow-wave sleep and receptor homeostasis. An earlier study measured the long-term effects on the offspring of rats from exposure to 40 mg/kg/day of phenobarbital from day 12 to day 19 of gestation (17). The effects included delays in the onset of puberty; disorders in the estrous cycle; infertility; and altered concentrations of sex steroids, gonadotropic hormones, and estrogen receptors. The changes

represented permanent alterations in sexual maturation. A similar study measured decreases in the concentration of testosterone in the plasma and brain of exposed fetal rats (18). These changes persisted into adult life, indicating that phenobarbital may lead to sexual dysfunction in mature animals.

In a 1991 human study, the cognitive development (as measured by school career, reading, spelling, and arithmetic skills) of children who had been exposed in utero to either phenobarbital alone or in combination with carbamazepine was significantly impaired in comparison with children of nonepileptic mothers (11). A similar finding, but not significant, was suggested when the phenobarbital-exposed children were compared with children exposed only to carbamazepine.

In a 1988 study designed to evaluate the effect of in utero exposure to anticonvulsants on intelligence, 148 Finnish children of epileptic mothers were compared with 105 controls (19). Previous studies had either shown intellectual impairment from this exposure or no effect. Of the 148 children of epileptic mothers, 129 were exposed to anticonvulsant therapy during the first 20 weeks of pregnancy, 2 were only exposed after 20 weeks, and 17 were not exposed. In those mothers treated during pregnancy, 22 received phenobarbital in combination with other anticonvulsants, all during the first 20 weeks. The children were evaluated at 5.5 years of age for both verbal and nonverbal measures of intelligence. A child was considered mentally deficient if the results of both tests were <71. Two of the 148 children of epileptic mothers were diagnosed as mentally deficient and 2 others had borderline intelligence (the mother of one of these latter children had not been treated with anticonvulsant medication). None of the controls was considered mentally deficient. Both verbal (110.2 vs. 114.5) and nonverbal (108.7 vs. 113.2) intelligence scores were significantly lower in the study group children than in controls. In both groups, intelligence scores were significantly lower when seven or more minor anomalies were present. However, the presence of hypertelorism and digital hypoplasia, two minor anomalies considered typical of exposure to phenytoin, was not predictive of low intelligence (19).

A 1996 study also described the effects of in utero phenobarbital exposure on cognitive performance (20). Intelligence scores of Danish adult men, born between 1959 and 1961, who had been exposed to prenatal phenobarbital were measured. Their mothers had no history of CNS disorder and there was no exposure to other psychopharmacological drugs. Two double-blind studies using different measures of general intelligence were conducted on subjects (total = 114) and controls (total = 153). The test scores of matched controls

were used to predict scores for each exposed subject. The exposure effects were then estimated by comparing the predicted to the observed scores. Phenobarbital exposure was associated with significantly lower verbal intelligence scores (about 0.5 standard deviations). Exposure in the 3rd trimester was the most detrimental. The magnitude of the intelligence deficit was increased by lower socioeconomic status and being the offspring of an unwanted pregnancy (20).

A two-part 2000 study evaluated the effects of prenatal phenobarbital and phenytoin exposure on brain development and cognitive functioning in adults (21). Subjects and matched controls, delivered at a mean 40 weeks' gestation, were retrospectively identified from birth records covering the years between 1957 and 1972. Maternal diseases of the subjects included epilepsy (treated with anticonvulsants) and other conditions in which anticonvulsants were used as sedatives (nausea, vomiting, or emotional problems), whereas the control group had no maternal pathologies. Only those exposed prenatally to phenobarbital alone or phenobarbital plus phenytoin had sufficient subjects to analyze. The mean occipitofrontal circumference for phenobarbital-exposed neonates was not different from controls (34.49 vs. 34.50 cm), but it was significantly smaller (33.82 cm) for phenobarbital plus phenytoin subjects compared with phenobarbital alone or controls. In the follow-up part of the study, no differences in adult cognitive functioning (intelligence, attention, and memory) were found between the exposed and control groups. More subjects than controls, however, were mentally slow (4 vs. 2; causes of retardation not known except for 1 case of autism in controls) and more had persistent learning problems (12% vs. 1%). The investigators concluded that phenobarbital plus phenytoin reduced occipitofrontal circumference but may affect cognitive capacity only in susceptible offspring (21).

The relationship between maternal anticonvulsant therapy, neonatal behavior, and neurologic function in children was reported in a 1996 study (22). Among newborns exposed to maternal monotherapy, 18 were exposed to phenobarbital (including primidone), 13 to phenytoin, and 8 to valproic acid. Compared with controls, neonates exposed to phenobarbital had significantly higher mean apathy and optimality scores. Phenytoin-exposed neonates also had a significantly higher mean apathy score. However, the neonatal optimality and apathy scores did not correlate with neurologic outcome of the children at 6 years of age. In contrast, those exposed to valproic acid had optimality and apathy scores statistically similar to controls but a significantly higher hyperexcitability score. Moreover, the hyperexcitability score correlated with

later minor and major neurologic dysfunction at age 6 years (22).

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 1415 of whom had 1st trimester exposure to phenobarbital (23, pp. 336–339). For use anytime during pregnancy, 8037 exposures were recorded (23, p. 438). In neither group was evidence found to suggest a relationship to large categories of major or minor malformations, although a possible association with Down’s syndrome was shown statistically. However, a relationship between phenobarbital and Down’s syndrome is unlikely.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 334 newborns had been exposed to phenobarbital during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 20 (6.0%) major birth defects were observed (14 expected). Specific data were available for six defect categories, including (observed/expected) 8/3 cardiovascular defects, 1/1 oral clefts, 1/0 spina bifida, 1/1 polydactyly, 0/1 limb reduction defects, and 1/1 hypospadias. Only the data for cardiovascular defects are suggestive of a possible association.

The effects of exposure (at any time during the 2nd or 3rd month after the last menstrual period) to folic acid antagonists on embryo–fetal development were evaluated in a large, multicenter, case–control surveillance study published in 2000 (24). The report was based on data collected between 1976 and 1998 from 80 maternity or tertiary care hospitals. Mothers were interviewed within 6 months of delivery about their use of drugs during pregnancy. Folic acid antagonists were categorized into two groups: group I—dihydrofolate reductase inhibitors (aminopterin, methotrexate, sulfasalazine, pyrimethamine, triamterene, and trimethoprim); and group II—agents that affect other enzymes in folate metabolism, impair the absorption of folate, or increase the metabolic breakdown of folate (carbamazepine, phenytoin, primidone, and phenobarbital). The case subjects were 3870 infants with cardiovascular defects, 1962 with oral clefts, and 1100 with urinary tract malformations. Infants with defects associated with a syndrome were excluded as were infants with coexisting neural tube defects (NTDs; known to be reduced by maternal folic acid supplementation). Too few infants with limb reduction defects were identified to be analyzed. Controls (N = 8387) were infants with malformations other than oral clefts and cardiovascular, urinary tract, limb reduction, and NTDs but included infants with chromosomal and genetic defects. The risk of malformations in control infants would not have been reduced by vitamin supplementation, and none of the controls used folic

acid antagonists. For group I cases, the relative risks (RRs) of cardiovascular defects and oral clefts were 3.4 (95% confidence interval [CI] 1.8–6.4) and 2.6 (95% CI 1.1–6.1), respectively. For group II cases, the RRs of cardiovascular and urinary tract defects, and oral clefts were 2.2 (95% CI 1.4–3.5), 2.5 (95% CI 1.2–5.0), and 2.5 (95% CI 1.5–4.2), respectively. Maternal use of multivitamin supplements with folic acid (typically 0.4 mg) reduced the risks in group I cases, but not in group II cases (24).

Thanatophoric dwarfism was found in a stillborn infant exposed throughout gestation to phenobarbital (300 mg/day), phenytoin (200 mg/day), and amitriptyline (>150 mg/day) (25). The cause of the malformation could not be determined, but both drug and genetic causes were considered.

A 2000 study, using data from the MADRE (an acronym for malformation and drug exposure) surveillance project, assessed the human teratogenicity of anticonvulsants (26). Among 8005 malformed infants, cases were defined as infants with a specific malformation, whereas controls were infants with other anomalies. Of the total group, 299 were exposed in the 1st trimester to anticonvulsants. Among these, exposure to monotherapy occurred in the following: phenobarbital (N = 65), mephobarbital (N = 10), carbamazepine (N = 46), valproic acid (N = 80), phenytoin (N = 24), and other agents (N = 16). Statistically significant associations were found with phenobarbital monotherapy and cardiac defects (N = 12), and cleft lip/palate (N = 11). When all 1st trimester exposures (monotherapy and polytherapy) were evaluated, significant associations were found between phenobarbital and cardiac defects (N = 20), cleft lip/palate (N = 19), and persistent left superior vena cava/other anomalies of the circulatory system (N = 3). Although the study confirmed some previously known associations, several new associations with anticonvulsants were discovered and require independent confirmation (see also Carbamazepine, Mephobarbital, Phenytoin, and Valproic Acid) (26).

The Lamotrigine Pregnancy Registry, an ongoing project conducted by the manufacturer, was first published in January 1997 (27). The final report was published in July 2010. The Registry is now closed. Among 24 prospectively enrolled pregnancies exposed to phenobarbital and lamotrigine, with or without other anticonvulsants, 22 were exposed in the 1st trimester resulting in 16 live births without defects, 4 elective abortions, and 2 birth defects. There were two exposures in the 2nd/3rd trimesters resulting in live births without defects (27).

Phenobarbital and other anticonvulsants (e.g., phenytoin) may cause early hemorrhagic disease of the newborn (28–37). Hemorrhage occurs during the first 24 hours after birth and may be severe or even fatal. The exact

mechanism of the defect is unknown but may involve phenobarbital induction of fetal liver microsomal enzymes that deplete the already low reserves of fetal vitamin K (37). This results in suppression of the vitamin K-dependent coagulation factors II, VII, IX, and X. A 1985 review summarized the various prophylactic treatment regimens that have been proposed (see Phenytoin for details) (37).

Barbiturate withdrawal has been observed in newborns exposed to phenobarbital in utero (38). The average onset of symptoms in 15 addicted infants was 6 days (range 3–14 days). These infants had been exposed during gestation to doses varying from 64 to 300 mg/day with unknown amounts in four patients.

Phenobarbital may induce folic acid deficiency in the pregnant woman (39–41). A discussion of this effect and the possible consequences for the fetus are presented under Phenytoin (see also reference 24 above).

High-dose phenobarbital, contained in an antiasthmatic preparation, was reported in a mother giving birth to a stillborn full-term female infant with complete triploidy (42). The authors speculated on the potential for phenobarbital-induced chromosomal damage. However, an earlier in vitro study found no effect of phenobarbital on the incidence of chromosome gaps, breaks, or abnormal forms (43). Any relationship between the drug and the infant's condition is probably coincidental.

Phenobarbital and cholestyramine have been used to treat cholestasis of pregnancy (44,45). Although no drug-induced fetal complications were noted, the therapy was ineffective for this condition. An earlier study, however, reported the successful treatment of intrahepatic cholestasis of pregnancy with phenobarbital, resulting in the normalization of serum bilirubin concentrations (46). The drug has also been used in the last few weeks of pregnancy to reduce the incidence and severity of neonatal hyperbilirubinemia (47).

Antenatal phenobarbital, either alone or in combination with vitamin K, has been used to reduce the incidence and severity of intraventricular hemorrhage in very-low-birth-weight infants (48–55). The therapy seemed to consistently reduce the frequency of grade 3 and grade 4 hemorrhage, and infant mortality from this condition. A 1991 review of this therapy summarized several proposed mechanisms by which phenobarbital might produce this beneficial effect (56). However, three studies (51,53,55), one involving 668 infants (treated and controls) (55), have concluded that the risk of intraventricular hemorrhage or early death in preterm infants is not decreased by antenatal phenobarbital.

In a study using the same subjects and controls as in reference (54) above, antenatal phenobarbital (10 mg/kg IV, then 100 mg orally every 24 hours until delivery or until completion of 34 weeks' gestation) had no effect, compared with nonexposed controls, on neurodevelopment as measured serially up to age 3 years (57). In contrast, another study using the same subjects and controls as a previous study (reference 53) found that antenatal phenobarbital (720–780 mg IV, then 60 mg IV every 6 hours until delivery or 34 weeks' gestation) significantly impaired developmental outcome as measured at age 2 years (58,59).

BREASTFEEDING SUMMARY

Phenobarbital is excreted into breast milk (60–65). In two reports, the milk:plasma ratio varied between 0.4 and 0.6 (61,62). The amount of phenobarbital ingested by the nursing infant has been estimated to reach 2–4 mg/day (63). The pharmacokinetics of phenobarbital during lactation have been reviewed (62). Because of slower elimination in the nursing infant, accumulation may occur to the point that blood levels in the infant may actually exceed those of the mother (62). Phenobarbital-induced sedation has been observed in three nursing infants probably caused by this accumulation (60).

A case of withdrawal in a 7-month-old nursing infant after abrupt weaning from a mother taking phenobarbital, primidone, and carbamazepine has been reported (65). The mother had taken the anticonvulsant agents throughout gestation and during lactation. The baby's serum phenobarbital level at approximately 8 weeks of age was 14.8 $\mu\text{mol/L}$, near the lower level of the therapeutic range. At 7 months of age, the mother abruptly stopped nursing her infant; shortly thereafter withdrawal symptoms were observed in the infant consisting of episodes of "startle" responses and infantile spasms confirmed by electroencephalography. The infant was treated with phenobarbital, with prompt resolution of her symptoms and she was gradually weaned from the drug during a 6-month interval. Her neurologic and mental development were normal during the subsequent 5-year follow-up period (65).

Women consuming phenobarbital during breastfeeding, especially those on high doses, should be instructed to observe their infants for sedation. Phenobarbital levels in the infant should also be monitored to avoid toxic concentrations (62,66). The American Academy of Pediatrics classifies phenobarbital as a drug that has caused major adverse effects in some nursing infants, and it should be given to nursing women with caution (66).

PHENOLPHTHALEIN

[Withdrawn from the market. See 9th edition.]

PHENOXYBENZAMINE

Antihypertensive

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential
Toxicity

PREGNANCY SUMMARY

The use of phenoxybenzamine during pregnancy to treat hypertension secondary to pheochromocytoma is indicated for the reduction of maternal and fetal mortality, especially after 24 weeks' gestation when surgical intervention is associated with high rates of these outcomes (1). Maternal α -blockade may also reduce or eliminate the adverse effect of hypertension on placental perfusion and subsequent poor fetal growth. No adverse fetal effects related to this drug treatment have been observed, but drug-induced hypotension in a newborn might have occurred.

FETAL RISK SUMMARY

Phenoxybenzamine, a long-acting α -adrenergic blocking agent, is used for the treatment of hypertension caused by pheochromocytoma. Because of the lack of well-controlled studies, the effect of phenoxybenzamine on pregnant animals is not known (B.A. Wallin, personal communication, Smith Kline & French Laboratories, 1987). Animal and in vitro experiments conducted by the manufacturer, however, have indicated that the drug has carcinogenic and mutagenic activity. Neither of these adverse outcomes, nor other fetal harm, has been reported in the relatively few human studies that have been published.

In a study using pregnant rats, phenoxybenzamine, with or without the β -blocker propranolol, had no effect on implantation of the fertilized ovum, nor was there any interference with the antifertility effect of an intrauterine contraceptive device placed in the uterus of rats (2).

One study has evaluated the human transplacental passage of phenoxybenzamine (3). A 22-year-old woman with pheochromocytoma was treated with phenoxybenzamine, 10 mg 3 times daily, and labetalol, 100 mg 3

times daily, for 26 days beginning at 33 weeks' gestation. She received her last dose of phenoxybenzamine 2 hours before delivery. The mean concentrations of the drug in the cord and maternal plasma and in the amniotic fluid were 103.3, 66, and 79.3 ng/mL, respectively, representing a cord:maternal plasma ratio of 1.6. Serum samples for phenoxybenzamine obtained from the infant at 32 and 80 hours of age contained mean concentrations of 22.3 ng/mL and none detected (limit of detection 10 ng/mL), respectively. The 2475-g male infant had depressed respiratory effort and hypotonia at birth and was hypotensive during the first 2 days of life. The cause of the hypotension could not be determined, but may have been caused by both drugs. He subsequently did well and was discharged home 14 days after birth (3).

No reports describing the use of phenoxybenzamine early in the 1st trimester of pregnancy have been located. Early in vitro studies of phenoxybenzamine indicated the drug abolished the l-norepinephrine-stimulated contractile activity of animal and human myometrium (4,5). However, a phenoxybenzamine infusion for 3 hours had no significant effect on the uterine activity in two pregnant women (5). One study included the use of phenoxybenzamine for the treatment of essential hypertension, toxemia, and cardiovascular renal disease occurring during pregnancy (4). No adverse fetal effects were observed.

Because of the relative rarity of pheochromocytoma, only a small number of cases have been found in which phenoxybenzamine was used during pregnancy. In 24 pregnancies, phenoxybenzamine administration was begun in the 2nd or 3rd trimesters and continued for periods ranging from 1 day to 35 weeks (1,6–22). Therapy was started at 10 weeks' gestation in a 24th case and continued for approximately 25 weeks when a healthy 2665-g male infant was delivered by cesarean section (23). Eighteen other pregnancies ended with either a cesarean section (N = 14) or vaginal delivery (N = 4) of a healthy infant before resection of the pheochromocytoma. In some of the cases the infant was growth restricted, probably secondary to uncontrolled maternal hypertension before treatment, but all survived. One fetus apparently survived the initial surgery to remove the mother's tumor, but the outcome of the pregnancy was not discussed (18). In another case, phenoxybenzamine was begun at 17 weeks' gestation and continued for 7 days before surgery (1). Following successful tumor resection, the patient's pregnancy went to term and terminated with the vaginal birth of a normal healthy female infant.

Fetal death has been reported in four cases, but only two occurred during pharmacologic therapy of the mother's disease (6,9,16). In one case, fetal death occurred when the mother, in her 5th to 6th month of pregnancy, died 2

days after extensive surgery to remove a metastatic pheochromocytoma (6). Another involved a therapeutic abortion performed at approximately 12 weeks' gestation during the surgical removal of the mother's tumor (16). The third fetal loss involved a woman whose pheochromocytoma was diagnosed at 7 months' gestation. Therapy with phenoxybenzamine was begun, but the fetus died in utero (details of therapy were not given) (16). In the fourth case, a 15-year-old patient at 25.5 weeks' gestation was treated for 3 days with oral phenoxybenzamine in preparation for surgery. On the 3rd day of therapy, her membranes spontaneously ruptured followed by a hypertensive crisis requiring a phentolamine infusion. A spontaneous abortion occurred shortly thereafter of a severely growth-restricted fetus (9).

The low incidences of maternal (4%; 1 of 24) and fetal (9%; 2 of 22) mortality when α -blockade with phenoxybenzamine is used is much better than the mortality observed in undiagnosed pheochromocytoma complicating pregnancy. A 1971 review of 89 cases of unsuspected tumor found that maternal and fetal mortality rates were 48% and 54.4%, respectively (24). A more recent review cited incidences of maternal and fetal mortality without α -blockade of 9% and 50%, respectively (20). When all cases of α -blockade (i.e., those receiving phenoxybenzamine, phentolamine, or both) administered during pregnancy were considered, maternal mortality was 3% (1 of 29) and fetal loss was 19% (5 of 27) (2 cases were excluded because fetal death in utero had occurred at the time of diagnosis) (20).

Long-term follow-up of infants exposed in utero to phenoxybenzamine has only been reported in three cases (8,11,14). The follow-up periods ranged from 2 to 8 years, and all three were normal healthy children.

BREASTFEEDING SUMMARY

No reports describing the use of phenoxybenzamine during human lactation have been located. The molecular weight of the drug (about 340) is low enough that excretion into breast milk should be expected. The potential effects of this exposure on a nursing infant, including but not limited to, hypotension are unknown.

PHENSUXIMIDE

[Withdrawn from the market. See 9th edition.]

PHENTERMINE

Anorexiant

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

It is doubtful if any real benefit is derived from the use of phentermine for weight control during pregnancy, and its use during gestation, especially during the 1st trimester, should be considered contraindicated. Moreover, although the causes of the stillbirths cited in one human study were not fully elucidated and may not have been caused by maternal phentermine treatment, the high incidence is disturbing and is another reason to withhold use of the drug during pregnancy.

FETAL RISK SUMMARY

Phentermine (phenyl-tertiary-butylamine) is a sympathomimetic amine that has activity as a CNS stimulant. Similar to other drugs in this class, such as the amphetamines, it is used as an appetite suppressant in the treatment of obesity. In addition to other adverse effects, hypertension has occurred in adults treated with this agent.

Reproduction studies in animals with phentermine have not been conducted. A closely related compound, chlorphentermine (30 mg/kg/day SC), was administered to pregnant rats during the last 5 days of gestation (1). Phospholipidosis was evident in the lungs of the mothers and the newborn rats, and 83% of the latter died within 24 hours of birth. Another group treated with phentermine (30 mg/kg/day SC) in a similar manner did not develop the complication and did not die. A subsequent reference suggested that the chlorphentermine-induced pup mortality was consistent with retardation of fetal pulmonary maturity (2).

No studies have been located that described the placental transfer of phentermine in animals or humans. The molecular weight (about 186) is low enough that exposure of the embryo–fetus should be expected.

A study published in 1962 described the use of phentermine in 118 women

who were treated for obesity during the 3rd trimester of pregnancy up to delivery (3). Women weighing <200 pounds were given 30 mg each morning, whereas those >200 pounds were given 30 mg twice daily. The weights of the patients before treatment ranged from 180 to 315 pounds. Adverse outcomes occurred in five women with stillborn infants, one of whom was caused by abruptio placentae. The cause of the other stillborns, whose weights ranged from 9 to 10 pounds, was not mentioned, other than the statement that one mother had mild preeclampsia.

As of 1997, the FDA had received two reports involving the use of the combination, fenfluramine and phentermine, in early pregnancy (F. Rosa, personal communication, FDA, 1997). A spontaneous abortion occurred in one of the pregnancies. In the other, an infant with bilateral valvular abnormalities, both aortic and pulmonary, with moderate stenosis and displacement was born. Because valvular toxicity has been reported in adults taking the combination, a causal relationship in the pregnancy case is potentially possible. No other details of these cases were available.

A 2002 controlled prospective cohort study compared 98 women who had taken phentermine/fenfluramine for weight loss (product withdrawn in 1997) during portions or all of the 1st trimester with 233 nonteratogen-exposed controls (4). About 88% of the subjects had begun the drug combination before conception and the remainder started after conception. The phentermine and fenfluramine daily doses ranged 15–45 mg and 20–60 mg, respectively. Most (96%) stopped the drug combination before the 12th week of gestation. In the two groups, 71% and 65% of the liveborn infants were examined by a dysmorphologist for the presence of major or minor malformations who was blinded to the exposures. There were no statistical differences between the groups in terms of major malformations or ≥ 3 or more minor malformations, spontaneous abortions, elective abortions, ectopic pregnancies, or preterm delivery. No pattern of malformations was identified. The increased rate of gestational diabetes (11% vs. 4%, $p = 0.05$) probably reflects the significantly greater prepregnancy body weight and pregnancy weight gain of exposed subjects. The significantly higher mean birth weight and head circumference in full-term infants of subjects were most likely due to the significantly greater mean prepregnancy body weight and weight gain during pregnancy of their mothers as well as to the increased rate of gestational diabetes (4).

BREASTFEEDING SUMMARY

No reports describing the use of phentermine during lactation have been

located. The molecular weight (about 186) is low enough that excretion of phentermine into breast milk should be expected. Because CNS stimulation and other adverse reactions may occur in a nursing infant exposed to this drug in milk, breastfeeding should be considered a contraindication if the mother is taking phentermine.

PHENTOLAMINE

Antihypertensive

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential
Toxicity

PREGNANCY SUMMARY

Phentolamine has been used for the short-term management of severe hypertension caused by pheochromocytoma, including those cases occurring during surgery to deliver a fetus or to resect the tumor (1–4). No adverse effects on the fetus or newborn attributable to phentolamine from this use have been reported, but fetal hypoxia is a potential complication.

FETAL RISK SUMMARY

Phentolamine, a short-acting α -adrenergic blocker, is used for the treatment of severe hypertension secondary to maternal pheochromocytoma. Animal studies with phentolamine have observed neither teratogenicity nor embryotoxicity (5). No reports of adverse fetal outcome in humans have been located, but 1st trimester experience with this agent has not been documented, nor have studies describing the placental transfer of phentolamine in humans been found. However, although apparently not teratogenic, phentolamine must be used with caution because of the marked decrease in maternal blood pressure that can occur with resulting fetal anoxia.

Early in vitro and in vivo investigations of phentolamine indicated the drug inhibited the l-norepinephrine-stimulated contractile activity of human myometrium (6–8). A 1971 investigation examined the effect of combined α -adrenergic blockade (phentolamine) and β -adrenergic stimulation (isoxsuprine) on oxytocin-stimulated uterine activity in six women just before undergoing therapeutic abortion at 16–20 weeks' gestation (9). The results indicated that phentolamine had no effect on uterine activity, while isoxsuprine inhibited uterine contractions. Moreover, the uterine inhibitory effect of β -stimulation was independent of α -blockade.

In one study, phentolamine was used for approximately 10 weeks for the treatment of toxemia (6). No adverse effects in the fetus were observed and the infant was alive and well at 18 months. The authors commented that they had stopped using phentolamine for this purpose because prolonged use in a few cases had resulted in “jitters” in the newborns, especially in premature infants (6).

The most common use of phentolamine in pregnancy is for the diagnosis of pheochromocytoma. Administration of phentolamine to patients with this disease causes a marked drop in blood pressure. Because of the drug’s very short half-life (19 minutes), the return to the pretest blood pressures usually occurs in <30 minutes (5). A 1971 review article of pheochromocytoma in pregnancy cited 22 cases of the disease identified in 1955–1966 in which the diagnosis was made during pregnancy with phentolamine (10). Three additional cases were published in 1969 (11) and 1973 (12). Reflecting the high maternal and fetal mortality that can occur with this disease, 21% (3 of 14) of the mothers and 43% (6 of 14) of the fetuses died.

BREASTFEEDING SUMMARY

No reports describing the use of phentolamine during human lactation have been located. Because of its indication, it is unlikely that such reports will appear. Moreover, the drug has a very short half-life (19 minutes), so if it is used in a lactating woman, waiting a few hours and then pumping and discarding the milk should prevent exposure of a nursing infant.

PHENYLBUTAZONE

[Withdrawn from the market. See 9th edition.]

PHENYLEPHRINE

Sympathomimetic (Adrenergic)

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Phenylephrine is a sympathomimetic used in emergency situations to treat hypotension and to alleviate allergic symptoms of the eye and ear. Uterine vessels are normally maximally dilated and they have only α -adrenergic receptors (1). Use of the predominantly α -adrenergic stimulant, phenylephrine, could cause constriction of these vessels and reduce uterine blood flow, thereby producing fetal hypoxia (bradycardia). Phenylephrine may also interact with oxytocics or ergot derivatives to produce severe persistent maternal hypertension (1). Rupture of a cerebral vessel is possible. If a pressor agent is indicated, other drugs such as ephedrine should be considered. Sympathomimetic amines are teratogenic in some animal species, but human teratogenicity has not been suspected (2,3).

FETAL RISK SUMMARY

No studies describing the placental passage of phenylephrine have been located. The molecular weight (about 167) of the drug is low enough that exposure of the embryo–fetus should be expected.

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 1249 of whom had 1st trimester exposure to phenylephrine (4, pp. 345–356). For use anytime during pregnancy, 4194 exposures were recorded (4, p. 439). An association was found between 1st trimester use of phenylephrine and malformations; association with minor defects was greater than with major defects (4, pp. 345–356). For individual malformations, several possible associations were found (4, pp. 345–356, 476, 491):

1st trimester

Eye and ear (8 cases)

Syndactyly (6 cases)

Preauricular skin tag (4 cases)

Clubfoot (3 cases)

Anytime use

Congenital dislocation of hip (15 cases)

Other musculoskeletal defects (4 cases)

Umbilical hernia (6 cases)

Independent confirmation of these findings is required. For the sympathomimetic class of drugs as a whole, an association was found between 1st trimester use and minor malformations (not life-threatening or major cosmetic defects), inguinal hernia, and clubfoot (4, pp. 345–356).

Sympathomimetics are often administered in combination with other drugs to alleviate the symptoms of upper respiratory infections. Thus, the fetal effects of sympathomimetics, other drugs, and viruses cannot be totally separated. However, indiscriminate use of this class of drugs, especially in the 1st trimester, is not without risk.

Phenylephrine has been used as a stress test to determine fetal status in high-risk pregnancies (5). In the United States, however, this test is normally conducted with oxytocin.

BREASTFEEDING SUMMARY

No reports describing the use of phenylephrine during human lactation have been located. The molecular weight (about 167) of the drug is low enough that passage into breast milk should be expected. The effect of this exposure on a nursing infant is unknown.

PHENYLPROPANOLAMINE

[Withdrawn from the market. See 9th edition.]

PHENYLTOLOXAMINE

Antihistamine

PREGNANCY RECOMMENDATION: No Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of phenyltoloxamine in human pregnancy have been located. In general, antihistamines are considered low risk in pregnancy. However, exposure near birth of premature infants has been associated with an increased risk of retrolental fibroplasia.

FETAL RISK SUMMARY

It is not known if phenyltoloxamine crosses the human placenta. The molecular weight (about 448 for phenyltoloxamine citrate) is low enough that exposure of the embryo–fetus should be expected.

An association between exposure during the last 2 weeks of pregnancy to antihistamines in general and retrolental fibroplasia in premature infants has been reported. See Brompheniramine for details.

BREASTFEEDING SUMMARY

No reports describing the use of phenyltoloxamine during human lactation have been located. The molecular weight (about 448 for phenyltoloxamine citrate) is low enough for excretion into breast milk.

PHENYTOIN

Anticonvulsant

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

The use of phenytoin during pregnancy involves significant risk to the fetus in terms of major and minor congenital abnormalities and hemorrhage at birth. Adverse effects on neurodevelopment have also been reported. The risk to the mother, however, is also great if the drug is not used to control her seizures. The risk:benefit ratio, in this case, favors continued use of the drug during pregnancy. Frequent determinations of phenytoin levels are recommended to maintain the lowest level required to prevent seizures and possibly to lessen the likelihood of fetal anomalies. Based on recent research, consideration should also be given to monitoring folic acid levels simultaneously with phenytoin determinations and administering folic acid very early in pregnancy or before conception to those women shown to have low folate concentrations. Alternatively, adding folic acid, such as 4–5 mg/day (the dose recommended for women with a history of a fetus or infant with a neural tube defect [NTD]), should be considered.

FETAL RISK SUMMARY

Phenytoin is a hydantoin anticonvulsant introduced in 1938. The teratogenic effects of phenytoin were recognized in 1964 (1). Since this report there have been numerous reviews and studies on the teratogenic effects of phenytoin and other anticonvulsants. Based on this literature, the epileptic pregnant woman taking phenytoin, either alone or in combination with other anticonvulsants, has a 2–3 times greater risk for delivering a child with congenital defects over the general population (2–9).

It was not always known whether this increased risk was caused by antiepileptic drugs, the disease itself, genetic factors, or a combination of these, although past evidence indicated that drugs were the causative factor.

Fifteen epidemiologic studies cited by reviewers in 1982 found an incidence of defects in treated epileptics varying from 2.2% to 26.1% (9). In each case, the rate for treated patients was higher than for untreated epileptics or normal controls. Animal studies have also implicated drugs and have suggested that a dose-related response may occur (9). Two studies cited below provide further evidence that the congenital defects observed in the offspring of epileptic mothers treated with anticonvulsants are caused by drugs.

A prospective study published in 1999 described the outcomes of 517 pregnancies of epileptic mothers identified at one Italian center from 1977 (10). Excluding genetic and chromosomal defects, malformations were classified as severe structural defects, mild structural defects, and deformations. Minor anomalies were not considered. Spontaneous (N = 38) and early (N = 20) voluntary abortions were excluded from the analysis, as were seven pregnancies that delivered at other hospitals. Of the remaining 452 outcomes, 427 were exposed to anticonvulsants of which 313 involved monotherapy: phenytoin (N = 31), carbamazepine (N = 113), phenobarbital (N = 83), valproate (N = 44), primidone (N = 35), clonazepam (N = 6), and other (N = 1). There were no defects in the 25 pregnancies not exposed to anticonvulsants. Of the 42 (9.3%) outcomes with malformations, 24 (5.3%) were severe, 10 (2.2%) were mild, and 8 (1.8%) were deformities. There were three malformations with phenytoin monotherapy: none were severe, one (3.2%) was mild (umbilical hernia), and two (6.4%) deformations (clubfoot and hip dislocation). The investigators concluded that the anticonvulsants were the primary risk factor for an increased incidence of congenital malformations (see also Carbamazepine, Clonazepam, Phenobarbital, Primidone, and Valproic Acid) (10).

A prospective cohort study, conducted from 1986 to 1993 at five maternity hospitals, was designed to determine if anticonvulsant agents or other factors (e.g., genetic) were responsible for the constellation of abnormalities seen in infants of mothers treated with anticonvulsants during pregnancy (11). A total of 128,049 pregnant women were screened at delivery for exposure to anticonvulsant drugs. Three groups of singleton infants were identified: (a) exposed to anticonvulsant drugs, (b) not exposed to anticonvulsant drugs but with a maternal history of seizures, and (c) not exposed to anticonvulsant drugs and with no maternal history of seizures (control group). After applying exclusion criteria, including exposure to other teratogens, 316, 98, and 508 infants, respectively, were analyzed. Anticonvulsant monotherapy occurred in 223 women: phenytoin (N = 87), phenobarbital (N = 64), carbamazepine (N =

58), and too few cases for analysis with valproic acid, clonazepam, diazepam, and lorazepam. Ninety-three infants were exposed to two or more anticonvulsant drugs. All infants were examined systematically (blinded as to group in 93% of the cases) for embryopathy associated with anticonvulsant exposure (major malformations, hypoplasia of the midface and fingers, microcephaly, and intrauterine growth restriction). Compared with controls, significant associations between anticonvulsants and anticonvulsant embryopathy were as follows: phenytoin monotherapy 20.7% (18/87), phenobarbital monotherapy 26.6% (17/64), any monotherapy 20.6% (46/223), exposed to ≥ 2 anticonvulsants 28.0% (26/93), and all infants exposed to anticonvulsants (monotherapy and polytherapy) 22.8% (72/316). Nonsignificant associations were found for carbamazepine monotherapy 13.8% (8/58), nonexposed infants with a maternal history of seizures 6.1% (6/98), and controls 8.5% (43/508). The investigators concluded that the distinctive pattern of physical abnormalities observed in infants exposed to anticonvulsants during gestation was due to the drugs, rather than to epilepsy itself (11).

A study published in 1990 provided evidence that, at least in some cases, the teratogenic effects of phenytoin are secondary to elevated levels of oxidative metabolites (epoxides) (12). Epoxides are normally eliminated by the enzyme epoxide hydrolase, but in some individuals, low activity of this enzyme is present. By measuring the enzyme's activity in a number of subjects, the investigators proposed a trimodal distribution that is regulated by a single gene with two allelic forms. The three phenotypes proposed were: low activity (homozygous for the recessive allele), intermediate activity (heterozygous), and high activity (homozygous for the dominant allele). In the prospective portion of the study, 19 pregnant women with epilepsy, who were being treated with phenytoin monotherapy, had an amniocentesis performed and the microsomal epoxide hydrolase activity in amniocytes was determined. Four of the 19 had low activity (<30% of standard), whereas 15 had normal activity (>30% of standard). As predicted, only the four fetuses with low activity had clinical evidence of the fetal hydantoin syndrome (FHS) (12).

In contrast to the above study, a 1999 study with mice involving fluconazole and phenytoin was unable to provide support for the theory that toxic intermediates, such as epoxides, were the cause of phenytoin-induced congenital defects (13). Because fluconazole inhibits the cytochrome P450 pathway responsible for phenytoin metabolism, the authors of this study reasoned that the drug combination could provide a test of the hypothesis. Pretreatment of mice with a nonembryotoxic fluconazole dose, however,

significantly doubled (from 6.2% to 13.3%) the incidence of phenytoin-induced cleft palate. Administering both drugs closely together significantly increased the incidence of resorptions but not malformations. This lack of effect on malformations may have been related to the increased embryoletality of the combination. The mechanism for the teratologic interaction between the drugs was unknown (13).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 332 newborns had been exposed to phenytoin during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 15 (4.5%) major birth defects were observed (13 expected), including (observed/expected) 5/3 cardiovascular defects, 1/0 spina bifida, and 1/1 hypospadias. No anomalies were observed in three other defect categories (oral clefts, polydactyly, and limb reduction defects) for which specific data were available.

A recognizable pattern of malformations, now known as the FHS, was partially described in 1968 when Meadow (14) observed distinct facial abnormalities in infants exposed to phenytoin and other anticonvulsants. In 1973, two groups of investigators, in independent reports, described unusual anomalies of the fingers and toes in exposed infants (15,16). The basic syndrome consists of variable degrees of hypoplasia and ossification of the distal phalanges and craniofacial abnormalities. Clinical features of the FHS, not all of which are apparent in every infant, are as follows (14–16):

Craniofacial

- Broad nasal bridge

- Wide fontanelle

- Low-set hairline

- Broad alveolar ridge

- Metopic ridging

- Short neck

- Ocular hypertelorism

- Microcephaly

- Cleft lip and/or palate

- Abnormal or low-set ears

- Epicanthal folds

- Ptosis of eyelids

- Coloboma

- Coarse scalp hair

Limbs

- Small or absent nails
- Hypoplasia of distal phalanges
- Altered palmar crease
- Digital thumb
- Dislocated hip

Impaired growth (physical and mental) and congenital heart defects are often observed in conjunction with FHS.

Numerous other defects have been reported to occur after phenytoin exposure in pregnancy. Janz, in a 1982 review (17), stated that nearly all possible types of malformations may be observed in the offspring of epileptic mothers. This statement is supported by the large volume of literature describing various anomalies that have been attributed to phenytoin with or without other anticonvulsants (1–9,14–58).

In one of the above cases the mother took phenytoin (300 mg/day) during the first 7 months of gestation and phenobarbital (90 mg/day) during the last 2 months (54). The full-term female infant had features of FHS (hypoplastic nails and flat nasal bridge), hydrocephalus, a left porencephalic cyst, and an encephalocele. She died at 2.5 months of age of bronchopneumonia. An autopsy of the brain revealed both gross and microscopic abnormalities. The defects were consistent with changes produced early in fetal development and with tissue destruction resulting in the second half of gestation (54).

A possible association between phenytoin and the rare defect, holoprosencephaly, was reported in 1993 (56). Because of psychomotor and petit mal seizures, the mother was treated with phenytoin (350 mg/day) and primidone (500 mg/day) during gestation. Except for microcephaly, fetal sonography detected no pathology. The female infant was born after 36 weeks of gestation with both weight and length above the 50th percentile. The Apgar scores were 3, 9, and 10 at 1, 5, and 10 minutes, respectively. The occipitofrontal head circumference (31 cm) was below the 25th percentile. Malformations evident on examination were microcephaly, narrow forehead, hypertelorism, hypoplastic midface with anteverted nostrils, smooth philtrum, and thin vermilion border lip. Distal phalanges and nails on all fingers and toes were noted to be hypoplastic. A sacral dimple was also noted. Ultrasound examination revealed a right-sided renal duplication, hepatomegaly, a mild ventricular septal defect, and bilateral hip dysplasia. An electroencephalogram revealed significantly delayed visual-evoked potentials. A partial lobar holoprosencephaly with ventral fusion of the cerebral hemispheres was noted on magnetic resonance imaging of the brain. Coarse gyri and horizontal

cleavage, but no sagittal cleavage, was noted in the frontal lobe. The corpus callosum was absent. Although both parents suffered from epilepsy, there was no consanguinity and the infant's karyotype was normal (46,XX), thus a genetic cause of the holoprosencephaly was thought to be unlikely (56).

Authors of correspondence relating to the above report noted that they had also identified a case of holoprosencephaly in a stillborn infant exposed in utero to anticonvulsants (59). Unfortunately, the clinical examination did not record the presence or absence of minor physical features characteristic of the FHS. Based on their experience, however, establishing an association between phenytoin and the defect would be very difficult because of the infrequent in utero exposure to anticonvulsants (1:250 births), the even lower frequency of exposure to phenytoin monotherapy (1:844 births), and the rarity of holoprosencephaly (1:10,000) (59).

Thanatophoric dwarfism was found in a stillborn infant exposed throughout gestation to phenytoin (200 mg/day), phenobarbital (300 mg/day), and amitriptyline (>150 mg/day) (60). The cause of the malformation could not be determined, but drug and genetic causes were considered.

A 2000 study, using data from the MADRE (an acronym for malformation and drug exposure) surveillance project, assessed the human teratogenicity of anticonvulsants (61). Among 8005 malformed infants, cases were defined as infants with a specific malformation, whereas controls were infants with other anomalies. Of the total group, 299 were exposed in the 1st trimester to anticonvulsants. Among these, exposure to monotherapy occurred in the following: phenytoin (N = 24), phenobarbital (N = 65), mephobarbital (N = 10), carbamazepine (N = 46), valproic acid (N = 80), and other agents (N = 16). No statistically significant associations were found with phenytoin monotherapy or polytherapy. Although the study confirmed some previously known associations, several new associations with anticonvulsants were discovered that require independent confirmation (see also Carbamazepine, Mephobarbital, Phenobarbital, and Valproic Acid) (61).

The Lamotrigine Pregnancy Registry, an ongoing project conducted by the manufacturer, was first published in January 1997. The final report was published in July 2010 (62). The Registry is now closed. Among 68 prospectively enrolled pregnancies exposed to phenytoin and lamotrigine, with or without other anticonvulsants, 62 were exposed in the 1st trimester resulting in 56 live births, 1 birth defect, 1 spontaneous abortion, and 4 elective abortions. There were six exposures in the 2nd/3rd trimesters resulting in six live births without birth defects (62).

Twelve case reports have been located that, taken in sum, suggest phenytoin is a human transplacental carcinogen (18–28,63). Tumors reported to occur in infants after in utero exposure to phenytoin include the following:

- Neuroblastoma (6 cases) (18–22,63)
- Ganglioneuroblastoma (1 case) (23)
- Melanotic neuroectodermal tumor (1 case) (24)
- Extrarenal Wilms' tumor (1 case) (25)
- Mesenchymoma (1 case) (26)
- Lymphangioma (1 case) (27)
- Ependymoblastoma (1 case) (28)

Children exposed in utero to phenytoin should be closely observed for several years because tumor development may take that long to express itself. A 1989 study, however, found no in utero exposures to phenytoin among 188 cases of childhood neuroblastoma diagnosed between 1969 and 1988 at their center (64). But the investigators did conclude that an increased risk of the neoplasm in children with FHS was still a possibility.

Phenytoin and other anticonvulsants (e.g., phenobarbital) may cause early hemorrhagic disease of the newborn (18,65–79). Hemorrhage occurs during the first 24 hours after birth and may be severe or even fatal. The exact mechanism of the defect is unknown but may involve phenytoin induction of fetal liver microsomal enzymes that deplete the already low reserves of fetal vitamin K (79). This results in suppression of the vitamin K-dependent coagulation factors II, VII, IX, and X. Phenytoin-induced thrombocytopenia has also been reported as a mechanism for hemorrhage in the newborn (76). A 1985 review summarized the various prophylactic treatment regimens that have been proposed (79):

- Administering 10 mg of oral vitamin K daily during the last 2 months of pregnancy
- Administering 20 mg of oral vitamin K daily during the last 2 weeks of pregnancy
- Avoiding salicylates and administering vitamin K during labor
- Cesarean section if a difficult or traumatic delivery is anticipated
- Administering IV vitamin K to the newborn in the delivery room plus cord blood clotting studies

Although all of the above suggestions are logical, none has been tested in controlled trials. The reviewers recommended immediate IM vitamin K and close observation of the infant (see also Phytonadione) (79).

Of interest, a 1995 study suggested that anticonvulsant-induced vitamin K deficiency may be the mechanism that causes the maxillofacial hypoplasia seen in the FHS (80). They proposed early vitamin K supplementation of at-risk pregnancies to prevent this disfiguring malformation.

Liver damage was observed in an infant exposed during gestation to phenytoin and valproic acid (81). Although they were unable to demonstrate which anticonvulsant caused the injury, the authors concluded that valproic acid was the more likely offending agent.

Phenytoin may induce folic acid deficiency in the epileptic patient by impairing gastrointestinal absorption or by increasing hepatic metabolism of the vitamin (82–84). Whether phenytoin also induces folic acid deficiency in the fetus is less certain because the fetus seems to be efficient in drawing on available maternal stores of folic acid (see Folic Acid). Low maternal folate levels, however, have been proposed as one possible mechanism for the increased incidence of defects observed in infants exposed in utero to phenytoin. In a 1984 report, two investigators studied the relationship between folic acid, anticonvulsants, and fetal defects (82). In the retrospective part of this study, a group of 24 women treated with phenytoin and other anticonvulsants produced 66 infants, 10 (15%) with major anomalies. Two of the mothers with affected infants had markedly low red blood cell folate concentrations. A second group of 22 epileptic women was then supplemented with daily folic acid, 2.5–5.0 mg, starting before conception in 26 pregnancies and within the first 40 days in 6. This group produced 33 newborns (32 pregnancies—1 set of twins) with no defects, a significant difference from the nonsupplemented group. Loss of seizure control caused by folic acid lowering of phenytoin serum levels, which is known to occur, was not a problem in this small series (82).

Negative associations between phenytoin and folate deficiency have been reported (83,84). In one study, mothers were given supplements with an average folic acid dose of 0.5 mg/day from the 6th to 16th week of gestation until delivery (84). Defects were observed in 20 infants (15%) from the 133 women taking anticonvulsants, which is similar to the reported frequency in pregnant patients not given supplements. Folate levels were usually within the normal range for pregnancy.

The effects of exposure (at any time during the 2nd or 3rd month after the last menstrual period) to folic acid antagonists on embryo–fetal development were evaluated in a large, multicenter, case–control surveillance study published in 2000 (85). The report was based on data collected between 1976 and 1998 from 80 maternity or tertiary care hospitals. Mothers were

interviewed within 6 months of delivery about their use of drugs during pregnancy. Folic acid antagonists were categorized into two groups: group I—dihydrofolate reductase inhibitors (aminopterin, methotrexate, sulfasalazine, pyrimethamine, triamterene, and trimethoprim); group II—agents that affect other enzymes in folate metabolism, impair the absorption of folate, or increase the metabolic breakdown of folate (carbamazepine, phenytoin, primidone, and phenobarbital). The case subjects were 3870 infants with cardiovascular defects, 1962 with oral clefts, and 1100 with urinary tract malformations. Infants with defects associated with a syndrome were excluded as were infants with coexisting NTDs (known to be reduced by maternal folic acid supplementation). Too few infants with limb reduction defects were identified to be analyzed. Controls (N = 8387) were infants with malformations other than oral clefts and cardiovascular, urinary tract, and limb reduction defects and NTDs, but included infants with chromosomal and genetic defects. The risk of malformations in control infants would not have been reduced by vitamin supplementation, and none of the controls used folic acid antagonists. For group I cases, the relative risks (RRs) of cardiovascular defects and oral clefts were 3.4 (95% confidence interval [CI] 1.8–6.4) and 2.6 (95% CI 1.1–6.1), respectively. For group II cases, the RRs of cardiovascular and urinary tract defects, and oral clefts were 2.2 (95% CI 1.4–3.5), 2.5 (95% CI 1.2–5.0), and 2.5 (95% CI 1.5–4.2), respectively. Maternal use of multivitamin supplements with folic acid (typically 0.4 mg) reduced the risks in group I cases, but not in group II cases (85).

The pharmacokinetics and placental transport of phenytoin have been extensively studied and reviewed (86–88). Plasma concentrations of phenytoin may fall during pregnancy. Animal studies and recent human reports suggest a dose-related teratogenic effect of phenytoin (89,90). Although these results are based on a small series of patients, it is reasonable to avoid excessively high plasma concentrations of phenytoin. Close monitoring of plasma phenytoin concentrations is recommended to maintain adequate seizure control and prevent potential fetal hypoxia.

Placental function in women taking phenytoin has been evaluated (91). No effect was detected from phenytoin as measured by serum human placental lactogen, 24-hour urinary total estriol excretion, placental weight, and birth weight.

In a study evaluating thyroid function, no differences were found between treated epileptic pregnant women and normal pregnant controls (92). Thyroxine levels in the cord blood of anticonvulsant-exposed infants were significantly

lower than in controls, but this was shown to be caused by altered protein binding and not altered thyroid function. Other parameters studied—thyrotropin, free thyroxine, and triiodothyronine—were similar in both groups.

The effect of phenytoin on maternal and fetal vitamin D metabolism was examined in a 1984 study (93). In comparison to normal controls, several significant differences were found in the level of various vitamin D compounds and in serum calcium, but the values were still within normal limits. No alterations were found in alkaline phosphatase and phosphate concentrations. The authors doubted whether the observed differences were of major clinical significance.

Phenytoin may be used for the management of digitalis-induced arrhythmias that are unresponsive to other agents and for refractory ventricular tachyarrhythmias (94–96). This short-term use has not been reported to cause problems in the exposed fetuses. The drug has also been used for anticonvulsant prophylaxis in severe preeclampsia (97).

A study published in 2009 examined the effect of antiepileptic drugs (AEDs) on the head circumference in newborns (98). Significant reductions in mean birth-weight-adjusted mean head circumference (bw-adj-HC) was noted for monotherapy with carbamazepine and valproic acid. No effect on bw-adj-HC was observed with gabapentin, phenytoin, clonazepam, and lamotrigine. A significant increase in the occurrence of microcephaly (bw-adj-HC smaller than 2 standard deviations below the mean) was noted after any AED polytherapy but not after any monotherapy, including carbamazepine and valproic acid. The potential effects of these findings on child development warrant study (98).

In a 1988 study designed to evaluate the effect of in utero exposure to anticonvulsants on intelligence, 148 Finnish children of epileptic mothers were compared with 105 controls (99). Previous studies had either shown intellectual impairment from this exposure or no effect. Of the 148 children of epileptic mothers, 129 were exposed to anticonvulsant therapy during the first 20 weeks of pregnancy, 2 were only exposed after 20 weeks, and 17 were not exposed. In those mothers treated during pregnancy, 103 received phenytoin (monotherapy in 54 cases), all during the first 20 weeks. The children were evaluated at 5.5 years of age for both verbal and nonverbal measures of intelligence. A child was considered mentally deficient if the results of both tests were <71. Two of the 148 children of epileptic mothers were diagnosed as mentally deficient and 2 others had borderline intelligence (the mother of 1 of these latter children had not been treated with anticonvulsant medication). None of the controls was considered mentally deficient. Both verbal (110.2 vs. 114.5)

and nonverbal (108.7 vs. 113.2) intelligence scores were significantly lower in the study group children than in controls. In both groups, intelligence scores were significantly lower when seven or more minor anomalies were present. However, the presence of hypertelorism and digital hypoplasia, two minor anomalies considered typical of exposure to phenytoin, was not predictive of low intelligence (99).

A prospective, controlled, blinded observational 1994 study compared the global IQ and language development of children exposed in utero to either phenytoin (N = 36) or carbamazepine (N = 34) monotherapy to their respective matched controls (100). The cognitive tests were administered to the children between the ages of 18 and 36 months. The maternal IQ scores and socioeconomic status in the phenytoin subjects and their controls were similar (90 vs. 93.9 and 40.8 vs. 40.9, respectively) as they were in the carbamazepine subjects and controls (96.5 vs. 96.0 and 44.7 vs. 46.1, respectively). Compared with controls, phenytoin-exposed children had a significantly lower mean global IQ than their matched controls (113.4 vs. 103.1). The verbal comprehension and expressive language scores were also significantly lower (0.2 vs. 1.1 and -0.47 vs. 0.2, respectively). In contrast, no significant differences were measured either in IQ or language development scores between carbamazepine-exposed children and their matched controls. No correlation between the daily dose (mg/kg) of either anticonvulsant and global IQ was found. Major malformations were observed in two phenytoin-exposed children (cleft palate and hypospadias; meningomyelocele and hydrocephalus), none of the phenytoin controls, two carbamazepine-exposed children (missing last joint of right index finger and nail hypoplasia; hypospadias), and one carbamazepine control (pulmonary atresia). The study results suggested that phenytoin had a clinically important negative effect on neurobehavioral development that was independent of maternal or environmental factors (100). In subsequent correspondence relating to the above study (101,102), various perceived problems were cited and were addressed in a reply (103).

A 2013 study reported dose-dependent associations with reduced cognitive abilities across a range of domains at 6 years of age after fetal valproate exposure (104). Analysis showed that IQ was significantly lower for valproate (mean 97, 95% CI 94–101) than for carbamazepine (mean 105, 95% CI 102–108; $p = 0.0015$), lamotrigine (mean 108, 95% CI 105–110; $p = 0.0003$), or phenytoin (mean 108, 95% CI 104–112; $p = 0.0006$). Mean IQs were higher in children whose mothers had taken folic acid (mean 108, 95% CI 106–111)

compared with children whose mothers had not taken the vitamin (mean 101, 95% CI 98–104; $p = 0.0009$) (104).

The relationship between maternal anticonvulsant therapy, neonatal behavior, and neurologic function in children was reported in a 1996 study (105). Among newborns exposed to maternal monotherapy, 18 were exposed to phenobarbital (including primidone), 13 to phenytoin, and 8 to valproic acid. Compared with controls, neonates exposed to phenobarbital had significantly higher mean apathy and optimality scores. Phenytoin-exposed neonates also had a significantly higher mean apathy score. However, the neonatal optimality and apathy scores did not correlate with neurologic outcome of the children at 6 years of age. In contrast, those exposed to valproic acid had optimality and apathy scores statistically similar to controls but a significantly higher hyperexcitability score. Moreover, the hyperexcitability score correlated with later minor and major neurologic dysfunction at age 6 years (105).

A two-part 2000 study evaluated the effects of prenatal phenobarbital and phenytoin exposure on brain development and cognitive functioning in adults (106). Subjects and controls, delivered at a mean 40 weeks' gestation, were retrospectively identified from birth records covering the years between 1957 and 1972. Maternal diseases of the subjects included epilepsy (treated with anticonvulsants) and other conditions in which anticonvulsants were used as sedatives (nausea, vomiting, or emotional problems), whereas the matched control group had no maternal pathologies. Only those exposed prenatally to phenobarbital alone or phenobarbital plus phenytoin had sufficient subjects to analyze. The mean occipitofrontal circumference for phenobarbital-exposed neonates was not different from controls (34.49 vs. 34.50 cm), but it was significantly smaller for phenobarbital plus phenytoin subjects compared with phenobarbital alone or controls (33.82 cm). In the follow-up part of the study, no differences in adult cognitive functioning (intelligence, attention, and memory) were found between the exposed and control groups. More subjects than controls, however, were mentally slow (4 vs. 2; 1 control had autism) and more had persistent learning problems (12% vs. 1%). The investigators concluded that phenobarbital plus phenytoin reduced occipitofrontal circumference but may only affect cognitive capacity in susceptible offspring (106).

BREASTFEEDING SUMMARY

Phenytoin is excreted into breast milk. Milk:plasma ratios range from 0.18 to 0.54 (86,106–110). The pharmacokinetics of phenytoin during lactation have been reviewed (86). The reviewers concluded that little risk to the nursing infant

was present if maternal levels were kept in the therapeutic range. However, methemoglobinemia, drowsiness, and decreased sucking activity were reported in one infant (111). Except for this one case, no other reports of adverse effects with the use of phenytoin during lactation have been located.

In a 2010 study, 199 children, who had been breastfed while their mothers were taking a single antiepileptic drug (carbamazepine, lamotrigine, phenytoin, or valproate), were evaluated at 3 years of age cognitive outcome (112). Mean adjusted IQ scores for exposed children were 99 (95% CI 96–103), whereas the mean adjusted IQ scores of nonbreastfed infants were 98 (95% CI 95–101).

The American Academy of Pediatrics classifies phenytoin as compatible with breastfeeding (113).

PHYSOSTIGMINE

Parasympathomimetic (Cholinergic)

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Physostigmine is rarely used in pregnancy. No reports linking its use with congenital defects have appeared.

FETAL RISK SUMMARY

Physostigmine is an anticholinesterase agent, but it does not contain a quaternary ammonium element. It crosses the blood–brain barrier and should be expected to cross the placenta (1). Crossing to the embryo–fetus would be consistent with its relatively low molecular weight (about 275).

One report described the use of the drug in 15 women at term to reverse scopolamine-induced twilight sleep (2). Apgar scores of 14 of the newborns ranged from 7 to 9 at 1 minute and 8 to 10 at 5 minutes. One infant was depressed at birth and required resuscitation, but the mother had also received meperidine and diazepam. No other effects in the infants were mentioned.

Transient muscular weakness has been observed in about 20% of newborns of mothers with myasthenia gravis (3–5). The neonatal myasthenia is caused by transplacental passage of anti-acetylcholine receptor immunoglobulin G antibodies (5).

BREASTFEEDING SUMMARY

No reports describing the use of physostigmine during human lactation have been located. The relatively low molecular weight (about 275) suggests that it will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown.

PHYTONADIONE

Vitamin

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Phytonadione (vitamin K₁) is the treatment of choice for maternal hypoprothrombinemia and for the prevention of hemorrhagic disease of the newborn (HDN). Maternal supplements are not needed except for those patients deemed at risk for vitamin K deficiency. A recommended dietary intake of 45 mcg (100 nmol) of vitamin K₁ from food during pregnancy has been proposed (1).

FETAL RISK SUMMARY

Phytonadione is a synthetic, fat-soluble substance identical to vitamin K₁, the natural vitamin found in a variety of foods. It is used for the prevention and treatment of hypoprothrombinemia caused by vitamin K deficiency (2). Animal reproduction studies have not been conducted with phytonadione.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 5 newborns had been exposed to phytonadione during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Four (80.0%) major birth defects were observed (none expected), including 2/0 cardiovascular defects and 1/0 spina bifida. No anomalies were observed in four other defect categories (oral clefts, polydactyly, limb reduction defects, and hypospadias) for which specific data were available.

The use of phytonadione (vitamin K₁) during pregnancy and in the newborn has been the subject of several large reviews (3–6). Administration of vitamin K during pregnancy is usually not required because of the abundance of natural sources in food and the synthesis of the vitamin by the normal intestinal flora. Vitamin K₁ is indicated for maternal hypoprothrombinemia and for the prevention of HDN induced by maternal drugs, such as anticonvulsants,

warfarin, rifampin, and isoniazid (3–6).

Only low amounts of vitamin K₁ cross the placenta (7,8). A 1982 study found no detectable vitamin K (<0.10 ng/mL) in the cord blood of nine term infants, although adequate levels (mean 0.20 ng/mL) were present in eight of the nine mothers (7). Vitamin K₁, 1 mg IV, was then given to six additional mothers shortly before delivery (11–47 minutes) resulting in plasma vitamin K₁ values of 45–93 ng/mL. Vitamin K₁ was detected in only four of the six cord blood samples (ranging from 0.10 to 0.14 ng/mL), and its appearance did not seem to be time dependent. In a 1990 study, women were administered one or two doses of vitamin K₁ 10 mg IM at 4-day intervals, and if not delivered, followed by daily oral 20-mg doses until the end of the 34th week or delivery (8). Treated subjects had significantly higher vitamin K₁ maternal and cord plasma levels than controls (11.592 vs. 0.102 ng/mL and 0.024 vs. 0.010 ng/mL, respectively). Although the median plasma vitamin K₁ levels in the mothers treated only with IM doses were similar to those treated with IM and oral doses, cord plasma levels in the latter group were significantly higher (0.42 vs. 0.017 ng/mL). No correlation was found between cord plasma levels of vitamin K₁ and gestational age or duration of therapy (8).

Vitamin K₁ is nontoxic in doses <20 mg (4). In a double-blind trial, 933 women at term were given 20 mg of either K₁ or K₂, the naturally occurring vitamins (9). No toxicity from either vitamin was found, including any association with low birth weight, asphyxia, neonatal jaundice, or perinatal mortality.

Oral vitamin K₁ has been suggested during the last 2 weeks of pregnancy for women taking anticonvulsants to prevent hypoprothrombinemia and hemorrhage in their newborns, but the effectiveness of this therapy has not been proven (3,4). In a group of mothers receiving phenindione, an oral anticoagulant, 10–30 mg of vitamin K₁ was given either IV or intra-amniotically 2–4 days before delivery (10). In a separate group, 2.5–3.0 mg of vitamin K₁ was injected IM into the fetuses at the same interval before delivery. Only in this latter group were coagulation factors significantly improved.

BREASTFEEDING SUMMARY

The natural vitamin K content of breast milk is too low to protect the newborn from vitamin K deficiency and resulting hemorrhagic disease. The administration of vitamin K to the mother to increase milk concentrations may be possible but needs further study. All newborns should receive parenteral prophylactic

therapy at birth consisting of 0.5–1.0 mg of phytonadione. Larger or repeat doses may be required for infants whose mothers are consuming anticonvulsants or oral anticoagulants (3,11). The American Academy of Pediatrics classifies vitamin K₁ as compatible with breastfeeding (12).

Levels of phytonadione (vitamin K₁) in breast milk are naturally low with most samples having <20 ng/mL and many having <5 ng/mL (3,4). In 20 lactating women, colostrum and mature milk concentrations were 2.3 and 2.1 ng/mL, less than half that found in cow's milk (13). Administration of a single 20-mg oral dose of phytonadione to one mother produced a concentration of 140 ng/mL at 12 hours with levels at 48 hours still about double normal values (13). In another study, 40-mg oral doses of vitamin K₁ or K₃ (menadione) were given to mothers within 2 hours after delivery (14). Effects from either vitamin on the prothrombin time of the breastfed newborns were nil to slight during the first 3 days.

Natural levels of vitamin K₁ or K₂ in milk will not provide adequate supplies of the vitamin for the breastfed infant (3,4). The vitamin K₁-dependent coagulation factors II, VII, IX, and X are dependent on gestational age (3). In the newborn, these factors are approximately 30%–60% of normal and do not reach adult levels until about 6 weeks (3). Although not all newborns are vitamin K₁ deficient, many are because of poor placental transfer of the vitamin. Exclusive breastfeeding will not prevent further decline of these already low stores and the possible development of deficiency in 48–72 hours (3,4). In addition, the intestinal flora of breastfed infants may produce less vitamin K than the flora of formula-fed infants (3). The potential consequence of this deficiency is HDN.

The American Academy of Pediatrics has suggested that HDN be defined as “a hemorrhagic disorder of the first days of life caused by a deficiency of vitamin K and characterized by deficiency of prothrombin and proconvertin (stable factor, factor VII), and probably of other factors” (11). The hemorrhage is frequently life-threatening with intracranial bleeds common. A 1985 review (3) identified three types of HDN:

- Early HDN (onset 0–24 hours)
- Classic HDN (onset 2–5 days)
- Late HDN (onset 1–12 months)

The maternal ingestion of certain drugs, such as anticonvulsants, warfarin, or antituberculous agents, is one of the known causes of early and classic HDN, whereas breastfeeding has been shown to be a cause of classic and late HDN (3). The administration of phytonadione to the newborn prevents HDN by

preventing further decline of factors II, VII, IX, and X (3).

The use of prophylactic vitamin K₁ in all newborns is common in the United States but is controversial in other countries (3). The American Academy of Pediatrics Committee on Nutrition recommended in 1961 and again in 1980 that all newborns receive 0.5–1.0 mg of parenteral vitamin K₁ (11,15). The Committee recommended that administration to the mother prenatally should not be substituted for newborn prophylaxis (11). The bleeding risk in breastfed infants who did not receive prophylactic vitamin K₁ is 15–20 times greater than in infants fed cow's milk, given vitamin K₁, or both (3). Despite this evidence, new cases of HDN are still reported (4,16). In a recent report, 10 breastfed infants with intracranial hemorrhage as a result of vitamin K deficiency were described (16). Onset of the bleeding was between 27 and 47 days of age with three infants dying and three having permanent brain injury. Milk levels of total vitamin K (K₁ + K₂) varied between 1.36 and 9.17 ng/mL. None of the infants had been given prophylactic therapy at birth.

PILOCARPINE

Parasympathomimetic (Cholinergic)

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Pilocarpine is used topically in the eye for glaucoma or as oral tablets in the treatment of dry mouth. No reports of developmental toxicity attributable to the drug have been located. However, animal reproduction studies have observed toxicity with oral doses ≤ 10 times the human dose.

FETAL RISK SUMMARY

In reproduction studies in rats at a dose about 26 times the maximum human oral dose of pilocarpine based on BSA (MRHD), adverse effects consisting of a decrease in fetal weight and an increase in the incidence of skeletal variations were observed. These effects may have been secondary to maternal toxicity (1). In another study with rats, doses approximately 10 times the MRHD during gestation and lactation were associated with an increased incidence of stillbirths, whereas doses ≥ 5 times the MRHD were associated with decreased neonatal survival and reduced pup body weights (1).

A single report of the topical use during pregnancy has been located. A woman with glaucoma was treated throughout gestation with topical pilocarpine (two drops twice daily), timolol (two drops each eye), and oral acetazolamide (2). Within 48 hours of delivery at 36 weeks' gestation, the infant presented with hyperbilirubinemia, hypocalcemia, hypomagnesemia, and metabolic acidosis. The toxic effects, attributed to the carbonic anhydrase inhibitor acetazolamide (see Acetazolamide), resolved quickly on treatment. Mild hypertonicity requiring physiotherapy was observed at examinations at 1, 3, and 8 months of age.

BREASTFEEDING SUMMARY

No reports describing the use of pilocarpine during lactation have been located. Because of the molecular weight (about 209 for the free base), excretion into breast milk should be expected, at least after oral doses.

PIMECROLIMUS

Immunologic Agent (Immunomodulator)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of pimecrolimus in human pregnancy have been located. The systemic absorption after topical application of the cream is minimal. Moreover, the animal reproduction data suggest low risk. Based on this information, the topical use of the drug during pregnancy appears to represent a low, if any, risk to the embryo or fetus.

FETAL RISK SUMMARY

Pimecrolimus, a selective inhibitor of inflammatory cytokine release, is an immunosuppressant that is available as a 1% cream for topical application. It is the same subclass of topical calcineurin inhibitor immunomodulators as tacrolimus. Pimecrolimus is indicated as second-line therapy for the short-term and noncontinuous chronic treatment of mild to moderate atopic dermatitis in nonimmunocompromised adults and children ≥ 2 years of age. Systemic absorption was minimal with blood concentrations < 0.5 ng/mL in 91% of adult subjects (1244/1362) tested. The maximum blood concentration observed in these subjects was 1.4 ng/mL. Based on in vitro tests, plasma protein binding of drug reaching the systemic circulation was 99.5%. Following a single oral dose given to volunteers, pimecrolimus was extensively metabolized to inactive metabolites and primarily excreted in the feces (1). Based on oral studies in adult patients with psoriasis, the terminal elimination half-life after 28 days of therapy was 50–100 hours (2).

Reproduction studies have been conducted in rats and rabbits. No maternal or fetal toxicity was observed in these species exposed during organogenesis to dermal doses that were 0.14 times the maximum recommended human dose of the cream (MRHD) based on BSA and 0.65 times the MRHD based on AUC,

respectively. A second dermal study in pregnant rats at doses up to 0.66 times the MRHD based on AUC revealed no maternal, reproductive, or embryo–fetal toxicity, including teratogenicity, attributable to the drug. When pimecrolimus was given orally to pregnant rats and rabbits, no evidence of developmental toxicity was observed at doses up to 38 and 3.9 times the MRHD based on AUC, respectively. In rabbits, an oral dose that was 12 times the MRHD based on AUC caused maternal, embryo, and fetal toxicity. No toxicity was observed at 5 times the MRHD based on AUC. Pimecrolimus crossed the placentas of rats and rabbits given oral doses (1).

In a 2-year dermal carcinogenicity study conducted in rats, a significant increase in the incidence of follicular cell adenoma of the thyroid was observed. In mice, lymphoproliferative changes, including lymphoma, were observed. A 39-week oral study in monkeys also observed dose-related and duration-related changes that could progress to lymphoma. A dose-dependent increase in opportunistic infections also was noted. No evidence of mutagenicity or clastogenicity was observed in several tests. No effect on fertility in female and male rats was observed with oral doses that were 12 and 23 times the MRHD based on AUC, respectively. In a second oral fertility study, the no effect doses were 5 and 0.7 times the MRHD based on AUC, respectively (1).

It is not known if pimecrolimus crosses the human placenta. The molecular weight (about 810) and the long elimination half-life suggest that if the drug reaches the maternal circulation, exposure of the embryo–fetus will occur. However, the minimal blood concentrations, high plasma protein binding, and extensive metabolism suggest that such exposure will be limited, if it occurs at all.

BREASTFEEDING SUMMARY

No reports describing the use of pimecrolimus during human lactation have been located. The molecular weight (about 810) and the long elimination half-life (50–100 hours after 28 days of therapy) suggest that if the drug reaches the maternal circulation, excretion into breast milk will occur. However, the minimal blood concentrations, high plasma protein binding (99.5%), and extensive metabolism to inactive metabolites suggest that such excretion will be limited, if it occurs at all. The risk to a nursing infant is unknown but does not appear to be clinically significant.

PIMOZIDE

Antipsychotic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

The human pregnancy experience with pimozide is limited, but no embryo–fetal harm has been reported. The animal data do not suggest a risk of teratogenicity, but the lack of a meaningful comparison with the human dose limits the data’s usefulness. The use of antipsychotics, including pimozide, close to delivery may cause extrapyramidal effects (Parkinson-like symptoms; akinesia) in the newborn (1). Until adequate human pregnancy experience has been reported, the safest course is to avoid pimozide in pregnancy, especially in the 1st trimester and close to delivery. However, it should not be withheld because of pregnancy if it is the best drug for the patient.

FETAL RISK SUMMARY

Pimozide is an orally active antipsychotic agent that blocks dopaminergic receptors on neurons in the CNS. It is indicated for the suppression of motor and phonic tics in patients with Tourette’s syndrome who have failed to respond satisfactorily to standard treatment. Pimozide is extensively metabolized, primarily in the liver, but the antipsychotic activity of the metabolites has not been determined. In schizophrenic patients, the mean serum elimination half-life was about 55 hours (2).

Reproduction studies have been conducted in rats and rabbits. In rats, oral doses up to 8 times the maximum human dose (HD) were not teratogenic, but decreased rates of pregnancies and increased rates of retarded fetal development were observed. The decreased pregnancy rates were thought to be due to an inhibition or delay in implantation, an effect in rodents that has been observed with other antipsychotic drugs. Although rat fertility studies were

not adequate to assess all aspects of fertility, pimozide caused prolonged estrus cycles similar to those observed with other antipsychotics. In the rabbit, dose-related (doses not specified) maternal toxicity, mortality, decreased weight gain, and embryo toxicity, including increased resorptions, were noted (2).

Dose-related increases in pituitary and mammary gland tumors in female mice were observed in long-term studies. The latter tumors may have been related to drug-induced elevated prolactin levels. Doses up to 50 times the HD were not tumorigenic in rats, but the limited number of animals surviving this study makes the findings unclear (2).

It is not known if pimozide crosses the human placenta. The molecular weight (about 462) and prolonged elimination half-life suggest that the drug will cross to the embryo–fetus.

A 2006 case report described the use of pimozide throughout pregnancy (3). The 26-year-old woman had been diagnosed with Tourette's syndrome at the age of 12–13 years and was treated with pimozide 1–3 mg/day. At age 19 years, in addition to the occurrence of tics from Tourette's syndrome, she began to experience symptoms of obsessive-compulsive disorder (OCD). Fluoxetine 20 mg daily partially controlled the new disorder. Pimozide 1 mg/day (the usual maintenance dose is 2–6 mg/day) and fluoxetine were continued until the 27th week of pregnancy at which time she discontinued fluoxetine. Ultrasound examinations of the fetus conducted 7 times from weeks 8 through 27 were normal. A cesarean section was planned for week 38 and, to prevent potential toxicity in the newborn, pimozide was discontinued at 36 weeks' gestation. However, 1 week after stopping pimozide the patient developed continuous, severe tics with drastic movements and grimaces always followed by coughing tics. In addition, she experienced intense symptoms of OCD and pulled out her hair. During this period, the woman took several doses of oxazepam. Because of the severity of the combined symptoms, an emergency cesarean section was performed to deliver a healthy, 2448-g male infant with Apgar scores of 7, 8, and 10 at 1, 5, and 10 minutes, respectively. Results of physical and neurologic examinations of the infant at delivery and on day 3 of life were normal. On day 3, an electroencephalogram was obtained, and although the infant was asleep during most of the examination, no abnormalities were observed. The mother restarted pimozide after delivery and decided not to breastfeed (3).

In a brief 2009 report, a 29-year-old woman with Tourette's syndrome was treated with pimozide 4 mg/day throughout gestation (4). She gave birth to a

healthy female infant (no other data available).

BREASTFEEDING SUMMARY

No reports describing the use of pimozide during human lactation have been located. The molecular weight (about 462) and prolonged elimination half-life (about 55 hours) suggest that the drug will be excreted into breast milk. The effects, including effects on neurodevelopment, of this exposure on a nursing infant are unknown. If a woman taking this drug decides to breastfeed, her infant should be closely monitored for adverse effects seen in adults, such as extrapyramidal reactions (Parkinson-like symptoms; akinesia), sedation, and constipation.

PINDOLOL

Sympatholytic (Antihypertensive)

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

β -Blockade in the newborn has not been reported in the offspring of pindolol-treated mothers. However, because this complication has been observed in infants exposed to other β -blockers (see Acebutolol, Atenolol, and Nadolol), close observation of the newborn is recommended during the first 24–48 hours after birth. Long-term effects of in utero exposure to β -blockers have not been studied but warrant evaluation.

Some β -blockers may cause intrauterine growth restriction (IUGR) and reduced placental weight, especially those lacking intrinsic sympathomimetic activity (ISA) (i.e., partial agonist). Treatment beginning early in the 2nd trimester results in the greatest weight reductions, whereas treatment restricted to the 3rd trimester primarily affects only placental weight. Pindolol does possess ISA. However, IUGR and reduced placental weight may potentially occur with all agents within this class. Although IUGR is a serious concern, the benefits of maternal therapy with β -blockers, in some cases, might outweigh the risks to the fetus and must be judged on a case-by-case basis.

FETAL RISK SUMMARY

Pindolol, a nonselective β -adrenergic blocking agent, has been used for the treatment of hypertension occurring during pregnancy (1–7). Reproductive studies in rats and rabbits at doses >100 times the maximum recommended human dose (MRHD) found no evidence of embryotoxicity or teratogenicity (8). Impaired mating behavior and increased mortality of offspring were observed in female rats given doses 35 times the MRHD before and through 21 days of lactation (8). At 118 times the MRHD, increased fetal resorptions were noted

(8).

A 1988 review compared the effects of β -blockers, including pindolol, in pregnancy and concluded that these agents are relatively safe (9) (see comment below).

Pindolol crosses the placenta to the fetus with maternal serum levels higher than cord concentrations (10). Cord:maternal serum ratios at 2 and 6 hours after the last dose were 0.37 and 0.67, respectively. Elimination half-lives in fetal and maternal serum were 1.6 and 2.2 hours, respectively.

The effect of pindolol on uteroplacental blood flow was studied in 10 women with gestational hypertension given a 10-mg oral dose (11). A significant fall in the mean maternal blood pressure and mean arterial blood pressure occurred, but no significant changes were observed in maternal or fetal heart rates, uteroplacental blood flow index, or uteroplacental vascular resistance. In contrast, a 1992 study, comparing the effects of pindolol and propranolol in women with preeclampsia, found a significant reduction in uterine artery vascular resistance, prompting the authors to conclude that pindolol acted, at least in part, through a peripheral vascular mechanism (12).

No fetal malformations attributable to pindolol have been reported, but experience in the 1st trimester is lacking. In a study comparing three β -blockers for the treatment of hypertension during pregnancy, the mean birth weight of pindolol-exposed babies was slightly higher than that of the acebutolol group and much higher than that of the offspring of atenolol-treated mothers (3375 vs. 3160 vs. 2745 g) (2). It is not known whether these differences were caused by the degree of maternal hypertension, the potency of the drugs used, or a combination of these and other factors.

The preliminary results of another study found that more than a third of the infants delivered from hypertensive women treated with pindolol were of low birth weight, but the authors thought this did not differ significantly from the expected rate for this population (3). In mothers treated with pindolol or atenolol, a decrease in the basal fetal heart rate was noted only in the atenolol-exposed fetuses (4). Additionally, in a prospective randomized study comparing 27 pindolol-treated women with 24 atenolol-treated women, no differences between the groups were found in gestational length, birth weight, Apgar scores, rates of cesarean section, or umbilical cord blood glucose levels (5). Treatment in both groups started at about 33 weeks' gestation.

A 1986 reference described the comparison of pindolol plus hydralazine with hydralazine alone for the treatment of maternal hypertension (6). Treatment in both groups was started at about 25 weeks' gestation. The newborn outcomes

of the two groups, including birth weights, were similar.

A 1992 report described the outcomes of 29 women with gestational hypertension in the 3rd trimester (7). The women were randomized to receive either the cardioselective β -blocker, atenolol (N = 13), or the nonselective β -blocker, pindolol (N = 16). The mean maternal arterial blood pressure decrease in the two groups was 9 and 7.8 mmHg, respectively (ns). In comparing before and after therapy, several significant changes were measured in fetal hemodynamics with atenolol but, except for fetal heart rate, no significant changes were measured with pindolol. The atenolol-induced changes included a decrease in fetal heart rate, increases in the pulsatility indexes (and thus, the peripheral vascular resistance) of the fetal thoracic descending aorta, the abdominal aorta, and the umbilical artery and a decrease in the umbilical venous blood flow. Although no difference was observed in the birth weights in the two groups, the placental weight in atenolol-treated pregnancies was significantly less (529 vs. 653 g, respectively).

An apparently significant drug interaction occurred when a woman, who was being treated with pindolol for preeclampsia, had indomethacin added for tocolysis to her therapy (13). Two weeks after starting pindolol, 15 mg/day, indomethacin was started with a 200-mg rectal loading dose followed by 25 mg daily for 5 days. A sudden rise in blood pressure (230/130 mmHg) occurred on the fifth day with cardiotocographic changes in fetal vitality (13). A low-birth-weight newborn infant was delivered by cesarean section and the mother's blood pressure returned to normal (125/85 mmHg) in the postpartum period. A similar interaction occurred in another patient who was being treated with propranolol (13).

BREASTFEEDING SUMMARY

No reports describing the use of pindolol during human lactation have been located. The manufacturer, however, states that pindolol is excreted in human milk (8). Because β -blockade has been observed in nursing infants exposed to other β -blockers (see Acebutolol and Atenolol), infants should be closely observed for bradycardia and other symptoms of β -blockade. Long-term effects of exposure to β -blockers from milk have not been studied but warrant evaluation.

PIOGLITAZONE

Antidiabetic Agent

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of pioglitazone during human pregnancy have been located. Insulin is the treatment of choice for pregnant diabetic patients because, in general, other hypoglycemic agents do not provide adequate glycemic control. Moreover, insulin, unlike most oral agents, does not cross the placenta to the fetus, thus eliminating the additional concern that the drug therapy itself will adversely affect the fetus. Carefully prescribed insulin therapy provides better control of the mother's glucose, thereby preventing the fetal and neonatal complications that occur with this disease. High maternal glucose levels, as may occur in diabetes mellitus, are closely associated with a number of maternal and fetal adverse effects, including fetal structural anomalies if the hyperglycemia occurs early in gestation. To prevent this toxicity, the American College of Obstetricians and Gynecologists recommends that insulin be used for types 1 and 2 diabetes occurring during pregnancy and, if diet therapy alone is not successful, for gestational diabetes (1,2).

FETAL RISK SUMMARY

Pioglitazone, a thiazolidinedione antidiabetic agent, is used as an adjunct to diet and exercise to improve glycemic control in patients with type 2 diabetes mellitus. It is used either alone or in combination with other antidiabetic agents (insulin, metformin, or sulfonylureas). Pioglitazone is not an insulin secretagogue, but acts to decrease insulin resistance in the periphery and in the liver (i.e., decreases insulin requirements). It requires the presence of insulin for its action. Pioglitazone undergoes extensive metabolism by hydroxylation and oxidation, and at least three of the metabolites are

pharmacologically active (3).

Reproduction studies with pioglitazone have been conducted in rats and rabbits at doses up to 17 and 40 times, respectively, the maximum recommended human dose based on BSA (MRHD) (1). In pregnant rats, at ≥ 10 times the MRHD, pioglitazone was embryotoxic as evidenced by increased postimplantation losses, delayed development, and reduced fetal weights. At ≥ 2 times the MRHD during late gestation and in the lactation period, delayed development was observed that was attributed to decreased body weights. Embryotoxicity was observed in rabbits dosed at 40 times the MRHD (3).

It is not known if pioglitazone or its active metabolites cross the placenta to the fetus. The molecular weight of the parent compound (about 357 for the free base) is low enough that transfer to the fetus should be expected.

BREASTFEEDING SUMMARY

No reports describing the use of pioglitazone during human lactation have been located. The molecular weight of pioglitazone (about 357 for the free base) is low enough that secretion into breast milk should be expected. At least three active metabolites have been identified and these also may be transferred into milk. The effect on a nursing infant from these exposures is unknown. However, weak bases are known to accumulate in milk with concentrations higher than those in maternal plasma.

PIPERACETAZINE

[Withdrawn from the market. See 8th edition.]

PIPERACILLIN

Antibiotic (Penicillin)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Although the reported pregnancy experience with piperacillin is limited, all penicillins are considered low risk in pregnancy.

FETAL RISK SUMMARY

Piperacillin, a piperazine derivative of ampicillin, is a broad-spectrum penicillin (see also Ampicillin). Animal reproduction studies in mice and rats at doses up to 4 times the human dose have shown no evidence of impaired fertility or fetal harm (1).

No reports linking the use of piperacillin with congenital defects in humans have been located. Piperacillin has been used between 24 and 35 weeks' gestation in women with premature rupture of the membranes to delay delivery (2). No adverse maternal or fetal effects were observed.

Piperacillin rapidly crosses the placenta to the fetus (3). Three women, between 22 and 33 weeks' gestation, were administered a single 4-g IV dose of the antibiotic immediately before intrauterine exchange transfusion for Rh isoimmunization. The mean concentrations of piperacillin in fetal serum, maternal serum, and amniotic fluid were 20, 121, and 0.9 mcg/mL, respectively. The fetal:maternal ratio was 0.17.

The pharmacokinetics of piperacillin during pregnancy have been reported (4). Women were administered a 4-g IV dose just before cesarean section. The mean venous cord concentration was 9.7 mcg/mL, representing a mean fetal:maternal ratio of 0.27. As with other penicillins, an increased clearance of the antibiotic was observed during pregnancy.

BREASTFEEDING SUMMARY

Piperacillin is excreted in small amounts into breast milk (1). Although concentrations are low, three potential problems exist for the nursing infant:

modification of bowel flora, direct effects on the infant, and interference with the interpretation of culture results if a fever workup is required.

PIPERAZINE

Anthelmintic

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: Hold Breastfeeding

PREGNANCY SUMMARY

No reports associating the use of piperazine with congenital defects have been located, but the data are very limited. There are no relevant animal data.

FETAL RISK SUMMARY

A review of the treatment of threadworm infestation during pregnancy cited a personal communication involving two infants with congenital malformations who were exposed to piperazine (1). One of the infants had bilateral hare lip, cleft palate, and anophthalmia, but exposure to piperazine had occurred at 12 and 14 weeks' gestation, after the period when an exposure could have caused the defects. The mother in the second case had taken the anthelmintic at 6 and 8 weeks' gestation and her infant had a defect of the right foot (1). Based on the timing and scarcity of reports, the possibility of a causal relationship in the both cases is doubtful.

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 3 of whom had 1st trimester exposure to piperazine. No evidence was found to suggest a relationship to malformations (2).

BREASTFEEDING SUMMARY

Piperazine is excreted in breast milk (1), but specific data have not been located. According to one reviewer, the mother should take her dose immediately following feeding her infant, and then express and discard her milk during the next 8 hours (1).

PIPERIDOLATE

[Withdrawn from the market. See 9th edition.]

PIRBUTEROL

Respiratory Drug (Bronchodilator)

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of pirbuterol in human pregnancy have been located. The animal reproduction data suggest low risk. Other agents in this class (see below) are considered low risk or compatible. Because of its β -2 adrenergic activity, the drug probably inhibits uterine contractions. However, this effect is not seen clinically because the drug has not been detected in blood after inhalation. Nevertheless, pirbuterol inhalers should only be used during labor if clearly indicated. If pirbuterol is used in pregnancy for the treatment of asthma, health care professionals are encouraged to call the toll-free number 877-311-8972 for information about patient enrollment in an Organization of Teratology Information Specialists (OTIS) study.

FETAL RISK SUMMARY

Pirbuterol is an inhaled sympathomimetic amine that has a preferential effect on β -2 adrenergic receptors (1). Other agents in this class are albuterol, metaproterenol, salmeterol, and terbutaline. Pirbuterol is indicated for the prevention and reversal of bronchospasm in patients ≥ 12 years of age with reversible bronchospasm including asthma. It may be used with or without concurrent theophylline and/or corticosteroid therapy. Each activation delivers a total dose of 453 mcg of pirbuterol acetate. Systemic blood concentrations of pirbuterol following inhalation of doses up to 800 mcg were below the level of detection (2–5 ng/mL). When the drug was given orally, the plasma elimination half-life was about 2 hours (1).

Reproduction studies have been conducted in rats and rabbits. In rats, no teratogenicity was observed with oral doses up to 1000 times the maximum

recommended daily inhalation dose in adults based on BSA (MRDID). Pirbuterol was not teratogenic in rabbits given oral doses up to 680 times the MRDID. At 2000 times the MRDID, abortions and fetal death were observed in rabbits (1).

In long-term studies with rats and mice, no evidence of carcinogenicity was seen with dietary doses up to 35 and 15 times the MRDID, respectively. Assays for mutagenicity and cytogenicity were negative. There also was no evidence of impaired fertility in rats given oral doses up to 35 times the MRDID (1).

It is not known if pirbuterol crosses the human placenta. Although the molecular weight (about 300) is low enough, the drug has not been detected in blood when administered by inhalation.

BREASTFEEDING SUMMARY

No reports describing the use of pirbuterol inhalers during human lactation have been located. Although the molecular weight (about 300) is low enough, the drug has not been detected in blood when administered by inhalation. Consequently, there should be no drug in breast milk.

PIROXICAM

Nonsteroidal Anti-inflammatory

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 1st and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Constriction of the ductus arteriosus in utero is a pharmacologic consequence arising from the use of prostaglandin synthesis inhibitors during pregnancy (see also Indomethacin) (1). Persistent pulmonary hypertension of the newborn may occur if these agents are used in the 3rd trimester close to delivery (1,2). These drugs also have been shown to inhibit labor and prolong pregnancy, both in humans (3) (see also Indomethacin) and in animals (4). Women attempting to conceive should not use any prostaglandin synthesis inhibitor, including piroxicam, because of the findings in a variety of animal models that indicate these agents block blastocyst implantation (5,6). Moreover, as noted below, nonsteroidal anti-inflammatory drugs (NSAIDs) have been associated with spontaneous abortions (SABs) and congenital malformations. The absolute risk for these defects, however, appears to be low.

FETAL RISK SUMMARY

Piroxicam is an NSAID used for relief of the signs and symptoms of rheumatoid arthritis and osteoarthritis. It is in the same NSAID subclass (oxicams) as meloxicam.

Animal reproduction studies in rabbits and rats have not shown drug-related embryotoxicity or teratogenicity (7–9). However, decreased fetal growth was observed in some species (8).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 161 newborns had been exposed to piroxicam during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Six (3.7%) major birth defects were observed (seven expected). Specific data were available for six defect categories,

including (observed/expected) 1/2 cardiovascular defects, 1/0 oral clefts, 1/0 spina bifida, 1/0.5 polydactyly, 0/0 limb reduction defects, and 0/0 hypospadias. These data do not support an association between the drug and congenital defects.

A combined 2001 population-based observational cohort study and a case–control study estimated the risk of adverse pregnancy outcome from the use of NSAIDs (10). The use of NSAIDs during pregnancy was not associated with congenital malformations, preterm delivery, or low birth weight, but a positive association was discovered with SABs. A similar study, also published in 2001, failed to find a relationship, in general, between NSAIDs and congenital malformations, but did find a significant association with cardiac defects and orofacial clefts (11). In addition, a 2003 study found a significant association between exposure to NSAIDs in early pregnancy and SABs (12). (See Ibuprofen for details on these three studies.)

A brief 2003 editorial on the potential for NSAID-induced developmental toxicity concluded that NSAIDs, and specifically those with greater cyclooxygenase 2 (COX-2) affinity, had a lower risk of this toxicity in humans than aspirin (13).

BREASTFEEDING SUMMARY

Piroxicam is excreted into breast milk. A nursing woman, 9 months postpartum, was treated with piroxicam 20 mg/day for 4 months (14). Maternal serum concentrations of the drug 2.5 and 15.0 hours after a dose were 5.85 and 4.79 mcg/mL, respectively. Milk levels varied between 0.05 and 0.17 mcg/mL. Based on an ingested volume of 600 mL/day, the investigators estimated the infant would have received a daily dose of about 0.05 mg. However, no drug was detectable in the infant's serum. A second woman stopped nursing her 8-month-old infant when she was treated with piroxicam 40 mg/day (14). Milk concentrations of the drug ranged from 0.11 to 0.22 mcg/mL, with the highest level measured 2.5 hours after the second dose. In both cases, the concentration of the drug in milk was approximately 1% of the mother's serum levels. These amounts probably do not present a risk to the nursing infant (15). The American Academy of Pediatrics classifies piroxicam as compatible with breastfeeding (16).

PITAVASTATIN

Antilipemic Agent

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of pitavastatin in human pregnancy have been located. The absence of human pregnancy experience prevents an assessment of the embryo and/or fetal risk. Because the interruption of cholesterol-lowering therapy during pregnancy should have no apparent effect on the long-term treatment of hyperlipidemia, pitavastatin should not be used during pregnancy. Moreover, cholesterol and other products of cholesterol biosynthesis are essential components for fetal development (1). Women taking this agent before conception should stop the therapy before becoming pregnant and certainly on recognition of pregnancy. Accidental use of the drug during gestation, though, apparently has no proven consequences for the fetus.

FETAL RISK SUMMARY

Pitavastatin, a synthetic 3-hydroxy-3-methyl-coenzyme A (HMG-CoA) reductase inhibitor (a statin) that is lipophilic, is indicated as an adjunctive therapy to diet to reduce elevated total cholesterol, low-density lipoprotein cholesterol, apolipoprotein B, and triglycerides and to increase high-density lipoprotein cholesterol. It has the same mechanism of action as other agents available in this class, atorvastatin, fluvastatin, lovastatin, pravastatin, rosuvastatin, and simvastatin (cerivastatin was withdrawn from the market in 2001). Pitavastatin is metabolized to inactive metabolites. Plasma protein binding is high (>99%), mainly to albumin and α -1-acid glycoprotein, and the mean plasma elimination half-life is about 12 hours (1).

Reproduction studies have been conducted in rats and rabbits. In rats during organogenesis, doses resulting in systemic exposures up to 22 times the human systemic exposure at 4 mg/day based on AUC (HSE), the lowest dose tested, caused no adverse effects. When the drug was given from

organogenesis through weaning, maternal toxicity (mortality at about ≥ 3 times the HSE and impaired lactation at about ≥ 1 times the HSE) contributed to the decreased survival of neonates. In rabbits, maternal toxicity (reduced body weight and abortions) were observed at 4 times the HSE (1).

Carcinogenicity studies in mice were negative, but high doses (295 times the HSE) caused thyroid follicular cell tumors in rats. Pitavastatin was not mutagenic in several assays but high doses that also caused cytotoxicity were clastogenic. High doses caused no adverse effects on male and female rat fertility (1).

It is not known if pitavastatin crosses the human placenta. The molecular weight (about 813 for the free acid) and elimination half-life suggest that it will cross, but the high plasma protein binding might limit the exposure. The drug does cross the rat placenta (1).

BREASTFEEDING SUMMARY

No reports describing the use of pitavastatin during human lactation have been located. The molecular weight (about 813 for the free acid) and elimination half-life (about 12 hours) suggest that it will be excreted into breast milk, but the high plasma protein binding might limit the amount. At least two similar agents (fluvastatin and pravastatin) appear in human milk. Because of the potential for adverse effects in the nursing infant, the drug should not be used during lactation.

PLERIXAFOR

Hematologic (Hematopoietic)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of plerixafor during human pregnancy have been located. The animal reproduction data suggest risk but only one species was studied. If a pregnant woman's disease requires the use of this agent, she should be informed of the potential risk to her embryo or fetus.

FETAL RISK SUMMARY

Plerixafor, a hematopoietic stem cell mobilizer, is an inhibitor of the CXCR4 chemokine receptor and blocks binding of its cognate ligand, stromal cell-derived factor-1 α . It is indicated in combination with granulocyte-colony stimulating factor to mobilize hematopoietic stem cells to the peripheral blood for collection and subsequent autologous transplantation in patients with non-Hodgkin's lymphoma and multiple myeloma. Plerixafor is not metabolized. Plasma protein binding is up to 58% and the terminal half-life is 3–5 hours in patients with normal renal function (1).

Reproduction studies have been conducted in rats. In this species, embryo–fetal toxicity was observed mainly at a dose that was about 10 times the recommended human dose of 0.24 mg/kg based on BSA or 10 times the AUC in subjects with normal renal function who received a single of 0.24 mg/kg. The embryo–fetal toxicities included fetal death, increased resorptions and postimplantation loss, decreased fetal weights, anophthalmia, shortened digits, cardiac interventricular septal defect, ringed aorta, globular heart, hydrocephaly, dilation of olfactory ventricles, and retarded skeletal development (1).

Carcinogenicity studies have not been conducted with plerixafor. The drug

was not genotoxic in various assays. Studies in animals on male or female fertility have not been conducted. However, no adverse effects were observed on spermatogenesis in rats in a 28-day repeated dose toxicity study, nor was there any evidence of toxicity in male or female reproductive organs (1).

It is not known if plerixafor crosses the human placenta. However, the molecular weight (about 503), lack of metabolism, moderate plasma protein binding, and moderately long terminal half-life suggest that the drug will cross to the embryo or fetus.

BREASTFEEDING SUMMARY

No reports describing the use of plerixafor during human lactation have been located. The molecular weight (about 503), lack of metabolism, moderate plasma protein binding (up to 58%), and moderately long terminal half-life (3–5 hours) suggest that the drug will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown. The safest course for the infant would be to hold nursing for about 24 hours after a dose. If the mother is given this drug and continues nursing, her infant should be closely monitored for the most common adverse reactions seen in adults: diarrhea, nausea, fatigue, headache, arthralgia, dizziness, and vomiting.

PLICAMYCIN

[Withdrawn from the market. See 9th edition.]

PODOFILOX

Keratolytic Agent

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Podofilox (podophyllotoxin) is the active compound in podophyllum resin. (See Podophyllum.)

FETAL RISK SUMMARY

No teratogenicity was observed in pregnant rabbits after once daily topical use for 13 days at doses up to 5 times the maximum human dose (1).

BREASTFEEDING SUMMARY

No reports describing the use of podofilox during human lactation have been located.

Reference

1. Product information. Condyllox. Oclassen Pharmaceuticals, 2000.

PODOPHYLLUM

Keratolytic Agent

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although it is uncertain whether podophyllum is a human teratogen, products containing this drug should not be used during pregnancy for the treatment of genital warts (human papillomavirus infections) because of the potential severe myelotoxicity and neurotoxicity in the mother. Although one author believes the topical application of podophyllum resin is safe during pregnancy (1), most other sources consider it a dangerous agent to use during this period, especially because of the availability of alternative, safer treatments. The American College of Obstetricians and Gynecologists (2) and other reviews (3) and reference sources (4) all state that the drug is contraindicated during pregnancy. The contraindications to the use of podophyllum agents include the use of podophyllotoxin (podofilox) during pregnancy and in the vagina or cervix at any time (2).

FETAL RISK SUMMARY

Podophyllum is the dried rhizomes and roots of *Podophyllum peltatum* (American mandrake, May apple) (4). Podophyllum resin is the dried mixture of resins extracted from podophyllum (4). Podophyllotoxin (podofilox), the major active compound in podophyllum resin, and podophyllum are keratolytic agents whose caustic action is thought to be caused by the arrest of mitosis in metaphase. In addition to its antimetabolic effect, podophyllum also has cathartic action, but should not be used for this purpose because of the potential for severe drug-induced toxicity (5).

Three reproductive studies in rats and mice with podophyllum or podophyllotoxin found no teratogenic effects, but resorptions occurred when the agents were used early in gestation (6–8). A 1952 study observed no teratogenic changes in mice, rats, and rabbits with podophyllotoxin (9). Two

other studies involving podophyllum reported embryotoxicity, but not teratogenicity, in mice (10) and only minor skeletal changes in rats (11). Another agent derived from *P. peltatum* that is present in podophyllum resin, peltatin (α and β forms), was not teratogenic in mice (12).

The first report of human teratogenicity related to podophyllum appeared in 1962 (13). A 24-year-old woman took herbal “slimming tablets,” containing podophyllum and other extracts, from the 5th to 9th weeks of gestation, a total of 3.5 weeks. The estimated daily dose of podophyllum was 180 mg. The term, female infant had multiple anomalies, including an absent right thumb and radius, a supernumerary left thumb, a probable septal defect of the heart, a defect of the right external ear, and skin tags. The malformations were attributed to the antimitotic action of podophyllum (13).

In contrast to the above outcome, a woman at 26 weeks’ gestation was treated with multiple applications of 20% podophyllum resin in compound benzoin tincture for condylomata acuminata (genital human papillomavirus infection) that covered the entire vulva, the minor and major labia, and a portion of the vagina (14). In addition, the woman was accidentally given 5 mL of the preparation orally, a potentially fatal dose. Toxic symptoms in the mother included persistent, severe coughing, nausea and vomiting, and hypotension, all of which had resolved within 72 hours. Three months later, the mother delivered a normal 3560-g male infant who was doing well.

A 1972 report described severe peripheral neuropathy and intrauterine fetal death in a woman at either 32 or 34 weeks’ (both dates were used) gestation following the administration of 7.5 mL (1.88 g of podophyllum) of 25% podophyllum resin to florid vulval warts that were friable and bled easily (15). General anesthesia (nitrous oxide and oxygen) was used during application of podophyllum. Fetal heart sounds were lost 2 days after the application of podophyllum, and 10 days later a stillborn female infant was delivered. The woman’s symptoms and death of her fetus were attributed to podophyllum poisoning, apparently from systemic absorption of the drug. She eventually recovered and within a year or two she had an uneventful pregnancy and normal infant (15).

Minor congenital malformations consisting of a simian crease on the left hand and a preauricular skin tag were observed in a newborn whose mother had been treated with five applications of 25% podophyllum resin between the 23rd and 29th weeks of pregnancy for condyloma acuminata (16). Although the authors attributed the skin tag to the drug, podophyllum was not related to either anomaly because of the late timing of exposure (17).

The Collaborative Perinatal Project recorded 14 1st trimester exposures to podophyllum (presumably oral) among 50 mothers who had used a group of miscellaneous gastrointestinal drugs (18). From this group, one (2%) infant with an unspecified congenital malformation was observed (standardized relative risk 0.27). It was not stated whether podophyllum was taken by the mother of the affected infant.

BREASTFEEDING SUMMARY

No reports describing the use of podophyllum during human lactation have been located.

POLIDOCANOL

Sclerosing Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The human pregnancy experience with polidocanol is limited. In animals, polidocanol was associated with both maternal and fetal toxicity in one species, but there was no evidence of an increase in structural abnormalities. The absence of human pregnancy experience prevents a better assessment of the risk to the embryo–fetus.

FETAL RISK SUMMARY

Polidocanol is given IV. It is a sclerosing agent indicated to treat uncomplicated spider veins (varicose veins ≤ 1 mm in diameter) and uncomplicated reticular veins (varicose veins 1–3 mm in diameter) in the lower extremities. Polidocanol causes local endothelial damage and occlusion of the varicose vein. In four patients, the mean half-life was 1.5 hours (1).

Reproduction studies have been conducted in rats and rabbits. No teratogenic or fetal toxic effects were noted in rats given IV doses up to the maximum human dose based on BSA (MHD) during gestation days 6–17. Polidocanol did not affect the ability of rats to deliver and rear pups when IV doses up to the MHD were given from gestation day 17 to postpartum day 21. In rabbits, IV doses up to the MHD during gestation days 6–20 caused maternal and fetal toxicity, including lower fetal weights and reduced fetal survival, but not skeletal or visceral abnormalities. No adverse maternal or fetal effects in rabbits were observed with a dose one-fifth the MHD (1).

Carcinogenicity studies have not been conducted with polidocanol. The drug was not genotoxic in multiple assays, but it induced numerical chromosomal aberrations in cultured newborn Chinese hamster lung fibroblasts. No effect on reproductive performance was observed in rats given intermittent IV doses

equivalent to the MHD (1).

It is not known if polidocanol crosses the human placenta. The molecular weight (about 600) suggests that the drug will cross, but the short elimination half-life may limit the embryo–fetal exposure. Low systemic blood levels have been noted in some patients treated for spider or reticular veins (1). This might result in very-low-level exposure of the embryo–fetus.

A 1991 case report described a woman who was treated for a variceal hemorrhage with endoscopic intravascular injection of polidocanol in mid-pregnancy (2). No adverse effects were observed in her infant. A 2008 case report involved 3rd trimester in utero treatment of two fetuses with polidocanol for congenital cystic adenomatoid malformation of the lung (3). No apparent treatment-related adverse effects were noted in the infants.

BREASTFEEDING SUMMARY

No reports describing the use of polidocanol during lactation have been located. The low-level systemic blood levels and the molecular weight (about 600) suggest that the drug may be excreted into human milk. The effects of this exposure on a nursing infant are unknown but most likely lack clinical significance.

POLYETHYLENE GLYCOL (3350 & 4000)

Laxative

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Although the published human pregnancy experience is limited, the substances are compatible in pregnancy because only minimal amounts are absorbed without significant change in fluid or electrolyte balance. Several sources have concluded that polyethylene glycol (PEG), either PEG-3350 or PEG-4000 (numbers refer to the average molecular weight) are safe and effective and should be considered as first-line therapy for constipation in pregnancy (1–3).

FETAL RISK SUMMARY

PEG-3350 with electrolytes is a white powder that is dissolved in water. It is indicated for bowel cleansing prior to colonoscopy. The osmotic activity of PEG-3350 and the electrolytes result in virtually no net absorption or excretion of ions so that large volumes can be given without significant change in fluid or electrolyte balance (4,5). Similar properties should be expected for PEG-4000.

Reproduction studies in animals have not been conducted. Studies for carcinogenic effects and impairment of fertility in animals have not been performed (4,5).

It is not known if PEG-3350 or PEG-4000 cross the human placenta. Although the average molecular weights are high (3350 and 4000), only minimal amounts are absorbed and clinically significant exposure of the embryo–fetus should not occur.

In a survey on the choice of colonoscopy preparations for pregnant patients, gastroenterologists favored the use of the PEG solution and avoided oral sodium phosphate, whereas obstetricians tended to prefer oral sodium phosphate over the PEG product (6). However, the majority in both groups avoided the sodium phosphate laxative.

In a 2004 observational open label study, 40 pregnant women with constipation were enrolled at 6–37 weeks' gestation (mean 21.0 weeks) and given a solution of PEG-4000 for 15 days at a dose of 250 mL once or twice daily (7). Pregnancy outcomes included one spontaneous abortion at 11 weeks' and two preterm deliveries at 26 weeks'; one for failure of a cervical cerclage and the other for severe gestational hypertension. Of the remaining 37 women, the mean gestational age at delivery was 39.2 weeks. No neonatal complications were observed (7).

A brief 1989 case report described the use of PEG (molecular weight not specified) electrolyte solution in a 18-year-old woman at 38 weeks' gestation who had ingested 55 tablets of a prenatal iron supplement (8). An x-ray demonstrated many iron tablets in her stomach. A whole bowel irrigation with PEG through a nasogastric tube at 2.0 L/hr was started and continued until the bowels were clear. Deferoxamine also was given for chelation. The patient was subsequently discharged in good health and, 5 weeks later, gave birth to a normal 3550-g female infant with no perinatal complications (8).

BREASTFEEDING SUMMARY

No reports describing the use of PEG-3350 or PEG-4000 during human lactation have been located. However, the substances probably are compatible with breastfeeding because only minimal amounts are absorbed. Large volumes can be given without significant change in fluid or electrolyte balance (4,5).

POLYMYXIN B

Antibiotic

PREGNANCY RECOMMENDATION: Compatible (Topical)

BREASTFEEDING RECOMMENDATION: Compatible (Topical)

PREGNANCY SUMMARY

No reports linking the use of polymyxin B with congenital defects have been located. Although available for injection, polymyxin B is used almost exclusively by topical administration.

FETAL RISK SUMMARY

In one study, seven polymyxin B exposures were recorded in the 1st trimester (1). No association with congenital defects was observed. In a brief 2005 report from the Hungarian Case–Control Surveillance of Congenital Abnormalities (1980–1996) database, 6 infants, among 22,843 cases (fetus or newborn) with birth defects, were exposed in utero to parenteral polymyxin B (2). Two of the cases, exposed in the 1st trimester (one in the 1st and the other in the 3rd month of gestation), had cardiovascular malformations. The other four cases, neural tube defect, microcephaly, limb reduction defect, and talipes equinovarus, were exposed after the 1st trimester. There were 13 exposed infants in the matched controls. The crude odds ratio for 1st trimester exposure was 0.8, 95% confidence interval 0.3–2.0 (2).

BREASTFEEDING SUMMARY

No reports describing the use of polymyxin B during human lactation have been reported.

POLYTHIAZIDE

[Withdrawn from the market. See 9th edition.]

PONATINIB

Antineoplastic (Tyrosine Kinase Inhibitor)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of ponatinib in human pregnancy have been located. Embryo–fetal toxicity was observed in the only species studied at a dose about one-fourth the human dose. The lack of human pregnancy experience prevents a more complete assessment of the embryo–fetal risk. If a woman who is or may be pregnant is given this drug, she must be informed of the potential embryo–fetal risk.

FETAL RISK SUMMARY

Ponatinib is an oral tyrosine kinase inhibitor. There are several other agents in this same subclass (see Appendix). It is indicated for the treatment of adult patients with chronic phase, accelerated phase, or blast phase chronic myeloid leukemia that is resistant or intolerant to prior tyrosine kinase inhibitor or Philadelphia chromosome positive acute lymphoblastic leukemia that is resistant or intolerant to prior tyrosine kinase inhibitor therapy. The drug undergoes partial metabolism to apparently inactive metabolites. Plasma protein binding is high (>99%) and the mean elimination half-life is about 24 hours (range 12–66 hours) (1).

Reproduction studies have been conducted in rats. In this species during organogenesis, a dose that was about 24% of the AUC in patients receiving the recommended dose (AUC-RD) caused embryo–fetal toxicities that involved multiple fetal soft-tissue and skeletal alterations, including reduced ossification. A dose equivalent to the AUC-RD was maternal toxic and caused embryo–fetal toxicity as shown by increased resorptions, reduced body weight, external alterations, multiple soft-tissue and skeletal alterations, and reduced ossification (1).

Carcinogenicity studies have not been conducted with ponatinib. The drug was not mutagenic or clastogenic in multiple assays. Although fertility studies in

animals have not been conducted, the drug has caused degeneration of epithelium of the testes in rats and monkeys and follicular atresia in monkey ovary with associated endometrial atrophy. The effects seen in rats were at a dose that was about equivalent to the AUC-RD, whereas those in monkeys were seen at about 4 times the AUC-RD (1).

It is not known if ponatinib crosses the human placenta. The molecular weight (about 569) and long elimination half-life suggest that the drug will cross to the embryo–fetus. However, the high plasma protein binding might limit the exposure.

BREASTFEEDING SUMMARY

No reports describing the use of ponatinib during human lactation have been located. The molecular weight (about 569) and long elimination half-life (mean 24 hours, range 12–66 hours) suggest that the drug will be excreted into breast milk. However, the high (>99%) plasma protein binding might limit the exposure. The effect of exposure to the drug on a nursing infant is unknown. However, in adults, the drug has caused multiple hematologic and nonhematologic adverse effects. A nursing infant of a woman who is taking this drug should be closely monitored.

PORFIMER

Antineoplastic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of porfimer in human pregnancy have been located. Although the dose comparisons used in the animal reproduction studies were based on body weight, there was no association with structural anomalies in two species at doses less than the human dose. Other aspects of developmental toxicity could not be assessed because the tested doses caused maternal toxicity. When the dose was decreased by 50% in one species and continued throughout lactation, there was a reduction in the body weights of the offspring. The absence of human pregnancy experience prevents a more complete assessment of the embryo–fetal risk. Nevertheless, if porfimer is required by a woman, the drug should not be withheld because of pregnancy. If inadvertent pregnancy does occur, the woman should be informed of the potential for embryo and fetal harm.

FETAL RISK SUMMARY

Porfimer is a mixture of oligomers formed by ether and ester linkages of up to eight porphyrin units. It is given IV as a photosensitizing agent used in photodynamic therapy. Photodynamic therapy with porfimer is indicated for cases of esophageal cancer, endobronchial non–small-cell lung cancer, and high-grade Barrett’s esophagus. In patients with cancer, the plasma elimination half-life was 250 ± 285 hours (about 10 ± 12 days), but in healthy volunteers, the half-life was 415 ± 104 hours (about 17 ± 4.3 days). Porfimer is about 90% protein bound in human serum.

Reproduction studies with porfimer have been conducted in rats and rabbits. In pregnant rats, an IV dose 0.64 times the human clinical dose based on BSA

(HCD) given daily during organogenesis did not cause congenital malformations but did result in maternal and fetal toxicity (resorptions, decreased litter size, delayed ossification, and reduced fetal weight). An IV dose that was 0.32 times the HCD given daily to pregnant rats during late pregnancy through lactation caused a reversible decrease in growth of offspring. An IV dose 0.65 times the HCD, given daily to pregnant rabbits during organogenesis did not cause fetal anomalies, but did cause maternal toxicity resulting in resorptions, decreased litter size, and reduced fetal weight (1).

Long-term studies for carcinogenicity have not been conducted. Porfimer was not mutagenic or clastogenic in several tests. In studies with male and female rats, an IV dose 0.32 times the HCD caused no impairment of fertility. Long-term dosing resulted in discoloration of the testes and ovaries, hypertrophy of the testes, and decreased body weights (1).

It is not known if porfimer crosses the human placenta. Because it is a mixture of oligomers, the exact molecular weight, which is high, cannot be determined. The long elimination half-life, however, does increase the possibility that some may cross to the embryo or fetus.

BREASTFEEDING SUMMARY

No reports describing the use of porfimer during human lactation have been located.

Because it is a mixture of oligomers, the exact molecular weight, which is high, cannot be determined,. The long elimination half-life, however, does increase the possibility that some drug may be excreted into breast milk. The effect of this potential exposure on a nursing infant is unknown, but this agent is a photosensitizer.

POSACONAZOLE

Antifungal

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of posaconazole in human pregnancy have been located. The animal reproduction data suggest risk, but the absence of human pregnancy experience prevents a more complete assessment of embryo–fetal risk. However, the drug will most likely cross the placenta to the embryo and/or fetus. High-dose fluconazole (400 mg/day) is suspected of causing birth defects (see Fluconazole), but doses <400 mg/day appear to be low risk. Developmental toxicity has not been associated with itraconazole. Thus, the best course is to avoid posaconazole during pregnancy, especially in the 1st trimester. However, if the woman's condition requires posaconazole, the benefit probably outweighs the unknown risk. The lowest possible dose should be used.

FETAL RISK SUMMARY

Posaconazole is a triazole antifungal agent in the same class as fluconazole, itraconazole, terconazole, and voriconazole. Oral posaconazole is indicated for prophylaxis of invasive *Aspergillus* and *Candida* infections in patients who are at high risk of developing these infections due to being severely immunocompromised, such as hematopoietic stem cell transplant recipients with graft-versus-host disease or those with hematologic malignancies with prolonged neutropenia from chemotherapy. It is also indicated for the treatment of oropharyngeal candidiasis, including oropharyngeal candidiasis refractory to itraconazole and/or fluconazole. Posaconazole is only partially metabolized (about 17%) but is highly protein bound (>98%) in the plasma, primarily to albumin. The mean elimination half-life of posaconazole is 35 hours (range 20–66 hours) (1).

Reproduction studies have been conducted in rats and rabbits. In pregnant rats, doses ≥ 1.4 times the human dose of 400 mg twice daily based on steady-state plasma concentrations in healthy volunteers (HD) resulted in skeletal malformations (cranial malformations and missing ribs). The no-effect dose was 0.7 times the HD. In pregnant rabbits, a dose 2.9 times the HD or higher caused an increase in resorptions. At 5.2 times the HD, maternal toxicity (reduction in body weight gain) and a reduction in litter size were seen. The no-effect dose in rabbits was about 1.4 times the HD (1).

No carcinogenicity was observed in 2-year studies in male and female rats and mice. In addition, the drug was not mutagenic or clastogenic in several tests. Posaconazole had no effect on fertility in male and female rats given doses that were 1.7 and 2.2 times the HD, respectively (1).

It is not known if posaconazole crosses the human placenta. The molecular weight (about 701), low metabolism, and long elimination half-life suggest that the drug will cross to the embryo and/or fetus. The high plasma protein binding, however, should limit the exposure.

BREASTFEEDING SUMMARY

No reports describing the use of posaconazole during human lactation have been located.

The molecular weight (about 701), low metabolism (about 17%), and long elimination half-life (35 hours; range 20–66 hours) suggest that the drug will be excreted into breast milk. The high plasma protein binding (>98%) should limit the amount in milk. The effects, if any, of this potential exposure on a nursing infant are unknown, but severe treatment-related toxicity has been reported in adults, particularly hepatic toxicity, and nausea and vomiting.

POTASSIUM CHLORIDE

Electrolyte

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Potassium chloride is a natural constituent of human tissues and fluids. Exogenous potassium chloride may be indicated as replacement therapy for pregnant women with low serum potassium levels, such as those receiving diuretics. Because high or low levels are detrimental to maternal and fetal cardiac function, serum levels should be closely monitored.

FETAL RISK SUMMARY

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 35 newborns had been exposed to oral potassium salts during the 1st trimester (F. Rosa, personal communication, FDA, 1993). One (2.9%) infant with major birth defects was observed (one expected), a case of limb reduction and hypospadias.

BREASTFEEDING SUMMARY

Breast milk is naturally high in potassium with levels that are 3–4 times those in plasma (1). The concentration of potassium in mature milk is about 55–57 mg/dL (about 14–15 mEq/L) (1). Because potassium freely passes into and out of milk, the use of potassium chloride by a lactating woman with normal plasma potassium levels would have no adverse effect on a nursing infant.

POTASSIUM CITRATE

Electrolyte/Urinary Alkalinizer

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Except for the case discussed below, no other reports describing the use of potassium citrate in human pregnancy have been located. In four animal species, no teratogenicity was observed with very high doses of citric acid. Citric acid is widely distributed in nature and is a key ingredient in intermediary metabolism. In addition, potassium is a natural constituent of human tissues and fluids. The primary risk appears to be from hyperkalemia, as this product could produce this in patients who have a condition predisposing them to high blood potassium levels. Because high levels are detrimental to maternal and embryo–fetal cardiac function, maternal serum potassium levels should be closely monitored.

FETAL RISK SUMMARY

Potassium citrate, the potassium salt of citric acid, is given orally to raise the urinary pH. Citric acid is the acid of citrus fruits and is widely distributed in nature. After absorption, metabolism of citrate increases the alkaline load. Potassium citrate is indicated for the management of renal tubular acidosis with calcium stones, hypocitraturic calcium oxalate nephrolithiasis of any etiology, and uric acid lithiasis with or without calcium stones (1).

Reproduction studies have been conducted with citric acid in mice, rats, rabbits, and hamsters. The highest doses studied were 241, 295, 425, and 272 mg/kg, respectively. No teratogenicity was observed in these species (2).

A 1964 report mentioned the use of potassium citrate in one pregnant patient (3). The liveborn infant had an unspecified malformation, but no other details, such as the timing of the exposure, dose, other drugs used, and the medical and obstetric history, were provided.

BREASTFEEDING SUMMARY

No reports describing the use of potassium citrate during lactation have been located. Breast milk is naturally high in potassium with levels that are 3–4 times those in plasma (4). The concentration of potassium in mature milk is about 55–57 mg/dL (about 14–15 mEq/L) (4). Because potassium freely passes into and out of milk, the use of potassium citrate by a lactating woman with normal plasma potassium levels would have no adverse effect on a nursing infant. However, if the woman has hyperkalemia, this could result in higher milk potassium concentrations. In this case, nursing infants should be observed for gastrointestinal complaints commonly observed in adults with oral potassium and plasma potassium concentrations should be monitored.

POTASSIUM IODIDE

Respiratory Drug (Expectorant)

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Because a large number of prescription and over-the-counter medications contain iodide or iodine, pregnant patients should consult with their physician before using these products. The American Academy of Pediatrics considers the use of iodides as expectorants during pregnancy to be contraindicated (1).

FETAL RISK SUMMARY

The primary concern with the use of potassium iodide and the anti-infective, iodine, during pregnancy relates to the effect of iodide on the fetal thyroid gland. Because aqueous solutions of iodine are in equilibrium with the ionized form, all iodide or iodine products are considered as one group.

Iodide readily crosses the placenta to the fetus (2). When used for prolonged periods or close to term, iodide may cause hypothyroidism and goiter in the fetus and newborn. Short-term use, such as a 10-day preparation course for maternal thyroid surgery, does not carry this risk and is apparently safe (3,4). A 1983 review tabulated 49 cases of congenital iodide goiter dating back to 1940 (66 references) (5). In 14 cases, the goiter was large enough to cause tracheal compression resulting in death. Cardiomegaly was present in three surviving newborns and in one of the fatalities. In a majority of the cases, exposure to the iodide was a result of maternal asthma treatment.

Four studies have shown the potential hazard resulting from the use of povidone-iodine during pregnancy (6–9). In each case, significant absorption of iodine occurred in the mother and fetus following topical, vaginal, or perineal use before delivery. Transient hypothyroidism was demonstrated in some newborns (6,9).

BREASTFEEDING SUMMARY

Iodide is concentrated in breast milk (5,10,11). In one report, a breastfeeding mother used povidone-iodine vaginal gel daily for 6 days without douching (10). Two days after stopping the gel, the mother noted an odor of iodine on the 7.5-month-old baby. The free iodide serum:milk ratio 1 day later was approximately 23:1. By day 7, the ratio had fallen to about 4:1 but then rose again on day 8 to 10:1. Serum and urine iodide levels in the infant were grossly elevated. No problems or alterations in thyroid tests were noted in the baby.

In a 2000 case report, a woman delivered a female infant at 29 weeks' gestation by cesarean section (11). An abscess of the abdominal wall 1 week after delivery was treated with IV antibiotics and iodine tampons (each tampon contained about 10.5 mg of iodine). Full breastfeeding of the infant was begun approximately 20 days after birth. At 29 days, neonatal hypothyroidism was diagnosed: the thyroid-stimulating hormone (TSH) level was 287.9 $\mu\text{U/mL}$ (normal range 0.45–10.0 $\mu\text{U/mL}$). Iodine levels in the mother's milk and infant urine were 4410 mcg/L (normal range 29–490 mcg/L) and 3932 mcg/L (normal <185 mcg/L), respectively. At 32 days, iodine tampons and breastfeeding were stopped and the infant was given levothyroxine (25 mcg/day). Six days later, thyroid function had normalized and breastfeeding was restarted. The infant's thyroid function remained normal over a 4-month follow-up period (11).

The use of povidone-iodine immediately before delivery as a topical anesthetic for epidural anesthesia or cesarean section produced iodine overload in newborn infants who were breastfed as evidenced by increased neonatal TSH concentrations (12). Breastfed infants had a 25- to 30-fold increase in the recall rate at screening for congenital hypothyroidism (TSH >50 mU/L) compared with bottle-fed infants.

The normal iodine content of human milk has been recently assessed (13). Mean iodide levels in 37 lactating women were 178 mcg/L. This is approximately 4 times the recommended daily allowance (RDA) for infants. The RDA for iodine was based on the amount of iodine found in breast milk in earlier studies (13). The higher levels now are probably caused by dietary supplements of iodine (e.g., salt, bread, cow's milk). The significance to the nursing infant from the chronic ingestion of higher levels of iodine is not known. The American Academy of Pediatrics, although recognizing that the maternal use of iodides during lactation may affect the infant's thyroid activity by producing elevated iodine levels in breast milk, classifies the agents as compatible with breastfeeding (14).

POVIDONE-IODINE

Anti-infective

See Potassium Iodide.

PRALATREXATE

Antineoplastic (Antimetabolite)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of pralatrexate in human pregnancy have been located. The animal data suggest risk based on the two animal species studied. Although the drug did not cause structural anomalies, it did cause embryo and fetal death. Moreover, pralatrexate is a folic acid antagonist in the same subclass of antimetabolites as aminopterin and methotrexate, agents known to cause embryo–fetal harm. Another agent in this subclass is pemetrexed. Pralatrexate should be avoided in pregnancy. If indicated during pregnancy for maternal benefit, the mother should be informed of the potential risk to her embryo and/or fetus.

FETAL RISK SUMMARY

Pralatrexate is a folate analog metabolic inhibitor that is given as weekly IV push doses. It is in the same antineoplastic subclass of folic acid antagonists (antimetabolites) as methotrexate and pemetrexed. Pralatrexate is indicated for the treatment of patients with relapsed or refractory peripheral T-cell lymphoma. The drug is partially metabolized (about a third of a dose excreted unchanged in urine), but the amount of plasma protein binding was not specified. The terminal elimination half-life is 12–18 hours (1).

Reproduction studies have been conducted in rats and rabbits. In rats, daily doses given on gestation days 7–20 that were about 1.2% of the clinical dose based on BSA (CD) were embryotoxic and fetotoxic. A dose-dependent decrease in fetal viability manifested as an increase in early, late, and total resorptions was observed. There was also a dose-dependent increase in postimplantation loss. In rabbits, similar daily doses given on gestation days 8–21 caused abortion and fetal lethality. The toxicity was manifested as early and total resorptions, postimplantation loss, and a decrease in the total number of live fetuses (1).

Neither carcinogenicity nor fertility studies have been conducted with pralatrexate. The drug was not mutagenic in multiple tests (1).

It is not known if pralatrexate crosses the human placenta. The molecular weight (about 477) and the long terminal elimination half-life suggest that the drug will cross to the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use of pralatrexate during human lactation have been located. The molecular weight (about 477) and the long terminal elimination half-life (12–18 hours) suggest that the drug will be excreted into breast milk. Moreover, the long half-life makes a “pump and dump” method impractical (i.e., the mother would have to wait about 60–90 hours to eliminate most of the drug from her circulation). The effect of this exposure on a nursing infant is unknown, but serious toxicities observed in adults (e.g., pyrexia, bone marrow depression, mucositis, nausea, and vomiting) are potential complications. Based on the potential risk, the best course is not to breastfeed.

PRALIDOXIME

Antidote

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: Hold Breastfeeding

PREGNANCY SUMMARY

Reproduction studies with pralidoxime have not been conducted and the human pregnancy experience is limited to two cases. No other reports describing the use of this drug in human pregnancy have been located. Although the risk this agent represents in pregnancy cannot be assessed, the maternal benefit clearly outweighs any concern regarding embryo or fetal toxicity. Therefore, pralidoxime should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Pralidoxime (2-PAM) reactivates cholinesterase (mainly outside of the CNS) that has been inactivated by phosphorylation due to an organophosphate pesticide or related compound. Its most critical effect is relieving the paralysis of the muscles of respiration. Pralidoxime is short-acting (apparent half-life 74–77 minutes) and is not bound to plasma proteins. Pralidoxime is available in an auto-injector that can be used rapidly in cases of exposure to nerve agents possessing anticholinesterase activity (organophosphate poisoning) (1).

Animal reproduction studies have not been conducted with pralidoxime.

It is not known if pralidoxime crosses the human placenta to the embryo or fetus. Pralidoxime chloride is a quaternary ammonium compound, but the molecular weight of the free base (about 137) is low enough for passage across the placenta. The rapid elimination of the drug should mitigate this transfer.

A 1988 report described the pregnancy outcomes of two women who were treated with pralidoxime for self-induced organophosphorus insecticide poisoning (2). In the first case, a 22-year-old primigravida at 36 weeks' gestation was admitted to the hospital 3 hours after ingesting methamidophos.

She was treated with pralidoxime and atropine and eventually recovered. Forty-four days after poisoning, she delivered a healthy 2.85-kg male infant with an Apgar score of 8 at 1 minute. The second case involved a 25-year-old woman at 16 weeks' gestation who ingested fenthion. She also was treated with pralidoxime and atropine and made a full recovery. She delivered a healthy 3.83-kg infant (Apgar 10 at 1 minute) 24 weeks after intoxication (2).

BREASTFEEDING SUMMARY

No reports describing the use of pralidoxime during lactation have been located. Pralidoxime chloride is a quaternary ammonium compound, but the molecular weight of the free base (about 137) is low enough for excretion into breast milk. The rapid elimination of the drug should mitigate this transfer into milk. Moreover, the emergency nature of its use suggests that nursing is unlikely when it has been used. In any event, the maternal benefit is clear and breastfeeding should be held for at least 6–7 hours (about five half-lives) after a dose is given.

PRAMIPEXOLE

Antiparkinson Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

One report described the use of pramipexole throughout pregnancy with the birth of a normal infant. The limited animal data do not suggest a significant risk for teratogenicity or toxicity. The toxicity observed in rats apparently was caused by mechanisms not present in human pregnancy. However, the near absence of human pregnancy experience prevents an assessment of the embryo–fetal risk. Since Parkinson disease is relatively uncommon during the childbearing years, the use of pramipexole during pregnancy also will be uncommon. Until data on such use are available, the safest course is to avoid, if possible, the use of pramipexole during the 1st trimester.

FETAL RISK SUMMARY

Pramipexole is a nonergoline dopamine agonist indicated for the treatment of the signs and symptoms of idiopathic Parkinson disease. The drug has high specificity for the D₂ and D₃ receptor subtypes. Pramipexole undergoes little if any metabolism, and no metabolites in plasma or urine have been identified. The plasma protein binding of the agent is low (about 15%) and the elimination half-life, in young healthy adults, is about 8 hours. Pramipexole is commonly used in combination with levodopa (1).

Reproduction studies have been conducted in rats and rabbits. In pregnant rats given pramipexole throughout gestation, a dose 5.4 times the highest recommended human clinical dose (1.5 mg 3 times daily) based on BSA (HRHCD) inhibited implantation. A lower dose (3.2 times the HRHCD), administered during organogenesis, caused a high incidence of total resorptions. At this dose, the AUC was 4.3 times the AUC of adults taking 1.5

mg 3 times daily. These adverse effects were thought to be secondary to the prolactin-lowering effect of the drug and prevented an adequate evaluation of the teratogenic potential of pramipexole. Prolactin is required for implantation and pregnancy maintenance in rats but not in rabbits or humans. Offspring postnatal growth was inhibited when pramipexole, at doses approximately equal to the HRHCD or higher, was given to rats during the latter half of pregnancy and throughout lactation. In pregnant rabbits treated during organogenesis with doses 71 times the AUC of adults taking 1.5 mg 3 times daily, no evidence of adverse effects on embryo or fetal development was observed (1).

In a 2-year carcinogenicity study in mice, dietary administration of pramipexole, at doses up to 11 times the HRHCD, was not associated with a significant increase in tumors. A similar study in rats, at doses up to 12.5 times the AUC of adults taking 1.5 mg 3 times daily, also was negative for tumors (1).

It is not known if pramipexole crosses the human placenta. The low molecular weight (about 211 for the free base), low protein binding, and prolonged elimination half-life suggest that the drug will cross to the embryo–fetus.

A 2004 case report described the use of pramipexole throughout pregnancy in a 41-year-old woman with movement disorder caused by Parkinson disease (2). She gave birth by cesarean section to a normal female infant at term with an Apgar score of 9. At 6 months of age, the infant was doing well with normal development (2).

BREASTFEEDING SUMMARY

No reports describing the use of pramipexole during human lactation have been located. The molecular weight (about 211 for the free base) and low protein binding (about 15%) suggest that it will be excreted into breast milk. Because it is a base, accumulation in milk should be expected. The effect of this exposure on a nursing infant is unknown. Infants should be monitored for adverse events commonly observed in adults, such as extrapyramidal disorders (e.g., dyskinesia), hallucinations, somnolence, nausea, and constipation. Pramipexole inhibits prolactin secretion and may inhibit lactation. Until data on its safe use are available, pramipexole should not be used during lactation.

PRAMLINTIDE

Antidiabetic Agent

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of pramlintide in human pregnancy have been located. The developmental toxicity (structural anomalies) that was observed in one animal species suggests moderate risk. Although pramlintide is an analog of a naturally occurring hormone and the human risk is probably low, the absence of any human pregnancy experience prevents a better assessment of the embryo–fetal risk.

FETAL RISK SUMMARY

Pramlintide, a synthetic analog of human amylin, acts as an amylinomimetic agent that slows the rate of gastric emptying, prevents the postprandial rise in plasma glucagon, and promotes satiety leading to decreased caloric intake and potential weight loss (1). Amylin is a naturally occurring neuroendocrine hormone that is synthesized by pancreatic beta cells. It is located with insulin in beta cells and is excreted with insulin in response to food intake. Pramlintide is 37-amino acid peptide that slightly differs in the amino acid sequence found in human amylin. The agent, given by SC injection, is indicated for type 1 and type 2 diabetes as an adjunct treatment in patients who use mealtime insulin therapy and have not achieved desired glucose control despite optimal insulin therapy. For type 2 diabetes, pramlintide can be given with or without a concurrent sulfonylurea agent and/or metformin. Pramlintide is metabolized primarily by the kidneys, and about 60% is bound to blood cells and albumin. The elimination half-life is about 48 minutes (1).

Reproduction studies with pramlintide have been conducted in rats and rabbits. In rats during organogenesis, increases in structural anomalies (neural tube defects, cleft palate, and exencephaly) were observed at doses producing

systemic exposures 10 or more times the exposure from the maximum recommended human dose based on AUC (MRHD). In pregnant rabbits, no evidence of fetal harm was observed with doses producing exposures 9 times the MRHD (1).

No evidence of carcinogenicity was observed in mice and rats given doses over a 2-year period that produced exposures up to 159 and 25 times the MRHD, respectively. Neither mutagenic nor clastogenic effects have been observed in tests with pramlintide. Fertility in male and female rats was not impaired at doses up to 82 times the maximum recommended human dose based on BSA. However, the highest dose resulted in dystocia in 67% of female rats secondary to significant decreases in serum calcium levels (1).

A 2003 ex vivo study using single human cotyledons from term placentas investigated if pramlintide crossed the placenta (2). Consistent with the drug's high molecular weight (about 3949) and the very short elimination half-life, the fetal:maternal ratio was ≤ 0.006 . Although these results might not be reproducible throughout gestation, it is likely that embryo and/or fetal exposure to pramlintide is negligible.

BREASTFEEDING SUMMARY

No reports describing the use of pramlintide during lactation have been located. The high molecular weight (about 3949) and the very short elimination half-life (48 minutes) suggest that little, if any, of the polypeptide will be excreted into breast milk. Even if the polypeptide were excreted into milk, it should be digested in the stomach of the nursing infant. Therefore, although the effect of exposure on a nursing infant is unknown, the risk appears to be negligible.

PRAMOXINE

Local Anesthetic

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Even though no studies describing the use of pramoxine during animal or human pregnancy have been located (1,2), since symptomatic hemorrhoids occur frequently in pregnancy, products containing pramoxine probably have been used during gestation. Because there is insignificant systemic absorption, there does not appear to be a risk to the embryo or fetus from pramoxine.

FETAL RISK SUMMARY

Pramoxine is a local anesthetic used for topical anesthesia. It is administered either alone or combined with hydrocortisone or other ingredients for the temporary relief of pain and itching secondary to minor skin irritations resulting from burns, sunburn, cuts, abrasions, insect bites, and hemorrhoids and other anorectal disorders. Pramoxine is typically formulated in a 1% concentration. Animal reproduction studies with pramoxine have not been conducted.

The molecular weight of pramoxine (about 294 for the free base) is low enough to cross the placenta, but the amount, if any, that is absorbed after topical administration into the systemic circulation is unknown. A 1985 review stated that pramoxine and similar anorectal products were not absorbed (1). However, even if some were absorbed systemically, the maternal plasma concentration would be very low, thus the amount available for transfer to the embryo or fetus should be negligible.

BREASTFEEDING SUMMARY

No studies describing the use of pramoxine during lactation have been located. The molecular weight of the free base (about 294) is low enough for excretion into breast milk, but the drug is not thought to be absorbed (1). Even if some

absorption does occur, the amount in the maternal plasma should be very low so that little, if any, drug would appear in milk. The risk to a nursing infant is probably nil.

PRASUGREL

Hematologic Agent (Antiplatelet)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of prasugrel in human pregnancy have been located. The drug did not cause developmental toxicity (in the absence of maternal toxicity) in two animal species, but the recommended combination of prasugrel and aspirin was not used in animal studies. (See also Aspirin.) The lack of human pregnancy experience prevents a complete assessment of the embryo–fetal risk. Prasugrel is a prodrug that has not been detected in the system circulation, but the active and inactive metabolites have been detected and exposure of the embryo–fetus to these compounds may occur. However, if a woman’s condition requires prasugrel combined with aspirin, the benefits appear to outweigh the unknown fetal risks and the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Prasugrel is an irreversible inhibitor of platelet activation and aggregation that is in the same subclass of aggregation inhibitors as cilostazol, clopidogrel, ticlopidine, and treprostinil. It is indicated to reduce the rate of thrombotic cardiovascular events (including stent thrombosis) in patients with acute coronary syndrome who are to be managed with percutaneous coronary intervention. Combination with aspirin (75–325 mg/day) is recommended. Prasugrel is a prodrug that is hydrolyzed in the intestine and converted to the active metabolite before reaching the plasma. The active metabolite has an elimination half-life of about 7 hours (range 2–15 hours) and is highly bound (98%) to serum albumin. The two major inactive metabolites also are highly bound plasma proteins (1,2).

Reproduction studies have been conducted in rats and rabbits. In these

species, oral doses up to 30 times the recommended therapeutic human exposure based on plasma exposures to the major circulating human metabolite (RTHE) revealed no evidence of fetal harm. When the doses were increased to a maternal toxic dose, 40 times the RTHE, a slight decrease in pup body weight was observed. At doses >150 times the RTHE, no effect on the behavioral or reproductive development of the offspring was noted (1,2).

In 2-year carcinogenicity studies with high doses, there was an increase in hepatocellular adenomas in mice but no tumors in rats. The drug was not genotoxic or clastogenic in several assays. It had no effect on the fertility of male and female rats at daily doses that were 80 times the human major metabolite exposure at a daily dose of 10 mg (1,2).

The prodrug prasugrel is not detected in plasma. It is not known if the active metabolite crosses the human placenta. The molecular weight of the active metabolite was not stated, but it should be close to the molecular weight of prasugrel (about 374 for the free base). Combined with the long elimination half-life, this suggests that the active metabolite will cross, although the high binding to albumin should limit the exposure.

BREASTFEEDING SUMMARY

No reports describing the use of prasugrel, a prodrug, during human lactation have been located. The prodrug is not detected in plasma, but the active and inactive metabolites have been detected. The molecular weight of the active metabolite was not stated, but it should be close to the molecular weight of prasugrel (about 374 for the free base). Combined with the long elimination half-life (7 hours; range 2–15 hours), this suggests that the active metabolite will be excreted into breast milk, although the high binding to albumin (98%) should limit the amount excreted. Moreover, daily aspirin is recommended for patients taking prasugrel. The effects of these possible exposures on a nursing infant are unknown. However, the American Academy of Pediatrics recommends that aspirin should be used cautiously by the mother during lactation because of potential adverse effects in the nursing infant (see Aspirin).

PRAVASTATIN

Antilipemic Agent

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Because the interruption of cholesterol-lowering therapy during pregnancy should have no effect on the long-term treatment of hyperlipidemia, and because of the human data reported with lovastatin, the use of pravastatin is contraindicated during pregnancy. However, evidence suggesting that pravastatin has a lower risk of developmental toxicity because of its hydrophilic properties has been published (see Lovastatin).

FETAL RISK SUMMARY

Pravastatin is used to lower elevated levels of cholesterol. It is a hepatic 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitor (a statin). It has the same mechanism of action as other available drugs in this class, atorvastatin, fluvastatin, lovastatin, pitavastatin, rosuvastatin, and simvastatin (cerivastatin was withdrawn from the market in 2001). Pravastatin is structurally related to lovastatin and simvastatin but, in contrast to the lipophilic properties of these agents, it is hydrophilic.

Pravastatin was not teratogenic in rats and rabbits administered doses up to 240 times and 20 times, respectively, the human exposure based on BSA (HE) (1). Similarly, no adverse effects on fertility or reproductive performance were observed in rats with doses up to 120 times the HE (1).

The FDA has received a single report of a fetal loss in a mother taking pravastatin, but further details are not available (F. Rosa, personal communication, FDA, 1995).

In a 2004 case report, a 39-year-old woman took pravastatin (80 mg/day), metformin (2 g/day), and nateglinide (360 mg/day) during the first 24 weeks of gestation (2). All therapy was discontinued and insulin was started for her diabetes. At term, the woman delivered a healthy 2.4-kg male infant (head circumference 34 cm, length 46 cm) with Apgar scores of 8 and 9 at 1 and 5

minutes, respectively. The infant's growth and development were normal at follow-up examinations during the first 6 months of life (2).

A 2004 report described the outcomes of pregnancy that had been exposed to statins and reported to the FDA (see Lovastatin).

Among 19 cases followed by a teratology information service in England, 4 involved 1st trimester exposure to pravastatin (3). The pregnancy outcomes included four healthy newborns (3).

BREASTFEEDING SUMMARY

No reports describing the use of pravastatin during lactation have been located. The manufacturer reports that pravastatin is excreted into breast milk in small amounts (1). Because of the potential for adverse effects in the nursing infant, the drug should not be used during lactation.

PRAZIQUANTEL

Anthelmintic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Praziquantel is not an animal teratogen, but human data are limited to one case. The lack of published human data prevents any assessment of a human risk. Recent data have indicated that the agent may be mutagenic and carcinogenic in humans, especially in developing countries where infections of trematodes and cestodes are frequent and multiple treatment courses may be prescribed. Moreover, the presence of other environmental mutagens combined with praziquantel may increase the risk for mutagenicity (1). Because of this potential toxicity, the use of praziquantel during pregnancy should be reserved for those cases in which the parasite is causing clinical illness or public health problems.

FETAL RISK SUMMARY

Praziquantel is a systemic anthelmintic used in the treatment of parasitic infections involving cestodes (tapeworms), including neurocysticercosis, and trematode (flukes) infestations of the liver and other tissues. The drug is rapidly and nearly completely (80%) absorbed following oral administration. The various metabolites are excreted primarily by the kidneys (2).

Praziquantel was not carcinogenic in rats and hamsters but mutagenic effects in Salmonella tests were observed in one laboratory. The mutagenicity was not confirmed in the same tested strain by other laboratories (2). Similarly, a study published in 1982 found no mutagenic effects in five strains of Salmonella exposed to praziquantel (3). A 1984 review also described negative mutagenic results in a variety of tests, including those with mice, rats, and humans, and negative carcinogenic results in tests with rats and hamsters (4). A 1997 review, however, cited studies that observed a co-mutagenic effect between

praziquantel and several mutagens and carcinogens (5). Praziquantel has also been shown in in vitro studies to induce micronuclei in hamster embryonic cells and lymphocytes. Moreover, in some pigs and humans, praziquantel was found to induce hyperploid lymphocytes and structural chromosomal aberrations (5).

Reproduction studies in mice, rats, and rabbits at doses up to 40 times the human dose (60–75 mg/kg over 1 day) showed no evidence of impaired fertility or teratogenicity (2,4). An increase in the abortion rate in rats, however, was observed at doses 3 times the single human therapeutic dose (2). No teratogenicity was observed in other studies in rats and rabbits with doses up to 300 mg/kg (5,6) or in rats with doses up to 450 mg/kg (3). Compared with controls, the administration of praziquantel and ivermectin (another anthelmintic agent) to possums at 8- to 10-week intervals throughout the breeding season to the time of emergence of young from the pouch had no significant effect on the number of births or survival of the young to emergence (7).

A study published in 1985 concluded that treatment of parasitic disease with potentially teratogenic or toxic drugs might not always be indicated in otherwise healthy pregnant women (8). For example, in their study, the authors found that treatment of some gastrointestinal parasites, including some tapeworms and liver flukes, could be postponed until after delivery unless the parasite was causing clinical disease or public health problems (8). Similarly, reviews in 1996 and 1997 recommended avoiding praziquantel during pregnancy (9,10).

There were two cases of neurocysticercosis treated with praziquantel during gestation, but no outcome information is available in either case. A 1996 case report, however, described the use of praziquantel for the treatment of neurocysticercosis in a 17-year-old pregnant woman (11).

She received praziquantel, 1050 mg 3 times daily, for 21 days starting at about 8 weeks' gestation. Seizures, which occurred at the time of presentation and again 4 days after the start of anticysticercus therapy, were successfully controlled with phenytoin and carbamazepine. She eventually delivered a 2.5-kg female at term. Other than documented anemia, no other abnormalities or malformations were found. The placenta appeared normal on gross examination.

BREASTFEEDING SUMMARY

Because praziquantel is excreted into breast milk at a concentration of about one-fourth that of the maternal serum, the manufacturer advises holding nursing on the day of treatment and during the subsequent 72 hours (2). The drug is excreted primarily in the urine with 80% of the dose being eliminated within 4

days (12). About 90% of this elimination, however, occurs in the first 24 hours (12).

No reports describing the use of praziquantel during nursing have been located, but a 1996 review recommended avoiding praziquantel during lactation (9). The effects, if any, on a healthy, noninfected nursing infant from exposure to the drug via breast milk are unknown. Because adverse reactions induced by the death of an infecting parasite have been observed in treated adults (7), nursing infants with parasitic infections sensitive to praziquantel may be at risk for similar adverse effects. Moreover, the potential for mutagenic and carcinogenic effects of the drug should be considered (see Fetal Risk Summary).

PRAZOSIN

Sympatholytic (Antihypertensive)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Prazosin is an α_1 -adrenergic blocking agent used for hypertension. The limited human pregnancy experience and the animal reproduction data suggest low embryo–fetal risk.

FETAL RISK SUMMARY

No evidence of teratogenicity was observed in reproduction studies with rats, rabbits, and monkeys at doses more than 225, 225, and 12 times, respectively, the usual maximum recommended human dose (1). A decreased litter size at birth in rats, however, was observed at the maximum dose.

The molecular weight of prazosin (about 384 for the free base) is low enough that transfer across the placenta to the embryo–fetus is likely. Consistent with this, a 1995 study using a 5-mg delayed-release formulation in three women measured umbilical cord blood concentrations at delivery that were 9%–23% of the maternal plasma levels 8–15 hours after the last dose (2).

In two studies, prazosin was combined with oxprenolol or atenolol, β -adrenergic blockers, in the treatment of pregnant women with severe essential hypertension or gestational hypertension (3,4). The combinations were effective in the first group but less so in the patients with gestational hypertension. No adverse effects attributable to the drugs were noted. Prazosin, 20 mg/day, was combined with minoxidil and metoprolol throughout gestation to treat severe maternal hypertension secondary to chronic nephritis (5). The child, normal except for hypertrichosis as a result of minoxidil, was doing well at 2 years of age.

Prazosin has been used during the 3rd trimester in patients with pheochromocytoma (6,7). In one case, blood pressure was well controlled, but

maternal tachycardia required the addition of a β -blocker. A healthy male infant was delivered by cesarean section (6).

A case report published in 1986 described the pregnancy of a 24-year-old woman at 30 weeks' gestation who was managed for recurrent pheochromocytoma with a combination of prazosin, metyrosine (a tyrosine hydroxylase inhibitor), and timolol (a β -adrenergic blocker) (7). Hypertension had been noted at her first prenatal visit at 12 weeks' gestation. Because of declines in fetal breathing, body movements, and amniotic fluid volume that began 2 weeks after the start of therapy, a cesarean section was conducted at 33 weeks'. The 1450-g female infant had Apgar scores of 3 and 5 at 1 and 5 minutes, respectively. Mild metabolic acidosis was found on analysis of umbilical cord blood gases. Multiple infarcts were noted in the placenta but there was no evidence of metastatic tumor. The growth-restricted infant did well and was discharged home on day 53 of life (7).

BREASTFEEDING SUMMARY

No reports describing the use of prazosin during lactation have been located. The manufacturer reports that small amounts are excreted into human milk (1). This is consistent with the molecular weight (about 384 for the free base) of prazosin. The effects on a nursing infant from exposure to the drug from breast milk are unknown.

PREDNISOLONE

Corticosteroid

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Prednisolone is the biologically active form of prednisone (see Prednisone). The placenta can oxidize prednisolone to inactive prednisone or less active cortisone (see Cortisone).

BREASTFEEDING SUMMARY

See Prednisone.

PREDNISONONE

Corticosteroid

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Prednisone and prednisolone apparently pose a small risk to the developing fetus. One of these risks appears to be orofacial clefts. Although the available evidence supports their use to control various maternal diseases, the mother should be informed of this risk so that she can actively participate in the decision on whether to use these agents during her pregnancy. If prednisone (or prednisolone) is used in pregnancy for the treatment of rheumatoid arthritis, health care professionals are encouraged to call the toll-free number (877-311-8972) for information about patient enrollment in the Organization of Teratology Information Specialists (OTIS) Rheumatoid Arthritis study.

FETAL RISK SUMMARY

Prednisone is metabolized to prednisolone. There are a number of studies in which pregnant patients received either prednisone or prednisolone (see also various antineoplastic agents for additional references) (1–14).

Although most reports describing the use of prednisone or prednisolone during gestation have not observed abnormal outcomes, four large epidemiologic studies have associated the use of corticosteroids in the 1st trimester with nonsyndromic orofacial clefts. Specific agents were not identified in three of these studies (see Hydrocortisone for details), but in one 1999 study, discussed below, the corticosteroids were listed.

In a case–control study, the California Birth Defects Monitoring Program evaluated the association between selected congenital anomalies and the use of corticosteroids 1 month before to 3 months after conception (periconceptual period) (15). Case infants or fetal deaths diagnosed with orofacial clefts, conotruncal defects, neural tubal defects (NTDs), and limb anomalies were identified from a total of 552,601 births that occurred from

1987 through the end of 1989. Controls, without birth defects, were selected from the same database. Following exclusion of known genetic syndromes, mothers of case and control infants were interviewed by telephone, an average of 3.7 years (cases) or 3.8 years (controls) after delivery, to determine various exposures during the periconceptual period. The number of interviews completed were orofacial cleft case mothers (N = 662, 85% of eligible), conotruncal case mothers (N = 207, 87%), NTD case mothers (N = 265, 84%), limb anomaly case mothers (N = 165, 82%), and control mothers (N = 734, 78%) (15). Orofacial clefts were classified into four phenotypic groups: isolated cleft lip with or without cleft palate (ICLP, N = 348), isolated cleft palate (ICP, N = 141), multiple cleft lip with or without cleft palate (MCLP, N = 99), and multiple cleft palate (MCP, N = 74). A total of 13 mothers reported using corticosteroids during the periconceptual period for a wide variety of indications. Six case mothers of infants with ICLP and three of infants with ICP used corticosteroids (unspecified corticosteroid N = 1, prednisone N = 2, cortisone N = 3, triamcinolone acetonide N = 1, dexamethasone N = 1, and cortisone plus prednisone N = 1). One case mother of an infant with NTD used cortisone and an injectable unspecified corticosteroid, and three controls used corticosteroids (hydrocortisone N = 1 and prednisone N = 2). The odds ratio (OR) for corticosteroid use and ICLP was 4.3 (95% confidence interval [CI] 1.1–17.2), whereas the OR for ICP and corticosteroid use was 5.3 (95% CI 1.1–26.5). No increased risks were observed for the other anomaly groups. Commenting on their results, the investigators thought that recall bias was unlikely because they did not observe increased risks for other malformations, and it was also unlikely that the mothers would have known of the suspected association between corticosteroids and orofacial clefts (15).

A prospective cohort study and meta-analysis of corticosteroid use in pregnancy was reported in 2000 (16). In the prospective study, 187 outcomes (184 pregnancies, 3 sets of twins) exposed to prednisone were compared with the outcomes in 188 controls. Prednisone-exposed infants were delivered at a lower gestational age (38 vs. 39.5 weeks), had an increased rate of premature delivery (17% vs. 5%), and had a lower birth weight (3112 vs. 3429 g) (all statistically significant). There was no significant difference in the rate of major birth defects (3.6% vs. 2%) and there was no cluster of malformations suggesting a common cause. The defects in the prednisone-exposed cases were: Hirschsprung disease; double outlet right ventricle, valvar and subvalvar pulmonary stenosis, hypothyroidism, hypospadias; undescended testicle; and cleft palate, hypospadias. Two cases were excluded from the analysis because

the cause of the defects was known (genetic history and maternal infection) (16). In their meta-analysis, they found a small increase in major malformations (OR 3.03, 95% CI 1.08–8.54) for 1st trimester corticosteroid exposure (16). In addition, case–control studies showed a significant association with oral clefts (OR 3.35, 95% CI 1.97–5.69) (16).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 143, 236, and 222 newborns had been exposed to prednisolone, prednisone, and methylprednisolone, respectively, during the 1st trimester (F. Rosa, personal communication, FDA, 1993). The number of birth defects, the number expected, and the percent for each drug were 11/6 (7.7%), 11/10 (4.7%), and 14/9 (6.3%), respectively. Specific details were available for six defect categories (observed/expected): cardiovascular defects (2/1, 2/2, 3/2), oral clefts (0/0, 0/0, 0/0), spina bifida (0/0, 0/0, 0/0), polydactyly (0/0, 0/1, 0/1), limb reduction defects (0/0, 0/0, 1/0), and hypospadias (1/0, 0/1, 1/1), respectively. These data do not support an association between the drugs and congenital defects, except for a possible association between prednisolone and the total number of defects. In the latter case, other factors, such as the mother's disease, concurrent drug use, and chance may be involved.

Immunosuppression was observed in a newborn exposed to high doses of prednisone with azathioprine throughout gestation (17). The newborn had lymphopenia, decreased survival of lymphocytes in culture, absence of immunoglobulin M and reduced levels of immunoglobulin G. Recovery occurred at 15 weeks of age. However, these effects were not observed in a larger group of similarly exposed newborns (18). A 1968 study reported an increase in the incidence of stillbirths following prednisone therapy during pregnancy (7). Increased fetal mortality has not been confirmed by other investigators.

An infant exposed to prednisone throughout pregnancy was born with congenital cataracts (1). The eye defect was consistent with reports of subcapsular cataracts observed in adults receiving corticosteroids. The relationship in this case between the cataracts and prednisone is unknown, but other reports have also described cataracts after corticosteroid use during gestation (see Hydrocortisone).

In a 1970 case report, a female infant with multiple deformities was described (19). Her father had been treated several years before conception with prednisone, azathioprine, and radiation for a kidney transplant. The authors speculated that the child's defects might have been related to the father's immunosuppressive therapy. A relationship to prednisone seems remote

because previous studies have shown that the drug has no effect on chromosome number or morphology (20). High, prolonged doses of prednisolone (30 mg/day for at least 4 weeks) may damage spermatogenesis (21). Recovery may require 6 months after the drug is stopped.

Prednisone has been used successfully to prevent neonatal respiratory distress syndrome when premature delivery occurs between 28 and 36 weeks of gestation (22). Therapy between 16 and 25 weeks of gestation had no effect on lecithin: sphingomyelin ratios (23).

BREASTFEEDING SUMMARY

Trace amounts of prednisone and prednisolone have been measured in breast milk (24–27). Following a 10-mg oral dose of prednisone, milk concentrations of prednisone and prednisolone at 2 hours were 26.7 and 1.6 ng/mL, respectively (24). The authors estimated the infant would ingest approximately 28.3 mcg in 1000 mL of milk. In a second study using radioactive-labeled prednisolone in seven patients, a mean of 0.14% of a 5-mg oral dose was recovered per liter of milk during 48–61 hours (25).

In six lactating women, prednisolone doses of 10–80 mg/day resulted in milk concentrations ranging from 5% to 25% of maternal serum levels (26). The milk:plasma ratio increased with increasing serum concentrations. For maternal doses of 20 mg 1–2 times daily, the authors concluded that the nursing infant would be exposed to minimal amounts of steroid. At higher doses, they recommended waiting at least 4 hours after a dose before nursing was performed. However, even at 80 mg/day, the nursing infant would ingest <0.1% of the dose, which corresponds to <10% of the infant's endogenous cortisol production (26).

A 1993 report described the pharmacokinetics of prednisolone in milk (27). Following a 50-mg IV dose, an average of 0.025% (range 0.010%–0.049%) was recovered from the milk. The data suggested a rapid, bidirectional transfer of unbound prednisolone between the milk and serum (27). The investigators concluded that the measured milk concentrations of the steroid did not pose a clinically significant risk to a nursing infant.

Although nursing infants were not involved in the above studies, it is doubtful whether the amounts measured are clinically significant. The American Academy of Pediatrics classifies prednisolone and prednisone as compatible with breastfeeding (28).

PREGABALIN

Anticonvulsant

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of pregabalin in human pregnancy have been located. The animal reproduction data suggest moderate risk, but the absence of human pregnancy experience prevents an assessment of the embryo–fetal risk. Until human pregnancy experience is available, the best course is to avoid pregabalin during gestation.

FETAL RISK SUMMARY

Pregabalin is a structural derivative of the inhibitory neurotransmitter gamma-aminobutyric acid (GABA). However, it does not directly bind to GABA or benzodiazepine receptors, augment GABA responses, alter rat brain GABA concentrations, or have acute effects on GABA uptake or degradation. Pregabalin is indicated as oral adjunctive therapy for adult patients with partial-onset seizures. It is also indicated for the management of neuropathic pain associated with diabetic peripheral neuropathy and postherpetic neuralgia. Pregabalin is freely soluble in water and in both acidic and basic aqueous solutions. It undergoes minimal metabolism and the elimination half-life is about 6 hours. The drug is not bound to plasma proteins (1).

Reproduction studies have been conducted in rats and rabbits. Skull alterations secondary to abnormally advanced ossification were observed in the embryos of rats given an oral dose of pregabalin during organogenesis that produced plasma exposures (AUC) about 42 times the human exposure at the maximum recommended dose of 600 mg/day (HE-MRD). Doses producing exposures about 17–85 times the HE-MRD resulted in increased incidences of skeletal variations and retarded ossification. Decreased fetal body weights were observed at about 85 times the HE-MRD. A no-effect dose for rat

embryo–fetal developmental toxicity was not established (1).

When rats were dosed throughout gestation and lactation, offspring growth and survival were decreased at exposures about ≥ 4 and ≥ 10 times the HE-MRD, respectively. Mortality was 100% at exposures about 85 times the HE-MRD. Neurobehavioral deficits (decreased auditory startle response) and reproductive impairment (decreased fertility and litter size) were observed in the adult offspring of rats given doses producing exposures about ≥ 10 and 42 times the HE-MRD, respectively. The no-effect dose for prenatal and postnatal developmental toxicity in rats produced a plasma exposure about 2 times the HE-MRD (1).

In pregnant rabbits given doses during organogenesis that produced plasma exposures about 40 times the HE-MRD, decreased fetal body weight and increased incidences of skeletal malformations, visceral variations, and retarded ossification were observed. The no-effect dose for developmental toxicity was about 16 times the HE-MRD (1).

Pregabalin produced dose-related carcinogenicity (hemangiosarcomas) in two strains of mice. The lowest dose resulting in the malignant vascular tumors was about equal to the HE-MRD; a no-effect dose in mice was not established. No carcinogenic effects were observed in rats. Mutagenic and clastogenic effects were not observed in various assays (1).

Pregabalin caused reproductive toxicity in male rats: decreased sperm counts and motility, increased sperm abnormalities, and reduced fertility. When the males were mated with untreated females, increased preimplantation embryo loss, decreased litter size, decreased fetal body weights, and an increased incidence of fetal abnormalities were observed. The no-effect dose for male reproductive toxicity was about 3 times the HE-MRD. Adverse effects were also noted on male reproductive organs (testes, epididymides) histopathology. The no-effect dose for male fertility toxicity produced plasma exposures about 8 times the HE-MRD. Pregabalin also impaired the fertility of female rats (disrupted estrous cyclicity) and increased the number of days to mating at exposures as low as 9 times the HE-MRD. A no-effect dose for female fertility toxicity was not established (1).

It is not known if pregabalin crosses the human placenta. The low molecular weight (about 159), minimal metabolism, lack of plasma protein binding, and the moderately long elimination half-life suggest that the drug will reach the embryo and fetus.

BREASTFEEDING SUMMARY

No reports describing the use of pregabalin during lactation have been located. The molecular weight (about 159), minimal metabolism, lack of plasma protein binding, and the moderately long elimination half-life (6 hours) suggest that the drug will be excreted into breast milk. Because it is freely soluble in water, the highest concentrations of the drug should be found in fore-milk. In adults, increased incidences of several adverse effects have been observed, including dizziness and somnolence, blurred vision, peripheral edema, myopathy, and decreased platelet count. The lack of data on the excretion of pregabalin into breast milk, combined with the potential for serious toxicity in a nursing infant, suggest that the drug should not be used by women who are breastfeeding.

PRIMAQUINE

Antimalarial

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of primaquine in human pregnancy have been located. Primaquine may cause hemolytic anemia in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency. Two 1978 references stated that pregnant patients at risk for this disorder should be tested accordingly (1), but if the G6PD status was unknown the drug should be withheld until after delivery (2). However, because the fetus is relatively G6PD-deficient (see below), the drug should not be used in pregnancy regardless of the mother's status.

FETAL RISK SUMMARY

Primaquine phosphate is indicated for the radical cure (prevention of relapse) of vivax malaria. Animal reproduction studies were not provided by the manufacturer (3).

It is not known if primaquine phosphate crosses the human placenta. The molecular weight (about 455 for primaquine) is low enough that exposure of the embryo–fetus should be expected.

A 1982 article stated that if prophylaxis or treatment is required with primaquine, it should not be withheld (4). However, more recent reviews have concluded that the drug should not be used in pregnancy because primaquine causes acute hemolysis in those who are G6PD-deficient and because the fetus is relatively G6PD-deficient (5–7).

BREASTFEEDING SUMMARY

No reports describing the use of primaquine during human lactation have been located. The molecular weight (about 259 primaquine) is low enough for excretion into breast milk. The effect of this exposure on a nursing infant is

unknown. However, the mother and the infant should be tested for G6PD deficiency before the drug is used during breastfeeding.

PRIMIDONE

Anticonvulsant

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Primidone, a structural analog of phenobarbital (see also Phenobarbital), is effective against generalized convulsive seizures and psychomotor attacks. The epileptic patient on anticonvulsant medication is at a higher risk for having a child with developmental toxicity compared with the general population (1–7).

FETAL RISK SUMMARY

A total of 323 infants who were exposed to primidone during the 1st trimester have been noted in various publications (4,8–17). Of the 41 malformed infants described in these reports, only 3 infants were exposed to primidone alone during gestation (8,15,16). The anomalies observed in these three infants were similar to those observed in the fetal hydantoin syndrome (see Phenytoin).

Acardia, a rare congenital defect, was described in a 1996 case report (18). The 28-year-old mother with two healthy children and a long history of epilepsy had taken primidone (500 mg/day) until the 3rd month of pregnancy. She stopped the drug at this time because of concern for malformations. Her pregnancy history included three epileptic seizures in months 4, 5, and 8. She had no prenatal care during the pregnancy until she presented at term. An ultrasound revealed a twin pregnancy. A cesarean section was performed to deliver a normal 2300-g female infant and a female acardiac acephalic monster. Both were in a single amniotic cavity. The normal female infant did well with no problems in the neonatal period. Genetic studies on the anomalous twin could not be conducted because of delay in receiving permission to study it. At autopsy, the head and upper extremities were totally absent and the major internal organs (heart, lungs, liver, spleen, pancreas, and the upper gastrointestinal tract) could not be identified. Structures that were identified

included the small intestine with a blind proximal ending, colon with an anal opening, two adrenal glands, two hypoplastic kidneys and ureters, bladder, uterus and tubes, two ovaries, and a single umbilical artery and vein. The cause of the rare defect could not be determined.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 36 newborns had been exposed to primidone during the 1st trimester (F. Rosa, personal communication, FDA, 1993). One (2.8%) major birth defect was observed (two expected). Details were not available on the single case, but no anomalies were observed in six defect categories (cardiovascular defects, oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available.

The effects of exposure (at any time during the 2nd or 3rd month after the last menstrual period) to folic acid antagonists on embryo–fetal development were evaluated in a large, multicenter, case–control surveillance study published in 2000 (19). The report was based on data collected between 1976 and 1998 from 80 maternity or tertiary care hospitals. Mothers were interviewed within 6 months of delivery about their use of drugs during pregnancy. Folic acid antagonists were categorized into two groups: group I—dihydrofolate reductase inhibitors (aminopterin, methotrexate, sulfasalazine, pyrimethamine, triamterene, and trimethoprim); group II—agents that affect other enzymes in folate metabolism, impair the absorption of folate, or increase the metabolic breakdown of folate (carbamazepine, phenytoin, primidone, and phenobarbital) (18). The case subjects were 3870 infants with cardiovascular defects, 1962 with oral clefts, and 1100 with urinary tract malformations. Infants with defects associated with a syndrome were excluded, as were infants with coexisting neural tube defects (NTDs; known to be reduced by maternal folic acid supplementation). Too few infants with limb reduction defects were identified to be analyzed. Controls (N = 8387) were infants with malformations other than oral clefts and cardiovascular, urinary tract, and limb reduction defects and NTDs, but included infants with chromosomal and genetic defects. The risk of malformations in control infants would not have been reduced by vitamin supplementation, and none of the controls used folic acid antagonists. For group I cases, the relative risks (RRs) of cardiovascular defects and oral clefts were 3.4 (95% confidence interval [CI] 1.8–6.4) and 2.6 (95% CI 1.1–6.1), respectively. For group II cases, the RRs of cardiovascular and urinary tract defects, and oral clefts were 2.2 (95% CI 1.4–3.5), 2.5 (95% CI 1.2–5.0), and 2.5 (95% CI 1.5–4.2), respectively. Maternal use of

multivitamin supplements with folic acid (typically 0.4 mg) reduced the risks in group I cases, but not in group II cases (19).

A prospective study published in 1999 described the outcomes of 517 pregnancies of epileptic mothers identified at one Italian center from 1977 (20). Excluding genetic and chromosomal defects, malformations were classified as severe structural defects, mild structural defects, and deformations. Minor anomalies were not considered. Spontaneous (N = 38) and early (N = 20) voluntary abortions were excluded from the analysis, as were 7 pregnancies that delivered at other hospitals. Of the remaining 452 outcomes, 427 were exposed to anticonvulsants of which 313 involved monotherapy: primidone (N = 35), carbamazepine (N = 113), phenobarbital (N = 83), valproate (N = 44), phenytoin (N = 31), clonazepam (N = 6), and other (N = 1). There were no defects in the 25 pregnancies not exposed to anticonvulsants. Of the 42 (9.3%) outcomes with malformations, 24 (5.3%) were severe, 10 (2.2%) were mild, and 8 (1.8%) were deformities. There were three malformations with primidone monotherapy: two (5.7%) were severe (intraventricular defect and hypospadias), and one (2.8%) was mild (undescended testis and inguinal hernia). The investigators concluded that the anticonvulsants were the primary risk factor for an increased incidence of congenital malformations (see also Carbamazepine, Clonazepam, Phenobarbital, Phenytoin, and Valproic Acid) (20).

The Lamotrigine Pregnancy Registry, an ongoing project conducted by the manufacturer, was first published in January 1997 (21). The final report was published in July 2010. The Registry is now closed. In nine prospectively enrolled pregnancies exposed in the 1st trimester to primidone and lamotrigine, with or without other anticonvulsants, the outcomes were seven live births without birth defects, one elective abortion, and one birth defect (21).

There are other potential complications associated with the use of primidone during pregnancy. Neurologic manifestations in the newborn, such as overactivity and tumors, have been associated with use of primidone in pregnancy (16,22). Neonatal hemorrhagic disease with primidone alone or in combination with other anticonvulsants has been reported (14,23–27). Suppression of vitamin K₁-dependent clotting factors is the proposed mechanism of the hemorrhagic effect (14,23). Administration of prophylactic vitamin K₁ to the infant immediately after birth is recommended (see Phytonadione, Phenytoin, and Phenobarbital).

BREASTFEEDING SUMMARY

Primidone is excreted into breast milk. Because primidone undergoes limited conversion to phenobarbital, breast milk concentrations of phenobarbital should be anticipated (see Phenobarbital). A milk:plasma ratio of 0.8 for primidone has been reported (28). The amount of primidone available to the nursing infant is small, with milk concentrations of 2.3 mcg/mL. No reports linking adverse effects to the nursing infant have been located, however, patients who breastfeed should be instructed to watch for potential sedative effects in the infant. The American Academy of Pediatrics classifies primidone as an agent that has been associated with significant effects in some nursing infants and should be used with caution in the lactating woman (29).

PROBENECID

Antigout (Uricosuric)

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports linking the use of probenecid with congenital defects have been located. Probenecid has been used during pregnancy without producing adverse effects in the fetus or in the infant (1–7).

FETAL RISK SUMMARY

Probenecid is a uricosuric and renal tubular blocking agent. It is indicated for the treatment of the hyperuricemia associated with gout and gouty arthritis. It also is indicated as an adjuvant to therapy with penicillin or with ampicillin, methicillin, ocacillin, cloxacillin, or nafcillin, for elevation and prolongation of plasma levels by whatever route the antibiotic is given (8).

Animal reproduction studies have apparently not been conducted.

The manufacturer reports that the drug crosses the placenta and appears in cord blood (8). This is consistent with its relatively low molecular weight (about 285).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 339 newborns had been exposed to probenecid during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 17 (5.0%) major birth defects were observed (14 expected). Specific data were available for six defect categories, including (observed/expected) 5/3 cardiovascular defects, 1/1 oral clefts, 0/0 spina bifida, 1/1 polydactyly, 0/1 limb reduction defects, and 1/1 hypospadias. These data do not support an association between the drug and congenital defects.

BREASTFEEDING SUMMARY

Consistent with its molecular weight (about 285), probenecid is excreted into breast milk. A 30-year-old, penicillin-allergic, breastfeeding woman developed erysipelas/cellulitis in her breasts 9 days after a cesarean section (9). She was treated with IV cephalothin, 1 g every 6 hours for 3 days, then oral cephalexin and probenecid (both 500 mg 4 times daily). Severe diarrhea, discomfort, and crying was observed in the nursing infant during IV therapy and continued with oral therapy, but at a decreased level. The symptoms had nearly resolved after partial replacement of breast milk with goat's milk for 7 days. Sixteen days after initiation of oral therapy, the woman collected 12 milk samples (6 pairs of fore- and hind-milk) by manual expression over a 16-hour interval. The average concentrations of probenecid and cephalexin were 964 and 745 mcg/L, respectively. The concentrations of the two substances in fore- and hind-milk were not significantly different. The infant doses, based on the milk AUC and an estimated intake of 150 mL/kg/day, of probenecid and cephalexin were 0.7% and 0.5%, respectively, of the mother's weight-adjusted dose. Although these doses were thought to be low enough to exclude systemic effects, it was concluded that cephalexin was the most likely cause of the diarrhea (9).

PROBUCOL

[Withdrawn from the market. See 9th edition.]

PROCAINAMIDE

Antiarrhythmic

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Procainamide is a cardiac drug used for the termination and prophylaxis of atrial and ventricular tachyarrhythmias (1). The limited human pregnancy data suggest low risk for the embryo–fetus, but there is no 1st trimester or animal reproduction data.

FETAL RISK SUMMARY

Animal reproduction studies with procainamide have not been conducted. The use of procainamide during human pregnancy has not been associated with congenital anomalies or other adverse fetal effects (1–9).

Successful cardioversion with procainamide of a fetal supraventricular tachycardia presenting at 30 weeks' gestation has been reported (4). Therapy with digoxin alone and digoxin combined with propranolol failed to halt the arrhythmia. Procainamide was then combined with digoxin, resulting in cardioversion to a sinus rhythm and resolution of fetal ascites and pericardial effusion. During the following 3 weeks, the mother was maintained on oral procainamide, 1 g every 6 hours, and digoxin. Maternal serum levels of procainamide varied from 2.4 to 4.1 mcg/mL. The abnormal rhythm returned at 33 weeks' gestation, and control became increasingly difficult. Additional therapy with procainamide increased the maternal serum concentration to 6.8 mcg/mL. During the last 24 hours, four IV bolus doses of procainamide (700 mg 3 times, 650 mg once) were administered plus a maintenance dose of 3 mg/minute. Three hours after the last bolus dose, a 2650-g female infant was delivered by cesarean section. Serum procainamide concentrations in the newborn and mother were 4.3 and 15.6 mcg/mL, respectively, a ratio of 0.28. During the subsequent neonatal course, the infant was successfully treated for

congestive heart failure and persistent supraventricular tachycardia. The electrocardiogram was normal at 6 months of age.

In a case similar to the one described above, therapy with digoxin, verapamil, and procainamide failed to control fetal supraventricular tachycardia presenting at 24 weeks' gestation (5). At cordocentesis, procainamide concentrations in the fetus and mother were 11.7 and 12.8 mcg/mL (ratio 0.91), respectively. Levels of the active metabolite, N-acetylprocainamide, were 3.0 and 3.5 mcg/mL (ratio 0.86), respectively. Cardioversion was eventually accomplished with direct fetal digitalization by periodic IM injection.

Procainamide was prescribed for a woman in her 24th week of gestation for ventricular tachycardia (7). She was treated with doses up to 2000 mg every 6 hours, combined with metoprolol 100 mg every 12 hours, until delivery of a healthy 3155-g female at 38 weeks' gestation. Maternal and mixed cord blood concentrations of procainamide were 6.0 and 6.4 mcg/mL (fetal:maternal ratio 1.1), respectively. Similar analysis for N-acetylprocainamide yielded levels of 9.4 and 8.7 mcg/mL (ratio 0.9), respectively. No fetal or newborn adverse effects were observed.

BREASTFEEDING SUMMARY

Procainamide and its active metabolite, N-acetylprocainamide, are accumulated in breast milk (10). A woman was treated with procainamide, 375 mg 4 times daily, for premature ventricular contractions during the 3rd trimester (10). The dose was increased to 500 mg 4 times daily 1 week before delivery at 39 weeks' gestation. Simultaneous serum and milk samples were obtained in the postpartum period (exact time not specified) every 3 hours for a total of 15 hours. Procainamide (500 mg) was administered orally at hours 0, 6, and 12 immediately after samples were obtained. Mean serum concentrations of procainamide and N-acetylprocainamide were 1.1 and 1.6 mcg/mL, respectively, while the concentrations in the milk were 5.4 and 3.5 mcg/mL, respectively. The mean milk:serum ratios for the parent drug and the metabolite were 4.3 (range 1.0–7.3) and 3.8 (range 1.0–6.2), respectively. The amount of drug available to the nursing infant based on a hypothetical serum level of 8 mcg/mL was estimated to be 64.8 mcg/mL (procainamide plus metabolite). Assuming the infant could ingest 1000 mL of milk/day (thought to be unlikely), this would only provide about 65 mg of total active drug. This amount was not expected to yield clinically significant serum concentrations (10).

The American Academy of Pediatrics classifies procainamide as compatible with breastfeeding (11). However, the long-term effects of exposure in the

nursing infant to procainamide and its metabolites are unknown, particularly in regard to potential drug toxicity (e.g., development of antinuclear antibodies and lupus-like syndrome).

PROCARBAZINE

Antineoplastic

PREGNANCY RECOMMENDATION: Contraindicated—1st Trimester

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Although combined with other antineoplastics, structural anomalies have been observed when procarbazine was used in the 1st trimester. The drug is best avoided during organogenesis.

FETAL RISK SUMMARY

The use of procarbazine, in combination with other antineoplastic agents, during pregnancy has been described in nine patients, five during the 1st trimester (1–8). One of the 1st trimester exposures was electively terminated, but no details on the fetus were given (5). Congenital malformations were observed in the remaining four 1st trimester exposures (1–4):

Multiple hemangiomas (1)

Oligodactyly of both feet with webbing of third and fourth toes, four metatarsals on left, three on right, bowing of right tibia, cerebral hemorrhage, spontaneously aborted at 24 weeks' gestation (2)

Malformed kidneys—markedly reduced size and malposition (3)

Small secundum atrial septal defect, intrauterine growth restriction (4)

A patient in her 12th week of pregnancy received procarbazine, 50 mg daily, in error for 30 days when she was given the drug instead of an iron/vitamin supplement (6). A normal 3575-g male infant was delivered at term.

Long-term studies of growth and mental development in offspring exposed to procarbazine during the 2nd trimester, the period of neuroblast multiplication, have not been conducted (9). Data from one review indicated that 40% of the infants exposed to anticancer drugs were of low birth weight (10). This finding was not related to the timing of exposure.

Procarbazine is mutagenic and carcinogenic in animals (11). In combination with other antineoplastic drugs, procarbazine may produce gonadal dysfunction

in males and females (12–17). Ovarian and testicular function may return to normal, with successful pregnancies possible, depending on the patient's age at the time of therapy and the total dose of chemotherapy received (16–20).

It is not known if procarbazine crosses the human placenta. The molecular weight (about 222 for the free base) is low enough that exposure of the embryo–fetus should be expected.

Occupational exposure of the mother to antineoplastic agents during pregnancy may present a risk to the fetus. A position statement from the National Study Commission on Cytotoxic Exposure and a research article involving some antineoplastic agents are presented in the monograph for cyclophosphamide (see Cyclophosphamide).

BREASTFEEDING SUMMARY

No reports describing the use of procarbazine during lactation have been located. The molecular weight (about 222 for the free base) is low enough that excretion into breast milk should be expected. Because of the potential for tumorigenicity, women receiving this drug should not nurse (21).

PROCHLORPERAZINE

Antipsychotic/Antiemetic

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although there are isolated reports of congenital defects in children exposed to prochlorperazine in utero, the majority of the evidence indicates that this drug and the general class of phenothiazines are low risk for both mother and fetus if used occasionally in low doses. Other reviewers have also concluded that the phenothiazines are not teratogenic (1,2).

FETAL RISK SUMMARY

Prochlorperazine is a piperazine phenothiazine. In one rat study, prochlorperazine produced significant postnatal weight decrease, increased fetal mortality, and minor behavioral changes, but no structural defects (3). In a second rat study, an increased incidence of cleft palate, a few anencephalic fetuses, and one double monster was observed (4).

The drug readily crosses the placenta (5). Prochlorperazine has been used to treat nausea and vomiting of pregnancy. Most studies have found the drug to be safe for this indication (see also Chlorpromazine) (6–8).

The Collaborative Perinatal Project (CPP) monitored 50,282 mother–child pairs, 877 of whom had 1st trimester exposure to prochlorperazine (8). For use anytime during pregnancy, 2023 exposures were recorded. No evidence was found in either group to suggest a relationship to malformations or an effect on perinatal mortality rate, birth weight, or IQ scores at 4 years of age (8).

In a separate study using data from the CPP, offspring of psychotic or neurotic mothers who had consumed prochlorperazine for 1–2 months during gestation (N = 30) were significantly taller than nonexposed controls (N = 71) at 4 months and at 1 year of age (9). Those who had been exposed for longer than 2 months (N = 8) were also taller than controls at both ages, but not significantly so. Offspring (N = 21) of normal women, who had taken the drug

for more than 2 months during pregnancy, were significantly taller than nonexposed controls (N = 68) at 1 year of age but no difference was measured at 7 years of age. Moreover, the mean weight of exposed children of normal mothers was significantly greater than controls at 1 year of age, but not at 7 years of age. The mechanisms behind these effects were not clear, but may have been related to the dopamine receptor-blocking action of the drug (9).

Five infants exposed to prochlorperazine, and, in some cases, to multiple other drugs, during the 1st trimester are described below:

Cleft palate, micrognathia, congenital heart defects, skeletal defects (10)

Thanatophoric dwarfism (short limb anomaly) (11)

Hypoplasia of radius and ulnar bones with a vestigial wrist and hand (12)

Below-the-elbow amputation in one arm and small atrophic hand attached to the stump (13)

Below-the-knee amputation in one limb, with rudimentary foot attached to stump (one twin) (13)

The relationship between prochlorperazine and the above defects is unknown. The case of dwarfism was probably caused by genetic factors. No evidence of amniotic bands was observed in the two cases involving amputations, both of whom were exposed during the mothers' treatment for hyperemesis gravidarum (13).

A 1963 report described phocomelia of the upper limbs in a male infant exposed to two phenothiazines during gestation (14). The mother had not taken prochlorperazine until approximately the 13th week of gestation, so no association between the drug and the defect is possible. However, the other agent, trifluoperazine, was taken early in pregnancy (see also Trifluoperazine). In another study, no increase in defects or pattern of malformations were observed in 76 infants (2 sets of twins) exposed in utero to the antiemetic (15).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 704 newborns had been exposed to prochlorperazine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 24 (3.4%) major birth defects were observed (29 expected). Specific data were available for six defect categories, including (observed/expected) 6/7 cardiovascular defects, 1/1 oral clefts, 0/0 spina bifida, 1/2 polydactyly, 1/1 limb reduction defects, and 0/2 hypospadias. These data do not support an association between the drug and congenital defects.

BREASTFEEDING SUMMARY

No reports describing the excretion of prochlorperazine into breast milk have been located. Because other phenothiazines appear in human milk (e.g., chlorpromazine), excretion of prochlorperazine should be expected. Sedation is a possible effect in the nursing infant.

PROCYCLIDINE

[Withdrawn from the market. See 9th edition.]

PROGUANIL

Antimalarial

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably
Compatible

PREGNANCY SUMMARY

No adverse fetal or newborn effects attributable to the use of proguanil during gestation have been reported. It is considered by some to be the least toxic prophylactic agent available (1).

FETAL RISK SUMMARY

Proguanil is not available in the United States as a single agent, but is available in combination with atovaquone (see also Atovaquone). Proguanil, a biguanide compound that inhibits plasmodial dihydrofolate reductase, has been frequently used in other parts of the world for causal prophylaxis (defined as absolute prevention) of falciparum malaria since 1948. It is now known, however, that no chemoprophylaxis regimen ensures complete protection against infection with malaria (2). Proguanil is also indicated for the suppression of other forms of malaria and reduced transmission of infection, but because of its slow action it is not used for the acute treatment of malaria. Combination with other antimalarial agents such as chloroquine is common because of the rapid development of drug resistance. Proguanil is converted in vivo to cycloguanil, the active metabolite. Because it is a folate antagonist, pregnant women taking proguanil should also take folic acid supplements (3–7). One reviewer recommended either 5 mg/day of folic acid or 5 mg/week of folinic acid (leucovorin) at least during the 1st trimester (7). Moreover, because iron-deficiency anemia is often present in some regions, a combination of proguanil, iron, and folic acid has been recommended (8).

A reproductive study in pregnant rats given proguanil and the active metabolite, cycloguanil, was summarized by Shepard (9) and also cited by Schardein (10). Proguanil, 30 mg/kg every 4 hours, was given by gavage on

days 1, 9, and 13 of gestation. No effects on the embryos or fetuses were observed. In contrast, the same dose of cycloguanil on day 1 of gestation caused death in 90% of the embryos. As with proguanil, no effects were observed from exposure to cycloguanil on days 9 and 13.

Antimalarial agents, including proguanil, are used routinely during pregnancy because the risks from the disease far outweigh the risks to the fetus from drug therapy (4,5). The risks of complications from maternal malarial infection are increased during pregnancy, especially in primigravidas and in women not living in endemic areas (i.e., nonimmune women) (11–14). Infection is associated with a number of severe maternal and fetal outcomes: maternal death, anemia, abortion, stillbirth, prematurity, low birth weight, intrauterine growth restriction, fetal tachycardia, fetal distress, and congenital malaria (11–16). One of these outcomes, low birth weight with the resulting increased risk of infant mortality, may have other causes, however, inasmuch as it has not been established that antimalarial chemoprophylaxis can completely prevent this complication (12). Increased maternal morbidity and mortality includes adult respiratory distress syndrome, pulmonary edema, massive hemolysis, disseminated intravascular coagulation, acute renal failure, and hypoglycemia (13–15). Severe *Plasmodium falciparum* malaria in pregnant nonimmune women has a poor prognosis and may be associated, in addition to the toxicities noted above, with asymptomatic uterine contractions, placental insufficiency because of intense parasitization, and hypoglycemia (12,15). Because of the severity of this disease in pregnancy, chemoprophylaxis is recommended for women of childbearing age traveling in areas where malaria is present (6,11–13).

Of 200 Nigerian women enrolled in a randomized double-blind trial, 160 were given an initial curative chloroquine course (600 mg base once), followed by prophylaxis regimens consisting of proguanil, 100 mg/day, with or without daily iron supplements, or 1 mg/day of folic acid (17,18). A control group of 40 women received no treatment. All patients were primigravidas seen before 24 weeks' gestation. In the treated groups, the prevalence of *falciparum* parasitemia was decreased from 32%–35% to about 2% at gestational weeks 28 and 36. Benefits of the regimens that included iron and/or folic acid were reductions in (a) severe anemia during pregnancy (from 18% to 3%), (b) megaloblastic erythropoiesis at or before delivery (from 56% to 25%), and (c) anemia at 6 weeks postpartum (from 61% to 29%). However, the mean birth weight was increased by only 132 g in treated compared with untreated pregnancies (difference not significant). Other than a single case of talipes and

two infants with umbilical hernias, no other birth defects were observed. The authors stated that no association with the maternal treatment groups was evident, but the groups the infants were in was not specified (17).

In the first of a series of four reports, a study published in 1993 described the use of proguanil, either alone (N = 124) (200 mg once daily) or in combination with chloroquine (N = 90) (300 mg base once weekly), or of chloroquine alone (N = 113) (300 mg base once weekly) as malarial chemoprophylaxis during pregnancy in Tanzania (19). Chemoprophylaxis was begun after a single curative dose of pyrimethamine/sulfadoxine (Fansidar) was administered to clear preexisting parasitemia. Both proguanil chemoprophylaxis regimens were superior to chloroquine alone. The proguanil regimens were well tolerated by the mothers, with no cases of mouth ulcers and palmar or plantar skin scaling, although a few of the women complained of nausea. Based on urinary levels of proguanil and cycloguanil, they concluded that better protection from infection would have been achieved if a 12-hour dosing regimen with proguanil had been used (19).

In the second report, the effects of drug therapy on maternal hemoglobin, placental malaria, and birth weight were examined (20). As above, either proguanil alone or proguanil in combination with chloroquine was superior to chloroquine alone, producing higher levels of maternal hemoglobin, higher birth weights, and less placental malaria. The difference in outcomes between the two proguanil groups was not significant, however, leading the investigators to the conclusion that chemoprophylaxis with proguanil alone was suitable for this particular region (20).

The third and fourth reports in the series related to the effects of the therapy on the maternal malaria immunity and the transfer of maternal antibodies to the fetus and subsequent immunity of the offspring during early infancy (21,22). The data demonstrated that the chemoprophylaxis regimens did not significantly interfere with the maternal–fetal transfer of antiparasite antibodies but that antibody levels at birth did not alter the first occurrence of malaria parasitemia in the infant (22).

The pharmacokinetics of proguanil in pregnant and postpartum women was described in a 1993 report (23). Ten healthy women in the 3rd trimester were given a single 200-mg oral dose and four of the women were restudied 2 months after delivery. The pharmacokinetics of proguanil during pregnancy and postpartum were similar, but the blood concentrations of the active metabolite, cycloguanil, were markedly decreased during late gestation. The mean maximum concentration (ng/mL) of cycloguanil in plasma and whole blood

during pregnancy was 12.5 and 11.9, respectively, compared with postpartum levels of 28.4 and 22.4, respectively. Moreover, the proguanil:cycloguanil ratio based on the area under the plasma concentration curve (AUC) was 16.7 during pregnancy and 7.8 following pregnancy. The decreased conversion to the active antimalarial metabolite may have been caused by estrogen inhibition of the enzyme that metabolizes proguanil. Although the antimalarial prophylaxis concentration of cycloguanil is not known with certainty, these data indicate that the currently recommended dose of 200 mg/day may need to be doubled during late pregnancy to achieve the same blood levels as those obtained 2 months postpartum (23).

Most investigators have concluded that proguanil is safe to use during pregnancy (1–7, 11, 19, 24, 25).

BREASTFEEDING SUMMARY

No reports quantifying the amount of proguanil excreted in breast milk have been located. At least two reports have stated that agents used for malaria prophylaxis, such as proguanil, are excreted in small amounts in milk (3, 11). These amounts, however, are too low for adequate malaria chemoprophylaxis of a nursing infant (3, 11). Because proguanil is recommended for malaria protection in infants of any age (3, 11, 25), the use of the agent by a nursing woman is probably safe. Studies are needed, however, to measure the amount of proguanil and the active metabolite, cycloguanil, in milk and to determine the safety of this exposure in the nursing infant.

PROMAZINE

[Withdrawn from the market. See 9th edition.]

PROMETHAZINE

Antihistamine/Antiemetic

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Promethazine is a phenothiazine antihistamine that is sometimes used as an antiemetic in pregnancy and as an adjunct to narcotic analgesics during labor. There are reports of embryo–fetal harm but confirming studies are required. In general, use of the drug in pregnancy appears to be low risk for the embryo–fetus.

FETAL RISK SUMMARY

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 114 of whom had promethazine exposure in the 1st trimester (1, pp. 323–324). For use anytime during pregnancy, 746 exposures were recorded (1, p. 437). In neither group was evidence found to suggest a relationship to large categories of major or minor malformations or to individual defects. A 1964 report also failed to show an association between 165 cases of promethazine exposure in the 1st trimester and malformations (2). In a 1971 reference, infants of mothers who had ingested antiemetics during the 1st trimester actually had significantly fewer abnormalities when compared with controls (3). Promethazine was the most commonly used antiemetic in this latter study.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 1197 newborns had been exposed to promethazine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 61 (5.1%) major birth defects were observed (51 expected). Specific data were available for six defect categories, including (observed/expected) 1/2 oral clefts, 0/1 spina bifida, 4/3 polydactyly, 1/2 limb reduction defects, 1/3 hypospadias, and 17/12 cardiovascular defects. Only with the latter defect is there a suggestion of a possible association, but other factors, including the mother’s disease, concurrent drug use, and chance,

may be involved.

At term, the drug rapidly crosses the placenta, appearing in cord blood within 1.5 minutes of an IV dose (4). Fetal and maternal blood concentrations are at equilibrium in 15 minutes, with infant levels persisting for at least 4 hours.

Several investigators have studied the effect of promethazine on labor and the newborn (5–13). Significant neonatal respiratory depression was seen in a small group of patients (5). However, in three large series, no clinical evidence of promethazine-induced respiratory depression was found (6–8). In a series of 33 mothers at term, 28 received either promethazine alone (1 patient) or a combination of meperidine with promethazine or phenobarbital (27 patients). Transient behavioral and electroencephalographic changes, persisting for <3 days, were seen in all newborns (10). These and other effects prompted one author to recommend that promethazine should not be used during labor (14).

Maternal tachycardia as a result of promethazine (mean increase 30 beats/minute) or promethazine-meperidine (mean increase 42 beats/minute) was observed in one series (9). The maximum effect occurred about 10 minutes after injection. The fetal heart rate did not change significantly.

The antiemetic effects of promethazine 25 mg and metoclopramide 10 mg following the use of meperidine in labor were described in a study involving 477 women (13). Both drugs were superior to placebo as antiemetics, but significantly more of the promethazine-treated mothers had persistent sedation that extended into the immediate postpartum period. Moreover, an antianalgesic effect, as evidenced by pain score, duration of analgesia, and an increased need for meperidine, was observed when promethazine was used.

Fatal shock was reported in a pregnant woman with an undiagnosed pheochromocytoma given promethazine (15). A precipitous drop in blood pressure resulted from administration of the drug, probably secondary to unmasking of hypovolemia (15).

Effects on the uterus have been mixed, with both increases and decreases in uterine activity reported (8,9,11).

Promethazine used during labor has been shown to markedly impair platelet aggregation in the newborn but less so in the mother (12,16). Although the clinical significance of this is unknown, the degree of impairment in the newborn is comparable to those disorders associated with a definite bleeding state.

Promethazine has been used to treat hydrops fetalis in cases of anti-erythrocytic isoimmunization (17). Six patients were treated with 150 mg/day orally between the 26th and 34th weeks of gestation while undergoing intraperitoneal transfusions. No details on the infants' conditions were given

except that all were born alive. Other authors have reported similarly successful results in Rh-sensitized pregnancies (18,19). As described by some authors, doses up to 6.5 mg/kg/day may be required (18). However, a 1991 review concluded that the benefits of promethazine in the treatment of Rh immunization were marginal and may be hazardous to the fetus (20).

Two female anencephalic infants were born to mothers after ovulatory stimulation with clomiphene (21). One of the mothers had taken promethazine for morning sickness. No association between promethazine and this defect has been suggested.

BREASTFEEDING SUMMARY

Available laboratory methods for the accurate detection of promethazine in breast milk are not clinically useful because of the rapid metabolism of phenothiazines (M. Lipshutz, personal communication, Wyeth Laboratories, 1981). Because of the low molecular weight (about 284), excretion into breast milk should be expected. The potential effects of this exposure on a nursing infant are unknown.

PROPAFENONE

Antiarrhythmic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Four reports and a review have described the use of propafenone in late pregnancy (1–5). There is no reported experience in the 1st trimester. No adverse effects were observed in the fetus or the newborn.

FETAL RISK SUMMARY

Propafenone is an orally active antiarrhythmic used in the treatment of ventricular tachycardia. The agent has an active metabolite, 5-OH-propafenone. No teratogenic effects have been observed in studies with rabbits and rats, but propafenone was embryotoxic in both species when given in doses of 10 and 40 times the maximum recommended human dose, respectively (6).

Propafenone crosses the human placenta at term (1). A woman, delivering at 36 weeks' gestation, was taking 300 mg 3 times daily in the 3rd trimester. Trough concentrations of propafenone and its active metabolite in the mother were 145 and 69 ng/mL, respectively, and in the newborn were 30 and 29 ng/mL, respectively.

BREASTFEEDING SUMMARY

Propafenone is excreted into breast milk. A woman took propafenone 300 mg 3 times a day during the latter part of pregnancy and during breastfeeding (1). Three days postpartum, trough concentrations of propafenone and its active metabolite were 32 and 47 ng/mL, respectively, whereas the maternal plasma levels were 219 and 86 ng/mL, respectively.

In a 2005 study, a single oral dose of propafenone 150 mg was given to a nursing mother (7). The infant was not allowed to breastfeed during the study. Six paired samples of milk and maternal plasma were drawn over 12 hours.

The milk:plasma ratio, based on AUC, was 0.25, and the relative infant dose was 0.1% of the mother's weight-adjusted dose (7).

PROPANTHELINE

Parasympatholytic (Anticholinergic)

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Propantheline is an anticholinergic quaternary ammonium bromide. There are no reports associating the use of this drug with developmental toxicity, but the data are limited. There also are no relevant animal data. (See also Atropine.)

FETAL RISK SUMMARY

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 33 of whom used propantheline in the 1st trimester (1). No evidence was found for an association with congenital malformations. When the group of parasympatholytics were taken as a whole (2323 exposures), a possible association with minor malformations was found (1).

BREASTFEEDING SUMMARY

No reports describing the use of propantheline during human lactation have been located. (See also Atropine.)

PROPOFOL

Hypnotic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

A number of studies have described the use of propofol during cesarean section. The drug has caused transient newborn depression. No reports describing the use of the drug during the 1st and 2nd trimesters have been located.

FETAL RISK SUMMARY

Propofol is a hypnotic agent used for the IV induction and maintenance of anesthesia (1–20). Reproduction studies in rats and rabbits at doses 6 times the recommended human induction dose have revealed no evidence of impaired fertility or fetal harm (21).

The pharmacokinetics of propofol in women undergoing cesarean section was reported in 1990 (1). Propofol rapidly crosses the placenta and distributes in the fetus (2–12). The fetal:maternal (umbilical vein:maternal vein) ratio is approximately 0.7. Doses were administered either by IV bolus, by continuous infusion, or by both methods.

Several studies have examined the effect of maternal propofol anesthesia on infant Apgar scores, time to sustained spontaneous respiration, and Neurological and Adaptive Capacity Score (NACS) or the Early Neonatal Neurobehavioural Scale (ENNS) (1,2,4,5,7,8,11–18). Most investigators reported no difference in the Apgar scores of infants exposed to propofol either alone or when compared with other general anesthesia techniques, such as thiopental with enflurane or isoflurane (2,5,7,8,14–18). Moreover, no correlation was found between the Apgar scores and umbilical arterial or venous concentration of propofol (2,5,8,11,15).

In one study, infants (N = 20) exposed to a maternal propofol dose of 2.8

mg/kg had significantly lower Apgar scores at 1 and 5 minutes compared with infants (N = 20) whose mothers were treated with thiopental 5 mg/kg (13). The Apgar scores in both groups were significantly lower when compared with infants born by spontaneous vaginal delivery. The induction-to-delivery and uterine incision-to-delivery intervals in the two treatment groups were nearly identical. Five propofol-exposed infants had profound muscular hypotonus at birth and at 5 minutes, and one newborn was somnolent (13). Propofol-exposed infants were evaluated using the ENNS and were found to have a depression in alert state, pinprick and placing reflexes, and mean decremental count in Moro and light reflexes 1 hour after birth but not at 4 hours (13). Five (25%) of the infants exhibited generalized irritability and continuous crying at 1 hour, but not at 4 hours.

In contrast, most studies found no difference in the NACS or time to sustained spontaneous respiration between various groups with propofol IV bolus doses of 2.5 mg/kg or when continuous infusion doses were no higher than 6 mg/kg/hr (2,5,8,14–16). Higher doses, such as 9 mg/kg/hr, were correlated with a depressed NACS (8,12,14–16,18).

BREASTFEEDING SUMMARY

Small amounts of propofol are excreted into breast milk and colostrum following use of the agent for the induction and maintenance of maternal anesthesia during cesarean section (3). Two groups of women were studied. The first group consisted of four women who had received a mean IV propofol dose of 2.55 mg/kg at a mean of 25.9 minutes before delivery. The mean total dose received by patients in this group was 155.5 mg. The second group consisted of three women who had received a mean IV dose of 2.51 mg/kg plus a mean infusion of 5.08 mg/kg/hr. The mean total dose in this group was 247.4 mg, and the mean time to delivery was 20.2 minutes. Breast milk or colostrum samples were collected at various intervals from 4 to 24 hours after delivery. Propofol concentrations in the seven patients varied between 0.048 and 0.74 mcg/mL, with the highest levels predictably occurring at 4–5 hours in group 2. In one patient from group 2, the milk/colostrum concentration was 0.74 mcg/mL at 5 hours and fell to 0.048 mcg/mL (6% of the initial sample) at 24 hours. These amounts were considered negligible when compared with the amounts the infants received before birth from placental transfer of the drug (3).

PROPOXYPHENE

[Withdrawn from the market. See 9th edition.]

PROPRANOLOL

Sympatholytic (Antihypertensive)

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Propranolol has been used during pregnancy for maternal and fetal indications. The drug is apparently not a teratogen, but fetal and neonatal toxicity may occur. Some β -blockers, including propranolol, may cause intrauterine growth restriction (IUGR) and reduced placental weight, especially those lacking intrinsic sympathomimetic activity (ISA) (partial agonist). Treatment beginning early in the 2nd trimester results in the greatest weight reductions, whereas treatment restricted to the 3rd trimester primarily affects only placental weight. Propranolol does not possess ISA. However, IUGR and reduced placental weight may potentially occur with all agents within this class. Although growth restriction is a serious concern, the benefits of maternal therapy with β -blockers, in some cases, might outweigh the risks to the fetus and must be judged on a case-by-case basis. Newborn infants of women consuming the drug near delivery should be closely observed during the first 24–48 hours after birth for bradycardia, hypoglycemia, and other symptoms of β -blockade. Long-term effects of in utero exposure to β -blockers have not been studied but warrant evaluation.

FETAL RISK SUMMARY

Propranolol, a nonselective β -adrenergic blocking agent, has been used for various indications in pregnancy:

- Maternal hyperthyroidism (1–7)
- Pheochromocytoma (8)
- Maternal cardiac disease (6,7,9–20)
- Fetal tachycardia or arrhythmia (21,22)

Maternal hypertension (7,20,23–30)

Dysfunctional labor (31)

Termination of pregnancy (32)

Reproduction studies, all apparently based on body weight, have been conducted in rats and rabbits. In rats, embryotoxicity (increased resorption sites and reduced litter sizes) and reduced neonatal survival were observed at doses ≤ 10 times the maximum recommended human dose (MRHD) (33). No embryotoxicity was observed in rabbits at doses ≤ 20 times the MRHD. No teratogenicity was noted in either species.

The drug readily crosses the placenta (2,6,12,16,22,29,34,35). Cord serum levels varying between 19% and 127% of maternal serum have been reported (2,16,22,29). Oxytocic effects have been demonstrated following IV, extra-amniotic injections, and high oral dosing (17, 31,32,36,37). IV propranolol has been shown to block or decrease the marked increase in maternal plasma progesterone induced by vasopressin or theophylline (38). The pharmacokinetics of propranolol in pregnancy have been described (39). Plasma levels and elimination were not significantly altered by pregnancy.

A number of fetal and neonatal adverse effects have been reported following the use of propranolol in pregnancy. Whether these effects were caused by propranolol, maternal disease, other drugs consumed concurrently, or a combination of these factors is not always clear. Daily doses of ≥ 160 mg seem to produce the more serious complications, but lower doses have also resulted in toxicity. Analysis of 23 reports involving 167 liveborn infants exposed to chronic propranolol in utero is shown in below table (1–4,6,7,9,11–14,20,22–24,26–29,40–43):

| | Number of Cases | Percent (%) |
|--|-----------------|-------------|
| Intrauterine growth restriction (IUGR) | 23 | 14 |
| Hypoglycemia | 16 | 10 |
| Bradycardia | 12 | 7 |
| Respiratory depression at birth | 6 | 4 |
| Hyperbilirubinemia | 6 | 4 |
| Small placenta (size not always noted) | 4 | 2 |
| Polycythemia | 2 | 1 |
| Thrombocytopenia (40,000/mm ³) | 1 | 0.6 |
| Hyperirritability | 1 | 0.6 |
| Hypocalcemia with convulsions | 1 | 0.6 |
| Blood coagulation defect | 1 | 0.6 |

Two infants were reported to have anomalies (pyloric stenosis; crepitus of hip), but the authors did not relate these to propranolol (27,40). In another case, a malformed fetus was spontaneously aborted from a 30-year-old woman with chronic renovascular hypertension (44). The patient had been treated with propranolol, amiloride, and captopril for her severe hypertension. Malformations included absence of the left leg below the midthigh and no obvious skull formation above the brain tissue. The authors attributed the defect either to captopril alone or to a combination effect of the three drugs (44), but recent reports have associated fetal calvarial hypoplasia with captopril (see Captopril).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 274 newborns had been exposed to propranolol during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 11 (4.0%) major birth defects were observed (12 expected), including (observed/expected) 3/3 cardiovascular defects and 2/1 hypospadias. No anomalies were observed in four other defect categories (oral clefts, spina bifida, polydactyly, and limb reduction defects) for which specific data were available.

Respiratory depression was noted in four of five infants whose mothers were given 1 mg of propranolol IV just before cesarean section (45). None of the five

controls in the double-blind study was depressed at birth. The author suggested the mechanism may have been β -adrenergic blockade of the cervical sympathetic discharge that occurs at cord clamping.

Fetal bradycardia was observed in 2 of 10 patients treated with propranolol, 1 mg/minute for 4 minutes, for dysfunctional labor (31). No lasting effects were seen in the babies. In a retrospective study, 8 markedly hypertensive patients (9 pregnancies) treated with propranolol were compared with 15 hypertensive controls not treated with propranolol (25). Other antihypertensives were used in both groups. A significant difference was found between the perinatal mortality rates, with seven deaths in the propranolol group (78%) and five deaths in the controls (33%). A possible explanation for the difference may have been the more severe hypertension and renal disease in the propranolol group than in the controls (46).

IUGR may be related to propranolol. Several possible mechanisms for this effect have been reviewed (47). Premature labor has been suggested as a possible complication of propranolol therapy in patients with gestational hypertension (42). In nine women treated with propranolol for gestational hypertension, three delivered prematurely. The author speculated that these patients were relatively hypovolemic and when a compensatory increase in cardiac output failed to occur, premature delivery resulted. However, another report on chronic propranolol use in 14 women did not observe premature labor (43).

In a randomized, double-blind trial, 36 patients at term were given either 80 mg of propranolol or placebo (48). Fetal heart rate reaction to a controlled sound stimulus was then measured at 1, 2, and 3 hours. The heart rate reaction in the propranolol group was significantly depressed, compared with placebo, at all three time intervals.

The reactivity of nonstress tests (NSTs) was affected by propranolol in two hypertensive women in the 2nd and 3rd trimesters (49). One woman was taking 20 mg every 6 hours and the other 10 mg 3 times daily. Repeated NSTs were nonreactive in both women, but immediate follow-up contraction stress tests were negative. The NSTs became reactive 2 and 10 days, respectively, after propranolol was discontinued.

A 1988 review on the use of β -blockers including propranolol, during pregnancy, concluded that these agents are relatively safe (50).

BREASTFEEDING SUMMARY

Propranolol is excreted into breast milk. Peak concentrations occur 2–3 hours

after a dose (12,20,43,51). Milk levels have ranged from 4 to 64 ng/mL, with milk:plasma ratios of 0.2–1.5 (12,20,29,50). Although such adverse effects as respiratory depression, bradycardia, and hypoglycemia have not been reported, nursing infants exposed to propranolol in breast milk should be closely observed for these symptoms of β -blockade. Long-term effects of exposure to β -blockers from milk have not been studied but warrant evaluation. The American Academy of Pediatrics classifies propranolol as compatible with breastfeeding (52).

PROPYLTHIOURACIL

Antithyroid

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Propylthiouracil (PTU) is routinely used in pregnancy for the treatment of hyperthyroidism. The maternal benefit outweighs the potential embryo–fetal risk.

FETAL RISK SUMMARY

PTU has been used for the treatment of hyperthyroidism during pregnancy since its introduction in the 1940s (1–39). The drug prevents synthesis of thyroid hormones and inhibits peripheral deiodination of levothyroxine (T4) to liothyronine (T3) (40).

PTU crosses the placenta. Four patients undergoing therapeutic abortion were given a single 15-mg ³⁵S-labeled oral dose 2 hours before pregnancy termination (41). Serum could not be obtained from two 8-week-old fetuses, but 0.0016%–0.0042% of the given dose was found in the fetal tissues. In two other fetuses at 12 and 16 weeks of age, the fetal:maternal serum ratios were 0.27 and 0.35, respectively, with 0.020% and 0.025% of the dose in the fetuses. A 1986 report described the pharmacokinetics of PTU in six pregnant, hyperthyroid women (42). Serum concentrations of PTU consistently decreased during the 3rd trimester. At delivery in five patients, 1–9 hours after the last dose of 100–150 mg, the mean maternal serum concentration of PTU was 0.19 mcg/mL (range <0.02–0.52 mcg/mL) compared with a mean cord blood level of 0.36 mcg/mL (range 0.03–0.67 mcg/mL). The cord:maternal serum ratio was 1.9 (42).

The primary effect on the fetus from transplacental passage of PTU is the production of a mild hypothyroidism when the drug is used close to term. This usually resolves within a few days without treatment (34). Clinically, the hypothyroid state may be observed as a goiter in the newborn and is the result

of increased levels of fetal pituitary thyrotropin (24). The incidence of fetal goiter after PTU treatment in reported cases is approximately 12% (29 goiters/241 patients) (1–37,43). Some of these cases may have been caused by co-administration of iodides (9,11,18,22). The use of PTU early in pregnancy does not produce fetal goiter, as the fetal thyroid does not begin hormone production until approximately the 11th or 12th week of gestation (44). Goiters from PTU exposure are usually small and do not obstruct the airway as do iodide-induced goiters (see also Potassium Iodide) (43–45). However, two reports have been located that described PTU-induced goiters in newborns that were sufficiently massive to produce tracheal compression resulting in death in one infant and moderate respiratory distress in the second (7,10). In two other PTU-exposed fetuses, clinical hypothyroidism was evident at birth with subsequent slow mental and physical development (10–12). One of these infants was also exposed to high doses of iodide during gestation (12). PTU-induced goiters are not predictable or dose dependent, but the smallest possible dose of PTU should be used, especially during the 3rd trimester (19,33,44–46). No effect on intellectual or physical development from PTU-induced hypothyroxinemia was observed in comparison studies between exposed and nonexposed siblings (19,47).

Congenital anomalies have been reported in seven newborns exposed to PTU in utero (14,17,21,27,34). This incidence is well within the expected rate of malformations. Maternal hyperthyroidism itself has been shown to be a cause of malformations (48). No association between PTU and defects has been suggested. The reported defects were as follows: congenital dislocation of hip (14), cryptorchidism (17), muscular hypotonicity (17), syndactyly of hand and foot (I^{131} also used) (21), hypospadias (27), aortic atresia (27), and choanal atresia (34).

In a large prospective study, 25 patients were exposed to ≥ 1 noniodide thyroid suppressants during the 1st trimester, 16 of whom took PTU (49). From the total group, four children with nonspecified malformations were found, suggesting that this group of drugs may be teratogenic. However, because of the maternal disease and the use of other drugs (i.e., methimazole in nine women and other thiouracil derivatives in two), the relationship between PTU and the anomalies cannot be determined. This study also noted that independent confirmation of the data was required (49).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 35 newborns had been exposed to PTU during the 1st trimester (F. Rosa, personal

communication, FDA, 1993). One (2.9%) major birth defect was observed (one expected), a case of hypospadias (none expected).

A 1992 abstract and a later full report described a retrospective evaluation of hyperthyroid pregnancy outcomes treated with either PTU (N = 99) or methimazole (N = 36) (50,51). Three (3.0%) defects were observed in those exposed to PTU (ventricular septal defect; pulmonary stenosis; patent ductus arteriosus in a term infant), whereas one newborn (2.8%) had a defect (inguinal hernia) in the methimazole group. No scalp defects were observed.

A 2002 review of the fetal effects of antithyroid drugs concluded that the risk of congenital defects with PTU is not increased over that of nontreated controls (52). However, PTU was more likely than methimazole to cause suppression of fetal thyroid function that could result in fetal thyroid hyperplasia and goiter. Suppression of the fetal thyroid function occurred in 1%–5% of newborns of PTU-treated mothers, and many exhibited goiter. In addition, little is known of the long-term consequences of suppression of the fetal thyroid gland on postnatal brain development (52).

In comparison with other antithyroid drugs, PTU is considered the drug of choice for the medical treatment of hyperthyroidism during pregnancy (see also Carbimazole, Methimazole, Potassium Iodide) (34,36,44–46). Combination therapy with thyroid–antithyroid drugs was advocated at one time but is now considered inappropriate (25,26,34,36,44–46,53). Two reasons contributed to this change: (a) use of thyroid hormones may require higher doses of PTU to be used, and (b) placental transfer of T4 and T3 is minimal and not sufficient to reverse fetal hypothyroidism (see also Levothyroxine and Liothyronine).

BREASTFEEDING SUMMARY

PTU is excreted into breast milk in low amounts. In a patient given 100 mg of radiolabeled PTU, the milk:plasma ratio was a constant 0.55 for a 24-hour period, representing about 0.077% of the given radioactive dose (54). In a second study, nine patients were given an oral dose of 400 mg (55). Mean serum and milk levels at 90 minutes were 7.7 and 0.7 mcg/mL, respectively. The average amount excreted in milk during 4 hours was 99 mcg, about 0.025% of the total dose. One mother took 200–300 mg daily while breastfeeding. No changes in any of the infant's thyroid parameters were observed (55).

Based on these two reports, PTU does not seem to pose a significant risk to the breastfed infant, but periodic evaluation of the infant's thyroid function would be prudent. A 1987 review of antithyroid medication during lactation considered

PTU the drug of choice because it is ionized at physiologic pH and protein bound (80%), both limiting its transfer into milk (56).

An interesting study published in 2000 found that the physician's advice was the only significant predictor of a woman's choice to breastfeed during PTU therapy (57). In the postpartum period, a group of 36 hyperthyroid women who required PTU were compared with 30 women who no longer required PTU therapy and 36 healthy women (controls). The breastfeeding initiation rates in the three groups were 44%, 83%, and 83%, respectively. In 15 of the women receiving PTU who breastfed, advice on breastfeeding was given by 22 physicians (20 in favor, 1 against, and 1 equivocal). In those women taking PTU who formula-fed, 11 received advice from 17 physicians (4 in favor, 12 against, and 1 equivocal) (57).

The American Academy of Pediatrics classifies PTU as compatible with breastfeeding (58).

PROTAMINE

Antiheparin

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably
Compatible

PREGNANCY SUMMARY

Protamine is used to neutralize the anticoagulant effect of heparin. No reports of its use in pregnancy have been located. Reproduction studies in animals have not been conducted (1).

BREASTFEEDING SUMMARY

No reports describing the use of protamine during human lactation have been located. Such reports are unlikely due to its indication.

Reference

1. Product information. Protamine sulfate. Eli Lilly, 1993.

PROTIRELIN

[Withdrawn from the market. See 9th edition.]

PROTRIPTYLINE

Antidepressant

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports on the use of protriptyline during human pregnancy have been located. (See also Amitriptyline and Nortriptyline.)

FETAL RISK SUMMARY

Protriptyline, a dibenzocycloheptene derivative, is a tricyclic antidepressant. Other antidepressants in this class are amitriptyline and its metabolite, nortriptyline.

Reproduction studies in mice, rats, and rabbits at doses about 10 times greater than the recommended human dose had no apparent adverse effects on reproduction (1).

It is not known if protriptyline crosses the human placenta. The molecular weight (about 264 for the free base) is low enough that exposure of the embryo–fetus should be expected.

BREASTFEEDING SUMMARY

No reports describing the use of protriptyline during lactation have been located. The molecular weight (about 264 for the free base) is low enough that excretion into breast milk should be expected. The effect on a nursing infant from exposure to the drug in breast milk is unknown. The American Academy of Pediatrics classifies amitriptyline, a similar antidepressant, as a drug whose effect on the nursing infant is unknown but may be of concern (see Amitriptyline).

PSEUDOEPHEDRINE

Sympathomimetic (Adrenergic)

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Although the limited human data suggest there may be a risk of gastroschisis and small intestinal atresia (SIA) from 1st trimester exposure to pseudoephedrine, the risk is low and may only be identifiable in case–control studies. Moreover, the risk may only be present when pseudoephedrine is combined with other agents, not when it used alone. Confirmation of these findings is required. Until such data are available, the best course is to avoid pseudoephedrine during the 1st trimester.

FETAL RISK SUMMARY

Pseudoephedrine is a sympathomimetic used to alleviate the symptoms of allergic disorders or upper respiratory infections. It is a common component of proprietary mixtures containing antihistamines and other ingredients. Thus, it is difficult to separate the effects of pseudoephedrine on the fetus from those of other drugs, disease states, and viruses.

Sympathomimetic amines are teratogenic in some animal species, but human teratogenicity has not been suspected (1). The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 3082 of whom had 1st trimester exposure to sympathomimetic drugs (2, pp. 345–356). For use anytime during pregnancy, 9719 exposures were recorded (2, p. 439). An association in the 1st trimester was found between the sympathomimetic class of drugs as a whole and minor malformations (not life-threatening or major cosmetic defects), inguinal hernia, and clubfoot (2, pp. 345–356). However, independent confirmation of these results is required (2, pp. 345–356).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 940 newborns had been exposed to pseudoephedrine during the 1st trimester (F. Rosa, personal

communication, FDA, 1993). A total of 37 (3.9%) major birth defects were observed (40 expected). Specific data were available for six defect categories, including (observed/expected) 3/9 cardiovascular defects, 2/2 oral clefts, 0/0 spina bifida, 3/3 polydactyly, 0/2 limb reduction defects, and 0/2 hypospadias. These data do not support an association between the drug and congenital defects.

A case–control surveillance study published in 1992 reported a significantly elevated relative risk of 3.2 (95% confidence interval [CI] 1.3–7.7) for the use of pseudoephedrine during the 1st trimester and 76 exposed cases with gastroschisis (3). A total of 2142 infants with other malformations formed a control group. Relative risks for other drugs were salicylates, 1.6; acetaminophen, 1.7; ibuprofen, 1.3; and phenylpropanolamine, 1.5. Because some of these drugs are vasoactive substances, and because the cause of gastroschisis is thought to involve vascular disruption of the omphalomesenteric artery (3), the investigators compared the use of 1st trimester pseudoephedrine and other drugs in relation to a heterogeneous group of malformations, other than gastroschisis, suspected of also having a vascular origin. In this case, however, the relative risk for the drugs approximated unity. These data suggested that the association between pseudoephedrine and the other drugs and gastroschisis may have been caused by an underlying maternal illness (3).

In a 2002 retrospective case–control study, conducted in 1995–1999, mothers of 206 gastroschisis cases, 126 SIA cases, and 798 controls were interviewed about medication use and illnesses (4). The interval of between birth and interview was <6 months for all cases. The risk of gastroschisis was increased for aspirin (odds ratio [OR] 2.7, 95% CI 1.1–5.9), all pseudoephedrine (OR 1.8, 95% CI 1.0–3.2), all acetaminophen (OR 1.5, 95% CI 1.1–2.2), and pseudoephedrine plus acetaminophen (OR 4.2, 95% CI 1.9–9.2). The risk for SIA was increased for all pseudoephedrine (OR 2.0, 95% CI 1.0–4.0), and pseudoephedrine plus acetaminophen (OR 3.0, 95% CI 1.1–9.0). However, when pseudoephedrine was used as a single agent, the ORs and 95% CIs for gastroschisis and SIA were 0.7 (0.2–2.1) and 1.1 (0.5–2.9), respectively. Fever (as reported by the patient), upper respiratory infection, and allergy were not associated with increased risks of gastroschisis or SIA. There were also no significant associations with phenylpropanolamine, ibuprofen, antihistamines, guaifenesin, or dextromethorphan. The results confirmed the association of an increased risk of gastroschisis with aspirin shown in previous studies. However, the data for pseudoephedrine raised

questions concerning interactions between drugs and possible confounding by underlying illness (4).

A 2005 abstract reviewed the fetal effects of pseudoephedrine after 1st trimester exposure (5). Two analyses of pharmacy data from health maintenance organizations revealed 9 malformed infants among 902 exposures, suggesting no association with congenital malformations overall. However, case–control studies have shown that 1st trimester exposure to decongestants is associated with small to moderate increases in the risk of gastroschisis, SIA, and hemifacial microsomia. Moreover, these risks are increased if the mother also smokes cigarettes (5).

Data from the Swedish Medical Birth Registry regarding pregnancy exposure to oral decongestants were reported in 2006 (6). The 1st trimester pregnancy exposures reported by 2474 women were 2304 phenylpropanolamine alone, 136 phenylpropanolamine plus cinnarizine, 23 pseudoephedrine alone, and 11 used 2 of these preparations. Compared with 1771 women who were prescribed an oral decongestant later in pregnancy, the risk ratio for any congenital malformation among the 2474 subjects was 0.96, 95% CI 0.80–1.16 (6).

A 1981 report described a woman who consumed, throughout pregnancy, 480–840 mL/day of a cough syrup (7). The potential maximum daily doses based on 840 mL of syrup were 5.0 g of pseudoephedrine, 16.8 g of guaifenesin, 1.68 g of dextromethorphan, and 79.8 mL of ethanol. The infant had features of the fetal alcohol syndrome (see Ethanol) and displayed irritability, tremors, and hypertonicity (7). It is not known whether the ingredients, other than the ethanol, were associated with the adverse effects observed in the infant.

BREASTFEEDING SUMMARY

Pseudoephedrine is excreted into breast milk (8,9). Three mothers, who were nursing healthy infants, were given an antihistamine-decongestant preparation containing 60 mg of pseudoephedrine and 2.5 mg of triprolidine (8). Two of the mothers had been nursing for 14 weeks, and one had been nursing for 18 months. Milk concentrations of pseudoephedrine were higher than plasma levels in all three patients, with peak milk concentrations occurring at 1.0–1.5 hours. The milk:plasma ratios at 1, 3, and 12 hours in one subject were 3.3, 3.9, and 2.6, respectively. The investigators calculated that 1000 mL of milk produced during 24 hours would contain 0.25–0.33 mg of pseudoephedrine base, approximately 0.5%–0.7% of the maternal dose (8).

A single-blind, cross-over study of pseudoephedrine 60 mg vs. placebo was conducted in eight lactating women (9). The mean milk volume was significantly reduced by pseudoephedrine, falling from 784 mL/day (placebo period) to 623 mL/day (pseudoephedrine period). The effect on milk volume was not due to breast blood flow, but the slightly reduced (ns) serum prolactin concentrations in the women may have contributed. The mean average milk concentration was 829 mcg/L. Assuming a pseudoephedrine 60 mg 4 times daily dose (maximum recommended dose), the estimated infant dose, based on AUC and 150 mL/kg/day, was 4.3% of the mother's weight-adjusted dose (9).

The American Academy of Pediatrics classifies pseudoephedrine as compatible with breastfeeding (10).

PUMPKIN SEED

Herb

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of pumpkin seed in human pregnancy have been located. Animal reproduction data also are lacking. However, this product has been used worldwide as a food and in traditional medicine for centuries (1). When used as a food, pumpkin seed probably is harmless for the embryo–fetus. High doses, such as those that might be used in traditional medicine or in eating disorders should be avoided.

FETAL RISK SUMMARY

Several subspecies of pumpkin are widely consumed as food and used in traditional medicine. The subspecies belong to the family Cucurbitaceae and include *Cucurbita pepo* (also known as *C. galeotti*, *C. mammeata*, and *Cucumis pepo*), *C. maxima* Duchesne (autumn squash), and *C. moschata* Poir (crookneck squash). Pumpkin seeds are used as a food, an anthelmintic and, in combination with other herbal products, in the treatment of dysuria caused by benign prostatic hyperplasia. The anthelmintic agent in pumpkin seeds is cucurbitin, a carboxypyrrolidine. The concentration of cucurbitin in pumpkin seeds depends on the subspecies, varying from 0.18% to 1.94%, with the highest concentrations in *C. maxima*. Other chemicals in pumpkin seeds are fatty acids (primarily palmitic, stearic, oleic, and linoleic), carotenoids (primarily β -carotene), amino acids and protein, and carbohydrates. In addition to β -carotene, the seeds are high in vitamin E (primarily γ -tocopherol) (1,2).

Animal reproduction studies involving pumpkin seed have not been located.

Vitamin A (i.e., from conversion of β -carotene), vitamin E, and fatty acids are known to cross the placenta and the other components of pumpkin probably also cross.

BREASTFEEDING SUMMARY

No reports describing the use of pumpkin seed during human lactation have been located. When used as a food, pumpkin seed probably is harmless for the nursing infant. High doses, such as those that might be used in traditional medicine or in eating disorders should be avoided.

PYRANTEL PAMOATE

Anthelmintic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports on the use of this drug in human pregnancy have been located. Shepard cited two studies in which no congenital defects or postnatal effects were observed in pregnant rats fed doses up to 3000 mg/kg or in pregnant rabbits given 1000 mg/kg (1,2).

FETAL RISK SUMMARY

It is not known if pyrantel pamoate crosses the human placenta. The molecular weight (about 595) is low enough that exposure of the embryo–fetus should be expected.

BREASTFEEDING SUMMARY

No reports describing the use of pyrantel pamoate during human lactation have been located. The molecular weight (about 595) is low enough for excretion into breast milk. The effect of this exposure on a nursing infant is unknown.

PYRAZINAMIDE

Antituberculosis Agent

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >> Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Pyrazinamide is a synthetic antituberculosis agent derived from niacinamide. There is no relevant animal data, but a small number of human pregnancy exposures without fetal harm have been reported (1). Therefore, because active tuberculosis is a far greater risk to the embryo–fetus than the drug, pyrazinamide, if indicated should not be withheld in pregnancy (2).

FETAL RISK SUMMARY

Pyrazinamide is indicated for the initial treatment of active tuberculosis in adults and children when combined with other antituberculosis agents. Plasma protein binding (about 10%) is low and the elimination half-life in patients with normal renal and hepatic function is 9–10 hours. The drug is metabolized in the liver to an active metabolite (3).

Animal reproduction studies have not been conducted with pyrazinamide. The drug was not carcinogenic in rats and male mice (data lacking for female mice) or mutagenic in one test. However, pyrazinamide did induce chromosomal aberrations in human lymphocyte cell cultures (3).

It is not known if pyrazinamide crosses the human placenta. The molecular weight (about 123), low plasma protein binding, and prolonged elimination half-life suggest that exposure of the embryo–fetus will occur.

A 1994 report described the use of pyrazinamide in a pregnant woman (4). She had been treated for cavitary pulmonary tuberculosis with three other agents for 5 months before the addition of pyrazinamide at 26 weeks' gestation for persistent positive sputum cultures. No drug-related fetal toxicity was mentioned (4). Although past investigators have cautioned that pyrazinamide

should not be routinely used because of the lack of information pertaining to its fetal effects (4–7), a more recent recommendation states that the drug can be used in pregnancy (2).

In a 1999 study involving 33 pregnant women with extrapulmonary tuberculosis, 6 (21%) were treated with isoniazid, rifampin, and pyrazinamide (8). Pyrazinamide was stopped after 2 months and all therapy was stopped after 9 months. No cases of congenital tuberculosis or fetal malformations were observed (8).

A 2003 report described the use of pyrazinamide in a pregnant woman with multidrug-resistant tuberculosis (9). The 22-year-old woman was diagnosed with the infection at 23 weeks' and daily treatment was initiated with rifampin (600 mg), isoniazid (300 mg), and ethambutol (700 mg). Because of lack of response, her therapy was changed after 3 weeks to capreomycin (IV 1000 mg 5 days/week), cycloserine (750 mg/day), levofloxacin (1000 mg/day), para-aminosalicylic acid (12 g/day), and pyrazinamide (1500 mg/day). After spontaneous rupture of the membranes, she gave birth at 35 weeks' to a healthy 2003-g infant. The results of a tuberculin skin test and three nasogastric aspiration cultures were negative, as were a neurologic examination and electrophysiology hearing studies. The infant was kept separated from the mother (9).

Pyrazinamide, in combination with isoniazid, rifampin, and ethambutol, was used in five pregnancies in a 2008 report (10). No adverse effects on the fetuses or newborns were observed.

BREASTFEEDING SUMMARY

Pyrazinamide is excreted into human milk. A patient who was not breastfeeding (days postpartum not stated) was given an oral 1-g dose of pyrazinamide (11). The peak milk concentration, 1.5 mcg/mL, occurred at 3 hours. The peak maternal plasma concentration, 42.0 mcg/mL, occurred at 2 hours (10).

In the above case, the milk:plasma ratio was approximately 0.04. The weight of the woman was not specified, but if her weight was 70 kg and a nursing infant consumed 150 mL/kg/day of breast milk, then the theoretically maximum infant dose as a percentage of the mother's weight-adjusted dose would be 1.6%. This suggests that if similar results are eventually reported in other studies, the risk of toxicity to a nursing infant is probably nil. Based on the one case, maternal treatment with pyrazinamide appears to be compatible with breastfeeding. However, nursing infants should be monitored for the rare toxicity observed in patients taking the drug, such as jaundice, fever, loss of

appetite, nausea and vomiting, thrombocytopenia, rash, and arthralgia.

PYRETHRINS WITH PIPERONYL BUTOXIDE

Pediculicide

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Pyrethrins with piperonyl butoxide is a synergistic combination product used topically for the treatment of lice infestations. It is considered the drug of choice for lice (1). Although no reports of its use in pregnancy have been located, topical absorption is poor, so potential toxicity should be less than that of lindane (see also Lindane) (2). For this reason, use of the combination is probably preferred over lindane in the pregnant patient.

BREASTFEEDING SUMMARY

No reports describing the use of pyrethrins with piperonyl butoxide during human lactation have been located. Because the drug is absorbed poorly after topical application, exposure of a nursing infant from breast milk is probably nil.

PYRIDOSTIGMINE

Parasympathomimetic (Cholinergic)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Pyridostigmine is a quaternary ammonium compound with anticholinesterase activity used in the treatment of myasthenia gravis. Most reports have described no fetal harm and the animal data suggest low risk.

FETAL RISK SUMMARY

Pyridostigmine was not teratogenic in rats at doses up to 30 mg/kg/day, but maternal and fetal toxicity (reduced weight) were observed at the highest dose (1).

Although it is ionized at physiologic pH, the low molecular weight of pyridostigmine (about 261) allows the nonionized fraction to cross to the fetus. Pyridostigmine concentrations have been determined at birth in maternal plasma, cord blood, and amniotic fluid (2). Two women with long-term myasthenia gravis were treated throughout gestation with pyridostigmine, 360 and 420 mg per day, respectively. The latter woman was also treated with neostigmine (105 mg/day) and ambenonium (60 mg/day). In the first case, the maternal plasma, cord blood, and amniotic drug concentrations were 77, 65, and 290 ng/mL, respectively, and in the second, 53, 39, and 300 ng/mL, respectively. Thus, the cord blood:maternal plasma ratios were 0.84 and 0.74, respectively, whereas the amniotic fluid:maternal plasma ratios were 3.8 and 5.7 respectively (2).

Caution has been advised against the use in pregnancy of IV anticholinesterases because they may cause premature labor (3,4). This effect on the pregnant uterus increases near term.

A number of reports have described the apparent safe use of pyridostigmine during human gestation (2–16). However, a case report published in 2000

described microcephaly and CNS injury in a newborn that was attributed to high-dose pyridostigmine (17). The infant's mother was a 24-year-old primigravida with a 14-year history of myasthenia gravis. She required high-dose pyridostigmine (1500–3000 mg/day) throughout gestation to control her diplopia and ptosis. In comparison, the average recommended daily dose is 600 mg, with daily doses \leq 1500 mg required in severe cases (18). The mother denied smoking and the use of other drugs during pregnancy. At 36 weeks' gestation, an emergency cesarean section for fetal bradycardia was conducted, delivering a severely growth-restricted (1880 g, <2nd percentile), hypotonic male infant with Apgar scores of 3 and 8 at 1 and 5 minutes, respectively. Shortly after birth, neonatal myasthenia gravis was diagnosed, two exchange transfusions were used to lower his acetylcholine receptor antibody titer, and IV immunoglobulin was administered. The infant required immediate intubation because of poor respiratory effort and was continued on the respirator until age 3.5 months. Mild finger and wrist contractures and bilateral cryptorchidism were noted at birth, but he had no abnormal ocular findings (17). The head circumference was 33.5 cm at birth and 37 cm (<5th percentile) at 3 months of age. By about 5 months of age, a number of dysmorphic features were noted, including a broad nasal bridge with a prominent nose, slight downslanting palpebral fissures, high arched palate, short neck, broad chest, campylodactyly, and hammer toes (17). He continued to do poorly, requiring additional hospitalizations and mechanical ventilation. At 4.5 months, he was discharged home but readmitted 1 week later because of prolonged apnea and cyanosis. His weight (5.1 kg, 10th percentile) and head circumference (38 cm, <2nd percentile) were still restricted and he remained hypotonic. A cranial ultrasound, karyotyping, and TORCH titers (i.e., toxoplasmosis, other infections, rubella, cytomegalovirus, and herpes simplex) were normal or negative and there was no evidence of craniosynostosis. A brain magnetic resonance imaging scan at 5 months revealed apparent brachycephaly and mild ventriculomegaly. At 9 months of age, he still required nasal oxygen, tone was normal, and the joint contractures had resolved, but his reflexes were brisk and ankle clonus was evident. Because no other cause could be identified, the authors attributed the microcephaly and CNS injury to pyridostigmine (17).

Both antenatal and neonatal myasthenia gravis have been reported and either may result in perinatal death. Both forms of the disorder are caused by transplacental passage of anti-acetylcholine receptor immunoglobulin G antibodies (11,19). The inhibited fetal skeletal muscle movement and

development may result in pulmonary hypoplasia, arthrogryposis multiplex, and polyhydramnios (19).

Transient muscular weakness has been observed in about 20% of newborns of mothers with myasthenia gravis (11,19).

BREASTFEEDING SUMMARY

Pyridostigmine is excreted into breast milk. Levels in two women receiving 120–300 mg/day were 2–25 ng/mL, representing milk:plasma ratios of 0.36–1.13 (15). Although pyridostigmine is an ionized quaternary ammonium compound, these values indicate that the nonionized fraction crosses easily into breast milk. The drug was not detected in the infants nor were any adverse effects noted. The authors estimated that the two infants were ingesting 0.1% or less of the maternal doses (15). The American Academy of Pediatrics classifies pyridostigmine as compatible with breastfeeding (20).

PYRIDOXINE

Vitamin

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Pyridoxine (vitamin B₆) deficiency during pregnancy is a common problem in unsupplemented women. Supplementation with oral pyridoxine reduces but does not eliminate the frequency of deficiency. No definitive evidence has appeared that indicates mild to moderate deficiency of this vitamin is a cause of maternal or fetal complications. Most of the studies with this vitamin have been open and uncontrolled. If a relationship does exist with poor pregnancy outcome, it is probable that a number of factors, of which pyridoxine may be one, contribute to the problem. A significant reduction in nausea and vomiting of pregnancy, however, appears to occur with pyridoxine. The available data are sufficient to conclude that the combination of pyridoxine and doxylamine is safe and effective for nausea and vomiting of pregnancy. Severe deficiency or abnormal metabolism is related to fetal and infantile convulsions and possibly to other conditions. However, the association of pyridoxine deficiency, with or without folate deficiency, and oral clefts requires confirmation. High doses apparently pose little risk to the fetus. Because pyridoxine is required for good maternal and fetal health, and an increased demand for the vitamin occurs during pregnancy, supplementation of the pregnant woman with the recommended dietary allowance (RDA) for pyridoxine is recommended.

FETAL RISK SUMMARY

Pyridoxine, a water-soluble B-complex vitamin, acts as an essential coenzyme involved in the metabolism of amino acids, carbohydrates, and lipids (1). The National Academy of Sciences' RDA for pyridoxine in pregnancy is 2.2 mg (1).

Pyridoxine is actively transported to the fetus (2–4). Like other B-complex vitamins, concentrations of pyridoxine in the fetus and newborn are higher than in the mother and are directly proportional to maternal intake (5–16). Actual

pyridoxine levels vary from report to report because of the nutritional status of the populations studied and the microbiologic assays used, but usually indicate an approximate newborn:maternal ratio of 2:1 with levels ranging from 22 to 87 ng/mL for newborns and 13–51 ng/mL for mothers (4,14–16).

Pyridoxine deficiency without clinical symptoms is common during pregnancy (10,16–34). Clinical symptoms consisting of oral lesions have been reported, however, in severe B₆ deficiency (35). Supplementation with multivitamin products reduces, but does not always eliminate, the incidence of pyridoxine hypovitaminemia (16).

Severe vitamin B₆ deficiency is teratogenic in experimental animals (36,37). No reports of human malformations linked to B₆ deficiency have been located. A brief report in 1976 described an anencephalic fetus resulting from a woman treated with high doses of pyridoxine and other vitamins and nutrients for psychiatric reasons, but the relationship between the defect and the vitamins is unknown (38).

The effects on the mother and fetus resulting from pyridoxine deficiency or excess are controversial. These effects can be summarized as follows:

- Gestational hypertension (GH)
- Gestational diabetes mellitus
- Infantile convulsions
- Nausea and vomiting of pregnancy
- Congenital malformations
- Miscellaneous effects

Gestational Hypertension

Several researchers have claimed that pyridoxine deficiency is associated with the development of GH (12,39–41). Others have not found this relationship (10,19,42,43). One group of investigators demonstrated that women with GH excreted larger amounts of xanthurenic acid in their urine after a loading dose of dl-tryptophan than did normal pregnant women (39). Although the test only was partially specific for GH, they theorized that it could be of value for early detection of the disease and was indicative of abnormal pyridoxine–niacin–protein metabolism. In another study, 410 women treated with 10 mg of pyridoxine daily were compared with 410 controls (40). GH occurred in 18 (4.4%) of the untreated controls and in 7 (1.7%) of the pyridoxine-supplemented patients, a significant difference. In an earlier report, no significant differences were found between women with GH and normal

controls in urinary excretion of 4-pyridoxic acid, a pyridoxine metabolite, after a loading dose of the vitamin (19). Some investigators have measured lower levels of pyridoxine in mothers with GH than in mothers without GH (12). The difference in levels between the newborns of GH and normal mothers was more than twofold and highly significant. In a 1961 Swedish report, pyridoxine levels in 10 women with GH were compared with those in 26 women with uncomplicated pregnancies (42). The difference between the mean levels of the two groups, 25 and 33 ng/mL, respectively, was not significant. Similarly, others have been unable to find a correlation between pyridoxine levels and GH (10,43).

Gestational Diabetes Mellitus

Pyridoxine levels were studied in 14 pregnant women with an abnormal glucose tolerance test (GTT), and 13 of these patients were shown to be pyridoxine deficient (44). All were placed on a diet and given 100 mg of pyridoxine per day for 14 days, after which only two were diagnosed as having gestational diabetes mellitus. The effect of the diet on the GTT was said to be negligible, although a control group was not used. Other investigators duplicated these results in 13 women using the same dose of pyridoxine but without mentioning any dietary manipulation and without controls (45). However, a third study was unable to demonstrate a beneficial effect in four patients with an abnormal GTT using 100 mg of vitamin B₆ for 21 days (46). Moreover, all of the mothers had large-for-gestational-age infants, an expected complication of diabetic pregnancies. In 13 gestational diabetic women treated with the doses of pyridoxine described above, an improvement was observed in the GTT in 2 patients, a worsening was seen in 6, and no significant change occurred in the remaining 5 (47).

Infantile Convulsions

An association between pyridoxine and infantile convulsions was first described in the mid-1950s (48–52). Some infants fed a diet deficient in this vitamin developed intractable seizures that responded only to pyridoxine. A 1967 publication reviewed this complication in infants and differentiated between the states of pyridoxine deficiency and dependency (53). Whether or not these states can be induced in utero is open to question. As noted earlier, pyridoxine deficiency is common during pregnancy, even in well-nourished women, but the fetus accumulates the vitamin, although at lower levels, even in the face of maternal hypovitaminemia. Reports of seizures in newborn infants delivered

from mothers with pyridoxine deficiency have not been located. On the other hand, high doses of pyridoxine early in gestation in one patient were suspected of altering the normal metabolism of pyridoxine, leading to intractable convulsions in the newborn (54). The woman, in whom two pregnancies were complicated by hyperemesis gravidarum, was treated with frequent injections of pyridoxine and thiamine, 50 mg each (54). The first newborn began convulsing 4 hours after birth and died within 30 hours. The second infant began mild twitching at 3 hours of age and progressed to severe generalized convulsions on the 5th day. Successful treatment was eventually accomplished with pyridoxine but not before marked mental retardation had occurred. The authors of this report postulated that the fetus, exposed to high doses of pyridoxine, developed an adaptive enzyme system that was capable of rapidly metabolizing the vitamin; following delivery, this adaptation was manifested by pyridoxine dependency and convulsions (54). Since this case, more than 50 additional cases of pyridoxine dependency have been reported, and the disease is now thought to be an inherited autosomal recessive disorder (55).

A 1967 report described in utero dependency-induced convulsions in three successive pregnancies in one woman (56). The first two newborns died—one during the 7th week and one on day 2—as a result of intractable convulsions. During the third pregnancy, in utero convulsions stopped after the mother was treated with 110 mg/day of pyridoxine 4 days before delivery. Following birth, the newborn was treated with pyridoxine. Convulsions occurred on three separate occasions when vitamin therapy was withheld and then abated when therapy was restarted. Late-onset seizures in a female infant were reported in 1999 (57). The mother had taken pyridoxine 80 mg/day throughout pregnancy and intermittently when the nursing infant was between 1 and 10 weeks of age. Four days after birth, the infant had two generalized tonic seizures. Then, at 3.5 months of age, the infant became irritable and fussy and had a cluster of 12 generalized seizures, each lasting 2–5 minutes, over 4 days. Laboratory tests and an electroencephalogram, taken when the infant was not seizing, were normal. A single dose of pyridoxine 100 mg IV was given and she was seizure-free for 3 weeks. Then three more seizures occurred over 4 days. She was given 100 mg oral pyridoxine and then 12.5 mg/day thereafter. At 7 months old, the infant was seizure free with normal temperament and development since starting oral pyridoxine (57).

Nausea and Vomiting of Pregnancy

The first use of pyridoxine for severe nausea and vomiting of pregnancy

(hyperemesis gravidarum) was reported in 1942 (58). Individual injections ranged from 10 to 100 mg, with total doses up to 1500 mg being given. Satisfactory relief was obtained in most cases. In one study, patients were successfully treated with IM doses of 50–100 mg 3 times weekly (59). Another report described a single patient with hyperemesis who responded to an IV mixture of high-dose B-complex vitamins, including 50 mg of pyridoxine, each day for 3 days (60). Much smaller doses were used in a study of 17 patients (61). IM doses of 5 mg every 2–4 days were administered to these patients, with an immediate response observed in 12 women and all responding by the second dose. Oral doses of 60–80 mg/day up to a total dose of 2500 mg gave partial or complete relief from nausea and vomiting in 68 patients; an additional 10 patients required oral plus injectable pyridoxine (62). A success rate of 95% was claimed in a study of 62 women treated with a combination of pyridoxine and suprarenal cortex (adrenal cortex extract) (63). None of the preceding six studies was double-blind or controlled. The effect of pyridoxine on blood urea concentrations in hyperemesis has been investigated (64). Blood urea was decreased below normal adult levels in pregnant women and even lower in patients with hyperemesis. Pyridoxine, 40 mg/day orally for 3 days, significantly increased blood urea only in women with hyperemesis. In another measure of the effect of pyridoxine on hyperemesis, elevated serum glutamic acid levels observed with this condition were returned to normal pregnant values after pyridoxine therapy (65). However, another investigator could not demonstrate any value from pyridoxine therapy in 16 patients (66). Placebos were used but the study was not blinded. In addition, only 1 of 16 patients had hyperemesis gravidarum with the remaining 15 presenting with lesser degrees of nausea and vomiting. Based on the above studies, it is impossible to judge the effectiveness of the vitamin in allaying true hyperemesis gravidarum. More than likely, the effect of hydration, possibly improved prenatal care, the attention of health care personnel, the transitory nature of hyperemesis, the lack of strict diagnostic criteria in classifying patients with the disease, and other factors were involved in the reversal of the symptoms of the women involved in these studies. The vitamin, however, does appear to reduce nausea and vomiting of pregnancy as demonstrated in the two investigations described below.

Two studies have demonstrated that oral doses of pyridoxine are effective in alleviating nausea and vomiting of pregnancy (67–69). A randomized, double-blind, placebo-controlled study, found that pyridoxine, 25 mg orally every 8 hours for 72 hours, administered to 31 women at a mean gestational age of 9.3 weeks, significantly reduced severe nausea and vomiting of pregnancy (67,68).

A second study, using pyridoxine 10 mg orally every 8 hours for 5 days in 167 women at a mean gestational age of 10.9 weeks, produced a significant reduction in nausea and nearly a significant decrease in the number of vomiting episodes (69).

Congenital Malformations

A case report suggested a link between high doses of pyridoxine and phocomelia (70). The mother, who weighed only 47 kg, took 50 mg of pyridoxine daily plus unknown doses of lecithin and vitamin B₁₂ through the first 7 months of pregnancy. The full-term female infant was born with a near-total amelia of her left leg at the knee. A relationship between any of the drugs and the defect is doubtful.

The combination of doxylamine and pyridoxine (Bendectin, others) has been the focus of considerable debate in the past. The debate centered on whether the preparation was teratogenic. The combination had been used by millions of women for pregnancy-induced nausea and vomiting but was removed from the market by the manufacturer because of a number of large legal awards against the company. Jury decisions notwithstanding, the available scientific evidence indicates the combination is not teratogenic (see Doxylamine).

Pyridoxine has been shown to protect fetal rats from β -aminopropionitrile-induced palatal clefting when given before and during administration of the chemical (71). The same protection may occur in humans. In a case-control study from two sites in the Philippines, women with offspring with an oral cleft (cleft lip, with or without cleft palate) had worst pyridoxine deficiency than controls (72). The association was strongest if the mother also had lower folate levels. However, folate-oral cleft associations were inconsistent and were thought to be due to differing pyridoxine status in the two populations studied. In contrast, poor maternal pyridoxine status was consistently associated with an increased risk of oral clefts (72).

Miscellaneous Effects

Among miscellaneous effects, two studies were unable to associate low maternal concentrations of pyridoxine with premature labor (29,43). Similarly, no correlation was found between low levels and stillbirths (10,40). However, 1-minute Apgar scores were significantly related to low maternal and newborn pyridoxine concentrations (14,73). The effects of pyridoxine supplementation in black pregnant women have been studied (74). Lower maternal serum lipid, fetal weight, and placental weight and the frequency of placental vascular

sclerosis were observed. Others have not found a correlation between pyridoxine levels and birth weight (15,43,73). In an unusual report, pregnant women given daily 20-mg supplements of pyridoxine by either lozenges or capsules had less dental disease than untreated controls (75). The best cariostatic effect was seen in patients in the lozenge group.

BREASTFEEDING SUMMARY

Pyridoxine is excreted into breast milk (14,76–82). Concentrations in milk are directly proportional to intake (76–82). In well-nourished women, pyridoxine levels varied, depending on intake, from 123 to 314 ng/mL (76–78). Peak pyridoxine milk levels occurred 3–8 hours after ingestion of a vitamin supplement (76,78,79). A 1983 study measured pyridoxine levels in pooled human milk obtained from preterm (26 mothers: 29–34 weeks) and term (35 mothers: 39 weeks or longer) patients (80). Levels in milk obtained from preterm mothers rose from 11.1 ng/mL (colostrum) to 62.2 ng/mL (16–196 days), whereas levels in milk from term mothers increased during the same period from 17.0 to 107.1 ng/mL. In a 1985 study, daily supplements of 0–20 mg resulted in milk concentrations of 93–413 ng/mL, corresponding to an infant intake of 0.06–0.28 mg/day (79). A significant correlation was found between maternal intake and infant intake. Most infants, however, did not receive the RDA for infants (0.3 mg) even when the mother was consuming 8 times the RDA for lactating women (2.5 mg) (79). In lactating women with low nutritional status, supplementation with pyridoxine, 0.4–40 mg/day, resulted in mean milk concentrations of 80–158 ng/mL (81).

Convulsions have been reported in infants fed a pyridoxine-deficient diet (see discussion in the Fetal Risk Summary) (49–54). Seizures were described in two breastfed infants, one of whom was receiving only 67 mcg/day in the milk (83). Intake in the second infant was not determined. A similar report involved three infants whose mothers had levels <20 ng/mL (at 7 days postpartum) or <60 ng/mL (at 4 weeks) of pyridoxine in their milk (84). The convulsions responded promptly to pyridoxine therapy in all five of these infants.

Very large doses of pyridoxine have been reported to have a lactation-inhibiting effect (85). Using oral doses of 600 mg/day, lactation was successfully inhibited in 95% of patients within 1 week as compared with only 17% of placebo-treated controls. Very high IV doses of pyridoxine, 600 mg infused for 1 hour in healthy, nonlactating young adults, successfully suppressed the rise in prolactin induced by exercise (86). However, because use of this dose and method of administration in lactating women would be

unusual, the relevance of these data to breastfeeding is limited. With dosage much closer to physiologic levels, such as 20 mg/day, no effect on lactation has been observed (79). In addition, two separate trials, using 450 mg and 600 mg/day in divided oral doses, failed to reproduce the lactation-inhibiting effect observed earlier or to show any suppression of serum prolactin levels (87,88). One writer, however, has suggested that pyridoxine be removed from multivitamin supplements intended for lactating women (89). This proposal has invoked sharp opposition from other correspondents who claimed the available evidence does not support a milk-inhibiting property for pyridoxine (90,91). Moreover, a study published in 1985 examined the effects of pyridoxine supplements, 0.5 or 4.0 mg/day started 24 hours after delivery, on lactation (92). Women receiving the higher dose of pyridoxine had significantly higher concentrations of plasma pyridoxal phosphate ($p < 0.01$) and milk total vitamin B₆ ($p < 0.05$) at 1, 3, 6, and 9 months. Plasma prolactin concentrations were similar between the two groups throughout the study.

The American Academy of Pediatrics classifies pyridoxine as compatible with breastfeeding (93). The National Academy of Sciences' RDA for pyridoxine during lactation is 2.1 mg (1). If the diet of the lactating woman adequately supplies this amount, maternal supplementation with pyridoxine is not required (82). Supplementation with the RDA for pyridoxine is recommended for those women with inadequate nutritional intake.

PYRILAMINE

Antihistamine

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Pyrilamine is used infrequently during pregnancy. One source found an increased risk of structural anomalies, but confirmation has not been reported. In general, antihistamines are considered low risk in pregnancy. However, exposure near birth of premature infants has been associated with an increased risk of retrolental fibroplasia.

FETAL RISK SUMMARY

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 121 of whom had pyrilamine exposure in the 1st trimester (1, pp. 323–324). No evidence was found to suggest a relationship to large categories of major or minor malformations. For use anytime during pregnancy, 392 exposures were recorded (1, pp. 436–437). A possible association with malformations was found on the basis of 12 defects, 6 of which involved benign tumors (1, p. 489).

It is not known if pyrilamine crosses the human placenta. The molecular weight (about 402) is low enough that exposure of the embryo–fetus should be expected.

An association between exposure during the last 2 weeks of pregnancy to antihistamines in general and retrolental fibroplasia in premature infants has been reported. See Brompheniramine for details.

BREASTFEEDING SUMMARY

No reports describing the use of pyrilamine during human lactation have been reported. The molecular weight (about 402) is low enough for excretion into breast milk. The effect of this exposure on a nursing infant is unknown.

PYRIMETHAMINE

Antimalarial

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably
Compatible

PREGNANCY SUMMARY

Two reviews of toxoplasmosis (*Toxoplasma gondii*) in pregnancy were published in 1994 (1,2). Pyrimethamine, in combination with sulfadiazine, was recommended in both as the most effective treatment after the infection had reached the fetus. No fetal adverse effects of this therapy have been observed. Despite one animal study that described increased embryotoxicity after oral folic acid, if pyrimethamine is used during pregnancy, folic acid (5 mg/day) or folinic acid (leucovorin; 5 mg/day) supplementation is recommended, especially during the 1st trimester, to prevent folate deficiency (1,3–9).

FETAL RISK SUMMARY

Pyrimethamine is a folic acid antagonist (inhibitor of dihydrofolate reductase) used in combination with other agents primarily for the treatment and prophylaxis of malaria, but also for toxoplasmosis. Shepard (10) reviewed 15 studies that evaluated the reproductive effects of pyrimethamine in rats, mice, and hamsters. Malformations in fetal rats included cleft palate, mandibular hypoplasia, limb defects, and neural tube defects. In some cases, the teratogenic dose was similar to the human dose. At slightly higher doses in rats, pyrimethamine caused chromosomal aberrations such as trisomy or chromosomal mosaicism (10).

A 1993 study found in pregnant rats and mice that oral folic acid potentiated the embryotoxicity of pyrimethamine but that decreased embryotoxicity was observed when folic acid was given intraperitoneally (11). The mechanism of the increased toxicity appeared to be reduced plasma levels of 5-methyltetrahydrofolic acid in the dams. 5-Methyltetrahydrofolic acid is the

principal active folate in plasma and it undergoes a large amount of enterohepatic circulating (11). Folic acid inhibited the absorption of the active folate from the intestine.

Reproduction studies, reported by the manufacturer, revealed teratogenicity in rats, hamsters, and miniature pigs (12). In rats, oral doses 7 times the human dose for chemoprophylaxis of malaria (HDCM) or 2.5 times the human dose for toxoplasmosis (HDT), caused cleft palate, brachygnathia, oligodactyly, and microphthalmia. Meningocele was seen in hamsters, given doses 170 times the HDCM or HDT, and cleft palate occurred in miniature pigs at 5 times the HDCM or HDT (12).

In an in vitro study using human perfused placentas, the transfer rate of pyrimethamine was about 30% (13). The results suggested that the placental transfer was independent of maternal concentration and the transfer occurred by passive diffusion.

Antimalarial agents, including pyrimethamine, are used routinely during pregnancy because the risks from the disease far outweigh the risks to the fetus from drug therapy (see Proguanil for a discussion on the maternal and fetal risks of malaria during pregnancy).

Although some folic acid antagonists are human teratogens (e.g., see Methotrexate), this does not seem to occur with pyrimethamine (3–7,14,15). One case report, however, did describe a severe defect of the abdominal and thoracic wall (exteriorization of the heart, lungs, and most of the abdominal viscera; possible variant of ectopia cordis) and a missing left arm in an infant exposed to the drug (16). The woman had been treated with chloroquine, 100 mg/day, plus a combination of dapsone (100 mg) and pyrimethamine (12.5 mg) (Maloprim) on postconception days 10, 20, and 30. However, an association between the drug and the defect has been questioned (8,17). Moreover, most studies describing the use of pyrimethamine in pregnant women for the treatment or prophylaxis of malaria have found the drug to be relatively safe and effective (8,9,18–31), although some recommend avoiding the drug during the 1st trimester (9).

BREASTFEEDING SUMMARY

Pyrimethamine is excreted into breast milk (32,33). Mothers treated with 25–75 mg orally produced peak concentrations of 3.1–3.3 mcg/mL at 6 hours (32). The drug was detectable up to 48 hours after a dose. Malaria parasites were completely eliminated in infants up to 6 months of age who were entirely breastfed. In a 1986 study, three women were treated with a combination

tablet containing 100 mg of dapsone and 12.5 mg of pyrimethamine at 2–5 days postpartum (33). Blood and milk samples were collected up to 227 hours after the dose. The milk:plasma AUC ratios ranged from 0.46 to 0.66. Based on an estimated ingestion of 1000 mL of milk per day, the infants would have consumed between 16.8% and 45.6% of the maternal doses during a 9-day period.

The American Academy of Pediatrics classifies pyrimethamine as compatible with breastfeeding (34).

PYRVINIUM PAMOATE

[Withdrawn from the market. See 9th edition.]

Q

QUAZEPAM

Hypnotic

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 1st and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports of human use of quazepam during human pregnancy have been located, but the effects of this agent on the fetus following prolonged use should be similar to those observed with other benzodiazepines (see also Diazepam). Maternal use near delivery may potentially cause neonatal motor depression and withdrawal.

FETAL RISK SUMMARY

Quazepam is a benzodiazepine that is used as a hypnotic for the short-term management of insomnia. No major abnormalities were observed in mice and rabbits at doses up to 400 and 134 times the human dose, respectively. Minor defects observed in mice were delayed ossification of the sternum, vertebrae, distal phalanges, and supraoccipital bones. The manufacturer considers the drug to be contraindicated during pregnancy (1).

BREASTFEEDING SUMMARY

Quazepam is excreted into breast milk (2). Four healthy, lactating volunteers, who agreed not to breastfeed their infants, were given a single 15-mg dose of the hypnotic. After the dose, blood and milk samples were collected at scheduled times during a 48-hour interval. Mean cumulative amounts of quazepam and its two major active metabolites excreted into milk during the

48-hour period were 11.6 mcg (range 2.4–32.8 mcg) quazepam, 4.0 mcg (range 1.3–10.0 mcg) 2-oxoquazepam, and 1.0 mcg (range 0.4–1.6 mcg) N-desalky-2-oxoquazepam. These amounts represented 0.08%, 0.02%, and 0.09% of the dose, respectively. Milk concentrations of quazepam and 2-oxoquazepam were always higher than those in the plasma, with milk:plasma ratios of 4.18 and 2.02, respectively. Because of the lipophilic properties of quazepam, these ratios are much higher than those observed with diazepam (see Diazepam). The investigators estimated that following a multiple-dose regimen, only 28.7 mcg/day of the three compounds combined would be excreted into milk, representing 0.19% of the daily dose. Moreover, they concluded that the pharmacokinetics of quazepam indicated that accumulation would not occur except for N-desalky-2-oxoquazepam, the metabolite excreted in milk in the smallest amounts (2).

Although the amounts measured in the above study are small, the effects, if any, on a nursing infant's central nervous system function are unknown. The American Academy of Pediatrics classifies quazepam, especially when taken by nursing mothers for long periods, as a drug for which the effect on nursing infants is unknown but may be of concern (3).

QUETIAPINE

Antipsychotic

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although no structural malformations attributable to quetiapine or other agents in this subclass have been reported, the number of exposures is too low to fully assess the embryo–fetal risk. In addition, there is a risk of extrapyramidal and/or withdrawal symptoms in the newborn if the drug is used in the 3rd trimester. Nevertheless, quetiapine is indicated for severe debilitating mental disease and the benefits to the mother appear to outweigh the potential embryo–fetal risks. Because of the limited human pregnancy experience with atypical antipsychotics, the American College of Obstetricians and Gynecologists does not recommend the routine use of these agents in pregnancy, but a risk–benefit assessment may indicate that such use is appropriate (1). However, the benefits to the mother appear to outweigh the unknown risk to the embryo-fetus (2). A 1996 review on the management of psychiatric illness concluded that patients with histories of chronic psychosis or severe bipolar illness represent a high-risk group (for both the mother and the fetus) and should be maintained on pharmacologic therapy before and during pregnancy (3). Folic acid 4 mg/day has been recommended for women taking atypical antipsychotics because they may have a higher risk of neural tube defects due to inadequate folate intake and obesity (4). A 2010 review of antipsychotic use in pregnancy concluded that most studies reported no adverse effects, including congenital anomalies in the offspring of mothers who had taken quetiapine during pregnancy (5).

FETAL RISK SUMMARY

Quetiapine is an atypical antipsychotic agent that is indicated for the treatment

of schizophrenia. The drug is an antagonist of histamine H₁ and adrenergic α₁-receptors and may cause somnolence and orthostatic hypotension, respectively. Other antipsychotic agents in the same subclass of dibenzapine derivatives are asenapine, clozapine, loxapine, and olanzapine. The drug is extensively metabolized to primarily inactive metabolites and one active metabolite. Plasma protein binding to albumin is 83% and the mean terminal half-life is about 6 hours (6).

Reproduction studies have been conducted in rats and rabbits. No evidence of teratogenicity was observed in pregnant rats or rabbits at oral doses up to 2.4 times the maximum human dose based on BSA (MHD) during organogenesis. However, minor soft-tissue malformations (carpal/tarsal flexure) were noted in rabbit fetuses at 2.4 times the MHD. Embryo–fetal toxicity was observed in both species but the doses used (in rats only with the highest dose and in rabbits with all doses) also caused maternal toxicity (decreased weight gain and/or death). Delays in skeletal ossification were observed in rats at doses equivalent to 0.6 and 2.4 times the MHD. Similar fetal effects were observed in rabbits at doses 1.2 and 2.4 times the MHD. Reduced fetal body weights were noted at the highest doses in both species. No drug-related effects were noted in rat offspring in a perinatal/postnatal study using oral doses that were 0.1–0.24 times the MHD (6).

Quetiapine decreased mating and fertility in male rats given oral doses up to 1.8 times the MHD. Adverse effects (increased interval to mate and number of matings required for successful impregnation) continued to be observed in the high-dose group 2 weeks after treatment had been stopped. In male rats, the no-effect dose for impaired mating and fertility was 0.3 times the MHD. Quetiapine also adversely effected mating and fertility in female rats. At an oral dose 0.6 times the MHD, drug effects included decreases in mating and in matings resulting in pregnancy, and increases in the interval to mate and in irregular estrus cycles (also noted at 0.1 times the MHD). The no-effect dose in female rats was 0.01 times the MHD (6).

In an in vitro study using dually perfused human placentas, small amounts (about 4%) of quetiapine crossed from the maternal side to the fetal venous outflow (7). This is consistent with the molecular weight (about 767 for the free base), moderate protein binding, and the moderately long elimination half-life. In another study, 21 women taking a staple dose (mean 336.9 mg/day) of quetiapine for a mean 28.9 weeks before delivery had maternal and cord concentrations of the drug determined at birth (8). The cord blood concentration was 24.1% of the maternal concentration. The pregnancy

outcomes include one premature infant (<37 weeks) and one growth-restricted infant (<2500 g). The mean Apgar scores were 7.6 and 8.9 at 1 and 5 minutes, respectively. There were nine neonatal complications, two cardiovascular and 7 respiratory (complications were not further described), and two infants were admitted to the neonatal intensive care unit (reasons not provided) (8).

A 38-year-old woman with paranoid-type schizophrenia was started on quetiapine (300 mg/day) after an unsuccessful trial with zuclopenthixol (9). After a marked improvement in her symptoms, she conceived with her pregnancy being diagnosed at 17 weeks' gestation when she reported amenorrhea. At 20 weeks' her dose was lowered to 200 mg/day, and then 2 weeks later to 150 mg/day. She eventually gave birth to a healthy 3120-g male infant with Apgar scores of 9 and 10 at 1 and 5 minutes, respectively. Birth length was 48 cm. The infant was developing normally at 6 months of age (9).

A 33-year-old woman with psychosis was treated with quetiapine (300 mg/day) beginning 2 weeks before conception and continuing during gestation (10). The dose was decreased to 200 mg/day at week 21. The dose was further reduced by 50 mg/day each week starting 4 weeks before her estimated due date to enable breastfeeding. At 39 weeks' gestation, she gave birth to a healthy, 3.61-kg female infant with Apgar scores of 8 and 9 at 1 and 5 minutes, respectively. The infant was doing well in the first month after birth (10).

A woman took quetiapine (200 mg/day) throughout pregnancy and gave birth to a term, male infant (11). No information was provided on the pregnancy outcome, but the mother planned to continue the drug while breastfeeding her infant (see below).

A 2005 study, involving women from Canada, Israeli, and England, described 151 pregnancy outcomes in women using atypical antipsychotic drugs (12). The exposed group was matched with a comparison group (N = 151) who had not been exposed to these agents. The drugs and number of pregnancies were olanzapine (N = 60), risperidone (N = 49), quetiapine (N = 36), and clozapine (N = 6). In those exposed, there were 110 live births (72.8%), 22 spontaneous abortions (14.6%), 15 elective abortions (9.9%), and 4 stillbirths (2.6%). Among the live births, one infant exposed in utero to olanzapine had multiple anomalies including midline defects (cleft lip, encephalocele, and aqueductal stenosis). The mean birth weight was 3341 g. There were no statistically significant differences, including rates of neonatal complications, between the cases and controls, with the exceptions of low birth weight (10% vs. 2%, $p = 0.05$) and elective abortions (9.9% vs. 1.3%, $p = 0.003$). The low birth weight

may have been caused by the increased rate of cigarette smoking (38% vs. 13%, $p \leq 0.001$) and heavy/binge alcohol use (5 vs. 1) in the exposed group (12).

A 2006 report mentioned three women treated with quetiapine and other agents during gestation (13). The drug therapy was continued during breastfeeding (see below).

In a second 2006 report, a 33-year-old woman with severe psychotic depression was treated with quetiapine (400 mg/day) and fluvoxamine (200 mg/day) (14). After appropriate counseling, she continued this therapy and conceived; after a normal pregnancy, she delivered a healthy, 2600-g, length 49 cm, female infant with Apgar scores of 9 and 10 at 1 and 5 minutes, respectively. The infant was developing normally at 3 months (14).

A 26-year-old woman was treated with quetiapine for resistant depression with comorbid chronic pain (15). She took 300 mg/day during the 1st trimester. The dose was increased to 400 mg/day in the 4th month and continued for the remainder of her pregnancy. Other drugs taken throughout pregnancy included oxycodone (20 mg 3 times daily) and fluoxetine (40 mg daily). She delivered a 3.4-kg (50th percentile) male infant at 37 weeks' gestation, but other details were not provided. She continued the three drugs during breastfeeding (see below) (15).

A 2006 review of prophylactic therapy of bipolar disorder briefly described the effects in pregnancy and breastfeeding of a number of drugs, including (16). Untreated pregnant and nursing women with the disorder are at an increased risk of poor obstetrical outcomes and relapse of affective symptoms. Although the limited data prevented conclusions on the relative safety of the drugs, the author did state that each case needed to be considered separately (16).

A 17-year-old pregnant adolescent with bipolar disorder was treated throughout gestation with quetiapine 300 mg/day, venlafaxine 75 mg/day, and trazodone 150 mg/day (17). In the 1st, 2nd, and 3rd trimesters, plasma concentrations of quetiapine were -27%, -42%, and -18%, respectively, of the concentrations at 6 months postpartum. She gave birth to a healthy 3-kg male infant with Apgar scores of 9, 10, and 10. The infant had jitteriness during the first 4 days of life that did not require intervention. He was seen monthly and met developmental milestones during the first year (17).

A woman with schizophrenia was treated with quetiapine 250 mg/day throughout two consecutive pregnancies (18). In the first pregnancy, she gave birth at term to a healthy 2.5-kg female infant. She conceived again about 1

year later and again delivered a healthy 2.4-kg female infant. Both infants were breastfed while the mother continued quetiapine. Both girls were healthy, the first one at about 2 years of age and the other at about 9 months (18).

A 2014 case study described the use of phenelzine (105 mg/day), lithium (900 mg/day), and quetiapine (600 mg/day) in a 31-year-old woman with bipolar affective disorder (19). She was also taking metformin (1 g/day) for polycystic ovarian syndrome with oligomenorrhea. Despite her oligomenorrhea, a pregnancy was confirmed at 17 weeks' gestation. A glucose tolerance test was negative at 26 weeks'. Lithium was suspended 24–48 hours before induction of labor at 39 weeks'. Because of obstructed labor, a cesarean section was performed to give birth to a 4.2-kg male infant with Apgar scores of 5 and 9 at 1 and 5 minutes, respectively. The baby required initial resuscitation during the first 10 minutes. The baby was discharged home with the mother at 5 days. At 10 weeks of age, the baby's growth and development were normal (19).

BREASTFEEDING SUMMARY

Consistent with its molecular weight (about 767 for the free base), protein binding (83%), and mean terminal half-life (about 6 hours), quetiapine is excreted into breast milk. A 36-year-old woman took quetiapine (200 mg/day) throughout gestation and planned to continue the drug while breastfeeding her term, male infant (11). However, the infant was initially given formula because it was not known how much of the drug was excreted in milk. At 3 weeks postpartum, manually expressed milk samples were obtained before a dose and again at 1, 2, 4, and 6 hours after a dose. The average milk AUC over 6 hours was 13 mcg/L, with a maximum concentration of 62 mcg/L measured at 1 hour. At 2 hours, the milk concentrations were almost predose levels. Based on a milk intake of 150 mL/kg/day, it was estimated that an exclusively breastfed infant would ingest 0.09% of the weight-adjusted maternal dose. Even at the maximum concentration, the estimated infant dose was only 0.43% of the maternal dose. When the mother was told of these findings, she began exclusive breastfeeding at 8 weeks. No adverse effects of quetiapine were reported and the infant was developing normally at 4.5 months (11).

A 2006 report described six women treated with quetiapine and other agents during lactation (13). In three cases, therapy was started before or during pregnancy (gestational age shown in parentheses): quetiapine (50 mg) and paroxetine (40 mg) (18 weeks); quetiapine (75 mg), trazodone (75 mg), and venlafaxine (75 mg) (before conception); and quetiapine (100 mg) and

venlafaxine (225 mg) (35.5 weeks). In the other three cases, quetiapine was added after delivery (postpartum weeks shown in parentheses): quetiapine (25 mg), paroxetine (60 mg), and clonazepam (0.5 mg) (16.5 weeks); quetiapine (25 mg) and paroxetine (12.5 mg) (3 weeks); and quetiapine (400 mg) and paroxetine (50 mg) (10.5 weeks). Breast milk samples, drawn at variable times after the dose, were obtained between 6.5 and 18.5 weeks postpartum. Quetiapine was not detected (<30 nmol/L) in the breast milk of four women (doses 25–75 mg). The estimated infant exposures in these four cases were <0.01 mg/kg/day. In the two women taking 100 or 400 mg doses, the quetiapine milk levels were 32 and 264 nmol/L, respectively, and the estimated infant exposures were <0.01 and <0.10 mg/kg/day, respectively. Milk levels for the other agents were clonazepam (not detected), paroxetine (not detected in three; 776 nmol/L in one; estimated infant exposure <0.26 mg/kg/day), trazodone (108 nmol/L; estimated infant exposure <0.01 mg/kg/day), and venlafaxine (371 and 1179 nmol/L; estimated infant exposure <0.01 mg/kg/day for both) (13).

At 9–18 months of age, infant behavior was evaluated using the Bayley Scales of Infant Development, Second Edition (13). Four scored within normal limits, whereas two showed mild developmental delay (evaluated at 9 and 12.72 months, respectively). Both infants were exposed to quetiapine and paroxetine; one from 18 weeks' gestation and the other starting at 3 weeks postpartum. Neither agent was detected in the breast milk of the mothers. Based on the limited sample, the authors concluded that there appeared to be no association between developmental outcomes and exposure to the drugs in breast milk (13).

In a case described in the Fetal Risk Summary section, a woman took quetiapine 400 mg/day and fluvoxamine 200 mg/day throughout a normal pregnancy (14). She continued this therapy while attempting to breastfeed her healthy female infant. Because of insufficient milk production, formula supplementation was required. The infant was developing normally and meeting all milestones at 3 months of age (14).

Another case, also described in the Fetal Risk Summary section, involved a 26-year-old mother taking quetiapine 400 mg/day, oxycodone 60 mg/day, and fluoxetine 40 mg/day during pregnancy and while breastfeeding her 3-month-old male infant (15). The infant's weight, 3.4 kg (50th percentile) at birth, was now 5.6 kg (25th percentile). Blood and milk samples were collected before the night quetiapine dose was administered and at various times over a 24-hour period. Sixteen milk samples were collected by manual expression at regular

feeding times. The average milk concentration of quetiapine was 41 mcg/L and the milk:plasma ratio was 0.29. Using 150 mL/kg/day as an estimated milk intake, the infant's dose was 0.09% of the maternal weight-adjusted dose. The infant's plasma level, 1.4 mcg/L, was about 6% of the corresponding maternal plasma concentration. No adverse effects were noted in the infant. The results of a Denver developmental assessment were consistent with the chronologic age (15).

The long-term effects of these exposures on nursing infants are unknown. The manufacturer recommends women receiving quetiapine should not breastfeed (6). Moreover, the American Academy of Pediatrics classifies other antipsychotics (e.g., see Clozapine) as drugs whose effect on the nursing infant is unknown but may be of concern (20).

QUINACRINE

[Withdrawn from the market. See 9th edition.]

QUINAPRIL

Antihypertensive

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

The fetal toxicity of quinapril in the 2nd and 3rd trimesters is similar to other angiotensin-converting enzyme (ACE) inhibitors. The use of this drug during the 2nd and 3rd trimesters may cause teratogenicity and severe fetal and neonatal toxicity. Fetal toxic effects may include anuria, oligohydramnios, fetal hypocalvaria, intrauterine growth restriction (IUGR), prematurity, and patent ductus arteriosus. Stillbirth or neonatal death may occur. Anuria-associated oligohydramnios may produce fetal limb contractures, craniofacial deformation, and pulmonary hypoplasia. Severe anuria and hypotension, which is resistant to both pressor agents and volume expansion, may occur in the newborn following in utero exposure. Newborn renal function and blood pressure should be closely monitored.

FETAL RISK SUMMARY

Quinapril is an ACE inhibitor. No teratogenic effects were observed in reproduction studies in rats and rabbits with doses 180 and 1 times the maximum recommended human dose, respectively (1).

A retrospective study using pharmacy-based data from the Tennessee Medicaid program identified 209 infants, born between 1985 and 2000, who had 1st trimester exposure to ACE inhibitors (2). Infants of mothers with evidence of diabetes, either before or during pregnancy, were excluded, as were those exposed to angiotensin-receptor antagonists (ARBs), ACE inhibitors or other antihypertensives beyond the 1st trimester, and exposure to known teratogens. Two comparison groups, other antihypertensives (N = 202) and no antihypertensives (N = 29,096), were formed. The number of major birth defects in each of the three groups was 18 (8.6%), 4 (2%), and 834 (2.9%),

respectively. Compared with the no-antihypertensives group, exposure to ACE inhibitors was associated with a significantly increased risk of major defects (relative risk [RR] 2.71, 95% confidence interval [CI] 1.72–4.27). When the analysis was conducted by the type of defect, the highest rates were with cardiovascular defects, 9, 2, and 294, respectively, RR 3.72, 95% CI 1.89–7.30, and with CNS defects, 3, 0, and 80, respectively, RR 4.39, 95% CI 1.37–14.02. The major defects observed in the subject group were: atrial septal defect (N = 6) (includes three with pulmonic stenosis and/or three with patent ductus arteriosus [PDA]), renal dysplasia (N = 2), PDA alone (N = 2), and one each of ventricular septal defect, spina bifida, microcephaly with eye anomaly, coloboma, hypospadias, intestinal and choanal atresia, Hirschsprung disease, and diaphragmatic hernia (2). In an accompanying editorial, it was noted that neither previous reports of 1st trimester exposure to ACE inhibitors nor the animal studies had observed an increased risk of birth defects (3). It also was noted that no mechanism for ACE inhibitor–induced teratogenicity was known. A subsequent communication raising concerns about the validity of the study in terms of adequate exclusion of diabetes, charting and coding errors in busy medical practices, and the effects of maternal obesity (4) was addressed by the investigators (5).

Quinapril and other ACE inhibitors are human teratogens when used in the 2nd and 3rd trimesters, producing fetal hypocalvaria and renal defects. The cause of the defects and other toxicity is probably related to fetal hypotension and decreased renal blood flow. The compromise of the fetal renal system may result in severe, and at times fatal, anuria, both in the fetus and in the newborn. Anuria-associated oligohydramnios may produce pulmonary hypoplasia, limb contractures, persistent PDA, craniofacial deformation, and neonatal death (6,7). IUGR, prematurity, and severe neonatal hypotension may also be observed. Two reviews of fetal and newborn renal function indicated that both renal perfusion and glomerular plasma flow are low during gestation and that high levels of angiotensin II may be physiologically necessary to maintain glomerular filtration at low perfusion pressures (8,9). Quinapril prevents the conversion of angiotensin I to angiotensin II and, thus, may lead to in utero renal failure. Because the primary means of removal of the drug is renal, the impairment of this system in the newborn prevents elimination of the drug resulting in prolonged hypotension. Newborn renal function and blood pressure should be closely monitored. If oligohydramnios occurs, stopping quinapril may resolve the problem but may not improve infant outcome because of irreversible fetal damage (6). In those cases in which quinapril must be used to treat the

mother's disease, the lowest possible dose should be used combined with close monitoring of amniotic fluid levels and fetal well-being. Guidelines for counseling exposed pregnant patients have been published and should be of benefit to health professionals faced with this task (6,10).

The observation in Tennessee Medicaid data of an increased risk of major congenital defects after 1st trimester exposure to ACE inhibitors raises concerns about teratogenicity that have not been seen in other studies (3). Medicaid data are a valuable tool for identifying early signals of teratogenicity, but are subject to a number of shortcomings, and their findings must be considered hypotheses until confirmed by independent studies.

A 2012 review of the use of ACE inhibitors and ARBs in the 1st trimester concluded that there may be an elevated teratogenic risk, but the risk appeared to be related to other factors (11). The factors, that typically coexist with hypertension in pregnancy, included diabetes, advanced maternal age, and obesity.

BREASTFEEDING SUMMARY

Quinapril is excreted into breast milk. Six healthy mothers who had been breastfeeding for at least 2 weeks were given a single 20 mg oral dose of quinapril (12). Serial blood and milk samples were collected over 24 hours. The mean milk:plasma ratio was 0.12 based on AUC, but no drug was detected in milk after 4 hours. The metabolite (quinaprilat) was not detected in any of the milk samples. The estimated infant dose was 1.6% of the mother's weight-adjusted dose (12).

The amount of quinapril measured in the above study is clinically insignificant. Although data from women receiving daily doses of the drug are needed, quinapril is probably compatible with nursing. The American Academy of Pediatrics classifies captopril and enalapril as compatible with breastfeeding (see Captopril and Enalapril).

QUINETHAZONE

[Withdrawn from the market. See 9th edition.]

QUINIDINE

Antiarrhythmic/Antimalarial

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

The use of quinidine during pregnancy has been classified in reviews of cardiovascular drugs as relatively low risk for the fetus (1–4). In therapeutic doses, the oxytocic properties of quinidine have been rarely observed, but high doses can produce this effect and may result in abortion (3,5).

FETAL RISK SUMMARY

No reports linking the use of quinidine with congenital defects have been located. Animal reproduction studies apparently have not been conducted with quinidine.

Quinidine has been in use as an antiarrhythmic drug for more than 100 years (6) and in pregnancy, at least back to the 1920s (7–13). Eighth cranial nerve damage has been associated with high doses of the optical isomer, quinine, but not with quinidine (9). Neonatal thrombocytopenia has been reported after maternal use of quinidine (10).

Quinidine crosses the placenta and achieves fetal serum levels similar to maternal levels (6,11–13). In a 1979 case, a woman taking 600 mg every 8 hours plus an additional dose of 300 mg (2100 mg/day) had serum and amniotic fluid levels of 5.8 and 10.6 mcg/mL, respectively, 10 days before term (11). Three days later, 10 hours after the last dose, a healthy male infant was delivered by elective cesarean section. Quinidine concentrations in the serum, cord blood, and amniotic fluid were 3.4, 2.8, and 9.3 mcg/mL, respectively. The cord blood:serum ratio was 0.82 (11). The cord blood level was greater than those measured in three other reports (6,12,13).

In a 1984 study, three women maintained on quinidine (300 mg every 6 hours) and digoxin had serum levels of quinidine at delivery ranging from 0.7 to 2.1 mcg/mL (12). A quinidine level in one amniotic fluid sample was 0.9

mcg/mL, whereas cord blood levels ranged from <0.5 to 1.6 mcg/mL. In two of the three cases, cord blood:serum ratios were 0.2 and 0.9 (12).

In a 1985 report, a woman taking quinidine (400 mg every 6 hours) plus digoxin and propranolol had an elective cesarean section 18 hours after the last dose (13). The quinidine concentration in the cord blood was 0.8 mcg/mL.

One case involved a woman in whom quinidine doses were escalated during a 6-day interval from 300 mg every 6 hours to 1500 mg every 6 hours (6). On day 8, the dosage was reduced to 1500 mg every 8 hours, then to 1200 mg every 8 hours on day 9, and then stopped on day 10. Amniotic fluid levels of quinidine and the metabolite, 3-hydroxyquinidine, on day 10 were 2.2 and 9.7 mcg/mL, respectively. At delivery 2 days later, cord blood contained 0.5 mcg/mL of quinidine and 0.7 mcg/mL of the metabolite (6).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 17 newborns had been exposed to quinidine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). One (5.9%) major birth defect was observed (one expected). No anomalies were observed in six defect categories (cardiovascular defects, oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available.

The drug has been used in combination with digoxin to treat fetal supraventricular and reciprocating atrioventricular tachycardia (12,13). The authors of one of these reports consider quinidine to be the drug of choice after digoxin for the treatment of persistent fetal tachyarrhythmias (13). A 1990 report described an unsuccessful attempt of maternal transplacental cardioversion with quinidine for a rare case of fetal ventricular tachycardia associated with nonimmune hydrops fetalis at 30 weeks' gestation (14). A dose of 200 mg quinidine 4 times daily was given for 3 days before worsening preeclampsia with breech presentation required delivery by cesarean section. The newborn died 5 hours after birth.

A 33-year-old woman with new-onset, sustained ventricular tachycardia was treated with metoprolol (50 mg twice daily) at 22 weeks' gestation (15). Because of recurrent palpitations, quinidine (dose not specified) was added to the regimen at 26 weeks' gestation, and with the attainment of a therapeutic quinidine level, the combination was successful in controlling the ectopic beats. Combination therapy was continued until term when a healthy, growth-restricted, approximately 2240-g infant was delivered. Intrauterine growth restriction apparently developed after maternal combination therapy was initiated, but a discussion of the cause was not included in the reference, nor

was maternal blood pressures given (15).

A mother treated with quinidine for a fetal supraventricular tachycardia developed symptoms of quinidine toxicity consisting of severe nausea and vomiting, diarrhea, lightheadedness, and tinnitus (6). Electrocardiographic changes were consistent with quinidine toxicity. Her dosage had been increased during an interval of 6 days in a manner described above, producing serum quinidine levels of 1.4–3.3 mcg/mL (therapeutic range in the author's laboratory was 1.5–5.0 mcg/mL). At the highest dose, her serum level was 2.3 mcg/mL. Levels of the metabolite, 3-hydroxyquinidine, rose from 1.1 to 6.8 mcg/mL during the 6-day interval, eventually reaching 9.7 mcg/mL 1 day after quinidine was discontinued. The 3-hydroxyquinidine:quinidine ratio varied from 0.8 (on day 2) to 3.7 (on day 10). These ratios were much higher than those observed in previously reported patients (1). Because the fetal heart rate continued to be elevated, with only occasional reductions to 120–130 beats/minute, and fetal lung maturity had been demonstrated; labor was induced, resulting in the delivery of a 3540-g infant with hydrops fetalis. The infant required pharmacologic therapy to control the supraventricular tachycardia. The maternal toxicity was attributed to the elevated levels of 3-hydroxyquinidine, because concentrations of quinidine were in the low- to midtherapeutic range (6).

In an in vitro study using plasma from 16 normal pregnant women, quinidine concentrations between 0.5 and 5.0 mcg/mL were shown to inhibit plasma pseudocholinesterase activity (16). Inhibition varied from 29% (0.5 mcg/mL) to 71% (5.0 mcg/mL). Pseudocholinesterase is responsible for the metabolism of succinylcholine and ester-type local anesthetics (e.g., procaine, tetracaine, cocaine, and chlorprocaine) (16). The quinidine-induced inhibition of this enzyme, which is already significantly decreased by pregnancy itself, could potentially result in toxicity if these agents were used in a mother maintained on quinidine.

A 21-year-old woman in premature labor at 31 weeks' gestation was treated with IV quinidine and exchange transfusion for severe, apparently chloroquine-resistant, malaria (17). Parasitemia with *Plasmodium falciparum* >12% was shown on blood smears before treatment and then fell to 1% after treatment. Initial therapy with 1 g oral chloroquine was unsuccessful and approximately 12 hours later, she was given an IV loading dose of quinidine, 10 mg base/kg during 2 hours, followed by a continuous infusion of 0.02 mg/kg/minute and exchange transfusion. No potentiation of labor was observed during quinidine therapy, although the mother was receiving IV magnesium sulfate for tocolysis.

Because of fetal distress, thought to be caused by uteroplacental insufficiency as a result of maternal parasitemia or fever, a cesarean section was performed to deliver a 1570-g male infant with Apgar scores of 5 and 7 at 1 and 5 minutes, respectively. Except for respiratory difficulty during the first 6 hours, the infant had an uneventful hospital course, including a negative blood smear for malaria (17).

BREASTFEEDING SUMMARY

Quinidine is excreted into breast milk (11). A woman taking 600 mg every 8 hours had milk and serum concentrations determined on the 5th postpartum day, 3 hours after a dose. Levels in the two samples were 6.4 and 9.0 mcg/mL, respectively, a milk:serum ratio of 0.71. A quinidine level of 8.2 mcg/mL was noted in a milk sample on the preceding day (time relationship to the dose not specified) but a simultaneous serum concentration was not determined. The infant in this case did not breastfeed (11). The American Academy of Pediatrics classifies quinidine as compatible with breastfeeding (18).

QUININE

Antimalarial

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Quinine has effectively been replaced by newer agents for the treatment of malaria. Although no increased teratogenic risk can be documented for therapeutic doses, its use during pregnancy should be avoided. One manufacturer considers the drug to be contraindicated in pregnancy (1). However, some investigators believe quinine should be used for the treatment of chloroquine-resistant *Plasmodium falciparum* malaria (2).

FETAL RISK SUMMARY

Nishimura and Tanimura (3) summarized the human case reports of teratogenic effects linked with quinine in 21 infants who were exposed during the 1st trimester after unsuccessful abortion attempts (some infants had multiple defects and are listed more than once):

- Central nervous system (CNS) anomalies (6 with hydrocephalus) (10 cases)

- Limb defects (3 dysmelias) (8 cases)

- Facial defects (7 cases)

- Heart defects (6 cases)

- Digestive organ anomalies (5 cases)

- Urogenital anomalies (3 cases)

- Hernias (3 cases)

- Vertebral anomaly (1 case)

The malformations noted are varied, although CNS anomalies and limb defects were the most frequent. Auditory defects and optic nerve damage have also been reported (3–7). These reports usually concern the use of quinine in toxic doses as an abortifacient. Quinine has also been used to induce labor in women with intrauterine fetal death (8). Epidemiologic observations do not support an increased teratogenic risk or increased risk of congenital deafness

over nonquinine-exposed patients (3,9). Neonatal and maternal thrombocytopenia purpura and hemolysis in glucose-6-phosphate dehydrogenase-deficient newborns has been reported (10,11).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 35 newborns had been exposed to quinine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Two (5.7%) major birth defects were observed (one expected). No anomalies were observed in six defect categories (cardiovascular defects, oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available.

BREASTFEEDING SUMMARY

Quinine is excreted into breast milk. Following 300- and 640-mg oral doses in six patients, the drug was detectable in milk up to 23 hours after a dose with concentrations ranging from trace to 2.2 mcg/mL (12). No adverse effects were reported in the nursing infants. Patients at risk for glucose-6-phosphate dehydrogenase deficiency should not be breastfed until this disease can be ruled out. The American Academy of Pediatrics classifies quinine as compatible with breastfeeding (13).

QUINUPRISTIN/DALFOPRISTIN

Antibiotic

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential
Toxicity

PREGNANCY SUMMARY

No reports describing the use of quinupristin/dalfopristin in human pregnancy have been located. The drug does not cause teratogenicity or embryo–fetal toxicity in experimental animals. However, in pregnant rats the antibiotic combination may not reach the embryo or fetus in significant amounts. Placental passage in humans has not been studied. Because the indication for the combination involves potentially life-threatening infections, the maternal benefit of therapy appears to far outweigh the unknown embryo or fetal risk.

FETAL RISK SUMMARY

The semisynthetic pristinamycin derivatives quinupristin/dalfopristin are streptogramin antibacterial agents that are combined in a ratio of 30:70 (weight/weight). The antibacterial combination is indicated for the treatment of vancomycin-resistant *Enterococcus faecium*. It also is active against *Staphylococcus aureus* and *Streptococcus pyogenes*. Depending on the bacterium, the combination exhibits both bacteriostatic and bactericidal action. Although quinupristin and dalfopristin are the main active components circulating in the plasma, both agents are converted to several active metabolites (1).

In reproduction studies with rats, no adverse effects on fertility, or perinatal/postnatal development were observed with the combination at doses up to approximately 0.4 times the human dose based on BSA (HD). In addition, no evidence of impaired fertility or fetal harm was observed in pregnant mice, rats, and rabbits at approximately 0.5, 2.5, and 0.5 times the HD, respectively (1). In four genetic toxicity assays, the results with the combination and the individual antibacterial agents were negative. In a fifth test (Chinese hamster

ovary cell chromosome aberration assay), dalfopristin was associated with structural chromosome aberrations but the combination and quinupristin were not (1).

It is not known whether quinupristin or dalfopristin crosses the human placenta to the fetus. Quinupristin is a combination of three peptide macrolactones in which the main component (>88%) has a molecular weight of about 1022. Dalfopristin has a molecular weight of about 691 (1). It is possible, therefore, that both agents and/or their metabolites could cross to the embryo and fetus. In a study with rats, the combination did not cross the placenta in significant amounts (2). Other than the fact that the antibiotic was given on gestation day 17, specific data, such as the dosage and amount crossing the placenta, were lacking.

BREASTFEEDING SUMMARY

The use of quinupristin/dalfopristin during human lactation has not been reported. The relatively high molecular weights for the two components (about 1022 and 691, respectively), suggest that only small amounts, if any, will pass into human milk. A 2000 review concluded that quinupristin/dalfopristin was unlikely to pass into breast milk because of its molecular size and weakly acidic nature (3). However, if the antibiotic were present in milk it could alter the bowel flora of a nursing infant. Because of the special indication for the antibiotic (vancomycin-resistant *E. faecium*) and the potential for the development of strains resistant to quinupristin/dalfopristin, breastfeeding is not recommended.

R

RABEPRAZOLE

Gastrointestinal Agent (Antisecretory)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of rabeprazole during human pregnancy have been located. A study showing an association between in utero exposure to gastric acid-suppressing drugs and childhood allergy and asthma requires confirmation. Human pregnancy experience with three other proton pump inhibitors (PPIs) (see Lansoprazole, Omeprazole, and Pantoprazole) has not shown a causal relationship with congenital malformations. In some cases, malformations may have been missed because of the design and size of the studies. The carcinogenic and mutagenic data are a potential concern, but the absence of follow-up studies prevents a risk assessment for exposed offspring. As with all drug therapy, avoidance of rabeprazole during pregnancy, especially during the 1st trimester, is the safest course. If rabeprazole is required or if inadvertent exposure does occur early in gestation, the known risk to the embryo–fetus for congenital defects, based on animal data for rabeprazole and the published experience with other PPIs, appears to be low. Long-term follow-up of offspring exposed during gestation is warranted.

FETAL RISK SUMMARY

Rabeprazole is a PPI that blocks gastric acid secretion by a direct inhibitory effect on the gastric parietal cell (1). It is used for the treatment of duodenal ulcer, erosive or ulcerative gastroesophageal reflux disease (GERD), and the

long-term treatment of pathologic hypersecretory conditions, such as Zollinger-Ellison syndrome. Rabeprazole is in the same class of PPIs as dexlansoprazole, esomeprazole, lansoprazole, omeprazole, and pantoprazole.

Reproductive studies have been conducted in rats and rabbits with IV doses up to 13 and 8 times, respectively, the recommended human dose based on AUC (1). No evidence was found at these doses of impaired fertility or fetal harm. In male and female rats, rabeprazole caused gastric cell hyperplasia and, in female rats, gastric cell tumors, at all doses tested (1). In addition, positive results with the drug and its inactive metabolite were demonstrated in hamsters and mice with the in vitro Ames mutation assay and in some other mutagenicity tests (1).

It is not known if rabeprazole crosses the human placenta. The molecular weight (about 381 for the sodium salt) is low enough that passage to the fetus should be expected. Another PPI, omeprazole, has a similar molecular weight and chemical structure and it is known to cross the human placenta (see Omeprazole).

A population-based observational cohort study formed by linking data from three Swedish national health care registers over a 10-year period (1995–2004) was reported in 2009 (2). The main outcome measures were a diagnosis of allergic disease or a prescription for asthma or allergy medications. The drug types included in the study were gastric acid suppressors, including H₂-receptor antagonists, prostaglandins, PPIs, combinations for eradication of *Helicobacter pylori*, and drugs for peptic ulcer and GERD. Of 585,716 children, 29,490 (5.0%) met the diagnosis and 5645 (1%) had been exposed to gastric acid-suppression therapy in pregnancy. Of these children, 405 (0.07%) were treated for allergic disease. For developing allergy, the odds ratio (OR) was 1.43, 98% confidence interval (CI) 1.29–1.59, irrespective of the drug, time of exposure during pregnancy, and maternal history of allergy. For developing childhood asthma, but not other allergic diseases, the OR was 1.51, 95% CI 1.35–1.69, irrespective of the type of acid-suppressive drug and the time of exposure in pregnancy. The authors proposed three possible mechanisms for their findings: (a) exposure to increased amounts of allergens could cause sensitization to digestion labile antigens in the fetus; (b) maternal Th2 cytokine pattern could promote an allergy-prone phenotype in the fetus; and (c) maternal allergen-specific immunoglobulin E could cross the placenta and sensitize fetal immune cells to food and airborne allergens. Several limitations of the study that might have affected their findings were identified, including a general increase in childhood asthma but not necessarily an increase in allergic asthma (2). The

study requires confirmation.

A meta-analysis of PPIs in pregnancy was reported in 2009 (3). Based on 1530 exposed compared with 133,410 not-exposed pregnancies, the OR for major malformations was 1.12, 95% CI 0.86–1.45. There also was no increased risk for spontaneous abortions (OR 1.29, 95% CI 0.84–1.97) or preterm birth (OR 1.13, 95% CI 0.96–1.33) (3).

In a 2010 study from Denmark, covering the period 1996–2008, there were 840,968 live births among whom 5082 were exposed to PPIs between 4 weeks before conception and the end of the 1st trimester (4). In the exposed group there were 174 (3.4%) major malformations compared with 21,811 (2.6%) not exposed to PPIs (adjusted prevalence odds ratio [aPOR] 1.23, 95 CI 1.05–1.44). When the analysis was limited to exposure in the 1st trimester, there were 118 (3.2%) major malformations among 3651 exposed infants (aPOR 1.10, 95% CI 0.91–1.34). For exposure to rabeprazole in the 1st trimester, there were 3 (7.1%) major birth defects among 42 live births (aPOR 2.14, 95% CI 0.60–7.68; see Esomeprazole, Lansoprazole, Omeprazole, and Pantoprazole for their data). The data showed that exposure to PPIs in the 1st trimester was not associated with a significantly increased risk of major birth defects (4). An accompanying editorial discussed the strengths and weaknesses of the study (5).

In a 2012 publication, the National Birth Defects Prevention study, a multisite population-based case–control study, examined whether nausea/vomiting of pregnancy (NVP) or its treatment were associated with the most common noncardiac defects (nonsyndromic cleft lip with or without cleft palate [CL/P], cleft palate alone [CP], neural tube defects [NTDs], and hypospadias) (6). PPI exposure included esomeprazole, lansoprazole, and omeprazole. There were 4524 cases and 5859 controls. NVP was not associated with cleft palate or NTDs, but modest risk reductions were observed for CL/P and hypospadias. Increased risks were found for PPIs (N = 7) and hypospadias (adjusted OR [aOR] 4.36, 95% CI 1.21–15.81), steroids (N = 10) and hypospadias (aOR 2.87, 95% CI 1.03–7.97), and ondansetron (N = 11) and CP (aOR 2.37, 95% CI 1.18–4.76) (6).

Another 2012 study, using the Danish nationwide registries, evaluated the risk of hypospadias after exposure to PPIs during the 1st trimester and throughout gestation (7). The study period, 1997 through 2009, included all liveborn boys that totaled 430,569 of whom 2926 were exposed to maternal PPI use. Hypospadias was diagnosed in 20 (0.7%) exposed boys, whereas 2683 (0.6%) of the nonexposed had hypospadias (adjusted prevalence ratio

[aPR] 1.1, 95% CI 0.7–1.7). For the 5227 boys exposed throughout pregnancy, 32 (0.6%) had hypospadias (PR 1.0, 95% CI 0.7–1.4). When the analysis was restricted to mothers with 2 or more PPI prescriptions, the aPR of overall hypospadias was 1.7, 95% CI 0.9–3.3 and 1.6, 95% CI 0.7–3.9 for omeprazole. The authors concluded that PPIs were not associated with hypospadias (7).

Several reports and reviews describing the use of PPIs during human pregnancy have observed no increased risk of developmental toxicity (see Lansoprazole, Omeprazole, and Pantoprazole).

BREASTFEEDING SUMMARY

No reports describing the use of rabeprazole during human lactation have been located. The molecular weight (about 381 for the sodium salt) suggests that the drug will be excreted into breast milk. Because of the positive carcinogenic tests and the potential for suppression of gastric acid secretion in the nursing infant, the use of rabeprazole during lactation should probably be avoided until clinical data are available.

RALOXIFENE

Selective Estrogen Receptor Modulator

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of raloxifene in human pregnancy have been located, but the animal reproduction studies suggest risk. The indications for this drug suggest that human pregnancy experience is unlikely. Moreover, raloxifene is an estrogen antagonist in uterine tissue and estrogen is required to maintain pregnancy. Therefore, the drug is contraindicated in pregnancy. If a woman inadvertently becomes pregnant while taking raloxifene, she should be informed of the risk to her embryo and/or fetus.

FETAL RISK SUMMARY

Raloxifene is an estrogen agonist/antagonist that is in the benzothiophene class of selective estrogen receptor modulators. It is indicated for the treatment and prevention of osteoporosis in postmenopausal women, reduction in risk of invasive breast cancer in postmenopausal women with osteoporosis, and reduction in risk of invasive breast cancer in postmenopausal women at high risk for invasive breast cancer. Raloxifene produces estrogen-like effects on bone and lipid metabolism, while antagonizing the effects of estrogen on uterine and mammary tissue. The drug undergoes hepatic metabolism to apparently inactive metabolites. Plasma protein binding is 95% to albumin and α_1 -acid glycoprotein, and the elimination half-life after multiple doses is 32.5 hours (1).

Reproduction studies have been performed in rats and rabbits. In rats, doses that were ≥ 0.2 times the human dose based on BSA (HD) caused retarded fetal development and developmental abnormalities (wavy ribs and kidney cavitation). Doses 0.02–1.6 times the HD during gestation and lactation resulted in delayed and disrupted parturition, decreased neonatal survival, and altered physical development; sex- and age-specific reductions in growth and changes in pituitary hormone content; and decreased lymphoid compartment

size in offspring. The highest dose disrupted parturition resulting in maternal and offspring death and morbidity. In rabbits, doses that were ≥ 0.04 times the HD caused abortions and a low rate of ventricular septal defects. At ≥ 4 times the HD, hydrocephaly was observed in fetuses (1).

In a study with female rats before mating, minor delays in development of offspring without affecting viability or growth were observed (2). Raloxifene produced estrous cycle disruption in this study. When female rats were given the drug for 5 days after mating, delayed or inhibited implantation, an effect consistent with anti-estrogen administration in rodents was noted (3,4). Although pups were born up to a week late, they were morphologically and developmentally normal. Raloxifene given to pregnant rats from postimplantation until a few days before term caused impaired fetal growth. A higher dose decreased fetal viability without an increase in malformations (5,6). None of these studies compared the doses with the human dose.

In a 21-month carcinogenicity study in female mice with doses that produced systemic exposures that were 0.3–34 times the exposure in postmenopausal women taking 60 mg/day, an increased incidence of ovarian tumors, benign and malignant, were observed. In male mice, doses that were 4.7–24 times the AUC in humans were associated with an increase in testicular and prostatic tumors. Raloxifene was not genotoxic in multiple assays (1).

In fertility studies, no pregnancies resulted when daily doses ≥ 0.8 times the HD were given to male and female rats. Daily doses up to 16 times the HD had no effect on sperm production or quality, or reproductive performance in male rats. However, in female rats, daily doses that were 0.02–1.6 times the HD disrupted estrous cycles and inhibited ovulation. Doses that were ≥ 0.02 times the HD given during the preimplantation period caused delayed and disrupted embryo implantation, resulting in prolonged gestation and reduced litter size. These reproductive and developmental effects are consistent with the estrogen receptor activity of the drug (1).

It is not known whether raloxifene crosses the human placenta. The molecular weight (about 474 for the free base) and the long elimination half-life suggest that the drug will cross to the embryo–fetus. However, the high plasma protein binding might limit the exposure.

BREASTFEEDING SUMMARY

No reports describing the use of raloxifene during human lactation have been located. However, such reports are unlikely because of the drug's indications. The molecular weight (about 474 for the free base) and the long elimination

half-life (32.5 hours) suggest that the drug will be excreted into breast milk, but the high plasma protein binding (95%) might limit the exposure. However, as with other weak bases, accumulation in the relatively acidic milk may occur. Raloxifene is an estrogen antagonist in breast tissue. We agree with the manufacturer that it is contraindicated during breastfeeding.

RALTEGRAVIR

Antiviral

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of raltegravir in human pregnancy have been located. Although the animal data suggest low risk, the absence of human pregnancy experience prevents an assessment of the embryo–fetal risk. If indicated, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Raltegravir is an HIV type 1 (HIV-1) integrase strand transfer inhibitor. There are no other antiviral agents in this class. Raltegravir, in combination with other antiretroviral agents, is indicated for the treatment of HIV-1 infection in treatment-experienced adult patients who have evidence of viral replication and HIV-1 strains resistant to multiple antiretroviral agents. The drug is partially metabolized by glucuronidation. Plasma protein binding is about 83% and the apparent terminal half-life is about 9 hours (1).

Reproduction studies have been conducted in rats and rabbits. In these species, at doses producing systemic exposures up to 3–4 times the human exposure at the recommended human dose (HERHD), no treatment-related effects on embryo–fetal survival or fetal weights were observed. In pregnant rats, an exposure 3 times the HERHD caused an increased incidence of supernumerary ribs. In pregnant rabbits receiving exposures that were 3–4 times the HERHD, no treatment-related external, visceral, or skeletal changes were observed (1).

Raltegravir crosses the placenta in rats and rabbits. In rats, doses producing systemic exposures that were 3–4 times the HERHD resulted in fetal plasma concentrations that were about 1.5–2.5 times the maternal plasma at 1 and 24 hours postdose, respectively. In rabbits, a similar maternal exposure produced mean drug concentrations in fetal plasma that were 2% of the mean maternal

concentration at both 1 and 24 hours postdose (1).

It is not known if raltegravir crosses the human placenta. Although the molecular weight (about 483), moderate plasma protein binding, and terminal half-life suggest that exposure of the embryo–fetus will occur, the low lipid solubility might mitigate the amount of exposure.

The Antiretroviral Pregnancy Registry reported, for the period January 1989 through July 2009, prospective data (reported before the outcomes were known) involving 4702 live births that had been exposed during the 1st trimester to one or more antiretroviral agents (2). Congenital defects were noted in 134, a prevalence of 2.8% (95% confidence interval [CI] 2.4–3.4). In the 6100 live births with earliest exposure in the 2nd/3rd trimesters, there were 153 infants with defects (2.5%, 95% CI 2.1–2.9). The prevalence rates for the two periods did not differ significantly. There were 288 infants with birth defects among 10,803 live births with exposure anytime during pregnancy (2.7%, 95% CI 2.4–3.0). The prevalence rate did not differ significantly from the rate expected in a nonexposed population. There were 18 outcomes exposed to raltegravir (8 in the 1st trimester and 10 in the 2nd/3rd trimesters) in combination with other antiretroviral agents. There were no birth defects. In reviewing the birth defects of prospective and retrospective (pregnancies reported after the outcomes were known) registered cases, the Registry concluded that except for isolated cases of neural tube defects with efavirenz exposure in retrospective reports, there was no other pattern of anomalies (isolated or syndromic) (2). Health care professionals are encouraged to register patients exposed to raltegravir during pregnancy in the Antiviral Pregnancy Registry by calling the toll-free number 800-258-4263. (See Lamivudine for required statement.)

Two reviews, one in 1996 and the other in 1997, concluded that all women currently receiving antiretroviral therapy should continue to receive therapy during pregnancy and that treatment of the mother with monotherapy should be considered inadequate (3,4). The same conclusion was reached in a 2003 review with the added admonishment that therapy must be continuous to prevent emergence of resistant viral strains (5). In 2009, the updated U.S. Department of Health and Human Services guidelines for the use of antiretroviral agents in HIV-1 infected patients continued the recommendation that therapy, with the exception of efavirenz, should be continued during pregnancy (6). If indicated, raltegravir should not be withheld in pregnancy since the expected benefit to the HIV-positive mother outweighs the unknown risk to the fetus. Updated guidelines for the use of antiretroviral drugs to reduce perinatal HIV-1 transmission also were released in 2010 (7). Women receiving

antiretroviral therapy during pregnancy should continue the therapy but, regardless of the regimen, zidovudine administration is recommended during the intrapartum period to prevent vertical transmission of HIV to the newborn (7).

BREASTFEEDING SUMMARY

No reports describing the use of raltegravir during lactation have been located. The molecular weight (about 483), moderate plasma protein binding (about 83%), and long terminal half-life (about 9 hours) suggest that the drug will be excreted into breast milk, but the low lipid solubility might mitigate the amount of exposure. The effect on a nursing infant is unknown.

Reports on the use of raltegravir during human lactation are unlikely, however, because the antiviral agent is used in the treatment of HIV infection. HIV-1 is transmitted in milk, and in developed countries, breastfeeding is not recommended (3,4,6,8–10). In developing countries, breastfeeding is undertaken, despite the risk, because there are no affordable milk substitutes available. Until 1999, no studies had been published that examined the effect of any antiretroviral therapy on HIV-1 transmission in milk. In that year, a study involving zidovudine was published that measured a 38% reduction in vertical transmission of HIV-1 infection despite breastfeeding when compared with controls (see Zidovudine).

RAMELTEON

Hypnotic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of ramelteon in human pregnancy have been located. The drug has caused developmental toxicity in one animal species, but only at maternally toxic doses and exposures that were much higher than those used or obtained in humans. Although the animal data are reassuring, the complete lack of human pregnancy experience prevents a more-complete assessment of the embryo–fetal risk. However, long-term exposure in rodents has been associated with carcinogenic effects and this should be considered if ramelteon is used frequently in pregnancy. Infrequent or inadvertent exposure during gestation does not appear to represent a significant risk to the embryo or fetus.

FETAL RISK SUMMARY

Ramelteon is a melatonin receptor agonist with high affinity for melatonin MT₁ and MT₂ receptors. It is indicated for the treatment of insomnia characterized by difficulty with sleep onset. Other than melatonin itself (available as an orphan drug and as a nutritional supplement), there are no other hypnotic agents commercially available with this mechanism of action. Ramelteon undergoes extensive first-pass hepatic metabolism and one of the metabolites is active. About 82% of ramelteon is bound to serum proteins, primarily albumin. The elimination half-life of ramelteon is 1–2.6 hours, whereas the elimination half-life of the active metabolite is 2–5 hours (1).

Reproduction studies have been conducted in rats and rabbits. During organogenesis in rats, a dose 197 times higher than the maximum recommended human dose (MRHD) based on BSA (MRHD-BSA) was teratogenic, but this dose also caused maternal toxicity (decreased weight).

Structural defects noted in the fetuses were diaphragmatic hernia and minor anatomical variations of the skeleton (irregularly shaped scapula). At 786 times the MRHD-BSA, reductions in fetal body weight and cysts on the external genitalia were additionally observed. The no-effect levels for teratogenicity for the parent compound and its active metabolite were 1892 and 45 times, respectively, the MRHD based on AUC (MRHD-AUC). The no-effect level for pre- and postnatal development (dosing from day 6 of gestation through weaning on postpartum day 21) in the rat was 39 times the MRHD-BSA (1).

During organogenesis in rabbits, doses producing exposures of the parent compound and metabolite that were 11,862 and 99 times, respectively, the MRHD-AUC caused maternal toxicity but no fetal effects. Therefore, these exposure comparisons were the no-effect levels for teratogenicity in rabbits (1).

In 2-year studies, ramelteon demonstrated dose-related carcinogenicity in mice and rats. The drug was not mutagenic in various tests, but a chromosomal aberration assay was positive. No effects were observed in mating behavior or fertility in male rats at doses up to 786 times the MRHD-BSA. In female rats, doses 79 times the MRHD-BSA were associated with irregular estrus cycles, reductions in the number of implants, and reductions in the number of live embryos. The no-effect dose for fertility endpoints in female rats was 26 times the MRHD-BSA (1).

It is not known if ramelteon or its active metabolite crosses the human placenta. The molecular weight of ramelteon (about 259) and the elimination half-lives of ramelteon and its active metabolite suggest that exposure of the embryo–fetus to both will probably occur.

BREASTFEEDING SUMMARY

No reports describing the use of ramelteon during human lactation have been located. The molecular weight (about 259) and the elimination half-lives of ramelteon (1–2.6 hours) and its active metabolite (2–5 hours) suggest that both will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown, but sedation is a potential complication.

RAMIPRIL

Antihypertensive

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The fetal toxicity of ramipril in the 2nd and 3rd trimesters is similar to other angiotensin-converting enzyme (ACE) inhibitors. The use of this drug during the 2nd and 3rd trimesters may cause teratogenicity and severe fetal and neonatal toxicity. Fetal toxic effects may include anuria, oligohydramnios, fetal hypocalvaria, intrauterine growth restriction (IUGR), prematurity, and patent ductus arteriosus. Stillbirth or neonatal death may occur. Anuria-associated oligohydramnios may produce fetal limb contractures, craniofacial deformation, and pulmonary hypoplasia. Severe anuria and hypotension, which is resistant to both pressor agents and volume expansion, may occur in the newborn following in utero exposure. Newborn renal function and blood pressure should be closely monitored.

FETAL RISK SUMMARY

Ramipril is an ACE inhibitor. Reproduction studies in rats, rabbits, and monkeys at doses 400, 2, and 400 times, respectively, the recommended human dose based on BSA revealed no teratogenic effects (1).

It is not known if ramipril crosses the human placenta. The molecular weight (about 417) is low enough that exposure of the embryo–fetus should be expected.

A 2005 case report described the pregnancy outcome of a 33-year-old woman treated with ramipril in the first 8 weeks of an unplanned pregnancy (2). Diseases in the patient included hypertension, morbid obesity, type 2 diabetes mellitus, and hypercholesterolemia. Other drugs used by the woman were glimepiride, orlistat, thiocolchicoside (a muscle relaxant), simvastatin, metformin, ciprofloxacin, and aspirin. When pregnancy was diagnosed at 8

weeks, all medications were stopped and she was started on methyldopa and insulin. She gave birth at 38 weeks to a 3470-g female infant with Apgar scores of 5 and 7 at 1 and 5 minutes, respectively. No minor or major malformations were observed in the infant (2).

A retrospective study using pharmacy-based data from the Tennessee Medicaid program identified 209 infants, born between 1985 and 2000, who had 1st trimester exposure to ACE inhibitors (3). Infants of mothers with evidence of diabetes, either before or during pregnancy, were excluded, as were those exposed to angiotensin-receptor antagonists (ARBs), ACE inhibitors or other antihypertensives beyond the 1st trimester, and exposure to known teratogens. Two comparison groups, other antihypertensives (N = 202) and no antihypertensives (N = 29,096), were formed. The number of major birth defects in each of the three groups was 18 (8.6%), 4 (2%), and 834 (2.9%), respectively. Compared with the no-antihypertensives group, exposure to ACE inhibitors was associated with a significantly increased risk of major defects (relative risk [RR] 2.71, 95% confidence interval [CI] 1.72–4.27). When the analysis was conducted by the type of defect, the highest rates were with cardiovascular defects, 9, 2, and 294, respectively, RR 3.72, 95% CI 1.89–7.30, and with CNS defects, 3, 0, and 80, respectively, RR 4.39, 95% CI 1.37–14.02. The major defects observed in the subject group were: atrial septal defect (N = 6) (includes three with pulmonic stenosis and/or three with patent ductus arteriosus [PDA]), renal dysplasia (N = 2), PDA alone (N = 2), and one each of ventricular septal defect, spina bifida, microcephaly with eye anomaly, coloboma, hypospadias, intestinal and choanal atresia, Hirschsprung disease, and diaphragmatic hernia (3). In an accompanying editorial, it was noted that neither previous reports of 1st trimester exposure to ACE inhibitors nor the animal studies had observed an increased risk of birth defects (4). It also was noted that no mechanism for ACE inhibitor–induced teratogenicity was known. A subsequent communication raising concerns about the validity of the study in terms of adequate exclusion of diabetes, charting and coding errors in busy medical practices, and the effects of maternal obesity (5) was addressed by the investigators (6).

A 2005 case report described a 28-year-old woman with chronic renal disease and hypertension (7). She presented at 25.5 weeks' gestation and had been taking before and throughout pregnancy ramipril 50 mg/day, nifedipine 60 mg/day, atenolol 50 mg/day, and hydroxychloroquine 200 mg/day. Severe oligohydramnios was noted and estimated fetal weight was at the 15th percentile. Ramipril was stopped and the dose of atenolol was increased.

Three weeks later, the amniotic fluid volume had returned to normal (amniotic fluid index 15.3). At 30 weeks, worsening hypertension and renal function was noted and the woman gave birth by cesarean section to an 880-g female infant with Apgar scores of 8 and 9. The infant had respiratory distress, but there was no evidence of cerebral hemorrhage and her renal impairment was resolving (7).

In a 2009 case report, a 42-year-old woman with type 2 diabetes and hypertension was treated during the first 17 weeks' gestation with gliclazide 30 mg/day and ramipril 10 mg/day (8). This therapy was discontinued and replaced with insulin and methyldopa. At 36 weeks', she gave birth by cesarean section to a healthy 3200-g female infant with Apgar scores of 8 and 10. No malformations were noted and the infant was doing well at 1.5 years of age (8).

Ramipril and other ACE inhibitors are human teratogens when used in the 2nd and 3rd trimesters, producing fetal hypocalvaria and renal defects. The cause of the defects and other toxicity is probably related to fetal hypotension and decreased renal blood flow. The compromise of the fetal renal system may result in severe, and at times fatal, anuria, both in the fetus and in the newborn. Anuria-associated oligohydramnios may produce pulmonary hypoplasia, limb contractures, persistent PDA, craniofacial deformation, and neonatal death (9,10). IUGR, prematurity, and severe neonatal hypotension may also be observed. Two reviews of fetal and newborn renal function indicated that both renal perfusion and glomerular plasma flow are low during gestation and that high levels of angiotensin II may be physiologically necessary to maintain glomerular filtration at low perfusion pressures (11,12). Ramipril prevents the conversion of angiotensin I to angiotensin II and, thus, may lead to in utero renal failure. Since the primary means of removal of the drug is renal, the impairment of this system in the newborn prevents elimination of the drug resulting in prolonged hypotension. Newborn renal function and blood pressure should be closely monitored. If oligohydramnios occurs, stopping ramipril may resolve the problem but may not improve infant outcome because of irreversible fetal damage (9). In those cases in which ramipril must be used to treat the mother's disease, the lowest possible dose should be used combined with close monitoring of amniotic fluid levels and fetal well-being. Guidelines for counseling exposed pregnant patients have been published and should be of benefit to health professionals faced with this task (9,13).

The observation in Tennessee Medicaid data of an increased risk of major congenital defects after 1st trimester exposure to ACE inhibitors raises

concerns about teratogenicity that have not been seen in other studies (4). Medicaid data are a valuable tool for identifying early signals of teratogenicity, but are subject to a number of shortcomings and their findings must be considered hypotheses until confirmed by independent studies.

A 2012 review of the use of ACE inhibitors and ARBs in the 1st trimester concluded that there may be an elevated teratogenic risk, but the risk appeared to be related to other factors (14). The factors, that typically coexist with hypertension in pregnancy, included diabetes, advanced maternal age, and obesity.

BREASTFEEDING SUMMARY

No reports describing the use of ramipril during lactation have been located. The molecular weight (about 417) is low enough that excretion into breast milk should be expected. Other ACE inhibitors are excreted into breast milk and the American Academy of Pediatrics classifies them as compatible with breastfeeding (see Captopril and Enalapril).

RANIBIZUMAB

Ophthalmic

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of ranibizumab in human pregnancy have been located. There also is no animal reproduction data. The predicted amount of antibody in the systemic circulation, however, is about 90,000-fold lower than the amounts in the vitreous and is below the estimated therapeutic concentration (1). Based on this estimation, the exposure and effect on an embryo or fetus probably is nil. Thus, if a woman requires ranibizumab, it should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Ranibizumab binds to and inhibits vascular endothelial growth factor A (VEGF-A). It is a recombinant humanized immunoglobulin G1 (IgG1) kappa isotype monoclonal antibody fragment that is indicated for the treatment of neovascular (wet) age-related macular degeneration. It is in the same class as pegaptanib. Ranibizumab is administered as a once-monthly, 0.5-mg intravitreal injection. After monthly injections, the maximum ranibizumab serum concentrations are low (0.3–2.36 ng/mL) occurring about 1 day after a dose. These concentrations are less than the therapeutic levels (11–27 ng/mL) thought to be necessary to inhibit the biological activity of VEGF-A. The estimated average vitreous elimination half-life is about 9 days (1).

Reproduction, carcinogenicity, mutagenicity, and fertility studies in animals or humans have not been conducted (1).

It is not known if ranibizumab crosses the human placenta. The high molecular weight (48,000) and very low concentrations in the systemic circulation suggest that the antibody will not cross to the embryo or fetus. However, IgG crosses the placenta and so might ranibizumab.

BREASTFEEDING SUMMARY

No reports describing the use of ranibizumab during lactation have been located. Although the long plasma elimination half-life (about 9 days) favors excretion, the molecular weight (48,000) and very low plasma concentrations suggest that the antibody will not be detected in milk. However, IgG is excreted into milk. Nevertheless, even if excretion does occur it should be in clinically insignificant amounts. If a lactating woman requires ranibizumab, it should not be withheld because she is breastfeeding.

RANITIDINE

Gastrointestinal Agent (Antisecretory)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

The absence of teratogenicity or toxicity in animals and the available human pregnancy data suggest that ranitidine is not a major teratogen. Because it has no antiandrogenic activity in animals or nonpregnant humans, ranitidine may be a safer choice than cimetidine for chronic use during pregnancy. The antiandrogenic activity of cimetidine, however, has not been observed or studied following in utero exposure (see Cimetidine). Ranitidine-induced anaphylactoid shock has been reported in four laboring women. A study showing an association between in utero exposure to gastric acid-suppressing drugs and childhood allergy and asthma requires confirmation.

FETAL RISK SUMMARY

Ranitidine is a competitive, reversible inhibitor of histamine H₂-receptors (H₂ blockers) used in treatment and maintenance of patients with duodenal or gastric ulcers, pathologic hypersecretory conditions such as Zollinger-Ellison syndrome, and gastroesophageal reflux disease (GERD). The drug is partially metabolized to apparently inactive metabolites. Serum protein binding is minimal (average 15%) and the elimination half-life is 2.5–3.0 hours (1).

Reproduction studies with ranitidine in rats and rabbits at doses up to 160 times the human dose have revealed no evidence of impaired fertility or fetal harm (1–3). In contrast to the controversy surrounding cimetidine, ranitidine apparently has no antiandrogenic activity in humans (4) or in animals (5,6) (see also Cimetidine).

Consistent with the molecular weight (about 351), limited metabolism, and elimination half-life, ranitidine crosses the human placenta. At term, mean fetal:maternal ratios after 50 mg IV and 150 mg orally were 0.9 and 0.38, respectively (7–9). An in vitro study also documented transfer in term human

placentas (10).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 516 newborns had been exposed to ranitidine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 23 (4.5%) major birth defects were observed (22 expected). Specific data were available for six defect categories, including (observed/expected) 6/5 cardiovascular defects, 1/1 oral clefts, 1/0.5 spina bifida, 1/1 polydactyly, 0/1 limb reduction defects, and 1/1 hypospadias. These data do not support an association between the drug and congenital defects.

Ranitidine has been used alone and in combination with antacids to prevent gastric acid aspiration (Mendelson's syndrome) before vaginal delivery or cesarean section (7–9,11–14). No effect was observed in the frequency and strength of uterine contractions, in fetal heart rate pattern, or in Apgar scores (7). Neonatal gastric acidity was not affected at 24 hours. No problems in the newborn attributable to ranitidine were reported in these studies.

Ranitidine has been studied for its effectiveness in alleviating the symptoms of heartburn during pregnancy (15–17). A twice-daily dosage regimen of ranitidine was effective for this indication (15–17), including in those cases resistant to antacids alone (17). Ranitidine was also effective in controlling gastric acid secretion in pregnant women with Zollinger-Ellison syndrome (18).

In a 1991 report, 23 women were exposed in the 1st trimester to ranitidine (N = 13), cimetidine (N = 9), or both (N = 1) (19). The pregnancy outcomes were 2 spontaneous abortions (SABs), 2 elective abortions (EABs), 18 normal births, and 1 infant with a large hemangioma of the upper eye lid (removed without incidence). The outcomes suggested that the agents were not teratogenic (19).

A 1996 prospective cohort study compared the pregnancy outcomes of 178 women who were exposed during pregnancy to H₂ blockers with 178 controls matched for maternal age, smoking, and heavy alcohol consumption (20). All of the women had contacted a teratology information service concerning gestational exposure to H₂ blockers (subjects) or nonteratogenic or nonfetotoxic agents (controls). Among subjects (mean daily dose in parentheses), 71% took ranitidine (258 mg), 16% cimetidine (487 mg), 8% famotidine (32 mg), and 5% nizatidine (283 mg). There were no significant differences between the outcomes of subjects and controls in terms of live births, SABs, EABs, gestational age at birth, delivery method, birth weight, infants small for gestational age, or major malformations. Among subjects,

there were 3 birth defects (2.1%) among the 142 exposed to H₂ blockers in the 1st trimester: one each of atrial septal defect, ventricular septal defect, and tetralogy of Fallot. There were 5 birth defects (3.0%) among the 165 exposed anytime during pregnancy. For controls, the rates of defects were 3.5% (1st trimester) and 3.1% (anytime). There were also no differences between the groups in neonatal health problems and developmental milestones, but two children (one subject and one control) were diagnosed as developmentally delayed. The investigators concluded that 1st trimester exposure to H₂ blockers did not represent a major teratogenic risk (20).

Data from the Swedish Medical Birth Registry were presented in 1998 (21). A total of 553 infants (6 sets of twins) were delivered from 547 women who had used acid-suppressing drugs early in pregnancy. The odds ratio (OR) for malformations after H₂ blockers was 0.86, 95% confidence interval (CI) 0.33–2.23. Of the 19 infants with birth defects, 9 had been exposed to H₂ blockers, 1 of whom was also exposed to omeprazole. Ranitidine was the only acid-suppressing drug exposure in 156 infants. Twenty other offspring were exposed in utero to ranitidine combined either with famotidine (2 infants) or with omeprazole (18 infants). Seven infants with birth defects were exposed to ranitidine: six where ranitidine was the only acid-suppressing agent used and one exposed to ranitidine combined with omeprazole. The defects were cerebral arteriovenous malformation, unspecified cardiac defect, hydronephrosis, undescended testicle, hypospadias, and unstable hip. Hypospadias was also observed in a newborn exposed to a combination of ranitidine and omeprazole (see Omeprazole for additional details of this study) (21).

Two databases, one from England and the other from Italy, were combined for a study published in 1999 that was designed to assess the incidence of congenital malformations in women who had received a prescription during the 1st trimester for an acid-suppressing drug (ranitidine, cimetidine, and omeprazole) (22). Nonexposed women were selected from the same databases to form a control group. SABs and EABs (except two cases for anomalies that were grouped with stillbirths) were excluded from the analysis. Stillbirths were defined as any pregnancy loss occurring at 28 weeks' gestation or later. Ranitidine was taken in 322 pregnancies, resulting in 330 live births (29 premature), 2 stillbirths, and 1 neonatal death. Twenty (6.1%) of the newborns had a congenital malformation (shown by system): CNS (spina bifida/hydrocephaly), craniofacial (cleft palate only; asymmetric skull/plagiocephaly; tongue tie), eye (Duane's eye syndrome), cardiac (septal

defect; anomaly of cardiac valve), musculoskeletal (dysplastic hip/dislocation/clicking hip, N = 3; syndactyly; sacral sinus), genital and urinary (undescended testes, N = 2; congenital hydrocele/inguinal hernia, N = 2; ovarian cyst), multiple (pyloric stenosis and talipes equinovarus), and two genetic anomalies (Hallerman-Streiff and Down's syndromes). In addition, two newborns were small for gestational age and nine had a small head circumference for gestational age. In comparison, the outcomes of 1547 nonexposed pregnancies included 1560 live births (115 premature), 15 stillbirths (includes 2 EABs for anomalies), and 10 neonatal deaths. Sixty-four (4.1%) of the newborns had malformations involving the following: CNS (N = 2), head/face (N = 13), eye (N = 2), heart (N = 7), muscle/skeletal (N = 13), genital/urinary (N = 18), gastrointestinal (N = 2), and those of polyformation (N = 3), or known genetic defects (N = 4). There were 21 newborns that were small for gestational age and 78 had a small head circumference for gestational age. The relative risk of malformation (adjusted for mother's age and prematurity) associated with ranitidine was 1.5 (95% CI 0.9–2.6), with cimetidine 1.3 (95% CI 0.7–2.6), and with omeprazole 0.9 (95% CI 0.4–2.4) (22).

A population-based observational cohort study formed by linking data from three Swedish national health care registers over a 10-year period (1995–2004) was reported in 2009 (23). The main outcome measures were a diagnosis of allergic disease or a prescription for asthma or allergy medications. The drug types included in the study were gastric acid suppressors, including H₂ blockers, prostaglandins, proton pump inhibitors, combinations for eradication of *Helicobacter pylori*, and drugs for peptic ulcer and GERD. Of 585,716 children, 29,490 (5.0%) met the diagnosis and 5645 (1%) had been exposed to gastric acid-suppression therapy in pregnancy. Of these children, 405 (0.07%) were treated for allergic disease. For developing allergy, the OR was 1.43, 98% CI 1.29–1.59, irrespective of the drug, time of exposure during pregnancy, and maternal history of allergy. For developing childhood asthma, but not other allergic diseases, the OR was 1.51, 95% CI 1.35–1.69, irrespective of the type of acid-suppressive drug and the time of exposure in pregnancy. The authors proposed three possible mechanisms for their findings: (a) exposure to increased amounts of allergens could cause sensitization to digestion labile antigens in the fetus; (b) the maternal Th2 cytokine pattern could promote an allergy-prone phenotype in the fetus; and (c) maternal allergen-specific immunoglobulin could cross the placenta and sensitize fetal immune cells to food and airborne allergens. Several limitations

of the study that might have affected their findings were identified, including a general increase in childhood asthma but not necessarily an increase in allergic asthma (23). The study requires confirmation.

Severe anaphylactoid reactions were observed in four women who had received IV or oral ranitidine during labor (24–27). Fetal bradycardia was observed in two cases, but the heart rates normalized before birth. The two cases as well as a third newborn had normal Apgar scores and did well (24–26). An emergency cesarean section was required in the fourth case when the mother developed severe systolic hypotension and the fetal heart rate decreased to 70 beats/minute (27). Apgar scores in the newborn were 1 and 4 at 1 and 5 minutes, respectively. The female infant had seizure-like movement in the NICU and was discharged home on day 19 on phenobarbital. At 8 months of age, the baby was still receiving phenobarbital but no seizures or physical or developmental abnormalities were noted (27).

A 2005 study evaluated the outcomes of 553 pregnancies after exposure to H₂ blockers, 501 (91%) in the 1st trimester (28). The data were collected by the European Network of Teratology Information Services (ENTIS). The agents and number of cases were ranitidine 335, cimetidine 113, famotidine 75, nizatidine 15, and roxatidine 15. No increase in the number of major malformations were noted (28).

Four reviews on the treatment of GERD have concluded that H₂ blockers, with the possible exception of nizatidine, could be used in pregnancy with relative safety (29–32).

A 2009 meta-analysis of published studies was conducted to assess the safety of H₂ blockers that were used in 2398 pregnancies (33). Compared with 119,892 nonexposed pregnancies, the OR for congenital malformations was 1.14 (95% CI 0.89–1.45), whereas the ORs and 95% CIs for SABs, preterm birth, and small for gestational age were 0.62 (0.36–1.05), 1.17 (0.94–1.147), and 0.28 (0.06–1.22), respectively. The authors concluded that H₂ blockers could be used safely in pregnancy (33).

A 2010 study from Israel identified 1148 infants exposed in the 1st trimester to H₂ blockers (34). No association with congenital malformations was found (OR 1.03, 95% CI 0.80–1.32). Moreover, no association was found with EABs, perinatal mortality, premature delivery, low birth weight, or low Apgar scores (34).

BREASTFEEDING SUMMARY

Following a single oral dose of 150 mg in six subjects, ranitidine milk concentrations increased with time, producing mean milk:plasma ratios at 2, 4, and 6 hours of 1.9, 2.8, and 6.7, respectively (35).

Markedly different results were observed in 1985 study (36). Ranitidine milk and blood concentrations were determined in a woman breastfeeding her healthy 54-day-old infant. The woman had taken four 150-mg (2.44 mg/kg) doses at 12-hour intervals immediately before sampling. Pooled milk/maternal blood concentrations (ng/mL) (milk:serum ratio) were: predose 993/53 (18.73), 1.5 hours postdose 722/106 (6.81), 5.5 hours postdose 2610/309 (8.44), and 1569/66 (23.77). The data suggested that steady-state conditions had not yet been achieved. No adverse effects in the nursing infant were noted (36).

The effects from long-term exposure to the above concentrations on the nursing infant are not known. Ranitidine decreases gastric acidity, but this effect has not been studied in nursing infants. However, cimetidine, an agent with similar activity, is classified as compatible during breastfeeding by the American Academy of Pediatrics (see Cimetidine).

RANOLAZINE

Antianginal Agent

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of ranolazine in human pregnancy have been located. The animal data suggest risk, but the absence of human pregnancy experience prevents a complete assessment of the embryo–fetal risk.

FETAL RISK SUMMARY

Ranolazine is an oral racemic mixture that has anti-ischemic and antianginal effects but is not a vasodilator. It is indicated for the treatment of chronic angina. There are no other agents in the cardiovascular subclass. The drug undergoes extensive metabolism. The activity of the metabolites has not been well characterized. Ranolazine is moderately bound (about 62%) to plasma proteins. The apparent terminal half-life is 7 hours (1).

Reproduction studies have been conducted in rats and rabbits. In pregnant rats, a dose 2 times the maximum recommended human dose based on BSA (MRHD) caused an increased incidence of misshapen sternebrae and reduced ossification of pelvic and cranial bones. In pregnant rabbits, a dose 1.5 times the MRHD was associated with reduced ossification of sternebrae. The doses in both species were associated with an increased maternal mortality rate (1).

No evidence of carcinogenic potential was found with long-term studies in mice and rats. The maximally tolerated doses in these species were 0.1 and 0.8 times the MRHD. There also was no evidence of genotoxicity in multiple assays (1). (No information was provided regarding effects on fertility.)

It is not known if ranolazine crosses the human placenta. The molecular weight (about 428), moderate plasma protein binding, and terminal half-life suggest that exposure of the embryo–fetus is likely.

BREASTFEEDING SUMMARY

No reports describing the use of ranolazine during human lactation have been located. The molecular weight (about 428), moderate (about 62%) plasma protein binding, and terminal half-life (7 hours) suggest that the drug will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown. In adults, the drug is extensively metabolized in the intestine and liver, but this may not occur in infants because of the relative immaturity of metabolizing systems. In adults, the most common (>4%) adverse effects were dizziness, headache, constipation, and nausea (1).

RASAGILINE

Antiparkinson Agent

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of rasagiline in human pregnancy have been located. The animal reproduction data when rasagiline was used alone or in combination with levodopa/carbidopa suggest risk, but the absence of human pregnancy experience prevents an assessment of the embryo–fetal risk. However, monoamine oxidase (MAO) inhibitors are characterized by interactions with several drugs, including some agents used for general anesthesia, and tyramine-rich foods, beverages, dietary supplements, or amines from over-the-counter medications. These interactions can result in severe, sometimes fatal, hypertension. Because this toxicity would have severe consequences for a woman and her pregnancy, rasagiline is best avoided during gestation.

FETAL RISK SUMMARY

Rasagiline is an oral irreversible MAO type B (MAO-B) inhibitor. Inhibition of MAO-B lasts at least 1 week after the last dose. Rasagiline is indicated for treatment of the signs and symptoms of idiopathic Parkinson's disease as initial monotherapy and as adjunctive therapy to levodopa. (See also Levodopa.) It is in the same class as selegiline. (See Selegiline.) The mean elimination half-life at steady state is 3 hours but there is no correlation between the half-life and pharmacologic effect as inhibition of MAO-B is irreversible. Plasma protein binding, primarily to albumin, is 88%–94%. Rasagiline undergoes nearly complete metabolism in the liver before excretion (1).

Reproduction studies with rasagiline, either alone or in combination with levodopa/carbidopa, have been conducted in rats and rabbits. Pregnant rats given daily doses from the beginning of organogenesis to day 20 postpartum

that produced plasma concentrations 10 and 16 times the maximum recommended human dose (MRHD) based on AUC (MRHD-AUC) caused decreased offspring survival and body weight. The plasma concentration for the no-effect dose was not determined, but it was one-third the lowest dose causing fetal toxicity and was equal to the MRHD based on BSA (MRHD-BSA). In another study, pregnant rats were given the same doses as above combined with levodopa/carbidopa throughout organogenesis. An increased incidence of wavy ribs in fetuses was observed at a dose producing exposures that were 8 times the MRHD-AUC for rasagiline and equal to the MRHD-BSA for levodopa/carbidopa (1).

Pregnant rabbits given daily doses producing exposures that were about ≥ 7 times the MRHD-AUC throughout organogenesis in combination with levodopa/carbidopa had an increase in fetal death. There was an increase in cardiovascular defects when levodopa/carbidopa was given alone at daily doses that were equal to the MRHD-BSA. This teratogenicity occurred to a greater extent when rasagiline, at exposures that were 1–13 times the MRHD-AUC, was given in combination with levodopa/carbidopa (1).

Carcinogenicity studies were conducted for 2 years in mice and rats. In mice, there was an increase in lung tumors (combined adenomas/carcinomas). The no-effect dose was about 5 times the MRHD-AUC. In rats, there was no increase in tumors at any dose tested. The highest doses tested in male and female rats were about 33 and 260 times, respectively, the MRHD-AUC. Rasagiline was mutagenic and/or clastogenic in some assays but negative in others. No effect was observed on mating performance or fertility in male and female rats with doses producing exposures that were ≤ 30 times the MRHD-AUC.

It is not known if rasagiline crosses the human placenta. The molecular weight (about 267 for the mesylate salt), protein binding, and elimination half-life suggest that the drug will cross to the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use of rasagiline during human lactation have been located. The molecular weight (about 267 for the mesylate salt), protein binding (88%–94%), and elimination half-life (3 hours) suggest that the drug will be excreted into breast milk. Rasagiline inhibits prolactin and may inhibit milk secretion (1). Nevertheless, the potential for severe adverse effects in a nursing infant suggest that women taking rasagiline should not breastfeed.

RASBURICASE

Antineoplastic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of rasburicase in human pregnancy have been located. The agent caused significant developmental toxicity in one animal species at a dose that was ≥ 10 times the recommended human dose (RHD) and in a second species at a much higher dose, but both comparisons to the human dose appeared to be based on body weight. Moreover, a no-observed-effect-level (NOEL) for such toxicity was not established in either species. The absence of human data prevents a complete assessment of the embryo–fetal risk but, if indicated, the maternal benefit appears to outweigh the unknown risk. If possible, avoiding the 1st trimester use would be preferred.

FETAL RISK SUMMARY

Rasburicase, a tetrameric protein with identical subunits, is a recombinant urate-oxidase produced from a *Saccharomyces cerevisiae* strain. It is in the same antineoplastic subclass of antimetabolites that reduce uric acid levels as allopurinol. Rasburicase is indicated for the initial management of plasma uric acid levels in pediatric and adult patients with leukemia, lymphoma, and solid tumor malignancies who are receiving anti-cancer therapy expected to result in tumor lysis and subsequent elevation of plasma uric acid. The drug is given as a 30-minute IV infusion daily for up to 5 days. The mean terminal half-life is 15.7–22.5 hours (1).

Reproduction studies have been conducted in rats and rabbits. In rats, doses that were about 250 times the RHD (assumed to be based on body weight) were associated with multiple heart and great vessel malformations. In rabbits during organogenesis, doses that were about 10–100 times the RHD resulted in maternal toxicity (weight loss and mortality), decreases in uterine weights

and viable fetuses, and increased fetal resorptions, preimplantation and postimplantation losses, and abortions. Decreased fetal body weights and malformations involving the heart and great vessel malformations also were observed at all dose levels (1).

Studies for carcinogenicity potential have not been conducted, but the drug was not mutagenic in multiple assays. No effects on reproductive performance were observed in male and female rats at a dose 50 times the RHD (1).

It is not known if rasburicase crosses the human placenta. The molecular weight (about 34,000) suggests that clinically significant amounts will not cross, but the dosing regimen and the long terminal half-life will place the agent at the maternal–fetal interface for prolonged periods.

BREASTFEEDING SUMMARY

No reports describing the use of rasburicase during human lactation have been located. The molecular weight (about 34,000) suggests that clinically significant amounts will not be excreted into breast milk. However, the dosing regimen (daily IV infusions for 5 days) and the long terminal half-life (15.7–22.5 hours) indicate that the drug will be in the maternal plasma and available for excretion for prolonged periods. The effects of this potential exposure on a nursing infant, as well as the amount of systemic absorption, are unknown. Serious toxicities, such as anaphylaxis, hemolysis, and methemoglobinemia have been reported in patients treated with rasburicase.

RASPBERRY LEAF

Herb

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Raspberry leaf tea is one of the most common tonics used by pregnant women. Although it appears to have little if any toxicity, its efficacy as a uterine tonic to shorten labor is questionable. One source recommended that pregnant women should not use the tea without guidance of a health care professional because it can cause uterine contractions and might have estrogenic effects (1). However, because of the absence of reports of embryo, fetal, or newborn harm, if a woman chooses to use it in pregnancy, there is no reason to counsel against it.

FETAL RISK SUMMARY

Raspberry leaf, also known as red raspberry, is derived from the plant, *Rubus idaeus* (Eurasian) or *R. strigosus* (North American). The principal compounds isolated from the leaves are tannins and flavonoids. Raspberry leaf tea has been used for diarrhea and as mouthwash because of its astringent properties. It also is used as a uterine tonic to stimulate labor. The typical doses taken as a tea are 1.5–2.4 g/day. Although the information is nearly nonexistent, there is no evidence that raspberry tea is toxic (2). One review considered the chemicals in raspberry to be so common that the need for caution was no different from that of foods consumed in pregnancy (3).

Raspberry tea is used by thousands of women during pregnancy (3–6). Raspberry leaf also is combined with other herbs to make teas promoted for pregnancy (7). One popular product recommends it for a “healthy” pregnancy and to “tone the uterine muscles and prepare the womb for childbirth.” The manufacturer of the product recommends its use throughout pregnancy and in first few postpartum weeks. The tea is a combination of the leaves of raspberry, spearmint, strawberry, lemongrass, alfalfa, lemon verbena, rose hip, and fennel seed (7).

Raspberry tea is often prescribed by nurse-midwives. The most common uses of the tea during gestation are to treat nausea and vomiting (3–5) and to stimulate labor (5,6). A national survey found that among nurse-midwives who used herbal preparations to stimulate labor, 45% used black cohosh, 60% used evening primrose oil, 63% used raspberry leaf, and 90% used castor oil (6). No pregnancy complications were reported with the free use of raspberry leaf tea in late pregnancy. Although the dose recommended by the nurse-midwives was not cited, the authors cited a common dosage of 2 g dried leaves steeped in 240 mL boiling water for 5 minutes (6).

A 2001 report described a double-blind, randomized, placebo-controlled trial conducted to determine if raspberry leaf tablets (1.2 g/tablet) were effective and safe in terms of labor and birth outcomes (8). Subjects (N = 96) and controls (N = 96) were given 2 tablets/day of either raspberry leaf or placebo from 32 weeks' gestation until labor. There were no significant differences between the groups in the length of labor or the stages of labor, the mode of delivery, admissions to the neonatal intensive care unit, or birth outcomes, including Apgar scores and birth weight (8).

BREASTFEEDING SUMMARY

There are no reports describing the use of raspberry leaf during lactation. The near absence of reported toxicity with raspberry leaf tea suggests that the tea can be safely consumed during lactation. The risk to a nursing infant appears to be nil.

REGORAFENIB

Antineoplastic (Multikinase Inhibitor)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of regorafenib in human pregnancy have been located. The animal data suggest but the absence of human pregnancy experience prevents a more complete assessment of the embryo–fetal risk. However, the mechanism of action suggests that the drug can cause fetal harm. The manufacturer recommends that women of reproductive potential should take effective contraception during treatment and up to 2 months after completion of therapy (1). If a woman takes this drug during pregnancy, she should be informed of the potential harm to her embryo and/or fetus.

FETAL RISK SUMMARY

Regorafenib is an inhibitor of multiple membrane-bound and intracellular kinases involved in normal cellular functions and in pathologic processes such as oncogenesis, tumor angiogenesis, and maintenance of the tumor microenvironment. There are several other agents in the same subclass (see Appendix). Regorafenib is indicated for the treatment of patients with metastatic colorectal cancer who have been previously treated with fluoropyrimidine-, oxaliplatin-, and irinotecan-based chemotherapy. Regorafenib has two major active metabolites, M-2 and M-5. The parent drug and its two active metabolites are highly bound (>99%) to human plasma proteins, whereas the mean elimination half-lives and ranges are 28 hours (14–58 hours), 25 hours (14–32 hours), and 51 hours (32–70 hours), respectively (1).

Reproduction studies have been conducted in rats and rabbits. In rats, 100% resorption of the litter was observed at about 6% of the recommended human dose (RHD) based on BSA (RHD-BSA) and in rabbits, at about 25% of the RHD based on AUC (RHD-AUC). In rats during organogenesis, doses that were about 5%–11% of the RHD-BSA or about 10% of the RHD-AUC caused

dose-dependent delayed ossification, skeletal malformations, cleft palate, enlarged fontanelle, cardiovascular malformations, external abnormalities, diaphragmatic hernia, and dilation of the renal pelvis. In rabbits during organogenesis, doses that were about 7%–15% of the RHD-AUC caused ventricular septal defects and dose-dependent increases in the incidence of additional cardiovascular malformations, skeletal anomalies, and urinary system adverse effects (missing kidney/ureter; small, deformed and malpositioned kidney; and hydronephrosis). In two rabbit embryo–fetal toxicity studies, there was a dose-dependent decrease in the number of viable male fetuses (1).

Carcinogenicity studies with regorafenib have not been conducted. The parent drug was not genotoxic in assays but the metabolite, M-2, was positive for clastogenicity, causing chromosome aberration in Chinese hamster cells. Fertility studies have not been conducted but the toxicity observed in male and female rats and dogs, at doses similar to or less than the RHD-AUC, suggest that the drug will adversely affect human fertility. In male rats and dogs, the toxic effects included tubular atrophy and degeneration in the testes, atrophy in the seminal vesicle, and cellular debris and oligospermia in the epididymides. In female rats and dogs, necrotic corpora lutea in the ovaries was observed (1).

It is not known if regorafenib or its two active metabolites cross the human placenta. The molecular weight of the parent drug (about 483 for the nonhydrated molecule) and the long elimination half-lives for the parent drug and active metabolites suggest that they will cross to the embryo–fetus, but the high plasma protein binding might limit the exposure.

BREASTFEEDING SUMMARY

No reports describing the use of regorafenib during human lactation have been located. The molecular weight of the parent drug (about 483 for the nonhydrated molecule) and the long elimination half-lives for the parent drug (28 hours) and two active metabolites (25 and 51 hours) suggest that they will be excreted into breast milk. However, the high plasma protein binding for the three agents (all >99%) might limit the amount in milk. Nevertheless, the severe toxicity that has been observed with regorafenib in adults suggest that a woman taking this drug should not breastfeed.

REMIFENTANIL

Narcotic Agonist Analgesic

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 3rd Trimester

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Remifentanil was not teratogenic or toxic in animals, but the absence of reports in early gestation prevents an assessment of its risk to the human fetus. However, narcotic analgesics are not considered to be human teratogens. Neonatal respiratory depression and sedation immediately after birth are potential complications of all narcotics when administered to a woman during labor. The short duration of remifentanil and its apparent rapid metabolism by the fetus may lessen these potential effects, but additional studies are needed to demonstrate this benefit. If remifentanil is used in pregnancy, health care professionals are encouraged to call the toll free number 800-670-6126 for information about patient enrollment in the Motherisk study.

FETAL RISK SUMMARY

Remifentanil is a rapid-onset, short-acting, synthetic mu-opioid agonist analgesic that is administered IV, in combination with other agents, for the induction and maintenance of general anesthesia. The elimination half-life is approximately 3–10 minutes. Because remifentanil is extensively metabolized by nonspecific esterases, not plasma cholinesterase (pseudocholinesterase), a normal duration of action is expected in patients with atypical cholinesterase. Further, remifentanil is not appreciably metabolized by the liver or lung (1), as are other opioid analgesics.

Fertility studies in male and female rats were conducted with IV doses 40 and 80 times, respectively, the maximum recommended human dose based on BSA (MRHD) (1). Reduced fertility was observed in male rats when the dose was administered daily for more than 70 days. In contrast, no effect was

observed on the fertility of female rats dosed daily for at least 15 days before mating. Reproduction studies conducted in pregnant rats and rabbits at doses up to 400 and 125 times, respectively, the MRHD revealed no evidence of teratogenicity (1). The timing of the exposures was not specified. When remifentanil was given to rats throughout late gestation and lactation at a dose about 400 times the MRHD, no significant effect on the survival, development, or reproductive performance was observed in the exposed offspring. The drug crosses the placenta in pregnant rats and rabbits (1).

Consistent with its molecular weight (about 413) and high lipid solubility, remifentanil crosses the human placenta (1–3). The manufacturer reported that in human clinical trials, the average maternal concentration was approximately twice the levels observed in the fetus (1). However, in some cases, the maternal:fetal ratios were similar. The umbilical artery:umbilical vein (UA:UV) ratio, however, was approximately 0.30 suggesting metabolism of the drug in the fetus (1).

In an abstract (2) and a full report (3), information was presented on the placental transfer of remifentanil in 16 healthy women who were delivered by nonemergent cesarean section. Anesthesia appropriate for cesarean section was established with a lidocaine/epinephrine epidural before starting an IV infusion of remifentanil (0.1 mcg/kg/minute) that was continued until skin closure. The mean umbilical vein:maternal artery (UV:MA) and UA:UV ratios for remifentanil were 0.88 and 0.29, respectively (3). For remifentanil acid, the inactive primary metabolite, the mean UV:MA and UA:UV ratios were 0.56 and 1.23, respectively (3). These results suggested to the investigators that the narcotic rapidly crossed the placenta and was metabolized and redistributed in the fetus. The mean Apgar scores (ranges in parentheses) at 1, 5, 10, and 20 minutes were 8 (4–9), 9 (8–9), 9 (9–10), and 9 (9–10), respectively. Neurobehavioral and Adaptive Capacity Scores noted at 30 and 60 minutes were 37 (range 35–39) and 35 (range 34–39), respectively, all within normal limits. Although there were no adverse effects in the newborns, sedative and respiratory depressant effects were noted in the mothers (3).

A 1998 report described the case of a woman at term with mixed mitral valve disease, marked obesity, asthma, and preeclampsia (4). After receiving a bupivacaine/fentanyl epidural, she was delivered by an emergency cesarean section under general anesthesia. Rapid-sequence induction was conducted with remifentanil (2 mcg/kg), etomidate (20 mg), and succinylcholine (100 mg). A male infant (birth weight not given) was delivered 3 minutes after induction of anesthesia. The Apgar scores were 6, 8, and 8 at 1, 5, and 10 minutes,

respectively. No signs of respiratory depression were observed (4).

A 30-year-old woman was delivered by cesarean section at 36 weeks' because of the need for surgical resection of a right acoustic neuroma (5). Remifentanil (0.1–0.2 mcg/kg/minute) was infused for induction of general anesthesia followed by propofol and succinylcholine. A healthy 2970-g female infant was delivered 7 minutes after the start of remifentanil. Apgar scores were 7 and 8 at 1 and 5 minutes, respectively. Although there were no clinical signs of respiratory distress, her initial room air oxygen saturation was 85%–91% and she was placed in a 40% oxygen tent for 1 hour. She was discharged home at 3 days of age (5).

A 23-year-old woman at 37 weeks' gestation whose condition was complicated by a recurrent aortic coarctation with 50% narrowing of the aortic arch was delivered by an elective cesarean section (6). Remifentanil infusion up to 0.2 mcg/kg/minute was combined with etomidate, succinylcholine, and isoflurane. Delivery took place 7 minutes after induction of anesthesia. The newborn (sex and weight not specified) had Apgar scores of 6 and 9 at 1 and 5 minutes, respectively. The infant did well after birth with no need for naloxone or evidence of respiratory distress (6).

Three studies have been located that describe the use of remifentanil for labor pain (7–9). In one study, four laboring women with singleton term pregnancies were treated with remifentanil either from a patient-controlled analgesia (PCA) pump (0.25 mcg/kg, 5-minute lockout duration) or with IV bolus doses (0.25–0.50 mcg/kg every 2 minutes as needed) (7). Failure of the pain to respond to increased doses and adverse effects (sedation, oxygen desaturation episodes, respiratory depression, nausea and vomiting, and pruritus) resulted in removal of the patients from the study. Healthy newborns (sex and weight not specified) were delivered 4–6 hours after discontinuance of remifentanil. All had Apgar scores of 9 or 10 (7). A study published in 2000 described two women in labor who were treated with remifentanil administered by a PCA pump (8). The on-demand dose was 20 mcg with a 3-minute lockout duration (no basal infusion). The total doses administered during labor were 740 and 940 mcg. No adverse effects attributable to the analgesic were observed in the newborns. The effects of remifentanil PCA on 42 laboring women were described in a 2001 abstract (9). The technique used was thought to be safe for the mother and newborn (9).

A 1999 study concluded that remifentanil-based general anesthesia (combined with propofol or isoflurane but without nitrous oxide) was a suitable alternative to sedation (induced by midazolam, diazepam, or propofol) for

oocyte retrieval in an in vitro fertilization program (10). In a comparison between the general anesthesia and sedation groups, no significant differences were observed in the number of fertilized oocytes, or in the cleavage and pregnancy rates. However, the number of collected oocytes was significantly higher in the general anesthesia group (10).

BREASTFEEDING SUMMARY

No reports describing the use of remifentanil in a lactating woman have been located. The molecular weight (about 413) and high lipid solubility suggest that it will be excreted into breast milk. Other narcotic agents (e.g., codeine, fentanyl, and morphine) are excreted into breast milk but are classified as compatible with breastfeeding by the American Academy of Pediatrics (see specific agents). The very short elimination time suggests that use of remifentanil during cesarean section or other surgery would not represent a significant risk to a newborn that started or continued breastfeeding a few hours later.

REPAGLINIDE

Antidiabetic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

The published human pregnancy experience is limited. No teratogenicity was observed in two animal species but, in one species, exposure during late pregnancy through lactation resulted in adverse effects on long-bone growth. The embryo–fetal risk from exposure to repaglinide cannot be fully assessed but, based on the animal and limited human data, inadvertent exposure early in gestation does not appear to represent a major risk. However, insulin is the treatment of choice for pregestational and gestational control of maternal hyperglycemia because, in general, most hypoglycemic agents do not provide adequate glycemic control. Moreover, insulin, unlike oral agents, does not cross the placenta to the fetus, thus eliminating the additional concern that the drug therapy itself will adversely affect the fetus. Carefully prescribed insulin therapy provides better control of the mother’s glucose, thereby preventing the fetal and neonatal complications that occur with this disease. High maternal glucose levels, as may occur in diabetes mellitus, are closely associated with a number of maternal and fetal adverse effects, including fetal structural anomalies if the hyperglycemia occurs early in gestation. To prevent this toxicity, the American College of Obstetricians and Gynecologists recommends that insulin be used for types 1 and 2 diabetes occurring during pregnancy and, if diet and exercise alone are not successful, for gestational diabetes (1,2).

FETAL RISK SUMMARY

Repaglinide is an oral blood glucose–lowering agent that is chemically unrelated to the sulfonylurea insulin secretagogues. It is in the same antidiabetic subclass of meglitinides as nateglinide. Repaglinide is indicated as an adjunct to diet and

exercise to improve glycemic control in adults with type 2 diabetes mellitus. The drug is completely metabolized to inactive metabolites. Plasma protein binding to albumin is >98% and the mean half-life is 1.0–1.4 hours (range 0.4–8 hours) (3). It is often combined with metformin.

Reproduction studies have been conducted in rats and rabbits. Repaglinide was not teratogenic in these species when given throughout pregnancy at doses that were about 40 and 0.8 times, respectively, the human clinical exposure based on BSA (HCE). When a dose that was 15 times the HCE was given to rats during gestational days 17–22 and during lactation, offspring developed nonteratogenic skeletal deformities consisting of shortening, thickening, and bending of the humerus during the postnatal period. This effect was not seen at doses up to 2.5 times the HCE given on gestational days 1–22 or at higher doses on gestational days 1–16 (3).

Another study found effects similar to those above in pregnant rats (4). Because the toxic effects on long bone development were observed only after organogenesis and only with high doses, the investigators concluded that the toxicity was limited to effects on growth and that repaglinide was not teratogenic (4).

No evidence of carcinogenicity was found in long-term studies in mice and female rats. In male rats there was an increased incidence of benign adenomas of the thyroid and liver. Multiple tests for genotoxicity were negative. No effects on fertility of male and female rats were observed with doses >40 times the HCE (3).

It is not known if repaglinide crosses the human placenta. The molecular weight (about 453) suggests that it will cross, but the extensive metabolism, high plasma protein binding, and short half-life suggest that the embryo–fetal exposure may be limited.

A 2006 report from Italy described the outcomes of two pregnancies treated with repaglinide for type 2 diabetes early in gestation (5). In both patients, the gestational age was confirmed by ultrasound and their therapy was changed to insulin. The first case involved a 38-year-old woman (pregestational body mass index [BMI] 26.2 kg/m²) who had been on long-term repaglinide 1.5 mg/day and metformin 3 g/day when she presented in the 7th week of pregnancy. Her HbA_{1c} values were 6.8% (preconception), 7% (conception), and 5.6% (3rd trimester). Gestational hypertension developed at 29 weeks' gestation and was treated with methyldopa. At 40 weeks', she gave birth to a healthy 3690-g female infant with Apgar scores of 9 and 10. The infant developed jaundice that needed phototherapy for 1 day. The second case was a nulliparous 34-year-

old woman (pregestational BMI 21.3 kg/m²) who had been taking repaglinide 2.5 mg/day for 2 years when she presented in the 6th gestational week. Her HbA_{1c} values at conception and in the 3rd trimester were 6.4% and 5.1%, respectively. At 39 weeks', she gave birth by cesarean section to a 2650-g male infant with Apgar scores 9 and 10. The birth weights for both infants were appropriate for gestational age, and no minor or major malformations were noted. Both infants were doing well at 6 weeks of age (5).

A report from England on the safety profile of repaglinide briefly mentioned five pregnancies exposed to the drug during pregnancy (6). The outcomes of the pregnancies were three infants with no abnormalities reported, one stillborn at 26 weeks' (mother had Fraser syndrome), and one outcome was unknown (no other details provided).

A brief 2007 report described the pregnancy outcome of a 38-year-old woman with type 2 diabetes who was exposed to repaglinide up to the 7th week (7). At that time her therapy was changed to insulin. In the 39th week, she delivered a normal 3350-g infant (sex not specified). The newborn had no evidence of hypoglycemia.

BREASTFEEDING SUMMARY

No reports describing the use of repaglinide during lactation have been located. The molecular weight (about 453) suggests that it will be excreted into breast milk, but the extensive metabolism and high plasma protein binding (>98%) suggest that the amount in milk will be limited. Although the mean half-life (1.0–1.4 hours) also suggests limited exposure, the range might be as great as 8 hours and suggests otherwise. The effect of this exposure on a nursing infant is unknown, but hypoglycemia is a potential complication. Thus, if a woman plans to breastfeed, changing her therapy to other agents, such as insulin or a second-generation sulfonylurea (see Glipizide and Glyburide) might be appropriate. In any case, monitoring the infant's blood glucose concentrations should be conducted.

RESERPINE

Antihypertensive

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

The limited human pregnancy experience and the absence of animal reproduction data prevent an assessment of the embryo–fetal risk. The data from one source suggest that avoiding exposure in the 1st trimester would be a wise choice.

FETAL RISK SUMMARY

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 48 of whom had 1st trimester exposure to reserpine (1, p. 376). There were four defects with 1st trimester use. Although this incidence (8%) is greater than the expected frequency of occurrence, no major category or individual malformations were identified. For use anytime in pregnancy, 475 exposures were recorded (1, p. 441). Malformations included the following: microcephaly (7 cases); hydronephrosis (3 cases); hydroureter (3 cases); and inguinal hernia (12 cases) (1, p. 495).

Reserpine crosses the placenta. Use of reserpine near term has resulted in nasal discharge, retraction, lethargy, and anorexia in the newborn (2). Concern over the ability of reserpine to deplete catecholamine levels has appeared (3). The significance of this is not known.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 15 newborns had been exposed to reserpine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). No major birth defects were observed (one expected).

BREASTFEEDING SUMMARY

Reserpine is excreted into breast milk (4). No reports of adverse effects in a nursing infant have been located.

RETAPAMULIN

Antibiotic

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of retapamulin in human pregnancy have been located. The animal reproduction data are not relevant because, although there was developmental toxicity (death and restricted weight), these effects occurred with maternal toxicity. The absence of human pregnancy experience prevents a complete assessment of the embryo–fetal risk. However, the very low plasma concentrations suggest that there is little or no risk when the antibiotic is used topically in pregnancy.

FETAL RISK SUMMARY

Retapamulin is a semisynthetic pleuromutilin antibiotic that is available as a 1% ointment. The antibiotic is isolated through fermentation from *Clitopilus passeckerianus* (formerly *Pleurotus passeckerianus*). It is indicated for the topical treatment of impetigo due to *Staphylococcus aureus* (methicillin-susceptible isolates only) or *Streptococcus pyogenes*. Small amounts of retapamulin are absorbed into the systemic circulation.

In 380 adult and 136 pediatric (age 2–17 years) patients undergoing treatment with twice daily applications, 11% had measurable plasma concentrations (lower limit of quantitation 0.5 ng/mL), of which the median concentration was 0.8 ng/mL. The maximum measured concentrations in adult and pediatric patients were 10.7 and 18.5 ng/mL, respectively. The antibiotic is about 94% bound to plasma proteins, but the elimination half-life has not been determined due to the very low plasma concentrations. Retapamulin is metabolized by the liver to numerous metabolites (1).

Reproduction studies have been conducted in rats and rabbits. In rats, oral doses of ≥ 150 mg/kg/day (relationship to the human exposure not stated)

caused maternal toxicity (decreased body weight and food consumption), decreased fetal weight, and delayed skeletal ossification. No treatment-related malformations were observed in the offspring. In rabbits, continuous IV infusions with doses producing exposures that were 8 times the estimated maximum achievable human exposure based on AUC were associated with maternal toxicity (decreased body weight and food consumption) and abortions. There were no other treatment-related effects on embryo–fetal development (1).

Carcinogenicity studies have not been conducted with retapamulin, but the drug was not genotoxic in multiple assays. No effects on fertility were noted in male and female rats given oral doses up to 450 mg/kg/day (1).

It is not known if retapamulin crosses the human placenta. The molecular weight (about 518) is low enough, but the very low plasma concentrations suggest that clinically significant exposure of the embryo and/or fetus is unlikely.

BREASTFEEDING SUMMARY

No reports describing the use of retapamulin during human lactation have been located. The molecular weight (about 518) is low enough for excretion into breast milk, but the very low plasma concentrations suggest that clinically significant exposure of a nursing infant is unlikely. Use of the antibiotic during breastfeeding probably is safe.

RETEPLASE

Thrombolytic

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably
Compatible

PREGNANCY SUMMARY

One report described the use of reteplase in human pregnancy. Bleeding appears to be the potential risk but was not observed in this case. Pregnancy may increase this risk (1). However, if indicated, the maternal benefit appears to outweigh the potential risk to the embryo–fetus.

FETAL RISK SUMMARY

The enzyme reteplase is a nonglycosylated deletion mutein of tissue plasminogen activator (tPA; see also Alteplase and Tenecteplase) produced by recombinant technology in *Escherichia coli*. It contains 355 of the 527 amino acids of natural human tPA. Reteplase is indicated for use in the management of acute myocardial infarction for the improvement of ventricular function, the reduction in the incidence of congestive heart failure, and the reduction of mortality. The effective half-life of reteplase is 13–16 minutes, based on the measurement of thrombolytic activity (1).

Reproduction studies have been conducted in rats and rabbits. In rats, doses up to 15 times the human dose (HD) revealed no evidence of impaired fertility or teratogenicity. In rabbits, a dose 3 times the HD administered in mid-gestation resulted in genital bleeding and abortions (1).

It is not known if reteplase crosses the human placenta. The molecular weight (39,571) and very short effective half-life suggest that clinically significant amounts of the protein will not cross to the embryo–fetus.

A 2002 report described the use of reteplase for acute massive pulmonary embolism in a pregnant woman at 30 weeks' gestation (2). The patient was given a 10 mg IV bolus followed by 90 mg IV over 2 hours with marked improvement in her condition. Heparin was given for remainder of the

pregnancy. At 36 weeks' she gave birth to a healthy male infant (no other details were provided) (2).

BREASTFEEDING SUMMARY

No reports describing the use of reteplase during human lactation have been located. However, the indication for reteplase suggests that such reports will not be forthcoming. In addition, the molecular weight (39,571) and very short effective half-life (13–16 minutes) suggest that the protein will not be excreted in clinically significant amounts into breast milk. Therefore, breastfeeding should be initiated or resumed based on the mother's condition and not the drug therapy.

REVIPARIN

Anticoagulant

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Reviparin is a low-molecular-weight heparin prepared by depolymerization of heparin obtained from porcine intestinal mucosa (1). It is not available in the United States (see also Dalteparin and Enoxaparin). Reviparin has an average molecular weight of 3500–4500 (range 2000–8000) (1). Because this is a relatively large molecule, it probably does not cross the placenta and presents a low risk to the embryo–fetus.

FETAL RISK SUMMARY

An abstract published in 1997 described the use of reviparin and aspirin (100 mg/day) in 50 women with unexplained recurrent fetal loss and autoantibodies (2). Reviparin was administered either as 4900 units SC once daily or as 2800 units SC twice daily. The once-daily injection produced comparable plasma anti-factor Xa levels to the twice-daily regimen. No maternal bleeding, thrombocytopenia, or decreased bone density was noted and no placental pathology was found in the 43 women who had completed their pregnancies (7 pregnancies were still in progress). The outcomes of the 43 completed pregnancies were 35 normal newborns (no premature deliveries), 7 spontaneous abortions, and 1 ectopic pregnancy. No congenital malformations or low-birth-weight newborns were observed.

BREASTFEEDING SUMMARY

No reports describing the use of reviparin during human lactation have been located. Reviparin, a low-molecular-weight heparin, still has a high molecular weight (average 3500–4500) and, as such, should not be expected to be excreted into human milk. Because reviparin would be inactivated in the gastrointestinal tract, the risk to a nursing infant from ingesting the drug is

probably nil.

RIBAVIRIN

Antiviral

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

The animal data suggest high risk, but the limited human pregnancy experience has not reported developmental toxicity attributable to ribavirin. However, only one case involved exposure during organogenesis. There also is no evidence of embryo–fetal harm when men were treated with ribavirin before fathering an infant. Although the data are very limited, this argues against a mutagenic effect of the drug and/or the transfer of clinically significant amounts of ribavirin in sperm. Nevertheless, if ribavirin is indicated, pregnancy should be avoided in female patients and in female partners of male patients for at least 6 months after the end of therapy (1,2).

FETAL RISK SUMMARY

Ribavirin is available in oral, IV, and inhalation formulations. The plasma elimination half-life is 12 days, but may persist in nonplasma compartments (e.g., red blood cells) for as long as 6 months.

Ribavirin has demonstrated dose-related teratogenicity or embryolethality at doses well below the recommended human dose in all animal species tested (1–3). Malformations observed in the offspring of hamsters, rats, and rabbits included defects of the skull, palate, eye, jaw, limbs, skeleton, and gastrointestinal tract. The manufacturers of oral ribavirin warn that the drug should not be used by men with female partners of reproductive age unless effective contraception (two reliable forms) is used or if their female partner is pregnant (1,2). Effective contraception should be continued for 6 months after ribavirin therapy has been stopped.

A 34-year-old woman, at 33 weeks' gestation, was treated with ribavirin inhalation therapy for influenza pneumonia complicated by respiratory failure

(4). Shortly after treatment, a cesarean section was performed because of worsening maternal cardiopulmonary function. A normal female infant was delivered, who was alive and well at 1 year of age (4).

In 1988, the CDC stated that the use of ribavirin during pregnancy is contraindicated (5). In a statement addressing the issue of inhaled ribavirin exposure among health care personnel, the CDC commented: "... health care workers who are pregnant, or may become pregnant should be advised of the potential risks of exposure during direct patient care when patients are receiving ribavirin through oxygen tent or mist mask and should be counseled about risk-reduction strategies, including alternative job responsibilities" (5).

In 13 pregnant or postpartum women hospitalized because of measles, 10 were treated for pneumonitis and/or severe disease in the 2nd or 3rd trimesters with ribavirin aerosol therapy (6). One woman was treated for 5 days before an elective abortion for worsening pulmonary status at 21 weeks' gestation. The remaining nine women had normal newborns with Apgar scores of 7–9 and 8–10 at 1 and 5 minutes, respectively (6).

A 36-year-old woman with an unknown pregnancy at 7 weeks received three ribavirin 200 mg injections over a 3-day period for suspected severe acute respiratory syndrome (SARS) (7). SARS was ruled out and she completed an uneventful pregnancy, delivering at term a 3.35-kg female infant with normal Apgar scores. At 8 months of age, the child was developing normally with normal growth and no evidence of major or minor malformations (7).

A 2001 case report described two men with chronic hepatitis C who were treated with a combination of ribavirin (800 and 1200 mg/day) and interferon alfa-2a (6 million units every other day) (8). After about 5 months of therapy, their wives became pregnant and both delivered healthy infants at term. The infants were developing normally at 4 months of age (8).

A second case report described a pregnancy outcome in which the father was treated with interferon alfa-2b (3 million units 3 times per week) and ribavirin (1000 mg/day) for 4 weeks before the last menstrual cycle and continued during the pregnancy of the patient's partner (9). A healthy 3380-g male infant was delivered at term with no evidence of malformations. The authors noted the lack of information relating the amount of ribavirin in sperm and the lack of experimental or clinical evidence for birth defects after paternal exposure (9).

A 2003 review summarized the developmental toxicity of ribavirin and interferon alfa-2b, a combination used for the treatment of hepatitis C (10). The authors lamented the lack of reported human pregnancy experience and the

possibility that the labels overstated the risks of men passing a potentially toxic amount of ribavirin in their sperm to a pregnant woman.

BREASTFEEDING SUMMARY

No reports describing the use of ribavirin during human lactation have been located. The molecular weight (about 244) and prolong plasma elimination half-life (12 days) suggest that the drug will be excreted into breast milk. The effects of this exposure on a nursing infant are unknown.

RIBOFLAVIN

Vitamin

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Riboflavin (vitamin B₂), a water-soluble B-complex vitamin, acts as a coenzyme in humans and is essential for tissue respiration systems. The National Academy of Sciences' recommended dietary allowance (RDA) for riboflavin in pregnancy is 1.6 mg (1).

FETAL RISK SUMMARY

Riboflavin is actively transferred to the fetus resulting in higher concentrations of the vitamin in the newborn than in the mother (2–12). The placenta converts flavin adenine dinucleotide existing in the maternal serum to free riboflavin found in the fetal circulation (5,6). This allows retention of the vitamin by the fetus because the transfer of free riboflavin back to the mother is inhibited (6,12). At term, the mean riboflavin values in 174 mothers was 184 ng/mL (range 80–390 ng/mL) and in their newborns was 318 ng/mL (range 136–665 ng/mL) (7). In a more recent study, the cord serum concentration was 158 nmol/L compared with 113 nmol/L in the maternal serum (11).

The incidence of riboflavin deficiency in pregnancy is low (7,13). In two studies, no correlation was discovered between the riboflavin status of the mother and the outcome of pregnancy even when riboflavin deficiency was present (14,15). A 1977 study found no difference in riboflavin levels between infants of low and normal birth weight (10).

Riboflavin deficiency is teratogenic in animals (16). Although human teratogenicity has not been reported, low riboflavin levels were found in six mothers who had given birth to infants with neural tube defects (17). Other vitamin deficiencies present in these women were thought to be of more significance (see Folic Acid and Vitamin B₁₂).

A mother has been described with multiple acylcoenzyme A dehydrogenase deficiency probably related to riboflavin metabolism (18). The mother had given

birth to a healthy child followed by one stillbirth and six infants who had been breastfed and died in early infancy after exhibiting a strong sweaty foot odor. In her 9th and 10th pregnancies, she was treated with 20 mg/day of riboflavin during the 3rd trimesters and delivered healthy infants. The authors thought the maternal symptoms were consistent with a mild form of acute fatty liver of pregnancy.

BREASTFEEDING SUMMARY

Riboflavin (vitamin B₂) is excreted into breast milk (19–23). Well-nourished lactating women were given supplements of a multivitamin preparation containing 2.0 mg of riboflavin (19). At 6 months postpartum, milk concentrations of riboflavin did not differ significantly from those in control patients not receiving supplements. In a study of lactating women with low nutritional status, supplementation with riboflavin in doses of 0.10–10.0 mg/day resulted in mean milk concentrations of 200–740 ng/mL (20). Milk concentrations were directly proportional to dietary intake. A 1983 English study measured riboflavin levels in pooled human milk obtained from preterm (26 mothers: 29–34 weeks) and term (35 mothers: ≥39 weeks) patients (21). Milk obtained from preterm mothers rose from 276 ng/mL (colostrum) to 360 ng/mL (6–15 days) and then fell to 266 ng/mL (16–196 days). During approximately the same time frame, milk levels from term mothers were 288, 279, and 310 ng/mL. In a Finnish study, premature infants (mean gestational age 30.1 weeks) fed human milk, but without riboflavin supplementation, became riboflavin deficient by 6 weeks of age (24).

The National Academy of Sciences' RDA for riboflavin during lactation is 1.8 mg (1). If the diet of the lactating woman adequately supplies this amount, supplementation with riboflavin is not needed (22). Maternal supplementation with the RDA for riboflavin is recommended for those women with inadequate nutritional intake. The American Academy of Pediatrics classifies riboflavin as compatible with breastfeeding (25).

RIFABUTIN

Antituberculosis Agent

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity Contraindicated (Patients with HIV Infection)

PREGNANCY SUMMARY

No reports describing the use of rifabutin in human pregnancy have been located. The animal data are suggestive of low risk, but the absence of human pregnancy experience prevents an assessment of the embryo–fetal risk. However, the maternal benefit appears to outweigh the unknown risk to the embryo or fetus, so therapy should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Rifabutin is an oral semi-synthetic ansamycin antibiotic that is derived from rifamycin S. It is indicated for the prevention of disseminated *Mycobacterium avium* complex (includes *M. avium* and *M. intracellulare*) disease in patients with advanced human HIV infection. Five metabolites have been identified, one of which is active (contributes up to 10% of the antimicrobial activity). Rifabutin is moderately (about 85%) bound to plasma proteins and has a mean terminal half-life of 45 hours (1).

Rifabutin was not carcinogenic in mice and rats at doses about 32 and 12 times, respectively, the recommended human daily dose (RHDD). In addition, no mutagenicity was observed in several assays (1).

Reproduction tests have been conducted in rats and rabbits. In rats, doses up to 40 times the RHDD were not teratogenic, but the highest dose caused a decrease in fetal viability. At 8 times the RHDD, an increase in fetal skeletal variants was observed. In rabbits, no teratogenic effects were observed with doses up to 40 times the RHDD. A dose 16 times the RHDD was maternal toxic and resulted in an increase in fetal skeletal anomalies (1).

It is not known if rifabutin or its active metabolite crosses the human

placenta. The molecular weight of the parent compound (about 847), moderate plasma protein binding, high lipid solubility, and prolonged terminal half-life suggest that passage to the embryo–fetus will occur.

Rifabutin induces the metabolism of ethinyl estradiol and norethindrone, thereby decreasing the efficacy of oral contraceptives (1). Therefore, additional, nonhormonal methods of birth control should be used during treatment with this antibiotic.

BREASTFEEDING SUMMARY

No reports describing the use of rifabutin during human lactation have been located. The molecular weight (about 847), moderate plasma protein binding, and prolonged terminal half-life suggest that excretion into milk should be expected. Milk may be stained a brown-orange color. The effect of this exposure on a nursing infant is unknown but serious toxicity (e.g., leukopenia, neutropenia, rash) is a potential complication. If the drug is used during breastfeeding, monitoring for these toxicities should be considered. Moreover, rifabutin is indicated for the prevention of disseminated *M. avium* complex in patients with advanced HIV infection, and women with HIV should not breastfeed.

RIFAMPIN

Antituberculosis Agent

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Several reviews have evaluated the available treatment of tuberculosis during pregnancy (1–3). All concluded that rifampin was not a proven teratogen and recommended use of the drug with isoniazid and ethambutol if necessary. Other reports on the use of the agent in pregnancy have observed no fetal harm (4,5). Prophylactic vitamin K₁ has been recommended to prevent hemorrhagic disease of the newborn (6).

FETAL RISK SUMMARY

Reproduction studies with rifampin in mice and rats at doses >150 mg/kg produced spina bifida in both species and cleft palates in the mouse fetuses (7). Teratogenicity in rodents has been reported with oral doses 15–25 times the human dose (8). Studies with pregnant rabbits revealed no evidence of teratogenicity (7).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 20 newborns had been exposed to rifampin during the 1st trimester (F. Rosa, personal communication, FDA, 1993). No major birth defects were observed (one expected).

No controlled studies have linked the use of rifampin with congenital defects (9,10). One report described nine malformations in 204 pregnancies that went to term (11). This incidence, 4.4%, is similar to the expected frequency of defects in a healthy nonexposed population but higher than the 1.8% rate noted in other tuberculosis patients. The malformations were anencephaly (one case), hydrocephalus (two cases), limb malformations (four cases), renal tract defects (one case), and congenital hip dislocation (one case) (11).

Rifampin crosses the placenta to the fetus (12–14). At term, the cord:maternal serum ratio ranged 0.12–0.33 (13). In a second report involving

pregnancy termination at 13 weeks' gestation, the fetal:maternal ratio 4 hours after a 300-mg dose was 0.23 (12).

Rifampin has been implicated as one of the agents responsible for hemorrhagic disease of the newborn (6). In one of the three infants affected, only laboratory evidence of hemorrhagic disease of the newborn was present, but in the other two, clinically evident bleeding was observed. Prophylactic vitamin K₁ is recommended to prevent this serious complication (see Phytonadione).

Rifampin may interfere with oral contraceptives, resulting in unplanned pregnancies (see Oral Contraceptives) (15).

BREASTFEEDING SUMMARY

Rifampin is excreted into human milk. In one report, the concentrations were 1–3 mcg/mL with about 0.05% of the daily dose appearing in the milk (16). In another study, milk levels were 3.4–4.9 mcg/mL, 12 hours after a single 450-mg oral dose (17). Maternal plasma samples averaged 21.3 mcg/mL, indicating a milk:plasma ratio of about 0.20. These amounts were thought to represent a very low risk to the nursing infant (18). No reports describing adverse effects in nursing infants have been located. The American Academy of Pediatrics classifies rifampin as compatible with breastfeeding (19).

RIFAPENTINE

Antituberculosis Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Rifapentine induced toxicity and teratogenicity in two experimental animal species at doses close to those used in humans. Human pregnancy experience is limited to three cases, two of which ended in 1st trimester spontaneous abortions. Although comorbid conditions were present and may have caused the losses, the outcomes are sufficiently concerning to warrant caution in prescribing rifapentine early in pregnancy. Until additional data are forthcoming, rifapentine is best avoided during the 1st trimester.

FETAL RISK SUMMARY

The antibiotic rifapentine is a semi-synthetic cyclopentyl derivative of rifamycin and has a similar profile of microbiologic activity to rifampin. It is indicated for the treatment of pulmonary tuberculosis. The antibiotic inhibits DNA-dependent RNA polymerase in *Mycobacterium tuberculosis*, but this effect does not occur in mammalian cells. The elimination half-lives of rifapentine and its active metabolite are each about 13 hours (1).

Reproduction studies with rifapentine in rats and rabbits produced teratogenic and toxic effects in both species. In rats, doses 0.6 times the human dose based on BSA (HD) administered during organogenesis resulted in cleft palates, right aortic arch, an increased incidence of delayed ossification, and an increased number of ribs. Embryo and fetal toxic effects included increases in resorption rates, postimplantation losses, and stillbirths, and decreased fetal weight. Administration of doses 0.3 times the HD from day 15 of gestation through postpartum day 21 was associated with decreased pup weights and stillbirths. Major anomalies observed in the offspring of pregnant rabbits administered doses 0.3–1.3 times the HD included ovarian agenesis,

pes varus (i.e., talipes varus), arhinia, microphthalmia, and irregularities of the ossified facial tissues. When doses 1.3 times the HD were given, increased incidences of postimplantation losses and stillbirths were observed (1).

It is not known if rifapentine crosses the human placenta. The molecular weight (about 877) is low enough that exposure of the embryo and fetus probably occurs. In addition, the prolonged elimination half-lives of the parent compound and its active metabolite increase the opportunity for passage of the agents into the fetal compartment.

In a clinical study by the manufacturer, three women became pregnant while receiving rifapentine, 600 mg twice weekly (combined with isoniazid, ethambutol, pyrazinamide, and pyridoxine) and three became pregnant during follow-up (1,2). The first patient had a positive serum pregnancy test at baseline and subsequently received a single 600-mg dose of rifapentine before being dropped from the study. An elective abortion was conducted to terminate the pregnancy. The second patient, with a history of alcohol abuse, received 10 doses of rifapentine 600 mg over 42 days before exclusion from the study. She had a 1st trimester spontaneous abortion 9 days after the last dose. The third woman had an HIV infection as well as tuberculosis. She was treated over 85 days with 22 rifapentine 600-mg doses and had a 1st trimester spontaneous abortion 16 days after the last dose. The investigator concluded that the abortion was secondary to the HIV infection. The outcomes of the three pregnancies in the follow-up stage of the study, which were not thought to have been exposed to the drug during gestation, were two normal deliveries and one lost to follow-up (1,2).

When taken in the last few weeks of pregnancy, rifapentine may cause hemorrhage in both the mother and newborn secondary to vitamin K deficiency (1). This effect is similar to that observed with rifampin. Prophylactic vitamin K₁ is recommended to prevent hemorrhage. (See also Phytonadione.)

Rifapentine may increase the metabolism and reduce the activity of oral or other systemic hormonal contraceptives (1). Unplanned pregnancies may result from this interaction. Patients receiving rifapentine should be advised to change to nonhormonal methods of birth control (1).

Because active untreated tuberculosis represents a greater risk to the fetus than does treatment, immediate initiation of drug therapy is usually recommended, regardless of the gestational stage (3–6). The CDC recommends a combination of isoniazid (plus pyridoxine), rifampin, and ethambutol as the treatment of choice for pulmonary tuberculosis during pregnancy and breastfeeding (5). An earlier statement by the World Health

Organization recommended a 6-month regimen of isoniazid (plus pyridoxine), rifampin, and pyrazinamide as first-line treatment in pregnancy (6). Ethambutol was recommended if a fourth drug was needed during the initial phase. Although the CDC did not recommend pyrazinamide, it classified this agent as probably safe in pregnancy (5). Moreover, the CDC stated that if pyrazinamide was not included in the initial treatment regimen, the minimum duration of therapy should be 9 months (39 weeks) instead of 6 months (26 weeks). Importantly, the CDC did not recommend rifapentine in pregnancy because of insufficient information (5).

BREASTFEEDING SUMMARY

No reports describing the use of rifapentine during lactation have been located. The molecular weight of rifapentine (about 877) and the prolonged half-lives of the parent compound and the active metabolite (both about 13 hours) suggest that these agents will be excreted into milk. Breast milk may be discolored because rifapentine produces a red-orange discoloration of body fluids. The effects of this exposure, if any, on a nursing infant are unknown. Rifampin, a closely related antibiotic with a similar molecular weight (about 823), is excreted in low amounts into breast milk. The American Academy of Pediatrics classifies rifampin as compatible with breastfeeding (see Rifampin).

RIFAXIMIN

Antibiotic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of rifaximin in human pregnancy have been located. The animal reproduction data suggest risk, but the amount absorbed from the gastrointestinal tract was not quantified. In humans, the very small amounts absorbed systemically suggest that the embryo–fetal risk is low, if it exists at all. Although inadvertent exposure early in gestation appears to represent a low risk, the safest course, because of the animal data, is to avoid the antibiotic in the 1st trimester. Until human pregnancy data are available, women should be counseled that the absence of human pregnancy experience prevents an accurate assessment of the embryo–fetal risk.

FETAL RISK SUMMARY

Rifaximin is a semi-synthetic antibiotic that is poorly absorbed after oral administration. Following oral dosing, a mean 0.32% of the dose was recovered in the urine. The remainder was found in the feces as unchanged drug. Rifaximin is indicated for the treatment of patients with travelers' diarrhea caused by noninvasive strains of *Escherichia coli* (1). It is a derivative of rifamycin that has antibacterial activity against a broad spectrum of gram-positive and gram-negative bacteria, including aerobic, anaerobic, and enteropathogens (2,3). In addition to an oral formulation, it is available outside of the United States as a 5% cream for topical application (3).

Reproduction studies have been conducted in rats and rabbits. In pregnant rats, doses about 2.5–5 times the human clinical dose adjusted for BSA (HCD) were teratogenic, as were doses in pregnant rabbits about 2–33 times the HCD. The effects included cleft palate, agnathia, jaw shortening, hemorrhage,

partially open eye, small eyes, brachygnathia, incomplete ossification, and increased thoracolumbar vertebrae. There was no effect on fertility in male or female rats given doses up to about 5 times the HCD. Carcinogenicity studies with rifaximin have not been conducted. Assays for genotoxicity were negative (1).

It is not known if rifaximin crosses the human placenta. The molecular weight (about 786) is low enough for passive transfer, but only a very small amount of the antibiotic is absorbed into the systemic circulation. After a 400-mg dose in healthy nonpregnant subjects, the mean maximum plasma concentrations were in the range of 4–10 ng/mL (1). The elimination half-life was about 6 hours.

A 2005 review concluded that the lack of absorption and the safety profile in nonpregnant adults suggested that rifaximin was safe in pregnancy for the treatment of infectious diarrhea (2). A second 2005 reference reviewed the use of rifaximin for infections other than diarrhea, such as skin infections, bacterial vaginosis (BV), and periodontal disease (3). The authors of this review concluded that for these uses, only the efficacy of rifaximin in skin infections had been documented, but that further study for BV and periodontal disease was warranted.

Pregnant women may be at higher risk for “traveler’s diarrhea” because of the lowered gastric acidity and increased transient time through the gastrointestinal tract that is characteristic of pregnancy (4). Although rifaximin is effective and minimally absorbed, the effects of the antibiotic in human pregnancy have not been studied.

BREASTFEEDING SUMMARY

No reports describing the use of rifaximin during lactation have been located. The molecular weight (about 786) is low enough for excretion into breast milk, but only very small amounts of the antibiotic are absorbed into the systemic circulation. The effects of this exposure on a nursing infant are unknown, but appear to be negligible.

RILONACEPT

Immunologic Agent (Immunomodulator)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of riloncept in human pregnancy have been located. The protein caused developmental toxicity (structural anomalies and death) in two animal species. If the agent is given shortly before or during pregnancy, the woman should be counseled as to the potential embryo–fetal risk.

FETAL RISK SUMMARY

Riloncept is a dimeric fusion protein that acts as an interleukin-1 blocker. It is indicated for the treatment of cryopyrin-associated periodic syndromes, including familial cold auto-inflammatory syndrome and Muckle-Wells syndrome in adults and children ≥ 12 years of age. Pharmacokinetic data are not available from the manufacturer, but after weekly SC doses, steady-state concentrations were reached at 6 weeks (1). In a 2009 reference, the circulation half-life was cited as 8.6 days (2).

Reproduction studies have been conducted in cynomolgus monkeys and mice. In monkeys given doses up to about 3.7 times the human doses of 160 mg based on BSA (HD), all doses reduced serum levels of estradiol up to 64% compared with controls. In addition, all doses increased the incidence of lumbar ribs compared with both control animals and historical control incidences. The fetus of the only monkey exposed during the later period of gestation showed multiple fusion and absence of the ribs and thoracic vertebral bodies and arches. In this monkey, the exposure was below that expected clinically. A murine analog of riloncept was used in mice. The highest dose, about 6 times higher than the HD, resulted in threefold increase in the number of stillbirths. In a perinatal and postnatal mouse study with the murine analog, all doses up to

about 6 times the HD caused an increased incidence of unscheduled death in the offspring.

Neither carcinogenic nor mutagenic studies have been conducted with riloncept. No adverse effects on fertility parameters were observed in male and female mice given multiple doses of the murine analog up to about 6 times the HD (1).

It is not known if riloncept crosses the human placenta. The molecular weight (about 251,000) suggests that passive transfer will not occur, but the long circulation half-life will place the protein at the maternal–fetal interface for a prolonged period. Moreover, other proteins (e.g., see Immune Globulin Intravenous) cross the placenta. If the toxicity observed in the two animal species were direct effects (i.e., effects on the embryo and/or fetus and not caused by maternal effects), this would be evidence that the protein can cross hemochorial placentas.

BREASTFEEDING SUMMARY

No reports describing the use of riloncept during human lactation have been located. The high molecular weight of this protein (about 251,000) suggests that excretion into mature breast milk will be inhibited. Because immunoglobulins and other high-molecular-weight substances are excreted into colostrum, exposure of the nursing infant to riloncept might occur during the first few days after birth. The effect of this exposure on a nursing infant is unknown. However, in children and adult patients treated with this drug, an increase in infections is a common complication due to interference with the immune response. Nursing infants of women receiving the drug should be monitored for this effect.

RILPIVIRINE

Antiviral

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of rilpivirine in human pregnancy have been located. The animal reproduction data suggest low risk but the absence of human pregnancy experience prevents a complete assessment of the embryo–fetal risk. Nevertheless, because HIV is a potentially fatal disease, the drug if indicated should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Rilpivirine is an HIV type1 specific, nonnucleoside reverse transcriptase inhibitor (NNRTI) that is given orally. It is in the same NNRTI class as delavirdine, efavirenz, etravirine, and nevirapine. Rilpivirine is indicated to be used in combination with other antiretroviral agents for the treatment of HIV-1 infection in treatment-naïve adult patients. The drug undergoes oxidative metabolism, apparently to inactive metabolites. Plasma protein binding, primarily to albumin, is about 99.7% and the terminal elimination half-life is about 50 hours (1).

Reproduction studies have been conducted in rats and rabbits. In these species during pregnancy and lactation, no evidence of embryo or fetal toxicity, or effect on reproductive function was observed at exposures that were 15 and 70 times higher, respectively, than the exposure in humans at the recommended dose of 25 mg once daily (RHD) (1).

In 2-year studies, no carcinogenic effects were observed in rats, but in mice hepatocellular neoplasms occurred in both males and females. The observed hepatocellular findings in mice may be rodent-specific. Assays for mutagenicity were negative. In fertility studies with rats, rilpivirine had no effect on mating or fertility with exposures up to about 40 times the RHD (1).

It is not known if rilpivirine crosses the human placenta. The molecular weight (about 367 for the free base) and long elimination terminal half-life suggest that

the drug will cross to the embryo–fetus. However, the high plasma protein binding might limit the exposure.

Although the use of rilpivirine for the treatment of HIV was discussed in three recent publications, no information was given about its use in pregnancy (2–4).

BREASTFEEDING SUMMARY

No reports describing the use of rilpivirine during lactation have been located. The molecular weight (about 367 for the free base) and long terminal elimination half-life (about 50 hours) suggest that the drug will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown.

Reports on the use of rilpivirine during human lactation are unlikely because the antiviral agent is used in the treatment of HIV infections. HIV-1 is transmitted in milk, and in developed countries, breastfeeding is not recommended (5–10). In developing countries, breastfeeding is undertaken, despite the risk, because there are no affordable milk substitutes available. Until 1999, no studies had been published that examined the effect of any antiretroviral therapy on HIV-1 transmission in milk. In that year, a study involving zidovudine was published that measured a 38% reduction in vertical transmission of HIV-1 infection despite breastfeeding when compared with controls (see Zidovudine).

RILUZOLE

Central Nervous System (Miscellaneous)

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential
Toxicity

PREGNANCY SUMMARY

Although the animal data suggest risk, the very limited human pregnancy experience does not allow an accurate assessment of the human embryo–fetal risk. Nevertheless, amyotrophic lateral sclerosis (ALS) is a severe progressive disease with marked morbidity resulting in eventual death. Consequently, the maternal benefit appears to be much greater than the unknown embryo–fetal risk.

FETAL RISK SUMMARY

Riluzole is indicated for the treatment of patients with ALS to extend survival and/or time to tracheostomy. It is a member of the benzothiazole class. The agent is extensively metabolized and some of the metabolites are pharmacologically active. Riluzole is 96% bound to plasma proteins, mainly to albumin and lipoproteins. The mean elimination half-life is 12 hours (1).

Reproduction studies have been conducted in rats and rabbits. In these species, doses that were 2.6 and 11.5 times, respectively, the maximum recommended daily dose based on BSA (MRDD) caused embryotoxicity. Maternal toxicity also was observed at these doses. When rats received a dose that was 1.5 times the MRDD before and during mating (males and females) and throughout pregnancy and lactation, decreased implantations, increased intrauterine death, and adverse effects in offspring viability and growth were observed (1).

Riluzole was not carcinogenic in mice and rats, and there was no evidence of mutagenic or clastogenic potential in multiple assays. The major active metabolite, N-hydroxyriluzole, did cause chromosomal damage in two tests, but negative results were observed in other assays. As discussed above, Riluzole

impaired fertility when administered to male and female rats (1).

It is not known if riluzole or its metabolites cross the human placenta. The molecular weight of the parent drug (about 234) and long elimination half-life suggest that riluzole and its metabolite will cross to the embryo–fetus.

The first report of riluzole use in human pregnancy appeared in 2009 (2). A 28-year-old woman was diagnosed with ALS and treated with riluzole (dose not specified). When her pregnancy was discovered at 9 weeks' gestation, riluzole was discontinued. She had a normal pregnancy and gave birth vaginally at 40 weeks' to a healthy male infant. No other information about the infant was given other than that he was in good health at the time of this report. The woman eventually had a second pregnancy, apparently without riluzole (2).

A 2010 case report described the pregnancy outcome of a 34-year-old primigravida Japanese woman with ALS (3). The woman had been taking riluzole (100 mg/day) for 2 years. Her pregnancy was diagnosed at 30 weeks' gestation and riluzole was continued. She gave birth vaginally at 38 weeks' to a 2280-g growth-restricted female infant with Apgar scores of 8 and 8 at 1 and 5 minutes, respectively. The growth restriction may have been wholly or partially due to cigarette smoking. The infant was developing normally at 1 year of age. In addition to this case, the authors reviewed the pregnancy outcomes of 11 women with ALS (all occurring before the availability of riluzole) (3).

BREASTFEEDING SUMMARY

No reports describing the use of riluzole during human lactation have been located. The molecular weight (about 234) and long elimination half-life (12 hours) suggest that the drug, and possibly its metabolites, will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown. However, the drug caused marked toxicity in adults with about 14% of patients in clinical trials discontinuing riluzole because of adverse effects (1).

RIMANTADINE

Antiviral

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

The human pregnancy experience with rimantadine is limited. As of late 1996, the FDA had not received any reports of pregnancy exposure to rimantadine (F. Rosa, personal communication, FDA, 1996). Although the lack of human data does not allow an assessment of fetal risk, the absence of significant animal teratogenicity may indicate that rimantadine is a lower risk during pregnancy than the closely related drug, amantadine.

FETAL RISK SUMMARY

Rimantadine is a synthetic antiviral agent used in the prophylaxis and treatment of influenza A virus infections. In nonpregnant patients, rimantadine shares the toxic profile of a similar antiviral agent, amantadine, which is also used for influenza A virus infections (see Amantadine) (1).

It is not known if rimantadine crosses the human placenta, but the relatively low molecular weight (about 216) suggests that exposure of the embryo–fetus probably occurs.

Rimantadine was embryotoxic (increased fetal resorption) in rats at a dose 11 times the recommended human dose based on BSA (RHD) (2). This dose also produced maternal toxicity. No embryotoxicity was observed in rabbits given up to 5 times the RHD, but a developmental abnormality was observed as evidenced by an increase in the ratio of fetuses with 12–13 ribs from the normal litter distribution of 50:50 to 80:20 (2).

A retrospective cohort study, covering the period 2003–2008, described 239 pregnancies that were treated with antiviral agents during pregnancy (3). Of these, 104 women received M2 ion channel inhibitors (rimantadine, amantadine, or both) and 135 received oseltamivir. The pregnancy outcomes of these

patients were compared with 82,097 controls from the site's overall obstetric patient population. The exposure timing for the combined treated groups was 13% in 1st trimester, 32% in 2nd trimester, and 55% in 3rd trimester. There were no significant differences between the treated groups and controls in terms of maternal and delivery characteristics except that M2 inhibitors had more multiple gestations. For M2 inhibitors, oseltamivir vs. controls, there also were no differences in stillbirths (0%, 0% vs. 1%), major defects (1% [trisomy 21], 0% vs. 2%), and minor defects (19%, 15% vs. 22%). The only significant finding in the characteristics of liveborn, singleton neonates, after exclusion of twins and major anomalies, was a higher risk of necrotizing enterocolitis in both treatment groups compared with controls—1.0%, 0.8% vs. 0.02%. (3).

BREASTFEEDING SUMMARY

No reports describing the use of rimantadine during human lactation have been located. The molecular weight (about 216) is low enough that excretion into breast milk should be expected. The effect of this exposure on a nursing infant is unknown. The manufacturer recommends the drug not be administered to nursing women (2).

RISEDRONATE

Bisphosphonate

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The use of risedronate before or during pregnancy has been described, but the data are very limited. No drug-induced toxicity was seen in the offspring. Although the animal data suggest risk of developmental toxicity, the near absence of human pregnancy experience prevents an assessment of the embryo–fetal risk. However, the very long elimination half-life from bone indicates that women treated with risedronate will have detectable concentrations of the drug for a prolonged interval. The amount of drug retained in bone and eventually released back into the systemic circulation is directly related to the dose and duration of treatment. Thus, administration before pregnancy may result in low-level, continuous exposure throughout gestation. The use of etidronate in women who may become pregnant or during pregnancy is not recommended. However, based on the animal and limited human data, inadvertent exposure during early pregnancy does not appear to represent a major risk to the embryo–fetus.

FETAL RISK SUMMARY

Bisphosphonates are synthetic analogs of pyrophosphate that bind to the hydroxyapatite found in bone. Other agents in this class include alendronate, etidronate, ibandronate, pamidronate, tiludronate, and zoledronic acid. Risedronate, a specific inhibitor of osteoclast-mediated bone resorption, is indicated for the treatment and prevention of osteoporosis in postmenopausal women. It also is indicated for the prevention and treatment of glucocorticoid-induced osteoporosis in men and women, and in the treatment of Paget's disease of bone (osteitis deformans). Risedronate is not metabolized, and

plasma protein binding is minimal (about 24%). The elimination half-life is biphasic with an initial serum half-life of about 1.5 hours. The very long terminal half-life (480 hours) is thought to be secondary to its slow dissociation from the surface of bone. The mean absolute oral bioavailability is 0.63% and is reduced even further by meals. Steady state serum drug concentrations are obtained within 57 days of daily dosing (1).

Reproduction studies have been conducted in rats and rabbits. Treatment during mating and gestation with doses as low as the maximum recommended human dose of 30 mg/day based on BSA (MRHD) resulted in periparturient hypocalcemia and mortality in pregnant rats. This same dose was associated with a low incidence of cleft palate in fetuses. During gestation, doses as low as about 5.2 times the MRHD resulted in decreased survival of neonates. At 26 times the MRHD, the body weight of surviving neonates decreased. A significant increase in the number of fetuses with incomplete ossification of sternbrae or skull was observed at about 2.3 times the MRHD, and both incomplete ossification and unossified sternbrae were increased at about 5.2 times the MRHD. In rabbits, no significant fetal ossification effects were observed at doses up to 6.7 times the MRHD. At this dose, however, 1 of 14 litters was aborted and 1 litter delivered prematurely (1).

Long-term studies in rats revealed no evidence of carcinogenesis. In addition, various assays have found no evidence of mutagenesis when nontoxic doses were used. Risedronate, however, did impair fertility in male rats and dogs at doses as low as about 5.2 and 8 times the MRHD, respectively. In female rats, ovulation was inhibited at a dose about 5.2 times the MRHD, and decreased implantation was noted at a dose about 2.3 times the MRHD (1).

It is not known if risedronate crosses the human placenta. The molecular weight (about 350 for the hemi-pentahydrate form), low protein binding, and lack of metabolism suggest that the drug will cross to the embryo–fetus. The amount available for diffusion across the placenta during treatment should be minimal because of the low oral bioavailability and short serum elimination half-life. When treatment has been discontinued, the amount of drug available for diffusion during the prolonged bone elimination should be even lower, but the drug will be present at the maternal–fetal interface for months or longer.

A 2008 review described 51 cases of exposure to bisphosphonates before or during pregnancy: alendronate (N = 32), pamidronate (N = 11), etidronate (N = 5), risedronate (N = 2), and zoledronic acid (N = 1) (2). The authors concluded that although these drugs may affect bone modeling and development in the fetus, no such toxicity has yet been reported.

BREASTFEEDING SUMMARY

No reports describing the use of risedronate during human lactation have been located. The molecular weight (about 350 for the hemi-pentahydrate form), low protein binding (about 24%), lack of metabolism, and very long bone elimination half-life (480 hours) suggest that some drug will be excreted into milk. However, the amount excreted into milk during human treatment should be minimal because of the low oral bioavailability (0.63%) and short serum elimination half-life (about 1.5 hours). When treatment has been discontinued, the amount of drug available for excretion during the prolonged bone elimination should be even lower, although excretion into milk could occur for several months. The effect of this exposure on a nursing infant is unknown but is probably negligible.

RISPERIDONE

Antipsychotic

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although no structural malformations attributable to risperidone have been reported, the number of exposures is too low to fully assess the embryo–fetal risk. In addition, there is a risk of extrapyramidal and/or withdrawal symptoms in the newborn if the drug is used in the 3rd trimester. Nevertheless, risperidone is indicated for severe debilitating mental disease and the benefits to the mother appear to outweigh the potential embryo–fetal risks. Folic acid 4 mg/day has been recommended for women taking atypical antipsychotics because they may have a higher risk of neural tube defects due to inadequate folate intake and obesity (1).

FETAL RISK SUMMARY

Risperidone, an atypical antipsychotic, is indicated for the management of the manifestations of psychotic disorders, such as schizophrenia. Risperidone is metabolized to an active metabolite, 9-hydroxyrisperidone (see Paliperidone), that has similar pharmacological activity as risperidone. Plasma protein binding is 90% and the mean elimination half-life of the parent drug and metabolite combined in extensive and poor metabolizers is about 20 hours (2). Risperidone is a benzisoxazole derivative in the same antipsychotic subclass as iloperidone, paliperidone, and ziprasidone. Although not approved for this indication by the FDA, it is also used for the management of bipolar disorder and in patients with dementia-related psychotic symptoms.

Reproduction studies have been conducted in pregnant rats and rabbits. No increase in the incidence of congenital malformations was observed in either species at doses 0.4–6 times the human dose based on BSA (HD). At 1.5 times the HD, however, an increase in stillbirths was noted in rats. In addition,

increased pup mortality during the first 4 days of lactation occurred at 0.1–3 times the HD. There was no no-effect dose for this toxicity. It was not known if the deaths were due to a direct effect on the pups or toxicity in the dams. Risperidone caused a dose-related decrease in serum testosterone in Beagle dogs, as well as a decrease in sperm motility and concentration, at doses 0.6–10 times the HD (2).

Consistent with the molecular weight (about 410), risperidone crosses the human placenta.

In a 2007 study, six women taking a staple dose (mean 3 mg/day) of quetiapine for a mean 25.9 weeks before delivery had maternal and cord concentrations of the drug determined at birth (3). The cord blood concentration was 49.2% of the maternal concentration. The pregnancy outcomes included one growth-restricted infant (<2500 g). The mean Apgar scores were 8.7 and 9.2 at 1 and 5 minutes, respectively. There were no neonatal complications and no infants were admitted to the neonatal intensive care unit (3).

The outcomes of 10 pregnancies involving 9 women were described in a large postmarketing study involving 7684 patients treated with risperidone (4). The outcomes were three elective terminations and seven live births. No congenital malformations were reported among the live births (4). The manufacturer has also reported an unpublished case of agenesis of the corpus callosum in an infant exposed to risperidone during gestation (2). The relationship between the drug and the defect is unknown.

A 1997 review of antipsychotic use in pregnancy concluded that the safety of risperidone in human pregnancy had not been established (5). The reviewers commented that although no teratogenicity or direct toxicity had been shown in animal studies, some indirect, prolactin- and CNS-mediated effects had been observed.

A brief 2002 report described the pregnancy outcomes of two women with schizophrenia who were treated with risperidone throughout gestation (6). Both women delivered apparently healthy infants at term. The weight of the male infant was 8 pounds (about 3.63 kg), whereas the female infant weighed 5.81 pounds (about 2.64 kg). Risperidone was continued after birth and during nursing. No developmental abnormalities were noted in the infants at 9 months and over 1 year, respectively (6).

A 36-year-old pregnant woman was treated with multiple medications for schizophrenia and other conditions (7). Risperidone 4 mg/day was taken in gestational weeks 6–7. Other psychotropic agents were (daily dose and

gestational weeks in parentheses): mirtazapine (30 mg; 1–5), thioridazine (300 mg; 1–5), diazepam (10 mg; 4–5), hydroxyzine (12.5 mg; 4–7), clomipramine (150 mg; 6–7), fluvoxamine (100 mg; 8–21), alprazolam (0.5 mg; 8–21), quetiapine (500–600 mg; 8–37), carbamazepine (600 mg; 8–21), and haloperidol (10 mg; 31–36). She gave birth at 37 weeks' to a healthy 3000-g female infant with Apgar scores of 8 and 9, who was developing normally after 4 months (7).

A 2005 study, involving women from Canada, Israeli, and England, described 151 pregnancy outcomes in women using atypical antipsychotic drugs (8). The exposed group was matched with a comparison group (N = 151) who had not been exposed to these agents. The drugs and number of pregnancies were olanzapine (N = 60), risperidone (N = 49), quetiapine (N = 36), and clozapine (N = 6). In those exposed, there were 110 live births (72.8%), 22 spontaneous abortions (14.6%), 15 elective abortions (9.9%), and 4 stillbirths (2.6%). Among the live births, one infant exposed in utero to olanzapine had multiple anomalies including midline defects (cleft lip, encephalocele, and aqueductal stenosis). The mean birth weight was 3341 g. There were no statistically significant differences, including rates of neonatal complications, between the cases and controls, with the exceptions of low birth weight (10% vs. 2%, $p = 0.05$) and elective abortions (9.9% vs. 1.3%, $p = 0.003$). The low birth weight may have been caused by the increased rate of cigarette smoking (38% vs. 13%, $p \leq 0.001$) and heavy/binge alcohol use (5 vs. 1) in the exposed group (8).

In a comparison of drugs used in the treatment of schizophrenia during pregnancy, the American Academy of Pediatrics (AAP) classified risperidone as high potency (9). The classification was based on the potential for extrapyramidal reactions (e.g., acute dystonia, akathisia, parkinsonism, and tardive dyskinesia). The AAP cautioned that large maternal doses of high-potency drugs could produce these effects in newborns. However, it did note that high-potency antipsychotics were preferred to minimize maternal anticholinergic, hypotensive, and antihistamine effects. No recommendation concerning the use of risperidone during pregnancy was made because of the lack of data (9).

The manufacturer reported a case of agenesis of the corpus callosum in an infant exposed to risperidone during pregnancy (2). No further details were provided.

A 2006 case report described a woman with a long history of paranoid schizophrenia who was treated with oral risperidone (10). Early in an unknown pregnancy she was started on IM risperidone 25 mg every 2 weeks; the

therapy was stopped when she was found pregnant in the 20th week. At 38 weeks, she was hospitalized because of psychotic decompensation with malnutrition (weight 59 kg). She gave birth spontaneously about 2 weeks later to a healthy but small-for-date 2900-g female infant without malformations. At 2.5 years of age, no major health problems had occurred. A minor retardation in her motor development was described but still within the normal range (10).

A 35-year-old woman with a 7-year history of schizophrenia was treated before and throughout pregnancy with long-acting IM risperidone 25 mg every 2 weeks (11). At 37 weeks, her membranes ruptured and she delivered vaginally a 2230-g female infant with Apgar scores of 9 at 1 and 5 minutes. No congenital anomalies were found and the infant was developing normally at 8 months of age (11).

In an extensive literature search, representatives of a manufacturer identified 713 pregnancies in which the mothers were treated with risperidone (12). The reported data were prospective in 516 cases and retrospective in the remaining 197 cases. Adverse pregnancy outcomes were more frequently reported in the retrospective cases. In the 68 prospectively reported pregnancies with a known outcome and after exclusion of 13 elective abortions, structural anomalies and spontaneous abortions occurred in 3.8% and 16.9%, respectively. These results were thought to be consistent with the background rates in the general population. In the retrospective cases, major structural anomalies were observed in 12 pregnancies. The defects most frequently reported involved the heart, brain, and lip and/or palate. In addition, there were 37 outcomes involving perinatal syndromes, of which 21 involved behavioral or motor disorders. The authors concluded that the results do not appear to show an increased risk of congenital anomalies or SABs, but limited extrapyramidal effects in the neonate did occur when risperidone was used in the 3rd trimester (12).

BREASTFEEDING SUMMARY

Risperidone and its active metabolite, 9-hydroxyrisperidone, are excreted into breast milk (13–15). A 21-year-old mother with a 2-year history of bipolar disorder stopped all medication when her pregnancy was diagnosed (13). She did well during pregnancy and delivered a healthy infant at 38 weeks' gestation. When her disease relapsed, she was admitted to the hospital 2.5 months after birth of her infant, stopped breastfeeding, and started on risperidone, eventually reaching a steady-state dose of 6 mg/day. Concentrations of risperidone and the active metabolite were determined in the plasma and milk.

The milk:plasma ratios for the parent drug and metabolite, based on AUC, were 0.42 and 0.24, respectively. Based on a daily milk intake of 150 mL/kg, the nursing infant would have received 0.84% of the mother's risperidone dose (mg/kg/day) and an additional 3.46% from the metabolite (as risperidone equivalents), or about 4.3% of the weight-adjusted maternal dose. Although the combined amounts of risperidone and metabolite in breast milk appear to be too low to cause extrapyramidal effects, concern was expressed for other effects, such as neuroleptic malignant syndrome, and effects on cognitive development (13).

A 2004 study measured the steady-state plasma and milk concentrations of risperidone and 9-hydroxyrisperidone in two breastfeeding women and one woman with risperidone-induced galactorrhea (14). The 29-year-old woman with galactorrhea was taking risperidone 3 mg at night (37.5 mcg/kg/day) for schizophrenia. The galactorrhea was attributed to elevated prolactin concentrations due to the D₂ antagonist effects of risperidone. Milk and plasma samples were collected 20 hours postdose, and then milk only on days 2 and 3, each at 21 hours postdose. The plasma concentrations of risperidone and the metabolite were <1 and 14 mcg/L, respectively. All milk risperidone concentrations were <1 mcg/L, whereas the mean concentration of the metabolite was 5.1 mcg/L (range 4.4–5.6 mcg/L). Although the woman was not nursing, the absolute and relative infant doses were 0.88 mcg/kg/day or 2.3% (as risperidone equivalents) (14).

The two women who were breastfeeding were treated for psychosis with risperidone doses of 42.1 mcg/kg/day (2 mg every 12 hours) and 23.1 mcg/kg/day (0.5 mg in the morning and 1 mg at night), respectively (14). The nursing infants were a 3.3-month-old female and a 6-week-old male, respectively. In the first woman, milk concentrations of the parent drug and metabolite were 49 and 142 mcg•hr/L (AUC), respectively, whereas the average concentrations were 2.1 and 6 mcg/L, respectively. The absolute infant doses were 0.32 and 0.9 mcg/kg/day, respectively. In the second woman, milk concentrations were 3.1 and 56.5 mcg•hr/L (AUC), respectively, whereas the average concentrations over 24 hours were 0.39 and 7.06 mcg/L, respectively. The absolute infant doses were 0.06 and 1.06 mcg/kg/day, respectively. The milk:plasma ratios were 0.1 and 0.5, respectively. Neither risperidone nor the metabolite was detected in the plasma of the infants and both were developing normally at 9 and 12 months, respectively (14).

No developmental abnormalities were observed in two infants of mothers treated with risperidone throughout gestation and during breastfeeding (6) (see

Fetal Risk Summary).

A 23-year-old woman, nursing a 4.2-kg male infant, was diagnosed with paranoid schizophrenia 1 week after birth (15). She was hospitalized and started on risperidone 1 mg twice daily. The dose was changed to 2 mg every evening on day 7, and then to 3 mg every evening on day 10. Milk (fore and hind) and maternal plasma concentrations of risperidone and paliperidone were determined on days 6, 10, and 20. No drug accumulation was observed and the concentrations of paliperidone always exceeded those of risperidone. The ranges of risperidone and paliperidone milk concentrations were 0–3 and 1.2–11 ng/mL, respectively, whereas the plasma concentrations were 0.4–10 and 4–43 ng/mL, respectively. Moreover, the concentrations in fore- and hind-milk were comparable. On day 10, 15 hours after a 2 mg dose, the concentrations of risperidone and paliperidone in infant plasma were 0 and 0.1 ng/mL, respectively. The mother was discharged home on risperidone after 5 weeks. The psychomotor development of the infant during the mother's hospitalization was normal and no adverse effects or sedation in the infant were observed. The mother and infant were doing well 2 months after discharge (15).

The AAP classifies other antipsychotic drugs as agents for which the effect on nursing infants is unknown but may be of concern, especially when given for long periods (16). Although risperidone was not mentioned, the AAP noted that antipsychotics are excreted into breast milk and could conceivably alter both short-term and long-term central nervous system function. Although no adverse effects from exposure to risperidone have been observed, studies have not been conducted to determine if there are long-term effects.

RITODRINE

[Withdrawn from the market. See 9th edition.]

RITONAVIR

Antiviral

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Although the limited human data do not allow an assessment of the risk of ritonavir during pregnancy, the animal data suggest that the drug may represent a low risk to the developing fetus. If indicated, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Ritonavir is an inhibitor of protease in HIV types 1 and 2 (HIV-1 and HIV-2). Protease is an enzyme that is required for the cleavage of viral polyprotein precursors into active functional proteins found in infectious HIV. The mechanism of action is similar to four other protease inhibitors: amprenavir, indinavir, nelfinavir, and saquinavir (1).

Reproduction studies have been conducted in pregnant rats and rabbits. Maternal toxicity and fetal toxicity, but not teratogenicity, were observed in rats at dose exposures equivalent to approximately 30% of that achieved with the human dose. Fetal toxicity consisted of early resorptions, decreased body weight, ossification delays, and developmental variations. At a dose exposure equivalent to 22% of that achieved with the human dose, a slight increase in cryptorchidism was observed. Fetal toxicity (resorptions, decreased litter size, and decreased weights) and maternal toxicity were observed in rabbits at a dose 1.8 times the human dose based on BSA (1).

A 1998 in vitro experiment using term perfused human placentas demonstrated that the placental transfer of ritonavir was concentration dependent and that the clearance index, at both maternal trough and peak concentrations, was very low (2). The investigators attributed the low transfer to the molecular weight (about 721) and solubility characteristics of ritonavir (2). In another report, the drug was detected in cord blood samples (577 and

1020 ng/mL) of twins born at 34 weeks from a woman treated with ritonavir 100 mg twice daily from 25 to 34 weeks (3).

The Antiretroviral Pregnancy Registry reported, for the period January 1989 through July 2009, prospective data (reported before the outcomes were known) involving 4702 live births that had been exposed during the 1st trimester to one or more antiretroviral agents (4). Congenital defects were noted in 134, a prevalence of 2.8% (95% confidence interval [CI] 2.4–3.4). In the 6100 live births with earliest exposure in the 2nd/3rd trimesters, there were 153 infants with defects (2.5%, 95% CI 2.1–2.9). The prevalence rates for the two periods did not differ significantly. There were 288 infants with birth defects among 10,803 live births with exposure anytime during pregnancy (2.7%, 95% CI 2.4–3.0). The prevalence rate did not differ significantly from the rate expected in a nonexposed population. There were 2552 outcomes exposed to ritonavir (1000 in the 1st trimester and 1552 in the 2nd/3rd trimesters) in combination with other antiretroviral agents. There were 61 birth defects (22 in the 1st trimester and 39 in the 2nd/3rd trimesters). In reviewing the birth defects of prospective and retrospective (pregnancies reported after the outcomes were known) registered cases, the Registry concluded that, except for isolated cases of neural tube defects with efavirenz exposure in retrospective reports, there was no other pattern of anomalies (isolated or syndromic) (4). (See Lamivudine for required statement.)

The experience of one perinatal center with the treatment of HIV-infected pregnant women was summarized in a 1999 abstract (5). Of 55 women receiving 3 or more antiviral drugs, 39 were treated with a protease inhibitor (6 with ritonavir). The outcomes included 2 spontaneous abortions, 5 elective abortions, 27 newborns, and 5 ongoing pregnancies. One woman was taken off indinavir because of ureteral obstruction and another (drug therapy not specified) developed gestational diabetes. None of the newborns tested positive for HIV, and none had major congenital anomalies or complications (5).

A public health advisory has been issued by the FDA on the association between protease inhibitors and diabetes mellitus (6). Because pregnancy is a risk factor for hyperglycemia, there was concern that these antiviral agents would exacerbate this risk. An abstract published in 2000 described the results of a study involving 34 pregnant women treated with protease inhibitors (5 with ritonavir) compared with 41 controls that evaluated the association with diabetes (7). No association between protease inhibitors and an increased incidence of gestational diabetes was found.

A case of combined transient mitochondrial and peroxisomal β -oxidation

dysfunction after exposure to nucleoside analog reverse transcriptase inhibitors (NRTIs) (lamivudine and zidovudine) combined with protease inhibitors (ritonavir and saquinavir) throughout gestation was reported in 2000 (8). A male infant was delivered at 38 weeks' gestation. He received postnatal prophylaxis with lamivudine and zidovudine for 4 weeks until the agents were discontinued because of anemia. Other adverse effects that were observed in the infant (age at onset) were hypocalcemia (shortly after birth), Group B streptococcal sepsis, ventricular extrasystoles, prolonged metabolic acidosis, and lactic acidemia (8 weeks), a mild elevation of long chain fatty acids (9 weeks), and neutropenia (3 months). The metabolic acidosis required treatment until 7 months of age, whereas the elevated plasma lactate resolved over 4 weeks. Cerebrospinal fluid lactate was not determined nor was a muscle biopsy conducted. Both the neutropenia and the cardiac dysfunction had resolved by 1 year of age. The elevated plasma fatty acid level was confirmed in cultured fibroblasts, but other peroxisomal functions (plasmalogen biosynthesis and catalase staining) were normal. Although mitochondrial dysfunction has been linked to NRTI agents, the authors were unable to identify the cause of the combined abnormalities in this case. The child was reported to be healthy and developing normally at 26 months of age (8).

A multicenter, retrospective survey of pregnancies exposed to protease inhibitors was published in 2000 (9). There were 92 liveborn infants delivered from 89 women (3 sets of twins) at 6 health care centers. One nonviable infant, born at 22 weeks' gestation, died. The surviving 91 infants were evaluated in terms of adverse effects, prematurity rate, and frequency of HIV-1 transmission. Most of the infants were exposed in utero to a single protease inhibitor, but a few were exposed to more than one because of sequential or double combined therapy. The number of newborns exposed to each protease inhibitor was indinavir (N = 23), nelfinavir (N = 39), ritonavir (N = 5), and saquinavir (N = 34). Protease inhibitors were started before conception in 18, and during the 1st, 2nd, or 3rd trimesters in 12, 44, and 14, respectively, and not reported in 1. Other antiretrovirals used with the protease inhibitors included four NRTIs (didanosine, lamivudine, stavudine, and zidovudine). The most common NRTI regimen was a combination of zidovudine and lamivudine (65% of women). In addition, seven women were enrolled in the AIDS Clinical Trials Group Protocol 316 and, at the start of labor, received a single dose of either the non-NRTI nevirapine or placebo. Maternal conditions, thought possibly or likely to be related to therapy, were mild anemia in eight, severe anemia in one (probably secondary to zidovudine), and thrombocytopenia in

one. Gestational diabetes mellitus was observed in three women (3.3%), a rate similar to the expected prevalence of 2.6% in a nonexposed population. One mother developed postpartum cardiomyopathy and died 2 months after birth of twins, but the cause of death was not known. For the surviving newborns, there was no increase in adverse effects over that observed in previous clinical trials of HIV-positive women, including the prevalence of anemia (12%), hyperbilirubinemia (6%; none exposed to indinavir), and low birth weight (20.6%). Premature delivery occurred in 19.1% of the pregnancies (close to the expected rate). The percentage of infants infected with HIV was 0 (95% CI 0%–3%) (9).

Two reviews, one in 1996 and the other in 1997, concluded that all women currently receiving antiretroviral therapy should continue to receive therapy during pregnancy and that treatment of the mother with monotherapy should be considered inadequate therapy (10,11). The same conclusion was reached in a 2003 review with the added admonishment that therapy must be continuous to prevent emergence of resistant viral strains (12). In 2009, the updated United States Department of Health and Human Services guidelines for the use of antiretroviral agents in HIV-1-infected patients continued the recommendation that therapy, with the exception of efavirenz, should be continued during pregnancy (13). If indicated, therefore, protease inhibitors, including ritonavir, should not be withheld in pregnancy because the expected benefit to the HIV-positive mother outweighs the unknown risk to the fetus. Pregnant women taking protease inhibitors should be monitored for hyperglycemia. The updated guidelines for the use of antiretroviral drugs to reduce perinatal HIV-1 transmission also were released in 2010 (14). Women receiving antiretroviral therapy during pregnancy should continue the therapy but, regardless of the regimen, zidovudine administration is recommended during the intrapartum period to prevent vertical transmission of HIV to the newborn (14).

BREASTFEEDING SUMMARY

No reports describing the use of ritonavir during lactation have been located. The molecular weight (about 721) is low enough that excretion into breast milk should be expected. The effect on a nursing infant is unknown.

Reports on the use of ritonavir during human lactation are unlikely because the antiviral agent is used in the treatment of HIV infection. HIV-1 is transmitted in milk, and in developed countries, breastfeeding is not recommended (10,11,13,15–17). In developing countries, breastfeeding is undertaken, despite the risk, because there are no affordable milk substitutes available. Until 1999,

no studies had been published that examined the effect of any antiretroviral therapy on HIV-1 transmission in milk. In that year, a study involving zidovudine was published that measured a 38% reduction in vertical transmission of HIV-1 infection despite breastfeeding when compared with controls (see Zidovudine).

RITUXIMAB

Antineoplastic/Immunologic Agent (Antirheumatic)

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

The use of rituximab in human pregnancy has been described in more than 200 cases. All of the live births were healthy, and none had structural anomalies that were thought to be related to rituximab. These outcomes are consistent with the reproduction studies with monkeys in which exposures that were nearly equivalent to human exposures were not associated with congenital defects. However, a functional deficit (depletion of B lymphocytes) was observed in monkey offspring and has occurred in at least two human newborns. The immunosuppression was reversible, with normal B-cell counts measured in monkey offspring by 6 months and in the infants. No increase in infectious disease was seen in any of the in utero exposed infants. Nevertheless, there is a risk for severe infections in immunosuppressed individuals, and this should be considered in all infants exposed in utero to rituximab.

FETAL RISK SUMMARY

Rituximab is a genetically engineered chimeric murine/human monoclonal immunoglobulin G1 (IgG1) kappa antibody that is directed against the CD20 antigen found on the surface of normal and malignant B lymphocytes. It has three indications: (a) for the treatment of patients with relapsed or refractory, low-grade or follicular, CD20-positive, B-cell, non-Hodgkin's lymphoma (NHL); (b) for the first-line treatment of diffuse large B-cell, CD20-positive, non-Hodgkin's lymphoma in combination with CHOP or other anthracycline-based chemotherapy regimens; and (c) in combination with methotrexate to reduce signs and symptoms in adult patients with moderately to severely active rheumatoid arthritis who have had an inadequate response to one or more TNF antagonist therapies. The elimination half-life of rituximab is dose-related. In

patients with NHL, the mean serum half-life after the first of four weekly infusions was 76.3 hours (range 31.5–152.6 hours), whereas the mean half-life after the fourth infusion was 205.8 hours (range 83.9–407.0 hours). In patients with rheumatoid arthritis, the mean terminal elimination half-life after two doses, 2 weeks apart, was 19 days (1).

Rituximab may cause severe infusion-related toxicity, including hypotension and other adverse effects. Premedication with acetaminophen and an antihistamine is recommended before each infusion (1). Hypotension in a pregnant woman could have deleterious effects on placental perfusion, resulting in embryo or fetal harm.

Reproduction studies have been conducted in cynomolgus monkeys. During organogenesis, monkeys were given three daily IV loading doses, then four weekly doses. The highest weekly dose resulted in exposures that were 0.8 times the human exposure from a 2-g dose based on AUC. There was no evidence of teratogenicity. However, the antibody did produce a decrease in B cells in the offspring. Subsequent studies showed that the decreased B cells and immunosuppression noted in the offspring returned to normal levels and functions within 6 months of birth. Long-term studies for carcinogenicity, mutagenicity, or effects on fertility have not been conducted (1).

Even though the molecular weight is high (about 145,000), the antibody crosses the monkey placenta (1). Rituximab also crosses the human placenta, at least near term. Very high levels of the antibody have been measured in cord blood and the young infant (2).

A 35-year-old woman was diagnosed with Burkitt's lymphoma of the left breast at 15 weeks' gestation (2). Starting at week 16, she was treated with four weekly infusions of rituximab 375 mg/m². Then at 3-week intervals, she was treated with four courses of the R-CHOP regimen followed by two courses of CHOP. The patient was in complete remission at 37 weeks. At 41 weeks', a healthy female infant was delivered via cesarean section. At birth, rituximab serum levels in the cord blood and mother were 32,095 and 9750 ng/mL (cord blood:mother ratio 3.3), respectively. Serum levels in the infant at 4 and 18 weeks of age were 5399 and 700 ng/mL, respectively, whereas the mother's serum level at 18 weeks was 500 ng/mL (infant:mother ratio 1.4). No CD19 B-cells were found in the mother or newborn. In the infant at 4 and 18 weeks of age, B-cell counts were 70 and 1460 cells/micro-L) (normal range for infants 3–6 months: 200–1100 cells/micro-L), respectively. At 20 months of age, the infant's B-cell count was normal and no infectious complications, malformations, or other immune dysfunction have been observed in the now 26-month-old child

(2).

A brief 2001 correspondence described the use of rituximab in the 2nd trimester (3). The 29-year-old woman, with diffuse large B-cell NHL, in her 21st week of pregnancy was treated with rituximab 375 mg/m² on day 1, doxorubicin 50 mg/m² on day 3, vincristine 2 mg on day 3, and prednisolone 100 mg on days 3–7, given in 4-week cycles. At 35 weeks' gestation, 2 weeks after the last of four cycles, she delivered a healthy female infant (birth weight or other details not given) via cesarean section. The child was developing normally and a normal peripheral B-cell population was noted at 4 months of age (3).

A 37-year-old woman with an 8-year history of follicular NHL was treated with weekly infusions (375 mg/m²) of rituximab for 4 weeks (4). Pregnancy was detected 1 week after the last dose with conception occurring between the first and second infusions. No further rituximab treatment was given. The woman delivered a normal, healthy 3610-g female infant at 40 weeks' gestation. No hematological or immunological adverse effects were detected in the infant. At 18 months of age, the child has normal immunity and has had no major infections (4).

A 31-year-old woman at 15 weeks' gestation was diagnosed with B-cell NHL (5). She was treated with six cycles of R-CHOP on a 14-day schedule (rituximab 375 mg/m², cyclophosphamide 750 mg/m², doxorubicin 50 mg/m², vincristine 1.4 mg/m², and prednisone 100 mg/day on days 1–5). Filgrastim 300 mcg/day was given on days 6–11. At 33 weeks' gestation, 2 months after the last cycle, the woman spontaneously delivered a healthy female infant (weight and size within the 50th–90th percentiles) with Apgar scores of 8, 10, and 10 at 1, 5, and 10 minutes, respectively. The 16-month-old child has been closely evaluated every 3 months since birth and has had no infections or evidence of physiological or developmental abnormalities (5).

A 2006 report briefly mentioned the use of weekly infusions of rituximab (375 mg/m²) for severe thrombotic thrombocytopenic purpura (TTP) (6). The woman had a left-sided stroke and seizure at 16 weeks' gestation and was diagnosed with acute TTP. Rituximab infusions were started at 27 weeks' to reduce the risk of further complications by reducing IgG antibodies. The woman suffered another seizure in the 30th week of pregnancy and an emergency cesarean section delivered a 1045-g male infant. The infant has had no infectious complications (6).

A 41-year-old woman, with a history of cardiac valvulopathy responsible for left ventricular failure, was treated for recurrent autoimmune hemolytic anemia

with four weekly IV doses of rituximab (375 mg/m²) and daily corticosteroids (7). Unbeknownst to her physicians, the patient also was pregnant, receiving the four rituximab doses between 7 and 10 weeks of gestation. No other exposures occurred during the remainder of a normal pregnancy and she delivered a normal, 3060-g female infant at 38 weeks' gestation. Apgar scores were 10 at 1, 5, and 10 minutes. Mature B-cells and B-cell precursors were present at birth, as well as during the first 55 days after birth. A mild bone depression at the sacrum–coccyx level was noted, but an evaluation completely excluded spina bifida occulta. Other than a possible mild infection at 24 hours of age, and a transient and slight lymphopenia on days 2 and 3, no other alterations in the infant were detected (7).

Treatment during pregnancy of a 36-year-old woman with long-standing immune-mediated thrombocytopenia was discussed in a 2008 report (8). Her initial treatment during pregnancy consisted of corticosteroids and IV immunoglobulins, but only a small rise was noted in the platelet count and she had persisting hemorrhagic diathesis. Treatment was changed to prednisone 60 mg/day and continued to 36 weeks'. At week 30, she was given rituximab weekly for 4 consecutive weeks followed by additional IV immunoglobulins. At 38 weeks', 4 weeks after the last dose of rituximab, labor was induced and a 3780-g female infant was born with Apgar scores of 7, 8, and 8 at 1, 5, and 10 minutes, respectively. The rituximab concentration in the newborn was 6.7 mg/L. The number of B-cells in the neonate was 0, but a rise was detected at 3 months of age so that at 6 months they were in the normal range. At 10 months of age, growth and development were normal. She did not have any infections and the vaccination titers were normal (8).

A 2011 study, authored by investigators from Stanford University School of Medicine and the manufacturer, described 231 pregnancies gathered worldwide that were exposed to rituximab in the 1st and 2nd trimesters (9). More than half of the pregnancies were also exposed to other potentially teratogenic agents. Of the 231 pregnancies, 67 outcomes were unknown, 11 were ongoing, and 153 outcomes were known. In the latter group, there were 90 live births, 1 maternal death (cerebral hemorrhage from preexisting autoimmune thrombocytopenia), 1 stillbirth (20 weeks' due to fetal hypoxemia from umbilical cord knot), 33 spontaneous abortions (all in 1st trimester), and 28 elective abortions (1 for trisomy 13). Among the live births, there were 22 premature infants, 1 neonatal death at 6 weeks, and 11 neonates with hematologic abnormalities, but none had corresponding infections. Four neonates had infection (fever, bronchitis, cytomegalovirus hepatitis, and

chorioamnionitis). Two infants had a structural anomaly, clubfoot in one twin, and a cardiac malformation in a singleton birth (9).

A brief 2011 report described the outcome of a pregnancy that was exposed to rituximab given 6 weeks before conception (10). The 32-year-old woman was treated with rituximab for long-standing rheumatoid arthritis resistant to other therapies. After an uncomplicated pregnancy, she gave birth to twin females at 37 weeks', one with a clubfoot and the other with transient erythema toxicum neonatorum. Normal B-cell counts and normal immunoglobulin levels were measured during 8 months of follow-up, but one girl had transient mild leucocytosis without signs of infection. Both were developing normally, without serious infectious complications, although one had mild asthma (10).

A 2012 case report described the pregnancy of a 34-year-old woman at 27 weeks' with systemic lupus erythematosus who developed severe thrombocytopenia (11). She was treated with high-dose corticosteroids, IV immunoglobulin, rituximab (weekly for 4 doses starting at about 27 weeks'), one dose of cyclophosphamide, eltrombopag, and anti-D immunoglobulin, but the thrombocytopenia was resistant to these agents. Romiplostim (weekly for 3 doses) was then given and the platelet count rose from $4 \times 10^9/L$ to $91 \times 10^9/L$. Because her platelet count began to fall, she was given the third dose of romiplostim 1 day before induction of labor at 34 weeks'. A healthy normal female baby was born with a normal platelet count (no additional details provided) (11).

In a second 2012 case report, a 22-year-old woman during the 12th week of pregnancy was diagnosed with primary mediastinal large B-cell lymphoma (12). In the 13th week, she was started on standard doses of R-CHOP regimen (rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone) given every 3 weeks for six cycles. Her last cycle was at her 31st week of pregnancy. At 34 weeks', she underwent labor induction and gave birth to a healthy male baby with Apgar scores of 9 and 9 (no other details given). At 1 year of age, the infant has shown no developmental delays or physical abnormalities (12).

A 2013 case report described the outcomes of two pregnancies exposed to rituximab in the 1st trimester (13). In the first case, a 25-year-old woman with rheumatoid arthritis conceived while receiving rituximab (500 mg on days 1 and 15 of each cycle) and methotrexate (10 mg/week). Rituximab was given at weeks 2 and 4. Both drugs were then stopped. The previous cycle had been given 6 months before the current cycle. A cesarean section was performed at week 37 to give birth to a healthy 3110-g neonate (sex not specified) with

Apgar scores of 10 and 10 at 5 and 10 minutes, respectively. The child was doing well at 4.5 years follow-up. The second case involved a 31-year-old woman with multiple relapsing TTP. Her last dose of rituximab occurred 9 weeks before conception. Serum concentrations of rituximab at 11 and 31 weeks' were 0.11 mcg/mL and undetected, respectively. Based on the pharmacokinetics, the theoretical concentration at conception was estimated to be 1 mcg/mL. At 39 weeks', a healthy 3024-g neonate (sex not specified) was born vaginally with Apgar scores of 10 and 10 at 5 and 10 minutes, respectively. The infant was doing well at 1.5 years of age (13).

A 2013 review summarized seven reports on the use of rituximab in pregnancy (14). The seven studies (2,5–9,11) are discussed above. The authors concluded that, although the drug could not be considered completely safe, it could be given if the maternal benefit outweighed the potential embryo–fetal risk (14). Another 2013 review examined the available evidence on drugs used for dermatologic diseases in pregnancy (15). Based on case reports or clinical experience, the authors classified rituximab as safe in pregnancy.

BREASTFEEDING SUMMARY

No reports describing the use of rituximab during human lactation have been located. The molecular weight (about 145,000) is very high, but human IgG is excreted into milk, and therefore, rituximab also may be excreted. The effects of this potential exposure on a nursing infant are unknown, but immunosuppression and other severe adverse effects are potential complications.

RIVAROXABAN

Anticoagulant

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of rivaroxaban during human pregnancy have been located. The animal data in one species suggest risk but the adverse embryo–fetal outcomes may have been caused by maternal hemorrhage. Structural malformations were not observed in the animals. Pregnancy-related hemorrhage and/or emergent delivery is a concern because the drug cannot be reliably monitored with standard laboratory testing, and the anticoagulant effect is not readily reversible other than waiting about 24 hours (1). For these reasons, the drug should be avoided in pregnancy (2). In addition, the treatments of deep venous thrombosis or pulmonary embolism are not approved indications and rivaroxaban should not be used as heparin is the treatment of choice for these indications (3). However, if rivaroxaban is the treatment of choice for its approved indications, it should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Rivaroxaban is an oral factor Xa inhibitor in the same pharmacologic class as apixaban. It is indicated to reduce the risk of stroke and systemic embolism in patients with nonvalvular atrial fibrillation and for the prophylaxis of deep vein thrombosis which may lead to pulmonary embolism in patients undergoing knee or hip replacement surgery. Rivaroxaban undergoes partial metabolism to inactive metabolites; the parent drug is the predominant moiety in plasma with no major or active circulating metabolites. Plasma protein binding, primarily to albumin, is 92%–95% and the terminal elimination half-life is 5–9 hours in healthy subjects (1).

Reproduction studies with oral rivaroxaban have been conducted in rats and

rabbits. Pronounced maternal hemorrhage occurred in rats but the dose was not specified. Decreased fetal body weights were observed with doses that were about 14 times the human exposure of unbound drug based on AUC at the highest recommended dose of 20 mg/day (HE). Maternal hemorrhage also occurred in rabbits given a dose that produced exposures during organogenesis that were about 4 times the HE. At this dose, embryo–fetal toxicity in rabbits included increased resorptions, decreased number of live fetuses, and decreased fetal body weight. Without mentioning the animal species, the manufacturer reported that during labor and delivery a dose about 6 times the HE resulted in maternal bleeding and maternal and fetal death. Rivaroxaban crossed the placenta in both rats and rabbits (1).

Two-year studies for carcinogenesis were negative in mice and rats. Studies for mutagenicity also were negative, as were studies for impaired fertility in male and female rats (1).

As demonstrated by autoradiography, moderate amounts of rivaroxaban cross the human placenta (4). The transfer is consistent with the molecular weight (about 436), limited metabolism, and moderately long elimination half-life. Although the amount crossing has not been determined, it may be limited by the high plasma protein binding.

BREASTFEEDING SUMMARY

No reports describing the use of rivaroxaban during human lactation have been located. A 2012 reference on the treatment of pulmonary embolism in pregnancy, however, stated without further details that the drug is excreted into breast milk (2). This would be consistent with the molecular weight (about 436), limited metabolism, and moderately long elimination half-life (5–9 hours), but the moderately high plasma protein binding (92%–95%) might limit the excretion. The effect of this exposure on a nursing infant is unknown, but hemorrhage is a potential complication. Until additional data on the amount in breast milk are available, the safest course is to not breastfeed when taking this drug.

RIVASTIGMINE

Cholinesterase Inhibitor (CNS Agent)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of rivastigmine in human pregnancy have been located. Because of its indication, such reports would be rare. Moreover, the animal data suggest that the risk to the embryo–fetus is low. Therefore, inadvertent exposure to rivastigmine during pregnancy should not be a reason for pregnancy termination.

FETAL RISK SUMMARY

Rivastigmine is a reversible cholinesterase inhibitor that is indicated for the treatment of mild to moderate dementia of the Alzheimer's type. Rivastigmine penetrates the blood–brain barrier with drug concentrations in the cerebral spinal fluid about 40% of those in the plasma. It is extensively metabolized to inactive metabolites. Protein binding is moderate (about 40%) and the plasma elimination half-life is about 1.5 hours (1).

Reproduction studies have been conducted in rats and rabbits. In rats, doses up to about 2 times the maximum recommended human dose based on BSA (MRHD) were not teratogenic. Decreased fetal/pup weights were observed in rats at doses several-fold lower than the MRHD, usually at doses causing some maternal toxicity. No effects on fertility or reproductive performance were observed at doses about 0.9 times the MRHD. No evidence of teratogenicity was noted in rabbits given doses up to about 4 times the MRHD (1). Rivastigmine and/or its metabolites cross the rabbit placenta producing an average fetal-to-placenta tissue ratio of 0.5 (2).

It is not known if rivastigmine or its metabolites cross the human placenta. The molecular weight of the parent compound (about 250 for the free base), moderate protein binding, and the ability to cross the blood–brain barrier

suggest that the drug will cross to the fetal compartment. The very short elimination half-life should decrease the amount of drug available for transfer.

BREASTFEEDING SUMMARY

No reports describing the use of rivastigmine during human lactation have been located.

Because of its indication, such reports should be rare. The molecular weight (about 250 for the free base), moderate protein binding, and the ability to cross the blood–brain barrier suggest that the drug will be excreted into breast milk. The very short elimination half-life should decrease the amount of drug available for excretion. The effect of this exposure on a nursing infant is unknown.

RIZATRIPTAN

Antimigraine

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Although no adverse outcomes were observed in liveborn offspring in the Merck Prospective Registry or clinical trials, the limited number of exposures studied is not sufficient to detect a risk of rare disorders such as individual birth defects (1). However, a 2008 review of triptans in pregnancy found no evidence for teratogenicity, but the data did suggest a possible increase in the rate of preterm birth (2).

FETAL RISK SUMMARY

Rizatriptan, an oral, selective 5-hydroxytryptamine_{1B/1D} receptor agonist, is indicated for the treatment of acute migraine attacks with or without aura in adults. The drug is metabolized to inactive metabolites. Plasma protein binding is low (14%) and the average plasma half-life is 2–3 hours (3).

Reproduction studies have been conducted in rats and rabbits. Female rats were treated before and during mating, and throughout gestation and lactation with doses that produced maternal exposures (AUC) 15 and 225 times, respectively, the exposure in humans from the maximum recommended human dose of 30 mg (MRHD). These doses were not maternal toxic, but did cause decreased birth weight and reduced preweaning and postweaning weight gain in offspring. In a prenatal and postnatal development toxicity study in rats, doses producing maternal exposures 225 to more than 500 times the MRHD caused toxicity in the offspring as shown by increased mortality at birth and for the first 3 days after birth, reduced preweaning and postweaning weight gain, and decreased learning capacity. The no-effect dose for all of these effects was approximately 7.5 times the MRHD. In embryo and fetal development studies, no teratogenic effects were observed in rats and rabbits given doses

during organogenesis producing maternal exposures 225 and 115 times, respectively, the MRHD. Fetal weights were decreased at these doses, but maternal weight gain was also reduced. The developmental no-effect doses, in both species, were approximately 15 times the MRHD. Rizatriptan crosses the placentas of rats and rabbits (3).

It is not known if rizatriptan crosses the human placenta. The molecular weight of the free base (about 269), low plasma protein binding, and moderate plasma half-life suggest that exposure of the embryo–fetus should be expected.

In the Merck Pregnancy Registry program, 81 women were prospectively enrolled after exposure to rizatriptan (1). The outcomes of these pregnancies were 26 lost to follow-up, 3 spontaneous abortions (SABs), 1 elective abortion (EAB) (chromosomal anomaly—partial replication of chromosome 3 in a 39-year-old woman), 2 fetal deaths (1 cord accident; twin B), 1 neonatal death (due to prematurity), and 50 live births. The 3 SABs occurred in the 1st trimester. In addition to the chromosomal anomaly noted above, three outcomes involved congenital defects: juxtaposition of the arteries (exposure timing unknown), bladder outlet obstruction in twin B (mother with gestational diabetes and hypertension; twin A live birth, twin B died at 23 weeks), and hypospadias of the glans (surgical correction required). Of nine retrospective reports, three involved outcomes with congenital anomalies: two cases of chromosomal abnormalities (one a de novo duplication of chromosome 2 and one with Turner syndrome) and one case of anencephaly (EAB at 16 weeks).

In international prospective reports, three cases of congenital anomalies were described (trimester of exposure): (a) premature infant with growth restriction, subependymal cyst, interatrial communication, and mild persistent ductus arteriosus (1st trimester); (b) hemangioma of unreported size of the head and neck (1st trimester); and (c) trisomy 21, died in utero at 20 weeks. International retrospective reports involved two cases of defects: a baby born with cataracts and the other with an unspecified fetal anomaly. In clinical trials, there were no known adverse effects among live births (1).

The manufacturer maintains a pregnancy registry for women exposed to rizatriptan. Health care professionals are encouraged to report pregnancy exposures to the registry by calling the toll-free number 800-986-8999.

BREASTFEEDING SUMMARY

No reports describing the use of rizatriptan in human lactation have been located. The molecular weight of the free base (about 269), low plasma protein binding (14%), and moderate plasma half-life (2–3 hours) suggest that the drug

will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown.

ROCURONIUM

Skeletal Muscle Relaxant

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Human pregnancy experience with rocuronium is limited to the 2nd and 3rd trimesters. Although the absence of exposures during organogenesis prevents a more thorough assessment, neuromuscular blocking agents generally do not appear to represent a significant risk for an embryo or fetus. The animal data for rocuronium suggest low embryo–fetal risk. Moreover, the agent contains a quaternary ammonium site in its structure that will limit its placental transfer. One review predicted that the maternal drug concentrations would always exceed fetal levels (1). Neuromuscular blockade in a newborn is probably a rare but potential toxicity (2). If indicated, rocuronium should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Rocuronium (rocuronium bromide) is a competitive (nondepolarizing) neuromuscular blocking agent. Structurally, it is a quaternary ammonium compound that is an analog of vecuronium. Rocuronium is indicated as an IV adjunct to general anesthesia to provide skeletal muscle relaxation during surgery or mechanical ventilation. In normal adult patients, the elimination half-life is about 2.4 hours. Approximately 30% is bound to plasma proteins (3).

Reproduction studies have been conducted in rats and rabbits. In these species, the maximum tolerated IV dose administered 3 times daily during organogenesis was not teratogenic. The doses were 15%–30% and 25%, respectively, of the human intubation dose of 0.6–1.2 mg/kg based on BSA. In rats, the incidence of fetal death was increased, an effect that was thought to be due to oxygen deficiency that resulted from acute symptoms of respiratory dysfunction in the dams (3).

Consistent with the molecular weight (about 610 for rocuronium bromide) and the limitation placed on placental passage by ionization at physiologic pH, small amounts of rocuronium cross the placenta. In 32 patients from the study below, the mean maternal venous (MV) and umbilical venous (UV) blood was about 2412 and 390 ng/mL, respectively. The UV:MV ratio was 0.16. In 12 patients, the mean drug concentration in umbilical arterial (UA) plasma was about 271 ng/mL, resulting in a UA:UV ratio of 0.62 (4).

In a 1994 prospective, nonrandomized, multicenter study, 40 women undergoing cesarean section at term received anesthesia induction with rocuronium and thiopental, followed by isoflurane and nitrous oxide maintenance (4). No adverse effects on the newborns attributable to rocuronium were observed as evaluated by Apgar scores, time to sustained respiration, total and muscular neuroadaptive capacity scores, acid–base status, and blood–gas tensions in umbilical arterial and venous blood (4). This study generated a number of letters referring either to the doses used or to what was considered the drug of choice (succinylcholine) (5–9).

A 1996 report described the use of rocuronium in a 31-year-old patient at 28 weeks' gestation who presented with a penetrating injury of her left eye secondary to a motor vehicle accident (10). Prior to induction of anesthesia, she was started on IV magnesium sulfate to treat newly onset uterine contractions. Anesthesia was induced with rocuronium (0.9 mg/kg), fentanyl (200 mcg), and sodium thiopental (400 mg). The fetal heart rate (140–150 beats/minute) was monitored throughout the 6-hour surgical procedure. Except for a decrease in short-term variability attributable to anesthesia of the fetus, no other effects on the fetal heart rate were observed. Although the authors were aware of the interaction with magnesium, they choose a higher dose (usual dose is 0.6 mg/kg) to allow for more rapid intubation. As expected, the duration of paralysis was prolonged secondary to the high dose and interaction with magnesium, but the authors thought that this was acceptable given the patient's condition. The woman was discharged from the hospital 6 days after surgery with an apparently normal ongoing pregnancy (10). Information on the pregnancy outcome was not provided. Later correspondence regarding this case report discussed the benefits and risks of the therapy and dose (11,12).

Rocuronium was used in a 35-year-old patient undergoing a combined cesarean section delivery and posterior fossa craniotomy at 37 weeks' gestation (13). The patient had von Hippel-Lindau disease and surgery was required for an enlarged hemangioblastoma. General anesthesia was induced with rocuronium (50 mg), fentanyl (200 mcg), and sodium thiopental (300 mg).

A male infant (weight not specified) was delivered with Apgar scores of 5, 7, and 9 at 1, 5, and 10 minutes, respectively. Naloxone was required because of weak respiratory efforts 2 minutes after delivery (13).

A 1997 study compared thiopental–rocuronium with ketamine–rocuronium (20 in each group) for rapid sequence intubation in women undergoing cesarean section (14). The authors concluded that either drug combination was suitable. Based on 1- and 5-minute Apgar scores, no significant differences in neonatal condition were found between the two groups.

BREASTFEEDING SUMMARY

No reports describing the use of rocuronium in a lactating woman have been located. Because of the indications for this agent, it is doubtful if such reports will be forthcoming. The molecular weight (about 610 for rocuronium bromide) is low enough for excretion into breast milk, but the amount excreted will be limited because the drug is ionized at physiologic pH. The effects of this exposure on a nursing infant are unknown, but are probably not clinically significant.

ROFECOXIB

[Withdrawn from the market. See 9th edition.]

ROFLUMILAST

Respiratory (Selective Phosphodiesterase 4 Inhibitor)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of roflumilast in human pregnancy have been located. Developmental toxicity, at doses that were ≤ 10 or less than the human dose, occurred in only one of three species tested, but teratogenicity was not observed. However, the lack of human pregnancy experience prevents a more complete assessment of the embryo–fetal risk. If the maternal benefit clearly outweighs the unknown risk, the drug should not be withheld but the woman should be informed of the unknown risk.

FETAL RISK SUMMARY

Roflumilast is an oral selective inhibitor of phosphodiesterase 4. It is indicated as a treatment to reduce the risk of chronic obstructive pulmonary disease (COPD) exacerbations in patients with severe COPD associated with chronic bronchitis and a history of exacerbations. The drug is metabolized to an active metabolite. Plasma protein binding of roflumilast and its active metabolite is about 99% and 97%, respectively. For the two agents, the median plasma effective half-life is about 17 and 30 hours, respectively (1).

Animal reproduction studies have been conducted in mice, rats, and rabbits. In mice, stillbirth and decreased pup viability occurred at doses that were about ≥ 16 times the maximum recommended human dose based on BSA (MRHD). Postimplantation loss was induced in rats at doses that were ≥ 10 times the MRHD. No treatment-related effects on embryo–fetal development were noted in mice, rats, and rabbits at doses that were about 12, 3, and 26 times the MRHD, respectively. However, the drug did adversely affect postnatal development of mice pups when dams were given the drug during pregnancy

and lactation. At about 49 times the MRHD, pup rearing frequencies were decreased and, at about 97 times the MRHD, decreased survival and forelimb grip reflex and delayed pinna detachment were noted. Moreover, at about 16 times the MRHD, the drug disrupted the labor and delivery process in mice (1).

In long-term studies, roflumilast was carcinogenic in hamsters but not in mice. The drug was mutagenic in one assay but negative in multiple other assays. In a 3-month human study, roflumilast had no effects on semen parameters or reproductive hormones. In contrast, a dose-related effect on male rat fertility was noted with increases in the incidence of tubular atrophy, degeneration in the testis and spermiogenic granulation in the epididymides. No effect on female fertility was observed at the highest dose tested (1).

It is not known if roflumilast or its active metabolite cross the human placenta. The molecular weight of the parent drug (about 403), and the long effective half-lives of the parent drug and active metabolite suggest that both will cross to the embryo–fetus. However, the high plasma protein binding may limit the exposure.

BREASTFEEDING SUMMARY

No reports describing the use of roflumilast during human lactation have been located. The molecular weight of the parent drug (about 403), and the long effective half-lives (17 and 30 hours, respectively) of the parent drug and active metabolite suggest that both will be excreted into breast milk. However, the high plasma protein binding (99% and 97%, respectively) may limit the excretion. The effect of this exposure on a nursing infant is unknown. If a mother chooses to breastfeed while taking roflumilast, her nursing infant should be monitored for the most common ($\geq 2\%$) adverse reactions observed in adults (diarrhea, weight decrease, nausea, headache, back pain, insomnia, dizziness, and decreased appetite) (1).

ROMIDEPSIN

Antineoplastic

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of romidepsin in human pregnancy have been located. Only one animal species was tested and a slight decrease in fetal weight was observed. The study did not expose pregnant rats to enough of the drug to evaluate adverse outcomes fully (1). Romidepsin competes with β -estradiol for binding to estrogen receptors. Because estrogen is required to maintain pregnancy throughout gestation, the competition between romidepsin and β -estradiol could cause pregnancy loss. Moreover, romidepsin may reduce the effectiveness of estrogen-containing contraceptives.

FETAL RISK SUMMARY

The antineoplastic romidepsin, a histone deacetylase inhibitor, is administered as an IV infusion on days 1, 8, and 15 of a 28-day cycle. It is in the same subclass as vorinostat. Romidepsin is indicated for the treatment of cutaneous T-cell lymphoma in patients who have received at least one prior systemic therapy. The drug competes with β -estradiol for binding to estrogen receptors and may reduce the effectiveness of estrogen-containing contraceptives. Romidepsin undergoes extensive metabolism. Plasma protein binding is high (92%–94%), primarily to α_1 -acid-glycoprotein, and the terminal half-life is about 3 hours. No accumulation in the plasma was observed after repeated dosing (1).

A reproduction study was conducted in rats. During organogenesis, rats were given daily IV doses up to about 18% of the estimated human daily dose based on BSA. This dose resulted in a 5% reduction in fetal weight. However, embryo–fetal toxicities and other adverse developmental outcomes were not adequately assessed in this study (1).

Carcinogenicity studies have not been conducted. The drug was not mutagenic or clastogenic in various assays. Romidepsin caused impaired fertility in rats and mice. In male rats and mice, at exposures much less than those obtained in humans, the drug caused testicular degeneration. In addition, seminal vesicle and prostate organ weights were decreased in male rats. In female rats, atrophy was observed in the ovary, uterus, vagina, and mammary gland, as well as maturation arrest of ovarian follicles and decreased weight of ovaries. These toxicities occurred at doses and systemic exposures that were a small fraction of the human dose and exposure and probably resulted from the drug's high affinity for binding to estrogen receptors (1).

It is not known if romidepsin crosses the human placenta. The molecular weight (about 541) and the elimination half-life suggest that the drug will cross, but the high plasma protein binding may limit the exposure.

BREASTFEEDING SUMMARY

No reports describing the use of romidepsin during human lactation have been located. The molecular weight (about 541) and the elimination half-life (3 hours) suggest that the drug will be excreted into breast milk, but the high plasma protein binding (92%–94%) might limit the amount excreted. The effect of this exposure on a nursing infant is unknown but the potential for severe toxicity is a concern. Because the drug caused a wide-range of toxicity in adults that involved many systems (e.g., gastrointestinal, CNS, hematologic) and competes with β -estradiol for binding to estrogen receptors, mothers should not breastfeed while receiving this drug. However, the elimination half-life and the dosing schedule (IV infusion over 4 hours on days 1, 8, and 15 of a 28-day cycle) might allow breastfeeding on the days a dose is not given. If this strategy is chosen, the mother should “pump and dump” to maintain milk production and decrease discomfort from engorgement for at least 15 hours (i.e., five half-lives would allow about 97% of the drug to be eliminated from her blood) after the end of the infusion.

ROMIPLOSTIM

Hematopoietic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Only two reports describing the use of romiplostim in human pregnancy have been located. Although fetal toxicity was observed in one of three animal species, maternal toxicity also occurred making the result uninterpretable. However, use of the protein in human pregnancy might cause increased fetal platelet counts, a potential complication. If romiplostim is used in pregnancy, health care providers are encouraged to enroll pregnant patients in the Nplate Pregnancy Registry by calling 1-877-Nplate 1 (1-877-675-2831). Pregnant patients also can enroll themselves by calling the same number.

FETAL RISK SUMMARY

Romiplostim is an Fc-peptide fusion protein. It is indicated for the treatment of thrombocytopenia in patients with chronic immune (idiopathic) thrombocytopenia purpura (ITP) who have had an insufficient response to corticosteroids, immunoglobulins, or splenectomy. It is given as weekly SC injections. The half-life is a median 3.5 days (range 1–34 days) (1).

Reproduction studies have been conducted in rats, rabbits, and mice. In pregnant rats and rabbits, no evidence of fetal harm was observed with doses up to 11 and 83 times, respectively, the maximum human dose based on systemic exposure (MHD). In rats, a dose 11 times the MHD caused an increase in perinatal pup mortality. Romiplostim crossed the rat placenta and increased fetal platelet counts at clinically equivalent and higher doses. In mice, a dose 5 times the MHD resulted in maternal toxicity (reduced body weight) and increased postimplantation loss (1).

Neither studies for carcinogenicity nor mutagenesis have been conducted

with romiplostim. There was no effect on fertility with doses up to 37 times the RHD (1).

It is not known if romiplostim crosses the human placenta. The molecular weight (59,000) (2) is high enough to limit transfer, but the long half-life may assist transfer, especially in the 2nd and 3rd trimesters.

A 2012 case report described the pregnancy of a 34-year-old woman at 27 weeks' with systemic lupus erythematosus who developed severe thrombocytopenia (3). She was treated with high-dose corticosteroids, IV immunoglobulin, rituximab (weekly for 4 doses), one dose of cyclophosphamide, eltrombopag, and anti-D immunoglobulin, but the thrombocytopenia was resistant to these agents. Romiplostim (weekly for 3 doses) was then given and the platelet count rose from $4 \times 10^9/L$ to $91 \times 10^9/L$. Because her platelet count began to fall, she was given the third dose of romiplostim 1 day before induction of labor at 34 weeks'. A healthy normal female baby was born with a normal platelet count (no additional details were provided) (3).

In a 2013 case report, a 28-year-old primigravid with chronic immune thrombocytopenic purpura conceived while receiving romiplostim (4). During the 1st trimester, her platelets were stable on 3 mcg/kg/week but, at week 14, thrombocytopenia associated with epistaxis developed. Dexamethasone and IV immunoglobulin were added to supplement romiplostim in response to thrombocytopenic episodes. Alternating periods of profound thrombocytopenia and thrombocytosis occurred during the remainder of pregnancy. At about 34 weeks' labor was induced to deliver a 1910-g male infant with Apgar scores of 8 and 8 at 1 and 5 minutes, respectively. The neonate's platelets decreased markedly within 8 hours of birth and treated with IV immunoglobulin and a platelet transfusion. Other problems in the infant, in addition to thrombocytopenia, were a grade III intraventricular hemorrhage, adrenal insufficiency, and phimosis. However, at 10 months, the infant was developmentally normal (4).

BREASTFEEDING SUMMARY

No reports describing the use of romiplostim during human lactation have been located. The molecular weight (59,000) (2) is high enough to limit excretion, but the long half-life (3.5 days) may assist excretion. The effect on a nursing infant is unknown. However, if excretion does occur, the protein might be digested in the infant's gut.

ROPINIROLE

Antiparkinson Agent

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of ropinirole in human pregnancy have been located. The agent, when given alone, produced digital malformations in rats at embryo–fetal toxic doses. In rabbits, an increased incidence and severity of digital anomalies also were observed when ropinirole, at a dose 8 times the human dose, was combined with levodopa. The complete absence of human pregnancy experience, however, prevents an assessment of the human risk. Since Parkinson's disease is relatively uncommon during the childbearing years, the use of ropinirole during pregnancy also will be uncommon. Until data on such use are available, the safest course is to avoid, if possible, the use of ropinirole during the 1st trimester.

FETAL RISK SUMMARY

Ropinirole is a nonergoline dopamine agonist that is indicated for the treatment of the signs and symptoms of idiopathic Parkinson's disease. The drug has high specificity for the D₂ and D₃ dopamine receptor subtypes. Ropinirole is metabolized to inactive compounds and eliminated renally with a half-life of about 6 hours. Up to 40% is bound to plasma proteins (1). The agent is commonly used in combination with levodopa.

Reproduction studies in pregnant rats and rabbits have revealed embryo–fetal toxicity and teratogenicity (1). In rats, decreased fetal weight, increased fetal deaths, and digital malformations were observed with doses 24, 36, and 60 times, respectively, the maximum recommended human clinical dose based on BSA administered during organogenesis and later. In pregnant rabbits during organogenesis, no harmful fetal effects were observed when ropinirole was

given at a maternally toxic dose 16 times the maximum recommended human dose based on BSA (MRHD). However, when ropinirole (8 times the MRHD) was combined with levodopa (250 mg/kg/day), a greater incidence and severity of fetal malformations (primarily digit defects) occurred than when levodopa was used alone. In a 2-year carcinogenicity study in mice, ropinirole was associated with an increase in benign uterine endometrial polyps at a dose 10 times the MRHD (1).

It is not known if ropinirole can cross the placenta. The molecular weight (about 260 for the free base) and the moderate degree of protein binding suggest that the drug will cross to the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use of ropinirole during human lactation have been located (1). The molecular weight (about 260 for the free base) and its moderate degree of protein binding (up to 40%) suggest that it will be excreted into breast milk. Because milk is slightly acidic compared with the plasma, accumulation (ion trapping) in milk may occur. The effect of this exposure on a nursing infant is unknown. Infants should be monitored for adverse events commonly observed in adults, such as fatigue, syncope, somnolence, dizziness, dyspepsia, and nausea and vomiting. Ropinirole inhibits prolactin secretion and may inhibit lactation. Until data are available, the best course is to not breastfeed if ropinirole is being taken.

ROPIVACAINE

Local Anesthetic

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The human and animal data suggest that the risk to a human fetus from the use of ropivacaine in pregnancy is very low or nonexistent. However, there is no human pregnancy experience in the 1st trimester. The amounts measured in the maternal circulation are very low and do not appear to represent a significant embryo–fetal risk.

FETAL RISK SUMMARY

Ropivacaine is a member of the amino amide class of local anesthetics. It is indicated for local or regional anesthesia for surgery and for acute pain management. Ropivacaine is a pure S-enantiomer that is structurally similar to bupivacaine. It has been used for local and regional anesthesia before cesarean section and during labor. Plasma protein binding (94%) is primarily to α_1 -glycoprotein. The mean terminal half-life is 4.2 hours after epidural administration (1).

Reproduction studies have been conducted in rats and rabbits. In rats, daily SC doses up to about 0.33 times the maximum recommended human dose (epidural, 770 mg/24 hours) based on BSA (MRHD) during organogenesis revealed no teratogenic effects. When rats were given daily SC doses from gestational day 15 through postpartum day 20, there were no treatment-related effects on late fetal development, parturition, lactation, neonatal viability, or growth of the offspring. In another study, female rats were given daily SC doses that were about 0.3 times the MRHD for 2 weeks before mating, then during mating, pregnancy, and lactation, up to day 42 post-coitus. There was an increased loss of pups during the first 3 days postpartum, an effect thought to have occurred because of reduced maternal care due to maternal toxicity. In rabbits, SC doses up to about 0.33 times the MRHD during organogenesis

revealed no teratogenicity (1).

Pregnant sheep were given a 60-minute IV infusion of a local anesthetic (ropivacaine, bupivacaine, or levobupivacaine) at a rate that obtained a maternal serum concentration equivalent to that obtained during routine epidural anesthesia for cesarean delivery (2). No significant changes (heart rate, mean arterial blood pressure, arterial blood pH, and arterial oxygenation) in the fetuses were observed. Maternal hemodynamic parameters also were not affected. All three anesthetics crossed the placenta to the fetus with varying concentrations measured in all fetal tissues tested (heart, brain, liver, lung, kidney, and adrenals). The ropivacaine fetal:maternal serum ratio was approximately 0.3 (2).

A 1999 study used a dual perfused, single cotyledon human placental model to compare the placental transfer of ropivacaine and bupivacaine (3). Simulation of the actual in vivo plasma protein concentration (using a 4% albumin solution) resulted in a 50% decrease in the amounts transferred compared with a 2% albumin solution. In addition, decreasing the pH on the fetal side resulted in a significant increase in placental transfer. The investigators concluded that the placental transfer of both anesthetics was highly influenced by the amount of maternal and fetal protein binding and fetal pH (3).

In another study, epidural ropivacaine was given to women for cesarean section (4). The umbilical:maternal (U:M) veins ratio of unbound drug at delivery was 0.72 (4). A 1997 report measured mean U:M vein ratios for total and unbound ropivacaine after epidural of 0.31 and 0.74, respectively (5). In a third study, total ropivacaine concentrations in the umbilical vein and artery were 0.13–0.52 and 0.12–0.41 mg/L, respectively, whereas the concentrations of unbound drug were 0.027–0.063 and 0.027–0.058 mg/L, respectively (6).

A number of studies have reported normal Apgar scores, umbilical acid–base values, and neurobehavioral assessments when ropivacaine epidurals were used in women in labor (4–11). In one study conducted at six different centers, fewer infants delivered vaginally from mothers receiving ropivacaine had abnormal neurological and adaptive capacity scores at 24 hours compared with those delivered vaginally from mothers receiving bupivacaine (11).

BREASTFEEDING SUMMARY

No reports describing the use of ropivacaine during human lactation have been located. As noted above, the primary use in pregnancy of this local anesthetic occurs during labor. Only very small amounts appear in the maternal circulation

after epidural use and these concentrations would be cleared within 24 hours. Therefore, there appears to be no risk for a nursing infant.

ROSIGLITAZONE

Antidiabetic Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Two cases of rosiglitazone use in pregnancy have been located and neither was associated with developmental toxicity. Insulin is the treatment of choice for pregnant diabetic patients because, in general, other hypoglycemic agents do not provide adequate glycemic control. Moreover, insulin, unlike most oral agents, does not cross the placenta to the fetus, thus eliminating the additional concern that the drug therapy itself will adversely affect the fetus. Carefully prescribed insulin therapy provides better control of the mother's glucose, thereby preventing the fetal and neonatal complications that occur with this disease. High maternal glucose levels, as may occur in diabetes mellitus, are closely associated with a number of maternal and fetal adverse effects, including fetal structural anomalies if the hyperglycemia occurs early in gestation. To prevent this toxicity, the American College of Obstetricians and Gynecologists recommends that insulin be used for types I and II diabetes occurring during pregnancy and, if diet therapy alone is not successful, for gestational diabetes (1,2).

FETAL RISK SUMMARY

Rosiglitazone, a thiazolidinedione antidiabetic agent, is used as an adjunct to diet and exercise to improve glycemic control in patients with type II diabetes (noninsulin-dependent diabetes mellitus). It is used either alone or in combination with metformin. Rosiglitazone is not an insulin secretagogue, but acts to decrease insulin resistance in the periphery and in the liver (i.e., decreases insulin requirements). Rosiglitazone undergoes extensive metabolism to inactive metabolites. The plasma half-life of rosiglitazone-related materials

(parent drug and inactive metabolites) ranges from 103 to 158 hours and the binding to plasma proteins, primarily albumin, is high (99.8%) (3).

Reproduction studies with rosiglitazone have been conducted in rats and rabbits at doses up to 20 and 75 times, respectively, the AUC at the maximum recommended human daily dose (MRHDD). No teratogenicity or adverse effect on implantation or the embryos were observed in either species, but placental pathology was noted in rats. Moreover, dosing during midgestation to late gestation was associated with fetal death and growth restriction in both rats and rabbits. Treatment extending through the lactation period in rats was associated with reduced litter size and decreased neonatal viability and postnatal growth. Growth restriction was reversible after puberty. For effects on the placenta, embryo, fetus, and offspring, the no-effect dose levels were approximately 4 times the MRHDD for both species (3).

Consistent with the molecular weight of the free base (about 357) and prolonged elimination half-life of the parent drug and/or inactive metabolites, rosiglitazone crosses the human placenta. In 31 women undergoing an elective abortion at 8–12 weeks' gestation and given two 4 mg doses before the procedure, rosiglitazone was detected in 19 fetuses (4). The mean fetal tissue concentration was about 53 ng/g. The drug was more likely to be detected at 10 or more weeks' gestation (4). Using the technique of dual perfusion of placental lobule, rosiglitazone, in the presence of human serum albumin, readily crossed the placenta (5). In contrast, a study using 10 near-term placentas in an ex vivo human perfusion model found minimal transfer and fetal accumulation of rosiglitazone (6).

A 2002 report described the use of rosiglitazone in early pregnancy (7). A 35-year-old woman with several diseases (hypertension, diabetes mellitus, hypercholesterolemia, anxiety disorder, epilepsy, and morbid obesity) who conceived while being treated with multiple drugs: rosiglitazone (4 mg/day), gliclazide (a sulfonylurea), atorvastatin, acarbose, spironolactone, hydrochlorothiazide, carbamazepine, thioridazine, amitriptyline, chlordiazepoxide, and piperzolate bromide (an antispasmodic). Pregnancy was diagnosed in the 8th week of gestation and all medications were stopped. She was treated with methyldopa and insulin for the remainder of her pregnancy. At 36 weeks' gestation, a repeat cesarean section delivered a healthy, 3.5-kg female infant with Apgar scores of 7 and 8 at 1 and 5 minutes, respectively. The infant was developing normally after 4 months (7).

A 2005 case report described the use rosiglitazone between the 13th and 17th week of gestation in a woman with type 2 diabetes (8). Before the 13th

week, the woman's diabetes had been managed with diet and exercise. Insulin was started after rosiglitazone was stopped and the woman delivered a healthy, 4.5-kg male infant at 37 weeks' gestation. No major or minor malformations were observed (8).

Rosiglitazone is sometimes used for the treatment of insulin resistance in women with polycystic ovarian syndrome. Spontaneous ovulation and enhancement of clomiphene-induced ovulation resulting in conception has been reported after the use of rosiglitazone (9–11). Because this treatment may result in pregnancy, appropriate contraception is advised (12).

BREASTFEEDING SUMMARY

No reports describing the use of rosiglitazone during human lactation have been located. The molecular weight of the free base (about 357) and long elimination half-life (103–158 hours) suggest that excretion into breast milk should be expected. The effect of this exposure on a nursing infant is unknown. However, weak bases are known to accumulate in milk with concentrations higher than those in maternal plasma.

ROSUVASTATIN

Antilipemic Agent

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of rosuvastatin in human pregnancy have been located. There was developmental toxicity (growth restriction and/or death) in two animal species at exposures that were close to those obtained in humans, but maternal toxicity also was observed in one of the species. The absence of human pregnancy experience prevents a more complete assessment of the embryo–fetal risk. Because the interruption of cholesterol-lowering therapy during pregnancy should have no apparent effect on the long-term treatment of hyperlipidemia, rosuvastatin should not be used during pregnancy. Moreover, cholesterol and other products of cholesterol biosynthesis are essential components for fetal development (1). Women taking this agent before conception should stop the therapy before becoming pregnant and certainly on recognition of pregnancy. Accidental use of the drug during gestation, though, apparently has no proven consequences for the fetus.

FETAL RISK SUMMARY

Rosuvastatin (a statin) is a lipophilic agent that is used to lower elevated levels of cholesterol. It has the same cholesterol-lowering mechanism (i.e., inhibition of hepatic 3-hydroxy-3-methylglutaryl-coenzyme A [HMG-CoA] reductase) as other agents available in this class: atorvastatin, fluvastatin, lovastatin, pitavastatin, pravastatin, and simvastatin (cerivastatin was withdrawn from the market in 2001). Rosuvastatin undergoes little metabolism (about 19%). The main metabolite has some activity but $\leq 50\%$ than that of the parent compound. Protein binding, mostly to albumin, is about 88%. The primary route of elimination is in the feces with an elimination half-life of about 19 hours (1).

Reproduction studies have been conducted in rats and rabbits. Decreased fetal body weight (female pups) and delayed ossification were observed in the

offspring when female rats were given a dose before mating and continuing through day 7 postcoitus that resulted in exposures 10 times the human exposure from 40 mg/day based on AUC (HE-AUC). Decreased pup survival was observed with continuous dosing from day 7 of gestation through lactation day 21 (weaning) at 10 times the HE-AUC or ≥ 12 times the human exposure based on BSA (HE-BSA). In pregnant rabbits given a dose equivalent to the HE-BSA from gestation day 6 through lactation day 18 (weaning), decreased fetal viability and maternal mortality were observed. Rosuvastatin was not teratogenic in rats or rabbits at systemic exposures equivalent to the HE-AUC or HE-BSA (1).

In 2-year carcinogenicity studies in rats and mice, increased incidences of uterine stromal polyps and hepatocellular adenoma/carcinoma, respectively, were observed at a dose 20 times the HE-AUC. No mutagenic or clastogenic effects were noted in a variety of tests. There also were no effects on fertility in male or female rats at doses up to 10 times the HE-AUC. However, in male dogs and monkeys, doses that were 20 and 10 times, respectively, the HE-BSA caused spermatidic giant cells. In addition, vacuolation seminiferous tubular epithelium was observed in male monkeys (1).

It is not known if rosuvastatin crosses the human placenta. The molecular weight is moderately high (about 966 for the free acid) as is protein binding, but the low metabolism and prolonged elimination half-life suggest that exposure of the embryo–fetus should be expected.

Pregnancy exposures to this class of drugs that had been reported to the FDA were described in 2004 (2). (See Lovastatin.) Twenty of the 178 reported cases involved major congenital malformations. Although none of the cases involved exposure to rosuvastatin (approved by the FDA in August 2003), and the sample was biased because of its voluntary nature and the likely reporting of severe outcomes, some of the defects might be consistent with the inhibition of cholesterol biosynthesis (2). In another 2004 report, among 214 exposures reported to the FDA (none involving rosuvastatin), there were 22 birth defects, 4 infants with intrauterine growth restriction, and 5 cases of fetal death (3). (See Lovastatin.) As in the first report, it was thought that some of the defects might be consistent with inhibition of cholesterol biosynthesis (3).

BREASTFEEDING SUMMARY

No reports describing the use of rosuvastatin during lactation have been located. The excretion of rosuvastatin into breast milk should be expected because of the molecular weight (about 966 for the free acid), low metabolism

(10%), and long elimination half-life (about 19 hours). At least two similar agents (fluvastatin and pravastatin) appear in human milk. Because of the potential for adverse effects in the nursing infant, the drug should not be used during lactation.

RUFINAMIDE

Anticonvulsant

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of rufinamide in human pregnancy have been located. The drug caused embryo–fetal toxicity in two animal species at systemic exposures less than the human exposure. If a pregnant woman is exposed to this drug, she should be informed of the absence of human pregnancy experience and the potential for embryo–fetal risk.

FETAL RISK SUMMARY

Rufinamide is an oral triazole derivative that is unrelated to other anticonvulsants. It is indicated for adjunctive treatment of seizures associated with Lennox-Gastaut syndrome in children ≥ 4 years of age and adults. Rufinamide is extensively metabolized to inactive metabolites. Only 34% of the drug is bound to plasma proteins, mostly to albumin, and the plasma half-life is about 6–10 hours (1).

Reproduction studies have been conducted in rats and rabbits. In rats, daily oral doses during organogenesis resulting in plasma exposures (AUC) that were 2 times the plasma exposure (AUC) from the maximum recommended human dose of 3200 mg/day (MRHD) caused decreased fetal weights and increased incidences of skeletal abnormalities, but maternal toxicity also was evident. In rabbits, daily oral doses during organogenesis resulting in exposures that were >0.2 times the MRHD resulted in embryo–fetal death, decreased fetal body weights, and increased incidences of visceral and skeletal abnormalities. A dose 2 times the MRHD caused abortions. In both species, the no-observed-effect-level (NOEL) for adverse effects on embryo–fetal development was 0.2 times the MRHD. In prenatal and postnatal studies with rats, daily oral doses given from implantation through weaning resulting plasma

exposures that were <0.1–1.5 times the MRHD caused decreased offspring growth and survival at all doses. A NOEL was not established in these studies (1).

Long-term exposures to rufinamide in mice and rats were carcinogenic, but the drug was not mutagenic or clastogenic in multiple assays. In male and female rats daily doses that were ≥ 0.2 times than the MRHD before and throughout mating, and continued in females up to gestational day 6, were associated with impaired fertility including decreased sperm count and motility, decreased conception rates, mating, and fertility indices, decreased numbers of corpora lutea, implantations, and live embryos, and increased preimplantation loss. A NOEL for impaired fertility was not established (1).

It is not known if rufinamide crosses the human placenta. The low molecular weight (about 238), lipophilic nature, and long plasma half-life suggest that exposure of the embryo–fetus will occur. However, the extensive metabolism to inactive compounds might limit the exposure.

BREASTFEEDING SUMMARY

No reports describing the use of rufinamide during human lactation have been located. The low molecular weight (about 238), lipophilic nature, and long plasma half-life suggest that the drug will be excreted into breast milk, but the extensive metabolism should limit the amount. The effect of this exposure on a nursing infant is unknown. If mother chooses to nurse her infant while taking rufinamide, the infant should be closely observed for changes in behavior and other signs of toxicity. Somnolence, vomiting, and headache were the three most frequent adverse reactions observed in pediatric patients treated with the drug (1).

RUXOLITINIB

Antineoplastic (Janus Associated Kinase Inhibitor)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of ruxolitinib in human pregnancy have been located. The animal data suggested risk (reduced fetal weights and late resorptions in two species) but these effects occurred with doses that were maternally toxic. However, lower nonmaternal toxic doses in rats were associated with postimplantation losses. Although the drug's mechanism of action suggests that use in pregnancy could cause fetal harm, the absence of human pregnancy experience prevents a better assessment of the embryo–fetal risk. If the drug is indicated in a pregnant woman, she should be informed of the potential risk to her embryo–fetus.

FETAL RISK SUMMARY

Ruxolitinib is an oral inhibitor of janus associated kinases which mediate the signaling of a number of cytokines and growth factors that are important for hematopoiesis and immune function. It is indicated for the treatment of patients with intermediate- or high-risk myelofibrosis, including primary myelofibrosis, postpolycythemia vera myelofibrosis, and postessential thrombocythemia myelofibrosis. Ruxolitinib is partially metabolized to two active metabolites. Plasma protein binding is about 97%, primarily to albumin. The mean elimination half-life for ruxolitinib alone is about 3 hours, whereas it is about 5.8 hours for the parent drug plus active metabolites (1).

Reproduction studies have been conducted in rats and rabbits. In these species, no teratogenic effects were observed at the highest doses tested resulting in exposures (AUC) that were about 2 times and 7%, respectively, of the clinical exposure at the maximum recommended dose of 25 mg twice daily (CEMRD). At these doses, reduced fetal weights were noted in rats and rabbits, and increased late resorptions in rabbits, but maternal toxicity occurred in both species. In a predevelopment and postnatal development study in rats,

doses up to 34% of the CEMRD given from implantation through lactation resulted in no drug-related adverse effects in pups for fertility indices or for maternal or embryo–fetal survival, growth, and developmental parameters (1).

Ruxolitinib was not carcinogenic in long-term studies in mice and rats, and was not mutagenic or clastogenic in multiple assays. In male and female rats, no effects were observed on fertility or reproductive performance, but increased postimplantation loss was noted at exposures that were about 34% of the CEMRD (1).

It is not known if ruxolitinib or its two active metabolites cross the human placenta. The molecular weight of the parent drug (about 404) suggests that the drug will cross, but the high plasma protein binding and relatively short mean elimination half-lives should limit the exposure.

BREASTFEEDING SUMMARY

No reports describing the use of ruxolitinib during human lactation have been located. The molecular weight of the parent drug (about 404) suggests that the drug, and possibly its two active metabolites, will be excreted into breast milk, but the high (97%) plasma protein binding and relatively short mean elimination half-lives (3 hours for the parent drug and 5.8 hours for the parent drug plus active metabolites) should limit the amount excreted. The effect of any exposure on a nursing infant is unknown. However, thrombocytopenia and anemia occurred in >20% of patients treated with the drug and >10% experienced bruising, dizziness, and headache (1). Thus, if the drug is given during breastfeeding, a nursing infant should be monitored for these adverse effects.

S

SACCHARIN

Artificial Sweetener

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

There is limited information available on the risk for humans following in utero exposure to saccharin. The Calorie Control Council believes that the agent can be safely used by pregnant women (1). However, others recommended avoidance of saccharin or, at least, cautious use of it in pregnancy (2–4).

FETAL RISK SUMMARY

Saccharin is a nonnutritive sweetening agent discovered accidentally in 1879; it has been used in the United States since 1901. The agent is approximately 300 times sweeter than sucrose. Saccharin, a derivative of naphthalene, is absorbed slowly after oral ingestion and is rapidly and completely excreted, as the unmetabolized compound, by the kidneys. Although a large amount of medical research has been generated concerning saccharin, very little of this information pertains to its use by pregnant women or to its effect on the fetus (2,3).

In pregnant rhesus monkeys administered IV saccharin, fetal accumulation of the sweetener occurred after rapid, but limited, transfer across the placenta (5). Saccharin appeared to be uniformly distributed to all fetal tissues except the CNS. Fetal levels were still present 5 hours after the end of the infusion and 2 hours after maternal concentrations were undetectable. A study, published in 1986, documented that saccharin also crosses the placenta to the human fetus (6). Six diabetic women, consuming 25–100 mg/day of saccharin by history,

were delivered at 36–42 weeks. Maternal serum saccharin concentrations, measured between 0.5 hour before to 2 hours after delivery, ranged from 20 to 263 ng/mL. Cord blood samples varied from 20 to 160 ng/mL (6).

Saccharin is not an animal teratogen (5,7,8). No increase in the incidence of spontaneous abortions among women consuming saccharin has been found (9). Concerns for human use focus on the potential carcinogenicity of the agent. In some animal species, particularly after second-generation studies, an increased incidence of bladder tumors was observed (3). However, epidemiologic studies have failed to associate the human use of saccharin with bladder cancer (3). Similarly, no evidence was found in a study of the Danish population that in utero saccharin exposure was associated with an increased risk of bladder cancer during the first 30–35 years of life (3,10). However, at least one investigator believes that these studies must be extended much further before they are meaningful, because bladder cancer is usually diagnosed in the elderly (4).

BREASTFEEDING SUMMARY

Saccharin is excreted into human milk (11). In six healthy women, saccharin, 126 mg/12 fluid ounces, contained in two commercially available soft drinks, was given every 6 hours for nine doses. After single or multiple doses, median peak concentrations of saccharin occurred at 0.75 hour in plasma and at 2.0 hours in milk. Milk concentrations ranged from <200–1056 ng/mL after one dose to 1765 ng/mL after nine doses. The AUC ratios for milk and plasma averaged 0.542 on day 1 and 0.715 on day 3, indicating that accumulation in the milk occurred with time. The amounts of saccharin a nursing infant could consume from milk were predicted to be much less than the usual intakes of children <2 years old (11).

SAFFLOWER

Herb

PREGNANCY RECOMMENDATION: Compatible (as a Food)

BREASTFEEDING RECOMMENDATION: Compatible (as a Food)

PREGNANCY SUMMARY

No reports describing the use of safflower in pregnancy have been located. However, safflower oil is widely used in cooking. It is doubtful that such use would have any adverse effect on a pregnancy. Abortifacient and emmenagogue effects have been suggested (1,2), but there apparently is no clinical evidence to support these effects when safflower oil is used as a food. Other uses or high doses of safflower should be avoided in pregnancy.

FETAL RISK SUMMARY

The seeds of safflower (*Carthamus tinctorius*), a plant widely cultivated throughout Europe and the United States, are primarily used as a source of edible oil. The oil contains a high concentration of n-6 polyunsaturated fatty acids, including the essential linoleic acid. In addition, the seeds contain tracheloside (a lignan glycoside) and serotonin derivatives. The oil is used in cooking and has been given for its laxative action. In addition, capsules containing safflower oil have sometimes served as controls in clinical trials. A tea prepared from safflower has been used to treat fever by inducing sweating. The flowers have been used as yellow and red dyes since ancient times, as well as a flavoring agent in foods (1,2).

An aqueous extract of the flowers was studied in pregnant mice (3). At doses of ≥ 1.6 mg/kg/day, embryo death was observed, whereas a lower dose (1.2 mg/kg/day) was teratogenic. An in vitro assay found a concentration-dependent cytotoxic effect (3).

BREASTFEEDING SUMMARY

No reports describing the use of safflower during human lactation have been located. However, safflower oil is widely used in cooking. Although mature

human milk contains n-3 fatty acids (4), the probable small amounts of n-6 fatty acids excreted into milk when safflower oil is used as a food should not adversely affect a nursing infant. Other uses or high doses of safflower should be avoided during breastfeeding.

SALMETEROL

Respiratory Drug (Bronchodilator)

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

One review concluded that salmeterol was safe during human pregnancy (1), but others thought it should not be a first-line drug because of the lack of published human experience (2,3). Although human data have been published and no congenital malformations attributable to salmeterol were observed, the data are too limited to assess the safety of salmeterol. Moreover, the above study lacked the sensitivity to identify minor anomalies because of the absence of standardized examinations. Late-appearing major defects may also have been missed because of the timing of the questionnaires. However, if a patient with moderate or severe asthma had demonstrated a good therapeutic response before conception, this may favor the drug's continuation during pregnancy (2). Moreover, salmeterol is more effective than doubling the dose of inhaled corticosteroids and may have advantages over theophylline in terms of effectiveness and tolerability (2). In addition, the very low or undetectable maternal plasma levels that occur with therapeutic inhaled doses suggest that the risk to the fetus from the drug is probably minimal or nonexistent. If salmeterol is used in pregnancy, healthcare professionals are encouraged to call the toll-free number (877-311-8972) for information about patient enrollment in an Organization of Teratology Information Specialists (OTIS) study.

FETAL RISK SUMMARY

Salmeterol is a selective β_2 -adrenergic bronchodilator that is indicated in the management of asthma. It is administered as an aerosol or powder for oral inhalation. Because the drug acts locally in the lung, plasma levels are very low or undetectable and are a result of swallowed salmeterol.

Animal reproduction studies have been conducted in the rat and rabbit (4). In the rat, oral doses up to approximately 160 times the maximum recommended daily human inhalation dose based on BSA (MRDHID-BSA) produced no evidence of impaired fertility or teratogenic effects. In pregnant Dutch rabbits, an oral dose about 10 times the maximum recommended daily human inhalation dose based on AUC (MRDHID-AUC) produced no fetal toxicity. When the dose was increased to about 20 times the MRDHID-AUC, fetal toxicity secondary to β -adrenoceptor stimulation was observed (precocious eyelid openings, cleft palate, sternebral fusion, limb and paw flexures, and delayed ossification of the frontal cranial bones). However, New Zealand White rabbits were much less sensitive—exhibiting only delayed ossification of the frontal cranial bones at oral doses 1600 times the MRDIHD-BSA. The fetal toxicity noted in rabbits was not thought to be relevant to humans because β -agonists characteristically induce these effects in animals (4).

In a study with pregnant rats, salmeterol concentrations in mammary tissue, placenta, and fetus after oral administration were comparable to those in maternal blood up to 6 hours after a dose (5). At 24 hours, the disposition of the drug in the fetus was primarily in the gastrointestinal tract.

It is not known if salmeterol crosses the placenta to the fetus. Although the molecular weight (about 604 for salmeterol xinafoate) is low enough, plasma levels after an inhaled therapeutic dose are very low or undetectable.

A 1998 noninterventional observational cohort study described the outcomes of pregnancies in women who had been prescribed ≥ 1 of 34 newly marketed drugs by general practitioners in England (6). Data were obtained by questionnaires sent to the prescribing physicians 1 month after the expected or possible date of delivery. In 831 (78%) of the pregnancies, a newly marketed drug was thought to have been taken during the 1st trimester, with birth defects noted in 14 (2.5%) singleton births of the 557 newborns (10 sets of twins). In addition, two birth defects were observed in aborted fetuses. However, few of the aborted fetuses were examined. Salmeterol was taken during the 1st trimester in 65 pregnancies. The outcomes of these pregnancies included 7 spontaneous abortions, 2 ectopic pregnancies, 4 elective abortions, 5 unknown outcomes, and 47 live births (3 premature). One full-term newborn was diagnosed with Aarskog's syndrome (a male child with short stature, and facial, digital, and genital malformations; pectus excavatum, metatarsus adductus, and joint laxity are frequent skeletal features [7]) (6). The syndrome is thought to be secondary to X-linked recessive inheritance (7).

BREASTFEEDING SUMMARY

No reports describing the use of salmeterol during human lactation have been located. The molecular weight (about 604 for salmeterol xinafoate) is low enough for excretion into breast milk, but maternal plasma levels after an inhaled therapeutic dose are very low or undetectable. Thus, it is unlikely that clinically significant amounts would be found in milk.

SALVIA DIVINORUM

Herb/Hallucinogen

pregnancy recommendation: No Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of *Salvia divinorum* or its active ingredient, salvinorin A, in human pregnancy have been located. The herb is used by some cultures in Mexico and exposure during gestation may have occurred. However, because smoking the herb has caused toxic, persistent psychosis in an 18-year-old female and a 21-year-old male (1–3), it is best avoided in pregnancy.

FETAL RISK SUMMARY

Salvia divinorum is a perennial herb that is a species of sage cultivated in certain regions of Mexico. The hallucinogenic substances from the leaves and juices of the herb have been used by some groups in Mexico for healing and divinatory rituals. In addition, it is thought to have antidiarrheal properties. The hallucinogenic effects are produced by smoking or chewing the leaves or drinking the juices. When taken orally, systemic effects are dependent upon absorption across the oral mucosa, as the active agent is deactivated in the gastrointestinal tract (1,4). The active psychotropic agent is the diterpene salvinorin A, also referred to as divinorin A, a nonalkaloid hallucinogen. It acts as kappa opioid receptor agonist. The major metabolite is salvinorin B (1), but it is not known if it is active. The substance crosses the blood–brain barrier, resulting in a rapid onset of effects but of short duration (1,5). In female monkeys, the elimination half-life of salvinorin A is 80 minutes (6).

Animal reproduction studies have not been conducted with *S. divinorum* or its active ingredient, salvinorin A.

BREASTFEEDING SUMMARY

No reports describing the use of *S. divinorum* or its active ingredient, salvinorin

A, during human lactation have been located. The herb is used by some cultures in Mexico and exposure during breastfeeding may have occurred. However, because smoking the herb has caused toxic, persistent psychosis in two persons (1–3), it is best avoided.

SAPROPTERIN

Antidote (Phenylketonuria)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of sapropterin in human pregnancy have been located. Phenylketonuria (PKU) can cause significant developmental toxicity (low birth weight, microcephaly, congenital heart disease, and mental retardation). (See Aspartame.) Although the animal data suggest moderate risk, the risk of uncontrolled PKU to the embryo and/or fetus probably is much greater. If diet alone is not adequate to control maternal phenylalanine concentrations, the use of sapropterin appears to be reasonable. However, in clinical trials with nonpregnant adults, only 20%–56% of PKU patients responded to treatment with sapropterin. The manufacturer plans to establish a pregnancy registry for women who are pregnant while receiving Kuvan treatment (details not available).

FETAL RISK SUMMARY

Sapropterin dihydrochloride is a synthetic preparation of naturally occurring tetrahydrobiopterin (BH₄), the cofactor for the enzyme phenylalanine hydroxylase (PAH). The enzyme hydroxylates phenylalanine to form tyrosine. In patients with PKU, PAH activity is absent or deficient. Treatment with sapropterin activates residual PAH, resulting in improved oxidative metabolism of phenylalanine, thereby decreasing the blood concentrations of phenylalanine in some, but not all, patients (1). Sapropterin is indicated to reduce blood phenylalanine levels in patients with hyperphenylalaninemia due to BH₄-responsive PKU. It is used in conjunction with a phenylalanine-restricted diet. Sapropterin tablets are dissolved in water or apple juice and taken once daily. The mean elimination half-life is about 6.7 hours (range 3.9–17 hours) (1).

Reproduction studies have been conducted in rats and rabbits. In pregnant

rats, oral doses up to about 3 times the maximum recommended human dose of 20 mg/kg/day based on BSA (MRHD) produced no clear evidence of teratogenicity. Similar findings were observed in pregnant rabbits at doses up to about 10 times the MRHD, but a nonsignificant increase in the incidence of holoprosencephaly was noted. No effect on fertility or reproductive function was observed in male and female rats at doses up to about 3 times the MRHD (1).

Carcinogenicity studies have been conducted in mice and rats with doses up to about 2 times the MRHD. In a 104-week study in rats, a significant increase in the incidence of benign adrenal pheochromocytoma was observed in male rats at the maximum dose. No evidence of carcinogenicity was observed in mice, but the study was conducted for only 78 weeks. Genotoxicity was observed in some in vitro and in vivo studies but not in others (1).

It is not known if sapropterin crosses the human placenta. The molecular weight (about 241 for the free base) and moderately long elimination half-life suggest that the drug will cross to the embryo and fetus.

BREASTFEEDING SUMMARY

No reports describing the use of sapropterin during human lactation have been located. The molecular weight (about 241 for the free base) and moderately long elimination half-life (6.7 hours; range 3.9–17 hours) suggest that the drug will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown. Although the drug probably is compatible with breastfeeding, infants should be monitored for adverse effects commonly seen in adults, such as headache, rhinorrhea, diarrhea, and pharyngolaryngeal pain.

SAQUINAVIR

Antiviral

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo/Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Although the limited human data do not allow an assessment of the risk of saquinavir during pregnancy, the animal data suggests that the embryo–fetal risk is low. If indicated, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Saquinavir, a synthetic peptide-like substrate analog, inhibits the activity of HIV protease, thus preventing the cleavage of viral polyproteins and the maturation of infectious virus. The mechanism of action is similar to four other protease inhibitors: amprenavir, indinavir, nelfinavir, and ritonavir (1).

In reproduction studies in rats and rabbits, embryotoxicity and teratogenicity were not observed at plasma concentrations up to approximately 50% and 40%, respectively, of the human exposure based on AUC achieved from the recommended clinical dose. There was also no evidence that at this dose the drug affected fertility or reproductive performance in rats. A similar lack of toxicity, as measured by survival, growth, and development of offspring to weaning, was found in rats treated during late pregnancy through lactation with doses producing the same plasma concentrations as those above (1).

It is not known if saquinavir crosses the human placenta. The molecular weight of the free base (about 671) is low enough that some degree of transfer should be anticipated. In rats and rabbits, placental transfer of saquinavir is low (<5% of maternal plasma concentrations) (1).

The Antiretroviral Pregnancy Registry reported, for the period January 1989 through July 2009, prospective data (reported before the outcomes were known) involving 4702 live births that had been exposed during the 1st trimester to one or more antiretroviral agents (2). Congenital defects were noted in 134,

a prevalence of 2.8% (95% confidence interval [CI] 2.4–3.4). In the 6100 live births with earliest exposure in the 2nd/3rd trimesters, there were 153 infants with defects (2.5%, 95% CI 2.1–2.9). The prevalence rates for the two periods did not differ significantly. There were 288 infants with birth defects among 10,803 live births with exposure anytime during pregnancy (2.7%, 95% CI 2.4–3.0). The prevalence rate did not differ significantly from the rate expected in a nonexposed population. There were 354 outcomes exposed to saquinavir (158 in the 1st trimester and 196 in the 2nd/3rd trimesters) in combination with other antiretroviral agents. There were 14 birth defects (6 in the 1st trimester and 8 in the 2nd/3rd trimesters). In reviewing the birth defects of prospective and retrospective (pregnancies reported after the outcomes were known) registered cases, the Registry concluded that, except for isolated cases of neural tube defects with efavirenz exposure in retrospective reports, there was no other pattern of anomalies (isolated or syndromic) (2). (See Lamivudine for required statement.)

A study published in 1999 evaluated the safety, efficacy, and perinatal transmission rates of HIV in 30 pregnant women receiving various combinations of antiretroviral agents (3). Many of the women were substance abusers. Protease inhibitors (nelfinavir [N = 7], indinavir [N = 6], and saquinavir [N = 1] in combination with nelfinavir) were used in 13 of the women. Antiretroviral therapy was initiated at a median of 14 weeks' gestation (range preconception to 32 weeks). Despite previous histories of extensive antiretroviral experience and of vertical transmission of HIV, combination therapy was effective in treating maternal disease and in preventing transmission to the current newborns. The outcomes of the pregnancies treated with protease inhibitors appeared to be similar to the 17 cases that did not receive these agents, except that the birth weights were lower (3).

The experience of one perinatal center with the treatment of HIV-infected pregnant women was summarized in a 1999 abstract (4). Of 55 women receiving more than three antiviral drugs, 39 were treated with a protease inhibitor (11 with saquinavir). The outcomes included 2 spontaneous abortions, 5 elective abortions, 27 newborns, and 5 ongoing pregnancies. One woman was taken off indinavir because of ureteral obstruction and another (drug therapy not specified) developed gestational diabetes. None of the newborns tested positive for HIV, had major congenital anomalies, or complications (4).

A public health advisory was issued by the FDA on the association between protease inhibitors and diabetes mellitus (5). Because pregnancy is a risk factor for hyperglycemia, there was concern that these antiviral agents would

exacerbate this risk. The manufacturer's product information also notes the potential risk for new-onset diabetes, exacerbation of preexisting diabetes, and hyperglycemia in HIV-infected patients receiving protease inhibitor therapy (1). An abstract published in 2000 described the results of a study involving 34 pregnant women treated with protease inhibitors (7 with saquinavir) compared with 41 controls that evaluated the association with diabetes (6). No relationship between protease inhibitors and an increased incidence of gestational diabetes was found.

A case of combined transient mitochondrial and peroxisomal β -oxidation dysfunction after exposure to nucleoside analog reverse transcriptase inhibitors (NRTIs) (lamivudine and zidovudine) combined with protease inhibitors (ritonavir and saquinavir) throughout gestation was reported in 2000 (7). A male infant was delivered at 38 weeks' gestation. He received postnatal prophylaxis with lamivudine and zidovudine for 4 weeks until the agents were discontinued because of anemia. Other adverse effects that were observed in the infant (age at onset) were hypocalcemia (shortly after birth), group B streptococcal sepsis, ventricular extrasystoles, prolonged metabolic acidosis, and lactic acidemia (8 weeks), a mild elevation of long-chain fatty acids (9 weeks), and neutropenia (3 months). The metabolic acidosis required treatment until 7 months of age, whereas the elevated plasma lactate resolved over 4 weeks. Cerebrospinal fluid lactate was not determined nor was a muscle biopsy conducted. Both the neutropenia and the cardiac dysfunction had resolved by 1 year of age. The elevated plasma fatty acid level was confirmed in cultured fibroblasts, but other peroxisomal functions (plasmalogen biosynthesis and catalase staining) were normal. Although mitochondrial dysfunction has been linked to NRTI agents, the authors were unable to identify the cause of the combined abnormalities in this case (7). The child was reported to be healthy and developing normally at 26 months of age.

A multicenter, retrospective survey of pregnancies exposed to protease inhibitors was published in 2000 (8). There were 92 liveborn infants delivered from 89 women (3 sets of twins) at six healthcare centers. One nonviable infant, born at 22 weeks' gestation, died. The surviving 91 infants were evaluated in terms of adverse effects, prematurity rate, and frequency of HIV type 1 (HIV-1) transmission. Most of the infants were exposed in utero to a single protease inhibitor, but a few were exposed to more than one because of sequential or double combined therapy. The number of newborns exposed to each protease inhibitor was indinavir (N = 23), nelfinavir (N = 39), ritonavir (N = 5), and saquinavir (N = 34). Protease inhibitors were started before conception

in 18, and during the 1st, 2nd, or 3rd trimester in 12, 44, and 14, respectively, and not reported in one. Other antiretrovirals used with the protease inhibitors included four NRTIs (didanosine, lamivudine, stavudine, and zidovudine). The most common NRTI regimen was a combination of zidovudine and lamivudine (65% of women). In addition, seven women were enrolled in the AIDS Clinical Trials Group Protocol 316 and, at the start of labor, received a single dose either of the nonnucleoside reverse transcriptase inhibitor, nevirapine, or placebo. Maternal conditions, thought possibly or likely to be related to therapy, were mild anemia in eight, severe anemia in one (probably secondary to zidovudine), and thrombocytopenia in one. Gestational diabetes mellitus was observed in three women (3.3%), a rate similar to the expected prevalence of 2.6% in a nonexposed population (8). One mother developed postpartum cardiomyopathy and died 2 months after birth of twins, but the cause of death was not known. For the surviving newborns, there was no increase in adverse effects over that observed in previous clinical trials of HIV-positive women, including the prevalence of anemia (12%), hyperbilirubinemia (6%; none exposed to indinavir), and low birth weight (20.6%). Premature delivery occurred in 19.1% of the pregnancies (close to the expected rate). The percentage of infants infected with HIV was 0 (95% CI 0%–3%) (8).

Two reviews, one in 1996 and the other in 1997, concluded that all women currently receiving antiretroviral therapy should continue to receive therapy during pregnancy and that treatment of the mother with monotherapy was inadequate therapy (9,10). The same conclusion was reached in a 2003 review with the added admonishment that therapy must be continuous to prevent emergence of resistant viral strains (11). In 2009, the updated U.S. Department of Health and Human Services guidelines for the use of antiretroviral agents in HIV-1-infected patients continued the recommendation that therapy, with the exception of efavirenz, should be continued during pregnancy (12). If indicated, therefore, protease inhibitors, including saquinavir, should not be withheld in pregnancy because the expected benefit to the HIV-positive mother outweighs the unknown risk to the fetus. Pregnant women taking protease inhibitors should be monitored for hyperglycemia. Updated guidelines for the use of antiretroviral drugs to reduce perinatal HIV-1 transmission also were released in 2010 (13). Women receiving antiretroviral therapy during pregnancy should continue the therapy but, regardless of the regimen, zidovudine administration is recommended during the intrapartum period to prevent vertical transmission of HIV to the newborn (13).

BREASTFEEDING SUMMARY

No reports describing the use of saquinavir during lactation have been located. The molecular weight of the free base (about 671) is low enough that excretion into breast milk should be expected. The effect on a nursing infant is unknown.

Reports on the use of saquinavir during lactation are unlikely because the drug is indicated in the treatment of patients with HIV. HIV type 1 (HIV-1) is transmitted in milk, and in developed countries, breastfeeding is not recommended (9,10,12,14–16). In developing countries, breastfeeding is undertaken, despite the risk, because there are no affordable milk substitutes available. Until 1999, no studies had been published that examined the effect of any antiviral therapy on HIV-1 transmission in milk. In that year, a study involving zidovudine was published that measured a 38% reduction in vertical transmission of HIV-1 infection despite breastfeeding when compared with controls (see Zidovudine).

SARGRAMOSTIM

Hematopoietic

PREGNANCY RECOMMENDATION: No Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of sargramostim in human pregnancy have been located. The absence of animal and human pregnancy data prevents an assessment of the risk from maternal administration that this cytokine presents to a human embryo or fetus.

However, sargramostim differs only slightly from endogenous granulocyte-macrophage colony stimulating factor (GM-CSF). In addition, maternal serum concentrations of natural GM-CSF increase throughout pregnancy with the highest levels occurring during term labor (1). Therefore, it is doubtful if recommended doses of sargramostim will cause direct toxicity to the embryo or fetus. Until human pregnancy data are available, however, the safest course is to avoid sargramostim during gestation. Planned or inadvertent pregnancy exposure appears to represent a low risk for the embryo and fetus.

FETAL RISK SUMMARY

The human GM-CSF sargramostim is produced by recombinant DNA technology. Sargramostim differs slightly from the natural human GM-CSF. It has several specific indications: (a) following induction chemotherapy in acute myelogenous leukemia; (b) for mobilization and following transplantation of autologous peripheral blood progenitor cells; (c) for myeloid reconstitution after allogeneic bone marrow transplantation; and (d) for bone marrow transplantation failure or engraftment delay. The mean beta half-lives after IV and SC administration were 60 and 162 minutes, respectively. Animal reproduction studies have not been conducted with sargramostim (2).

Sargramostim is a 127-amino-acid glycoprotein that is characterized by three

primary molecular species with molecular weights of 19,500, 16,800, and 15,500, respectively. Although studies involving placental passage of sargramostim have not been conducted, endogenous GM-CSF does cross the human placenta. In an in vitro experiment using term placentas, small amounts (about 2.4%) of GM-CSF crossed to the fetal side (3). Therefore, sargramostim also probably crosses the placenta, at least at term.

Endogenous GM-CSF promotes the growth and development of preimplantation embryos (4). GM-CSF is synthesized in the uterus with the highest concentrations occurring around the interval when implantation would occur (5).

In a 2003 study, levels of endogenous free GM-CSF were measured in peripheral blood in pregnant and nonpregnant women and in women with recurrent spontaneous abortions (RSAs) (6). In healthy women, a significant increase in GM-CSF levels was measured during pregnancy, but there was no increase in women with RSA. After an IV infusion of immunoglobulin, however, the GM-CSF levels almost doubled in women with RSA (6).

Other investigators have reached conflicting conclusions on the presence of endogenous GM-CSF in maternal blood and amniotic fluid. One study was unable to detect GM-CSF expression (using mRNA coding) in maternal serum at any stage of pregnancy or in nonpregnant women (7). Similarly, amniotic fluid GM-CSF was undetectable in laboring and nonlaboring women at term in another study (8). In contrast, a third study found that amniotic fluid GM-CSF concentrations increased as a function of gestational age, the status of the membranes (intact or ruptured), and the presence of labor (9). In addition, a fourth study found a significant increase in placental and peripheral blood levels of GM-CSF in women with preeclampsia (10).

BREASTFEEDING SUMMARY

No reports describing the use of sargramostim during human lactation have been located. Endogenous granulocyte-macrophage GM-CSF is excreted into breast milk (11). Based on an immunoradiometric assay, milk concentrations of GM-CSF (100 pg/mL) were much higher than the levels in the cord blood or maternal and infant serums. At 5 days of age, breastfed infants had higher serum GM-CSF concentrations than formula-fed infants, but the difference was not significant. However, there was no difference in neutrophil chemotaxis between the groups, suggesting that either GM-CSF was inactivated or not absorbed from the milk (11). In contrast, a study using an enzyme-linked immunosorbent assay (ELISA) was unable to detect GM-CSF (<10 pg/mL) in

breast milk (12).

Whether sargramostim, a glycoprotein that is slightly different from the natural protein, is excreted into milk is not known, but its close similarity to native GM-CSF suggests that it also will be excreted into milk. The effect on a nursing infant from this exposure is unknown, but because endogenous GM-CSF is present in milk and appears to be inactivated or not absorbed, the risk from sargramostim is probably very low or nonexistent.

SAXAGLIPTIN

Antidiabetic Agent

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of saxagliptin in human pregnancy have been located. The animal reproduction data suggest low risk, but the absence of human pregnancy experience prevents a complete assessment of the embryo–fetal risk. Although the use of saxagliptin may help decrease the incidence of fetal and newborn morbidity and mortality in developing countries where the proper use of insulin is problematic, insulin still is the treatment of choice for this disease during pregnancy. Moreover, insulin does not cross the placenta, which eliminates the additional concern that the drug therapy is adversely affecting the fetus. Carefully prescribed insulin therapy will provide better control of the mother’s blood glucose, thereby preventing the fetal and neonatal complications that occur with this disease. High maternal glucose levels, as might occur in diabetes mellitus, are associated with a number of maternal and fetal adverse effects, including fetal structural anomalies if the hyperglycemia occurs early in gestation. To prevent this toxicity, the American College of Obstetricians and Gynecologists recommends that insulin be used for types 1 and 2 diabetes occurring during pregnancy and, if diet therapy alone is not successful, for gestational diabetes (1,2). If a woman becomes pregnant while taking saxagliptin, changing the therapy to insulin should be considered.

FETAL RISK SUMMARY

Saxagliptin is an oral inhibitor of the dipeptidyl peptidase-4 (DPP4) enzyme. It is in the same antidiabetic subclass as linagliptin and sitagliptin. Saxagliptin is indicated as an adjunct to diet and exercise to improve glycemic control in

adults with type 2 diabetes mellitus. The lipophilic drug is metabolized to an active metabolite, which is one-half as potent as saxagliptin. The plasma protein binding of the parent drug and the active metabolite are negligible, and the mean terminal half-life of the two compounds is 2.5 and 3.1 hours, respectively (3,4).

Reproduction studies have been conducted in rats and rabbits. In these species, no teratogenic effects were observed at any dose given during organogenesis. The drug did cross the rat placenta (not specified for the rabbit). In rats, incomplete ossification of the pelvis, a form of developmental delay, was observed at a dose that was about 1503 and 66 times the human exposure to saxagliptin and the active metabolite, respectively, at the maximum recommended human dose of 5 mg (MRHD). At 7986 and 328 times, respectively, the MRHD, maternal toxicity and reduced fetal body weights were observed. When saxagliptin was combined with metformin (metformin exposure 4 times the human exposure of 2000 mg/day), no teratogenic or embryolethal effects were observed at saxagliptin exposures that were 21 times the MRHD. At 109 times the saxagliptin MRHD, the combination was associated with craniorachischisis (a rare neural tube defect characterized by incomplete closure of the skull and spinal column) in two fetuses from a single dam. When given to rats from gestation day 6 to lactation day 20, decreased body weights in male and female offspring were observed only at maternally toxic doses that were \geq 1629 and 53 times, respectively, the MRHD. No functional or behavioral toxicity was observed in rat offspring at any dose. In rabbits, minor skeletal variations were observed at a maternally toxic dose that was about 1432 and 992 times, respectively, the MRHD (3,4).

Saxagliptin did not induce tumors in mice or rats. The parent drug (with or without metabolic activation) was not mutagenic or clastogenic in multiple assays and, in a separate assay, the active metabolite was not mutagenic. In a study with rats, the drug did not affect male or female fertility at exposures that were 603 and 776 times, respectively, the MRHD. Much higher doses that caused maternal toxicity were associated with increased fetal resorptions and effects on estrous cycling, fertility, ovulation, and implantation (3,4).

It is not known if saxagliptin or its active metabolite crosses the human placenta. The molecular weight of the parent compound (about 315 for the nonhydrated form), lipophilic properties, lack of plasma protein binding, and terminal half-lives suggest that exposure of the embryo–fetus is likely.

BREASTFEEDING SUMMARY

No reports describing the use of saxagliptin during human lactation have been located. The molecular weight of the parent compound (about 315 for the nonhydrated form), lipophilic properties, lack of plasma protein binding, and terminal half-lives (2.5 hours for saxagliptin and 3.1 hours for the active metabolite) suggest that saxagliptin and its metabolite will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown. Saxagliptin overdose (80 times the maximum recommended human dose for 2 weeks) in healthy adults caused no dose-related adverse reactions (3,4). Thus, hypoglycemia in a nursing infant appears to be unlikely but should be monitored. The most common ($\geq 5\%$) adverse reaction in adults was headache (3,4).

SCOPOLAMINE

Parasympatholytic (Anticholinergic)

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Except for a single case of overdose during labor, there is no evidence of embryo–fetal harm when scopolamine is used in pregnancy.

FETAL RISK SUMMARY

Scopolamine is an anticholinergic agent. A scopolamine transdermal system is used to prevent nausea and vomiting associated with motion sickness and recovery from anesthesia and surgery.

Reproduction studies in rats with daily IV doses did not observe fetal harm. A marginal embryotoxic effect was seen in rabbits at daily IV doses that produced plasma concentrations approximately 100 times the level achieved in humans with the transdermal system (1).

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 309 of whom used scopolamine in the 1st trimester (2, pp. 346–353). For anytime use, 881 exposures were recorded (2, p. 439). In neither case was evidence found for an association with malformations. However, when the group of parasympatholytics was taken as a whole (2323 exposures), a possible association with minor malformations was found (2, pp. 346–353).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 27 newborns had been exposed to scopolamine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). One (3.7%) major birth defect was observed (one expected), but specific information on the malformation is not available. No anomalies were observed in six categories of defects, including cardiovascular defects, oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias.

Scopolamine readily crosses the placenta (3). When administered to the

mother at term, fetal effects include tachycardia, decreased heart rate variability, and decreased heart rate deceleration (4–6). Maternal tachycardia was comparable to that with other anticholinergic agents, such as atropine or glycopyrrolate (7).

Scopolamine toxicity in a newborn has been described (8). The mother had received six doses of scopolamine (1.8 mg total) with several other drugs during labor. Symptoms in the female infant consisted of fever, tachycardia, and lethargy; she was also “barrel chested” without respiratory depression. Therapy with physostigmine reversed the condition.

In a clinical study in women undergoing cesarean section, a scopolamine transdermal system was used with epidural anesthesia and opiate analgesia and no evidence of CNS depression was observed in the newborns (1).

BREASTFEEDING SUMMARY

No reports of adverse effects secondary to scopolamine in breast milk have been located. The drug is excreted into breast milk (1). The American Academy of Pediatrics classifies scopolamine as compatible with breastfeeding (9).

SECOBARBITAL

Sedative/Hypnotic

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports linking the use of secobarbital with congenital defects have been located.

FETAL RISK SUMMARY

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 378 of whom had 1st trimester exposure to secobarbital (1). No evidence was found to suggest a relationship to large categories of major or minor malformations or to individual defects. Hemorrhagic disease of the newborn and barbiturate withdrawal are theoretical possibilities (see also Phenobarbital).

An in utero study found no evidence of chromosomal changes on exposure to secobarbital (2).

BREASTFEEDING SUMMARY

Secobarbital is excreted into breast milk (3). The amount and effects on the nursing infant are not known. The American Academy of Pediatrics classifies secobarbital as compatible with breastfeeding (4).

SELEGILINE

Antiparkinson Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Only two cases of exposure to selegiline during human pregnancy have been located, and only one of them involved exposure throughout gestation. Although there is no indication of physical teratogenicity in animal studies or the two human cases, selegiline did result in significant neurochanges in rats when combined with another monoamine oxidase (MAO) inhibitor. Until additional human data are available, the use of selegiline during pregnancy should be avoided if possible (1,2).

FETAL RISK SUMMARY

Selegiline (l-deprenyl), a selective irreversible inhibitor of MAO type B (MAO-B), is used as an adjunct in the management of parkinsonian patients being treated with levodopa/carbidopa. The drug has no beneficial effect when used alone (3,4).

Reproduction studies in pregnant rats and rabbits at doses up to 35 and 95 times the human therapeutic dose based on BSA (HTD), respectively, did not reveal any evidence of teratogenicity. At the highest doses tested, however, rat fetal body weight was decreased, and the number of resorptions and postimplantation losses in rabbits increased, resulting in fewer live fetuses. An increase in the number of stillbirths and decreases in pup survival and body weight (at birth and throughout the lactation period) were observed when rats were given doses up to 15 and 62 times the HTD during late gestation and throughout lactation. At 62 times the HTD, no pups born alive survived to day 4 postpartum (3,4)

In a 1994 study, rats were treated daily throughout gestation with a combination of SC selegiline (3 mg/kg) and clorgyline, an MAO type A (MAO-

A) inhibitor (3 mg/kg) (5). In another treatment group, the same doses of the drugs were administered to pregnant females throughout gestation but, at birth, the daily injections of the drugs were administered to the pups until sacrifice. Saline control groups were used for comparison. Pregnancy duration was significantly longer in the treated groups than in controls, but the litter sizes were the same. Other developmental milestones (eye opening, incisor eruption, or olfactory responses) were similar to that of controls. Pup weight gain in both treatment groups was significantly slower than that in controls. The decreased weight gain may have been due to less frequent nursing, a condition that was not resolved even when the pups were cross-fostered with control dams. None of the exposed offspring had changes in the development of the dopamine system (as indicated by dopamine terminal density). Moreover, MAO activity in the brain tissue of pups exposed to the drugs only during gestation was not significantly different from that of controls at 5 days of age. In contrast, MAO activity in pups continually exposed to the drugs was significantly less than that of controls. Compared with controls, the treatment groups were very aggressive, frequently biting the investigators. In addition, significant deficits in passive avoidance were observed at 24 days of age, and open field activity was significantly increased at 30 days of age. These two results were thought to be a measure of impulsivity. Major alterations of the serotonin system were also observed (as indicated by serotonin terminal density) in the hippocampus (higher density), caudate (higher density), and cortex (less density at 5 and 30 days, but increased at 15 days). Seizures and visual impairment were noted in pups that received the drugs during pregnancy and after birth, but not in those exposed only in utero (5).

It is not known if selegiline crosses the human placenta. The low molecular weight (about 188 for the free base) suggests that passage to the embryo–fetus should be expected.

Human pregnancy experience with selegiline is limited. A 1998 report described a case involving a 34-year-old woman with an 8-year history of Parkinson's disease, who became pregnant while under treatment with selegiline (10 mg/day), levodopa (450 mg/day), and benserazide (128.25 mg/day) (1). Because of insufficient pregnancy safety information, selegiline was discontinued (gestational time not specified). A normal healthy, 3050-g, 49-cm-long male infant was delivered at term with Apgar scores of 9, 10, and 10 at 1, 5, and 10 minutes, respectively (1).

In a second case, a 39-year-old woman with a 5-year history of Parkinson's disease took selegiline (10 mg/day), levodopa (400–600 mg/day), and

benserazide (100–150 mg/day) throughout gestation (2). She was advised to stop selegiline but continued it against medical advice. She delivered a healthy 3800-g male infant at term with Apgar scores of 10 at 1 and 10 minutes. She breastfed the infant for 3 days and then changed to bottle feeding out of concern over drug transfer into her breast milk. The boy, monitored closely by a pediatrician and a neurologist, was doing very well at 10 years of age with normal somatic and mental development, and was excelling at school and in sports (2).

BREASTFEEDING SUMMARY

Except for the one case above (breastfeeding for 3 days), no reports have described the use of selegiline during human lactation. The low molecular weight (about 188 for the free base) suggests that excretion into breast milk will occur. The effect of this exposure on a nursing infant is unknown. Because of significant neurotoxicity observed in animals (see above), the safest course is to avoid selegiline during nursing until data are available.

SENNA

Laxative

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Senna, a naturally occurring laxative, contains the stereoisomeric glucosides, sennosides A and B. No reports of human teratogenicity or other fetal toxicity have been located.

FETAL RISK SUMMARY

Senna contains prodrug anthraquinone glucosides that are converted by bacterial enzymes in the colon to rhein-9-anthrone. This metabolite is then oxidized to rhein, the active cathartic agent of senna (1). Senna is not teratogenic in animals (2).

A 2009 population-based, case-control study examined the association of senna exposure during pregnancy with congenital anomalies (3). The population-based large data set of the Hungarian Case-Control Surveillance System of Congenital Abnormalities was used for the study. Most women were taking daily doses of 20 mg (range 10–30 mg). There were 22,843 cases with and 38,151 cases without congenital anomalies. In these groups, senna was used by 506 (2.2%) vs. 937 (2.5%), respectively, of the mothers. Compared with 500 matched controls, there was no higher risk for 23 different congenital anomalies groups in the 260 study mothers who were treated with senna during the second and/or third gestational months. The results indicated that senna treatment was not associated with a higher risk of congenital anomalies in offspring (3).

BREASTFEEDING SUMMARY

Sennosides A and B are not excreted into breast milk. A 1973 study using colorimetric analysis (sensitivity limit 0.34 mcg/mL) failed to detect the natural agents (4). The active metabolite, rhein, however, is excreted into milk in very small amounts (1). Lactating women administered 5 g of senna daily for 3 days

excreted a mean 0.007% of the dose in their milk and no adverse effects were observed in the nursing infants. This is compatible with the fact that the anthraquinone laxatives are absorbed only slightly after oral administration (5).

In addition to the study above (1), use of the laxative during lactation has been reported in three other studies (4,6,7). Although diarrhea occurred in some of the infants, this was probably related to other causes, not to senna. In one study, mothers who ingested a single 100-mg dose of senna (containing 8.6 mg of sennosides A and B) and whose infants developed diarrhea were later given a double dose of the laxative (4). No diarrhea was observed in the infants after the higher dose. The American Academy of Pediatrics classifies senna as compatible with breastfeeding (8).

SERTACONAZOLE

Antifungal

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of sertaconazole in human pregnancy have been located. The lack of animal developmental toxicity and the failure to detect the drug in the plasma after multiple applications to diseased skin suggest that risk to the human embryo–fetus is negligible. If indicated, the topical antifungal appears to be compatible with pregnancy.

FETAL RISK SUMMARY

Sertaconazole is available as a topical cream. It is in the same antifungal class of imidazole derivatives as butoconazole, clotrimazole, econazole, ketoconazole, miconazole, oxiconazole, sulconazole, and tioconazole. Sertaconazole is indicated for the treatment of interdigital tinea pedis caused by *Trichophyton rubrum*, *T. mentagrophytes*, and *Epidermophyton floccosum* in immunocompetent patients. Systemic absorption of sertaconazole from diseased skin after multiple applications is negligible as plasma concentrations were below the level of detection (2.5 ng/mL) (1).

Reproduction studies have been conducted with sertaconazole in rats and rabbits. No evidence of maternal toxicity, embryo toxicity, or teratogenesis was observed in pregnant rats and rabbits given oral doses 40 and 80 times, respectively, the maximum recommended human dose based on BSA (MRHD). In a peri-postnatal study in rats, doses 20–40 times the MRHD caused a decrease in live birth indices and an increase in the number of stillborn pups. The antifungal agent had no effect on fertility in male and female rats at doses 16 times the MRHD. Although long-term studies for carcinogenicity have not been conducted, tests for mutagenicity or clastogenicity were negative (1).

It is not known if sertaconazole crosses the human placenta. Since systemic

absorption after topical application was not detected in one study, it appears that exposure of the embryo and/or fetus does not occur.

BREASTFEEDING SUMMARY

No reports describing the use of sertaconazole during human lactation have been located. The drug does not produce detectable plasma concentrations after multiple applications to diseased skin. Therefore, the risk to a nursing infant can be considered negligible, and the antifungal agent is probably compatible with breastfeeding.

SERTRALINE

Antidepressant

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 3rd Trimester

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

The limited animal and human data suggest that sertraline is not a major teratogen. Two large case–control studies did find increased risks for some birth defects, but the absolute risk appears to be small (1,2). However, selective serotonin reuptake inhibitor (SSRI) antidepressants, including sertraline, have been associated with several developmental toxicities, including spontaneous abortions, low birth weight, preterm delivery, neonatal serotonin syndrome, neonatal behavioral syndrome (withdrawal), possible sustained abnormal neurobehavior beyond the neonatal period, respiratory distress, and persistent pulmonary hypertension of the newborn (PPHN).

FETAL RISK SUMMARY

Although the mechanism of action of the antidepressant, sertraline, is unknown, it is an SSRI similar to other drugs in this class. This effect of sertraline results in the potentiation of serotonin activity in the brain. The chemical structure of sertraline is unrelated to other antidepressants.

All the antidepressant agents in the SSRI class (citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline) are thought to share a similar mechanism of action, although they have different chemical structures. These differences could be construed as evidence against any conclusion that they share similar effects on the embryo, fetus, or newborn. In the mouse embryo, however, craniofacial morphogenesis appears to be regulated, at least in part, by serotonin. Interference with serotonin regulation by chemically different inhibitors produces similar craniofacial defects (3). Regardless of the structural differences, therefore, some of the potential adverse effects on

pregnancy outcome may also be similar.

Reproductive studies in rats and rabbits, conducted with doses up to approximately 4 times the maximum recommended human dose based on BSA (MRHD), did not reveal evidence of teratogenicity. Delayed ossification of rat and rabbit fetuses, however, occurred at doses during organogenesis that were half and four times the MRHD, respectively. When female rats received a dose equal to the MRHD during the last third of gestation and throughout lactation, an increased number of stillbirths, decreased pup survival, and decreased pup weights were observed. The decreased pup survival was shown to be due to in utero exposure to sertraline. The no-effect dose for rat pup mortality was half the MRHD (4).

Consistent with the molecular weight of the free base (about 307), sertraline crosses the human placenta. A 2003 study of the placental transfer of antidepressants found cord blood:maternal serum ratios for sertraline and its metabolite that were 0.14–0.66 and 0.14–0.77, respectively (5). The dose-to-delivery interval was 7–35 hours, with the highest ratio for the parent drug and metabolite occurring at 24 hours.

A 24-year-old woman was treated before and during the first few weeks of gestation with sertraline for depression and bulimia (K. Murray and D. Jackson, personal communication, Eugene, Oregon, 1994). Ultrasound revealed a single fetus with anencephaly and an abdominal wall defect. Chromosomal analysis performed after termination indicated that the fetus had trisomy 18 (47,XX+18). Because trisomy 18 is a naturally occurring mutation, in the absence of any animal or other evidence for a causal relationship, it is doubtful that the drug therapy was related to the outcome of this pregnancy.

Fifteen diverse birth defects from sertraline-exposed pregnancies were reported to the FDA as of December 1995 (F. Rosa, personal communication, FDA, 1996).

A 1995 report described the use of sertraline 100 mg/day and nortriptyline 125 mg/day in a woman with recurrent major depression (6). The patient was treated before and throughout gestation. Attempts to discontinue the agents in the 1st and 2nd trimesters were unsuccessful. She eventually gave birth at term to a healthy infant (sex and weight not specified) who, at age 3 months, was doing well and achieving the appropriate developmental milestones (see also Breastfeeding Summary below) (6).

A brief 1995 report described a case of a 32-year-old woman who took sertraline 200 mg/day throughout pregnancy (7). Lithium and thioridazine were also taken during the first 6 weeks of gestation. She continued the same dose

of sertraline for 3 weeks after delivery of a healthy, full-term male infant. During this period, she breastfed the infant, who was feeding and developing normally. One day after she stopped sertraline, the infant developed agitation, restlessness, poor feeding, constant crying, insomnia, and enhanced startle reaction. The infant's symptoms continued for another 48 hours before gradually resolving over several days. Similar symptoms were not observed in the mother. Because the same types of symptoms have been observed in adults after discontinuing sertraline (1), the authors attributed them to withdrawal (7).

A 1998 noninterventive observational cohort study described the outcomes of pregnancies in women who had been prescribed ≥ 1 of 34 newly marketed drugs by general practitioners in England (8). Data were obtained by questionnaires sent to the prescribing physicians 1 month after the expected or possible date of delivery. In 831 (78%) of the pregnancies, a newly marketed drug was thought to have been taken during the 1st trimester with birth defects noted in 14 (2.5%) singleton births of the 557 newborns (10 sets of twins). In addition, two birth defects were observed in aborted fetuses. However, few of the aborted fetuses were examined. Sertraline was taken during the 1st trimester in 51 pregnancies. The outcomes of these pregnancies included 1 ectopic pregnancy, 2 spontaneous abortions, 11 elective abortions, 1 intrauterine death, 26 normal full-term newborns, 2 infants with birth defects, and 8 pregnancies lost to follow-up. The congenital malformations were one case each of congenital laryngeal stridor and a duplication cyst (gastrointestinal) (8).

A prospective, multicenter, controlled cohort study published in 1998 evaluated the pregnancy outcomes of 267 women exposed to ≥ 1 SSRI antidepressants during the 1st trimester: fluvoxamine (N = 26); paroxetine (N = 97); and sertraline (N = 147) (9). The women were combined into a study group without differentiation as to the drug they had consumed. A randomly selected control group (N = 267) was formed comprising women who had exposures to nonteratogenic agents. In most cases, the pregnancy outcomes were determined 6–9 months after delivery. No significant differences were observed in the number of live births, spontaneous or elective abortions, stillbirths, major malformations, birth weight, or gestational age at birth. Nine major malformations were observed in each group. The relative risk (RR) for major anomalies was 1.06 (ns). No clustering of defects was apparent. The outcomes of women who took an antidepressant throughout gestation were similar to those who took an antidepressant only during the 1st trimester (9). All

of the women in the study group had taken an antidepressant during embryogenesis (10).

A 1999 abstract detailed the prospectively ascertained outcomes of 112 pregnant women taking sertraline compared with 191 controls (11). The rate of major congenital defects did not differ significantly between subjects and controls (3.8% vs. 1.9%). Infants exposed to sertraline in the 3rd trimester were more likely to be premature, to have neonatal transition difficulty, or to be admitted to a special care nursery. A dose–response relation was noted for the latter two complications (11).

The effect of SSRIs on birth outcomes and postnatal neurodevelopment of children exposed prenatally was reported in 2003 (12). Thirty-one children (mean age 12.9 months) exposed during pregnancy to SSRIs (15 sertraline, 8 paroxetine, 7 fluoxetine, and 1 fluvoxamine) were compared with 13 children (mean age 17.7 months) of mothers with depression who elected not to take medications during pregnancy. All of the mothers had healthy lifestyles. The timing of the exposures was 71% in the 1st trimester, 74% in the 3rd trimester, and 45% throughout. The average duration of breastfeeding in the subjects and controls was 6.4 and 8.5 months. Twenty-eight (90%) subjects nursed their infants, 17 of whom took an SSRI (10 sertraline, 4 paroxetine, and 3 fluoxetine) compared with 11 (85%) controls, 3 of whom took sertraline. There were no significant differences between the groups in terms of gestational age at birth, premature births, birth weight and length or, at follow-up, in sex distribution or gain in weight and length. Seven (23%) of the exposed infants were admitted to a neonatal intensive care unit (six respiratory distress, four meconium aspiration, and one cardiac murmur) compared with none of the controls (ns). Follow-up examinations were conducted by a pediatric neurologist, a psychologist, and a dysmorphologist who were blinded to the mother's medications status. The mean Apgar scores at 1 and 5 minutes were lower in the exposed group than in controls, 7.0 vs. 8.2, and 8.4 vs. 9.0, respectively. There was one major defect in each group: small asymptomatic ventricular septal defect (exposed) and bilateral lacrimal duct stenosis that required surgery (control). The test outcomes for mental development were similar in the groups, but significant differences in the subjects included a slight delay in psychomotor development and lower behavior motor quality (tremulousness and fine motor movements) (12).

A 2004 prospective study examined the effect of four SSRIs (citalopram, fluoxetine, paroxetine, and sertraline) on newborn neurobehavior, including behavioral state, sleep organization, motor activity, heart rate variability,

tremulousness, and startles (13). Seventeen SSRI-exposed, healthy, full-birth-weight newborns and 17 nonexposed, matched controls were studied. A wide range of disrupted neurobehavioral outcomes were shown in the subject infants. After adjustment for gestational age, the exposed infants were found to differ significantly from controls in terms of tremulousness, behavioral states, and sleep organization. The effects observed on motor activity, startles, and heart rate variability were not significant after adjustment (13).

A 2003 prospective study evaluated the pregnancy outcomes of 138 women treated with SSRI antidepressants during gestation (14). Women using each agent were 73 fluoxetine, 36 sertraline, 19 paroxetine, 7 citalopram, and 3 fluvoxamine. Most (62%) took an SSRI throughout pregnancy and 95% were taking an SSRI at delivery. Birth complications were observed in 28 infants, including preterm birth (9 cases), meconium aspiration, nuchal cord, floppy at birth, and low birth weight. Four infants (2.9%) had low birth weight, all exposed to fluoxetine (40–80 mg/day) throughout pregnancy, including two of the three infants of mothers taking 80 mg/day. One infant had Hirschsprung disease, a major defect, and another had cavum septi pellucidi (neither the size of the cavum nor the SSRI agents were specified) (14). The clinical significance of the cavum septi pellucidi is doubtful as it is nearly always present at birth but resolves in the first several months (15).

A 2005 meta-analysis of seven prospective comparative cohort studies involving 1774 patients was conducted to quantify the relationship between seven newer antidepressants and major malformations (16). The antidepressants were bupropion, fluoxetine, fluvoxamine, nefazodone, paroxetine, sertraline, and trazodone. There was no statistical increase in the risk of major birth defects above the baseline of 1%–3% in the general population for the individual or combined studies (16).

The database of the World Health Organization (WHO) was used in a 2005 report on neonatal SSRI withdrawal syndrome (17). Ninety-three suspected cases with either neonatal convulsions or withdrawal syndrome were identified in the WHO database. The agents were 64 paroxetine, 14 fluoxetine, 9 sertraline, and 7 citalopram. The analysis suggested that paroxetine might have an increased risk of convulsions or withdrawal compared with other SSRIs (17).

Evidence for the neonatal behavioral syndrome that is associated with in utero exposure to SSRIs and serotonin and norepinephrine reuptake inhibitors (SNRIs) (collectively referred to as serotonin reuptake inhibitors [SRIs]) in late pregnancy was reviewed in a 2005 reference (18). The report followed a

recent agreement by the FDA and manufacturers for a class labeling change about the neonatal syndrome. Analysis of case reports, case series, and cohort studies revealed that late exposure to SSRIs carried an overall risk ratio of 3.0 (95% confidence interval [CI] 2.0–4.4) for the syndrome compared with early exposure. The case reports (N = 18) and case series (N = 131) involved 97 cases of paroxetine, 18 of fluoxetine, 16 of sertraline, 12 of citalopram, 4 of venlafaxine, and 2 of fluvoxamine. There were nine cohort studies analyzed. The typical neonatal syndrome consisted of CNS, motor, respiratory, and gastrointestinal signs that were mild and usually resolved within 2 weeks. Only one of 313 quantifiable cases involved a severe syndrome consisting of seizures, dehydration, excessive weight loss, hyperpyrexia, and intubation. There were no neonatal deaths attributable to the syndrome (18).

Possible sustained neurobehavioral outcomes beyond the neonatal period were reported in 2005 (19). Based on the previous findings that prenatally exposed newborns had reduced pain responses, biobehavioral responses to acute pain (heel lance) were prospectively studied in 2-month-old infants. The responses included facial action (Neonatal Facial Coding System) and cardiac autonomic reactivity (derived from respiratory activity and heart rate variability). Three groups of infants were formed: 11 infants with prenatal SSRI exposure alone (2 fluoxetine and 9 paroxetine); 30 infants with prenatal and postnatal (from breast milk) SSRI exposure (6 fluoxetine, 20 paroxetine, and 4 sertraline); and 22 nonexposed controls (mothers not depressed). The exposure during breastfeeding was considered to be very low. Heel lance-induced facial action increased in all three groups but was significantly lowered (blunted) in the first group. Heart rate was significantly lower in the exposed infants during recovery. Moreover, exposed infants had a greater return of parasympathetic cardiac modulation, whereas controls had a sustained sympathetic response. The findings were consistent with the patterns of pain reactivity observed in exposed newborns and suggested sustained neurobehavioral outcomes (19).

A significant increase in the risk of low birth weight (<10th percentile) and respiratory distress after prenatal exposure to SSRIs was reported in 2006 (20). The population-based study, representing all live births (N = 119,547) during a 39-month period in British Columbia, Canada, compared pregnancy outcomes of depressed mothers treated with SSRIs with outcomes in depressed mothers not treated with medication and in nonexposed controls. The severity of depression in the depressed groups was accounted for by propensity score matching (20).

A 30% incidence of SSRI-induced neonatal abstinence syndrome was found in a 2006 cohort study (21). Sixty neonates with prolonged in utero exposure to SSRIs were compared with nonexposed controls. The agents used were paroxetine (62%), fluoxetine (20%), citalopram (13%), venlafaxine (3%), and sertraline (2%). Assessment was conducted by the Finnegan score. Ten of the infants had mild and eight had severe symptoms of the syndrome. The maximum mean score in infants with severe symptoms occurred within 2 days of birth, but some occurred as long as 4 days after birth. Because of the small numbers, a dose–response study could only be conducted with paroxetine. Infants exposed to mean maternal doses that were <19 mg/day had no symptoms, <23 mg/day had mild symptoms, and 27 mg/day had severe symptoms (21).

A meta-analysis of clinical trials (1990–2005) with SSRIs was reported in 2006 (22). The SSRI agents included were citalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline. The specific outcomes analyzed were major, minor, and cardiac malformations, and spontaneous abortions. The odds ratio (OR) with 95% CI (in parentheses) for the four outcomes were 1.394 (0.906–2.145), 0.97 (0.13–6.93), 1.193 (0.531–2.677), and 1.70 (1.28–2.25), respectively. Only the risk of spontaneous abortions was significantly increased (22).

A brief 2005 report described significant associations between the use of SSRIs in the 1st trimester and congenital defects (23). The data were collected by the CDC-sponsored National Birth Defects Prevention Study in an on-going case–control study of birth defect risk factors. Case infants (N = 5357) with major birth defects were compared with 3366 normal controls. A positive association was found with omphalocele (N = 161; OR 3.0, 95% CI 1.4–6.1). Paroxetine, which accounted for 36% of all SSRI exposures, had the strongest association with the defect (OR 6.3, 95% CI 2.0–19.6). The study also found a significant association between the use of any SSRI and craniosynostosis (N = 372; OR 1.8, 95% CI 1.0–3.2) (23). An expanded report from this group was published in 2007 (1).

In 1999, the Swedish Medical Birth Registry compared the use of antidepressants in early pregnancy and delivery outcomes for the years 1995–1997 (24). There were no significant differences for birth defects, infant survival, or risk of low birth weight (<2500 g) among singletons between those exposed to any depressant, SSRIs only, or non-SSRIs only, but a shorter gestational duration (<37 weeks) was observed for any antidepressant exposure (OR 1.43, 95% CI 1.14–1.80) (24). A second Registry report, published in 2006 and covering the years 1995–2003, analyzed the relationship

between antidepressants and major malformations or cardiac defects (25). There was no significant increase in the risk of major malformations with any antidepressant. The strongest effect among cardiac defects was with ventricular or atrial septum defects (VSDs-ASDs). Significant increases were found with paroxetine (OR 2.22, 95% CI 1.39–3.55) and clomipramine (OR 1.87, 95% CI 1.16–2.99 (25)). In 2007, the analysis was expanded to include the years 1995–2004 (26). There were 6481 women (6555 infants) who had reported the use of SSRIs in early pregnancy. The number of women using a single SSRI during the 1st trimester was 2579 citalopram, 1807 sertraline, 908 paroxetine, 860 fluoxetine, 66 escitalopram, and 36 fluvoxamine. After adjustment, only paroxetine was significantly associated with an increased risk of cardiac defects (N = 13, RR 2.62, 95% CI 1.40–4.50) or VSDs-ASDs (N = 8, RR 3.07, 95% CI 1.32–6.04). Analysis of the combined SSRI group, excluding paroxetine, revealed no associations with these defects. The study found no association with omphalocele or craniostenosis (26).

A 2007 study evaluated the association between 1st trimester exposure to paroxetine and cardiac defects by quantifying the dose–response relationship (27). A population-based pregnancy registry was used by linking three administrative databases so that it included all pregnancies in Quebec between 1997 and 2003. There were 101 infants with major congenital defects, 24 involving the heart, among the 1403 women using only one type of antidepressant during the 1st trimester. The use of paroxetine or other SSRIs did not significantly increase the risk of major defects or cardiac defects compared with non-SSRI antidepressants. However, a paroxetine dose >25 mg/day during the 1st trimester was significantly associated with an increased risk of major defects (OR 2.23, 95% CI 1.19–4.17) and of cardiac defects (OR 3.07, 95% CI 1.00–9.42) (27).

A 2007 retrospective cohort study examined the effects of exposure to SSRIs or venlafaxine in the 3rd trimester on 21 premature and 55 term newborns (28). The randomly selected unexposed control group consisted of 90 neonates of mothers not taking antidepressants, psychotropic agents, or benzodiazepines at the time of delivery. There were significantly more premature infants among the subjects (27.6%) than in controls (8.9%), but the groups were not matched. The antidepressants, and number of subjects and daily doses (in parentheses) in the exposed group were paroxetine (46; 5–40 mg), fluoxetine (10; 10–40 mg), venlafaxine (9; 74–150 mg), citalopram (6; 10–30 mg), sertraline (3; 125–150 mg), and fluvoxamine (2; 50–150 mg). The behavioral signs that were significantly increased in exposed compared with

nonexposed infants were CNS: abnormal movements, shaking, spasms, agitation, hypotonia, hypertonia, irritability, and insomnia; respiratory system: indrawing, apnea/bradycardia, and tachypnea; and other: vomiting, tachycardia, and jaundice. In exposed infants, CNS (63.2%) and respiratory system (40.8%) signs were most common, appearing during the first day of life and lasting for a median duration of 3 days. All of the exposed premature infants exhibited behavioral signs compared with 69.1% of exposed term infants. The duration of hospitalization was significantly longer in exposed premature compared with nonexposed premature infants, 14.5 days vs. 3.7 days, respectively. In 75% of the term and premature infants, the signs resolved within 3 and 5 days, respectively. There were six infants in each group with congenital malformations, but the drugs involved were not specified (28).

A 2007 review conducted a literature search to determine the risk of major congenital malformations after 1st trimester exposure to SSRIs and SNRIs (29). Fifteen controlled studies were analyzed. The data were adequate to suggest that citalopram, fluoxetine, sertraline, and venlafaxine were not associated with an increased risk of congenital defects. In contrast, the analysis did suggest an increased risk with paroxetine. The data were inadequate to determine the risk for the other SSRIs and SNRIs (29).

A case–control study, published in 2006, was conducted to test the hypothesis that exposure to SSRIs in late pregnancy was associated with PPHN (30). A total of 1213 women were enrolled in the study, 377 cases whose infants had PPHN and 836 matched controls and their infants. Mothers were interviewed by nurses who were blinded to the hypothesis. Fourteen case infants had been exposed to an SSRI after the 20th week of gestation compared with six control infants (OR 6.1, 95% CI 2.2–16.8). The numbers were too small to analyze the effects of dose, SSRI used, or reduction of the length of exposure before delivery. No increased risk of PPHN was found with the use of SSRIs before the 20th week or with the use of non-SSRI antidepressants at any time during pregnancy. If the relationship was causal, the absolute risk was estimated to be about 1% (30).

Two large case–control studies assessing associations between SSRIs and major birth defects were published in 2007 (1,2). The findings related to SSRIs as a group, as well as to four specific agents: citalopram, fluoxetine, paroxetine, and sertraline. An accompanying editorial discussed the findings and limitations of these and other related studies (31). Details of the studies and the editorial are described in the paroxetine review (see Paroxetine).

A prospective cohort study evaluated a large group of pregnancies exposed

to antidepressants in the 1st trimester to determine if there was an association with major malformations (32). The patient population came from the Motherisk database and involved 928 cases that met their criteria. The 928 matched (for age, smoking, and alcohol use) controls were pregnancies not exposed to antidepressants or known teratogens. In addition to the 61 sertraline cases, the other cases were 113 bupropion, 184 citalopram, 21 escitalopram, 61 fluoxetine, 52 fluvoxamine, 68 mirtazapine, 39 nefazodone, 148 paroxetine, 17 trazodone, and 154 venlafaxine. In the antidepressant group, there were 24 (2.5%) major defects compared with 25 (2.6%) in controls (odds ratio 0.9, 95% CI 0.5–1.61). There was one major anomaly, a hiatus hernia, in the sertraline group. There were no major defects in the pregnancies exposed to bupropion, escitalopram, or trazodone (32).

BREASTFEEDING SUMMARY

Eight reports describing the use of sertraline during lactation have been located (6,33–39). In a 1995 case (described above), a woman with recurrent major depression consumed sertraline 100 mg/day and nortriptyline 125 mg/day throughout gestation and while exclusively breastfeeding her term infant (6). Milk levels (over a 24-hour period) were obtained at 3 weeks, and maternal and infant serum levels were measured at 3 and 7 weeks. Milk levels were 8.8–43 ng/mL, with the highest concentrations at 5 and 9 hours postdose. Maternal serum levels at 3 and 7 weeks were 48 and 47 ng/mL, respectively, but were undetectable in the infant. At the 3-week sampling, serum levels of nortriptyline in the mother and child were 120 ng/mL and undetectable, respectively. The infant was doing well at 3 months of age with normal weight gain and development (6).

A brief 1995 correspondence described a 32-year-old woman who was treated with sertraline 150 mg/day during the second half of gestation and while breastfeeding (33). She stopped nursing after 11 days. No adverse effects were noted in the healthy infant either during or after breastfeeding.

Four lactating women were treated for postpartum depression with sertraline 50 mg/day (N = 2) or 100 mg/day (N = 2) (34). Whole blood 5-hydroxytryptamine (serotonin; 5-HT) levels in the mothers and infants were determined before and after 9–12 weeks of therapy. Sertraline and desmethylsertraline plasma levels were also measured at the time of postexposure sampling. One infant in each dose group was fully breastfed and the other two infants were breastfed 3 or 4 times daily. The ages of the infants at the start of maternal treatment were 15 days, 26 days, 6 months, and 12

months. Sertraline and metabolite plasma levels in the infants were <2.5 and 5 ng/mL, respectively, compared with maternal plasma levels 10.3–48.2 and 19.7–64.5 ng/mL, respectively. Little to no change was observed in the platelet (equivalent to whole-blood) levels of serotonin in the infants, in contrast to the marked decreases measured in the mothers (34).

Milk samples were collected from 12 women after a sertraline dose at 4–6 hours for 24 hours (35). Additionally, maternal (24 hours after a dose) and infant serum levels (2–4 hours after nursing) were also determined in 11 mother–infant pairs. All of the subjects had been taking a fixed dose (25–200 mg/day) for 14–21 days. Sertraline (range 17–173 ng/mL) and the relatively inactive metabolite, desmethylsertraline (range 22–294 ng/mL), were present in all milk samples. The first 10–20 mL of milk (foremilk) had approximately one-half of the drug concentrations of sertraline and metabolite as did the hindmilk. The mean milk:serum ratios for the parent drug and metabolite were 2.3 and 1.4, respectively. In maternal serum (doses 25–150 mg/day), the concentrations of sertraline and metabolite ranged from 9 to 92 and from 15 to 212 ng/mL, respectively. In contrast, only three infants had measurable serum sertraline levels (2.7–3.0 ng/mL), whereas six had measurable metabolite levels (1.6–10.0 ng/mL). The calculated sertraline and metabolite doses received by the infants from milk were 0.019–0.124 and 0.023–0.181 mg/day, respectively (35).

In a 1998 study, the mean milk:plasma ratios of sertraline and the metabolite in eight lactating women (mean dose 1.05 mg/kg/day) were 1.93 and 1.64, respectively (36). The estimated infant doses were 0.2% and 0.3%, respectively, of the weight-adjusted maternal dose. Neither sertraline nor desmethylsertraline was detected in the plasma samples obtained from four infants. No adverse effects from the drug exposure were noted in the infants. All had achieved normal development milestones (36).

In another 1998 study, serum levels of sertraline and desmethylsertraline were measured in nine nursing mother:infant pairs (37). The maternal serum levels were 12–134 and 28–285 ng/mL, respectively. In six infants, the serum concentration of sertraline was below the quantification limit (<2 ng/mL), undetectable in one, and 3 ng/mL in another. The metabolite serum levels in these eight infants ranged from nonquantifiable to 24 ng/mL. In the ninth infant, however, the serum sertraline concentration was 64 ng/mL, 55% of the mother's serum level (117 ng/mL). The metabolite serum concentrations in the infant and mother were 68 and 117 ng/mL, respectively. The mother's dose in this case was 100 mg/day. The serum samples from the mother and infant

were drawn 2 hours after a dose. Because the levels were so unusual, the investigators checked the values twice. Although they speculated as to possible cause(s), they were unable to determine why the levels in this particular case were so high (37).

The effect of sertraline on 5-HT reuptake in nursing infants was studied in 14 mother–infant pairs in a 2001 report (38). Preexposure levels of 5-HT were drawn from the infants at a mean age of 17.3 weeks, whereas postexposure levels were drawn at a mean age of 26.3 weeks. The mean maternal plasma levels of sertraline and the metabolite, desmethylsertraline, were 30.7 ng/mL and 45.3 ng/mL, respectively. In the mothers, sertraline (25–200 mg/day) caused marked declines (70%–96%) in whole blood 5-HT levels. In contrast, 5-HT levels in whole blood of the nursing infants were not affected (preexposure 223.7 vs. postexposure 227.0 ng/mL). Infant plasma levels of sertraline and the metabolite were undetectable. The results suggested that treatment of the mother with sertraline would not affect peripheral or central 5-HT transport in their nursing infants (38).

A 2004 study was conducted in 25 women (nursing 26 infants) to quantify the concentration of the SSRI or SNRI in their breast milk (39). The antidepressants taken by the women were citalopram (nine), paroxetine (six), sertraline (six), fluoxetine (one), and venlafaxine (three). The maternal mean dose of sertraline was 64 mg/day (50–100 mg/day). The mean milk concentration was 151 nmol/L (97–230 nmol/L), resulting in a theoretical maximum infant dose that was 0.9% of the mother's weight-adjusted dose. Sertraline was not detected in the serum of the infants. There was no evidence of adverse effects in the breastfeeding infants (39).

A 1999 review of SSRI agents concluded that if there were compelling reasons to treat a mother for postpartum depression, a condition in which a rapid antidepressant effect is important, the benefits of therapy with SSRIs would most likely outweigh the risks (40). However, because the long-term effects of exposure to SSRI antidepressants in breast milk on the infant's neurobehavioral development are unknown (no such adverse effects have been identified to date, but research is needed), stopping or reducing the frequency of breastfeeding should be considered if therapy with these agents is required. Avoiding nursing around the time of peak maternal concentration (about 4 hours after a dose) may limit infant exposure. However, the long elimination half-lives of all SSRIs and their weakly basic properties, which are conducive to ion trapping in the relatively acidic milk, probably will lessen the effectiveness of this strategy. The American Academy of Pediatrics classifies sertraline as a

drug for which the effect on nursing infants is unknown but may be of concern (41).

A 2010 study using human and animal models found that drugs that disturb serotonin balance such as SSRIs and SNRIs can impair lactation (42). The authors concluded that mothers taking these drugs may need additional support to achieve breastfeeding goals.

SEVELAMER

Antidote (Phosphate Binder)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of sevelamer in human pregnancy have been located. The limited animal data suggest a moderate risk of toxicity that may be partially due to a deficiency of fat-soluble vitamins, such as vitamin D. The effect of sevelamer on the absorption of vitamins in pregnant women has not been studied (1). However, supplementation with higher oral doses of vitamins, especially fat-soluble vitamins (except vitamin A), might be required or IV vitamins should be considered.

FETAL RISK SUMMARY

Sevelamer is a polymeric phosphate binder that is administered orally. It is used in patients with end-stage renal disease for the reduction of serum phosphorus. The drug inhibits intestinal phosphate absorption by binding phosphorus. Sevelamer is not absorbed into the systemic circulation (1).

Reproduction studies have been conducted in rats and rabbits. No evidence of impaired fertility was observed in male and female rats. In pregnant rats, doses about 15 times the human dose (HD) or higher caused reduced or irregular ossification of fetal bones. The toxicity was thought to be due to reduced absorption of vitamin D. In rabbits, a dose about 10 times the HD caused an increased incidence of early resorptions, resulting in a slight increase in prenatal mortality (1).

BREASTFEEDING SUMMARY

No reports describing the use of sevelamer during human lactation have been located. The drug is not absorbed into the systemic circulation, but it may cause vitamin deficiencies in the mother by preventing intestinal vitamin

absorption, especially of fat-soluble vitamins. Because vitamins are excreted into breast milk, thereby further reducing maternal vitamin concentrations, women who are taking sevelamer might have to take higher oral doses of vitamins, especially fat-soluble vitamins (except vitamin A), or IV vitamin administration should be considered.

SEVOFLURANE

General Anesthetic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Sevoflurane is teratogenic in mice, but no reports of its use in early human gestation have been located. The absence of human experience during organogenesis prevents an assessment of the risk for structural anomalies. In addition, general anesthesia usually involves the use of multiple pharmacological agents. Although no teratogenicity has been observed with other halogenated general anesthetic agents, only halothane has 1st trimester human exposure data (see Halothane). Sevoflurane has been used immediately prior to delivery, but its effect on the newborn has not been studied. However, its effect on the newborn is probably no different from other general anesthetic agents. The uterine effects of sevoflurane (relaxation and increased blood loss) also appear to be similar to other agents in this class, but the low concentrations used clinically minimize these actions (see Enflurane). All anesthetic agents can cause depression in the newborn that may last for 24 hours or more but, again, this is lessened by the low doses. The potential reproductive toxicity (spontaneous abortion and infertility) of occupational exposure to halogenated general anesthetic agents has not been adequately studied.

FETAL RISK SUMMARY

Sevoflurane, a noninflammable general anesthetic agent administered via vaporizer, is indicated for the induction and/or maintenance of anesthesia during surgery. Sevoflurane is in the same class of volatile liquid halogenated agents as desflurane, enflurane, halothane, isoflurane, and methoxyflurane. It has a lower solubility in lipids (oil:gas partition coefficient about 47–53) and blood (blood:gas partition coefficient 0.68) than halothane or isoflurane, but higher

than desflurane (1). The anesthetic potency, based on the minimum alveolar anesthetic concentration (MAC), is about 50% less than that of isoflurane but about 30% more than that of desflurane (1). (Note: MAC is the concentration that causes immobility in 50% of patients exposed to a noxious stimulus such as a surgical incision; it represents the ED₅₀ [2]).

In an animal reproduction study, mice were exposed for 8 hours to sevoflurane and enflurane combined with three different concentrations of oxygen (3). Both anesthetic agents caused cleft palate, but the incidence was lower than that observed with halothane. Increasing the concentrations of oxygen lowered the incidence of the defect (3).

The teratogenic potential of sevoflurane, enflurane, and isoflurane was studied by evaluating the effect of each agent on the proliferation and differentiation of cells exiting from the G1-phase of the cell cycle (4). The theory behind the study was that normal development during embryogenesis, organogenesis, and histogenesis depended upon the proliferation and differentiative processes of cell migration (4). For example, valproate, a known human teratogen, is a potent G1-phase inhibitor of the in vitro proliferation rate at concentrations less than two times the therapeutic plasma concentration. At anesthetic concentrations less than two times the MAC, the antiproliferative potency of the three agents was isoflurane = enflurane >> sevoflurane. However, in the growth-arrested cell population, there was no specific accumulation of any cell-cycle phase and no specific effect on the G1 phase. The investigators concluded that the three agents lacked the specific in vitro characteristics of valproate (4).

In an in vitro experiment with pregnant rats, sevoflurane, halothane, and isoflurane significantly inhibited oxytocin-induced contractions of uterine smooth muscle (5).

Two reviews have concluded that, in general, inhalational anesthetics are freely transferred to fetal tissues (6,7) and, in most cases, the maternal and fetal concentrations are equivalent (7). The low molecular weight (about 200) and the presence of sevoflurane in the maternal brain support this assertion.

A 1999 case report described the use of sevoflurane for maintenance of general anesthesia during a nonobstetric surgery in a 25-year-old woman at 13 weeks' gestation (8). Six months later, a cesarean section delivered a 2820-g female infant without abnormalities.

Two reports described the use of sevoflurane for emergency cesarean section (9,10). Although successful outcomes occurred in both cases, the former report generated several letters and a reply (11–16).

Chronic occupational exposure to anesthetic gases in operating rooms during pregnancy has raised concerns that such exposure could cause birth defects and spontaneous abortions (17). A 1988 review cited a number of studies investigating the possible association between occupational exposure to anesthetic gases and adverse pregnancy outcomes (6). The reviewer concluded that serious methodological weaknesses in these studies precluded arriving at a firm conclusion, but a slightly increased risk of miscarriage was a possibility. However, there was no evidence of an association between occupational exposure and congenital anomalies (6).

A 2004 study, however, found a significant association between maternal occupational exposure to waste anesthetic gases during pregnancy and developmental deficits in their children, including gross and fine motor ability, inattention/hyperactivity, and IQ performance (see Nitrous Oxide).

BREASTFEEDING SUMMARY

Although sevoflurane has been administered during delivery, the effects of this exposure on the infant who begins nursing immediately after birth have not been described. Sevoflurane is probably excreted into colostrum and milk as suggested by its presence in the maternal blood and its low molecular weight (about 200), but the toxic potential of this exposure for the infant is unknown. However, the risk to a nursing infant from exposure to sevoflurane via milk is probably very low (18). Halothane, another halogenated inhalation anesthetic, is classified as compatible with breastfeeding by the American Academy of Pediatrics (see Halothane).

SIBUTRAMINE

[Removed from the market. See 9th edition.]

SILDENAFIL

Vasodilator/Impotence Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Pregnancy is not advised in women with pulmonary arterial hypertension because of the high risk of morbidity and death. However, pregnancies have continued because of the mother's wishes and have been treated successfully with sildenafil. Although the data are very limited, no embryo–fetal harm has been observed. The drug has not caused developmental toxicity in animals. Because pulmonary arterial hypertension is a high-risk condition, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Sildenafil is an inhibitor of cyclic guanosine monophosphate-specific phosphodiesterase type-5 in the smooth muscle of the pulmonary vasculature and in the corpus cavernosum of the penis. It is indicated for the treatment of pulmonary arterial hypertension (WHO Group 1) to improve exercise ability and delay clinical worsening (1). It is also indicated for the treatment of erectile dysfunction (2). The drug is available in formulations for oral and IV use. Sildenafil has an active metabolite and both are about 96% bound to plasma proteins. The terminal half-life of sildenafil and its active metabolite are about 4 hours (1,2).

Reproduction studies have been conducted in rats and rabbits. In these species, doses up to 20–32 and 40–68 times, respectively, the recommended human dose based on BSA (RHD) revealed no evidence of teratogenicity, embryotoxicity, or fetotoxicity (1,2). In the rat prenatal and postnatal development study, the no-observed-adverse-effect-level (NOAEL) was 5 times the RHD (1) or about 20 times human exposure based on AUC (2).

Studies for carcinogenicity, mutagenicity, and clastogenicity were negative. In

addition, the drug did not impair the fertility of male and female rats (1,2).

It is not known if sildenafil crosses the human placenta. The molecular weight (about 667) and terminal half-life suggest that the drug and its active metabolite will cross to the embryo–fetus, but the high plasma protein binding should limit the exposure.

A 22-year-old woman with Eisenmenger's syndrome that was managed with sildenafil 50 mg/day was diagnosed with an atrial septal defect that was closed surgically (3). Eight days after surgery, the patient reported 7 weeks of amenorrhea and a pregnancy test was positive. Sildenafil 150 mg/day and diltiazem 60 mg/day were started. Two weeks later, sildenafil was discontinued because of its high cost and the dose of diltiazem was increased to 180 mg/day. Because of worsening pulmonary hypertension at 31 weeks, sildenafil 150 mg/day was restarted and diltiazem was discontinued. The fetal weight was estimated to be in the 15th percentile. At 32 weeks, L-arginine (a nitric oxide donor) 3 g/day was started. During the next 2 weeks, the estimated fetal weight increased to the 35th percentile. Because of superimposed preeclampsia, a cesarean section was performed at 36 weeks' to deliver a 2.290-kg male infant with Apgar scores of 9 and 9. No additional information on the infant was provided (3).

A 2005 case report described the use of bosentan throughout pregnancy in a woman with Eisenmenger's syndrome due to pulmonary hypertension (4). Sildenafil was added at 27 weeks' gestation. At 30 weeks, a planned cesarean section delivered a healthy 1.41-kg female infant. Postoperatively, the mother was treated with bosentan, sildenafil, and warfarin. Her infant was nursed in the hospital for 11 weeks without problems, but died at 26 weeks of age from a respiratory infection (4).

Sildenafil (150 mg/day), bosentan (250/day), hydroxychloroquine (200 mg/day), azathioprine (100 mg/day), and phenprocoumon were used up to 5 weeks' gestation in a 29-year-old woman with systemic lupus erythematosus-associated pulmonary arterial hypertension (5). At that time, bosentan and phenprocoumon were discontinued and the other three agents were continued along with low-molecular-weight heparin. At 35 weeks, inhaled iloprost was added. At 37 weeks', a planned cesarean section delivered a healthy 2.760-kg female infant with Apgar scores of 8, 9, and 10. Breastfeeding was declined. At the time of the report, the child was doing well (5).

BREASTFEEDING SUMMARY

No reports describing the use of sildenafil during human lactation have been

located. The molecular weight (about 667) and terminal half-life (about 4 hours) suggest that the drug and its active metabolite will be excreted into breast milk, but the high plasma protein binding should limit the amount excreted. The effect of this exposure on a nursing infant is unknown. In clinical trials in adults, the three most common adverse effects were headache, flushing, and dyspepsia (1,2).

SILICONE BREAST IMPLANTS

Miscellaneous

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Approximately 2 million women in the United States alone have received silicone implants (1), but no estimation of the number of pregnant women exposed to these devices has been located. The passage of polydimethylsiloxane (PDMS) to the fetus should not occur because of the high molecular weight of this polymer, and no evidence has been published that any of its multiple breakdown products cross the placenta. However, silicon, the second most abundant element in the earth's crust and a major component of biologic systems including the human skeleton (2), crosses to the fetus with concentrations in the amniotic fluid ranging from 34 to 800 ng/mL (mean 154.7 ng/mL) at 16–19 weeks' gestation (3). Transplacental passage of maternal immunoglobulin antibodies (IgG, IgA, or IgM) from silicone-induced immune disease is potentially possible, but this was not found in the study cited below. Moreover, some data presented in the Breastfeeding Summary argue against the clinical significance of this occurrence. Furthermore, a meta-analysis found no evidence that silicone implants are associated with connective-tissue or autoimmune diseases.

FETAL RISK SUMMARY

Silicone breast implants are composed of a shell of high-molecular-weight PDMS (dimethicone) gum (i.e., elastomer or rubber) containing either saline, a silicone "oil" composed of unlinked polymers, or a lower-viscosity PDMS gel (2,4). The difference in the viscosity of the organosiloxane shell and filler is dependent on the average molecular weight and molecular number distribution of the polymer (4). Leakage (bleeding) of the filler onto the surface of the shell may occur by simple diffusion and is associated with contracture of fibrous tissue around the implant, a foreign body response, or both. Gel bleeding may decrease the tensile strength of the shell and, by implication, may increase the

incidence of implant rupture. The prevalence of implant rupture has been estimated to be 4%–6% (4).

Silicone breast implants have been generally available since the early 1980s, although they were first used experimentally in the 1940s (2). Several serious health concerns have been raised in relation to these implants, including silicone gel implant bleed, contracture (moderate degrees of contracture may be beneficial), implant rupture, carcinogenesis, immune disorders, and impaired breast cancer detection (1,2,4). However, a causal relationship between breast implants and connective-tissue and autoimmune disease seems unlikely based on the results of a meta-analysis described below.

A 2000 study conducted a meta-analysis of 20 studies (9 cohort, 9 case–control, and 2 cross-sectional) to determine if breast implants were associated with an increased risk of connective-tissue and autoimmune diseases (5). The study was part of a report prepared by a scientific panel formed to advise the federal judiciary on silicone breast implants (6). No evidence of an increase in individual connective-tissue diseases (rheumatoid arthritis, systemic lupus erythematosus, scleroderma or systemic sclerosis, and Sjogren's syndrome), all connective-tissue diseases combined, or other autoimmune or rheumatic conditions was found. Similarly, no evidence of a significantly increased risk was found specifically for silicone-gel-filled implants (5).

A study published in 1996 found no significant difference in the prevalence of autoantibodies between children (N = 80) born to mothers with silicone breast implants and control children (N = 42) born to mothers without implants (7). Moreover, no association between the clinical symptoms in the children and the presence of autoantibodies was found. Control children had been referred to the authors because of irritable bowel syndrome or lactose intolerance (N = 21) or fibromyalgia (N = 21), whereas the children in the study group had been referred because of concerns about adverse effects from the mother's implants. The authors concluded that determination of the antibodies was of limited clinical value in this patient population (7).

In a three-part study, investigators studied whether the immunogenicity of silicone, which appears to have been confirmed in humans and in at least one animal model, could be transferred from the mother to her offspring (8). In part 1 of the study, using silicon dioxide (silica), T lymphocyte cell-mediated immune responses were elicited in 21 of 24 children from 15 women with silicone breast implants. Subjects in part 2 of the study were the offspring of three women who gave birth to four children before they received their implants and to seven children after the implants. Five of the postimplant offspring were found to be

positive to T-cell memory for silica compared with none of the preimplant offspring. Part 3 was a blinded study that evaluated 30 children of mothers with silicone implants compared with 10 control children of mothers without implants. A significant increase in T-cell stimulation was measured in the exposed children in comparison to the controls. Because not all of the above offspring were breastfed, the investigators concluded that the results indicated either the transplacental passage of immunogens from silicone or the transfer by maternal–fetal cellular exchange (8).

A 1998 epidemiologic cohort study conducted in Denmark examined the occurrence of esophageal disorders, connective tissue diseases, and congenital malformations in children (born during 1977–1992) of mothers with breast implants (9). A total of 939 children born from mothers with breast implants for cosmetic reasons (660 before the implant surgery and 279 after) were compared with 3906 children born from mothers who had undergone breast reduction surgery (1739 before surgery and 2167 after). The mean times from surgery to delivery for the two groups were 5.0 and 5.5 years, respectively. In the implant group, the observed/expected ratios (95% confidence intervals in parentheses) for various offspring outcomes before and after implants were as follows: esophageal disorders 2.7 (1.4–4.7) and 2.9 (0.8–7.4); rheumatic diseases 0.7 (0.0–4.1) and 0.0 (0.0–12.9); all types of congenital malformations 1.2 (0.9–1.5) and 1.3 (0.8–2.0); and defects of the digestive organs 1.4 (0.5–3.0) and 1.3 (0.2–4.6). Among the four children with an esophageal disorder who were born after the implants, three were hospitalized because of mild regurgitation that resolved without treatment. The fourth case involved a child with microcephaly, which was diagnosed as part of a genetic syndrome, and cerebral palsy. The results provided no evidence that silicone breast implants were associated with an increased risk of connective tissue diseases or malformations. Similar, nonsignificant differences for each of the categories were also found in the breast reduction group. The investigators concluded that women in both groups were more likely to seek professional medical care for problems normally solved outside the hospital (9).

BREASTFEEDING SUMMARY

Studies concerning the excretion of PDMS (see above) or the breakdown products of this macromolecule into milk have not been located, but two reports discussed below have described unusual disease symptoms in breastfed infants of mothers with silicone breast implants (10,11). For the present, any association between the symptoms and the organosiloxane components of the

implants is speculative and further studies are needed to establish a causal relationship.

A 1994 report described 67 (56 breastfed, 11 bottle-fed) children born to mothers with silicone breast implants, who had been self-referred because of concerns relating to implant-induced toxicity (10). Forty-three (35 breastfed, 8 bottle-fed) of the children had complaints of recurrent abdominal pain, and 26 (20 breastfed, 6 bottle-fed) of this group had additional symptoms, such as recurrent vomiting, dysphagia, decreased weight:height ratio, or a sibling with these complaints. Of these latter 26 children, 11 (8 breastfed, 3 bottle-fed; mean age 6.0 years, range 1.5–13 years; 6 boys and 5 girls) agreed to undergo further evaluation. A group composed of 17 subjects (mean age 10.7 years; range 2–18 years; 11 boys and 6 girls) with abdominal pain who had not been exposed to silicone breast implants served as controls. No significant differences were found between the implant-exposed breastfed and bottle-fed subjects or between the total exposed group and controls (7 of the 17 were tested) in autoantibodies to eight antigens (nuclear, Sci-70, centromere, ribonucleoprotein, Sm, Ro, La, and phospholipid). Endoscopy was performed on all subjects, and no gross visual abnormalities were observed. Chronic esophagitis was discovered on biopsy specimens in 8 exposed (6 breastfed, 2 bottle-fed) children (all graded as mild) and in 13 of 16 controls (1 not tested) (mild-to-moderate in 7, severe in 6). No granulomas or crystals were identified in the biopsy specimens. The histology of the specimens did not differ between the exposed children or between the exposed children and controls. When esophageal manometry was used to test the esophageal motility of the subjects, six of the eight breastfed exposed children were found to have significantly abnormal motility with nearly absent peristalsis in the distal two-thirds of the esophagus. Esophageal sphincter pressure, esophageal wave propagation, and wave amplitude were measured and compared in the breastfed exposed, bottle-fed exposed, and control groups by an investigator blinded to the clinical status of the children. The following results were obtained in the three groups: 13.1 (ns compared with controls), 22.7, and 24.8 mmHg, respectively; 14.7% (ns compared with controls), 64.3%, and 53.0%, respectively; and 42.3, 60.3, and 50.6 mmHg, respectively. No improvement in the motility abnormalities was found in three of the breastfed exposed subjects who were retested 10 months later after long-term ranitidine therapy had reduced the episodes of abdominal pain (10).

The symptoms present in the breastfed exposed children were considered to be characteristic of systemic sclerosis, although the children did not meet the

clinical criteria for the disease (10). Moreover, the investigators excluded the possibility that the abnormal motility was a consequence of chronic esophagitis. The blinded manometric findings suggested that the esophageal disorder might have been related to exposure to substances in breast milk because the bottle-fed exposed children had values similar to those of controls. The nature of these substances, if any, could not be determined by this study, but the investigators considered the possibilities to include silicone and other breakdown products of the implants that could be transferred across the immature intestinal barrier of the nursing infant and eventually lead to immunologically mediated damage (10).

In an accompanying editorial to the above report, several possible mechanisms for silicone-induced toxicity were explored (12). These included mother-to-child transmission of silicone products or maternal autoantibodies across the placenta or through breast milk. However, an argument against the latter mechanism is the usually short-term effects of passively acquired antibodies compared with the prolonged nature of the disorders in the affected children (12).

The second study, also published in 1994, described two female children, ages 2.67 and 9 years of age, who had long-standing, unusual, diffuse myalgias and arthralgias, not consistent with juvenile arthritis, and positive antinuclear antibodies (1:80 and 1:160, respectively; both speckled pattern) (11). The 9-year-old girl had a markedly elevated titer of antibodies against denatured human type II collagen. Both girls had been breastfed, the youngest for 3 months and the other for 6 months, by mothers with silicone breast implants. The right implant in the mother of the youngest girl had ruptured during pregnancy, and a recent breast ultrasound of the other mother was suggestive for implant rupture, but the timing was unknown (11).

A number of comments were published in response to the above two studies (13–25). In one of the comments, the authors described the results of a study in which no silicone was detected (detection level 0.5 mcg/mL) in two women with silicone breast implants (17). Two of the references stated that without more evidence, breastfeeding by women with silicone breast implants should not be contraindicated (22) or should be recommended (23).

Macrophage activation was suggested from the results of a case–control study of 38 breastfed children from mothers with silicone breast implants compared with 30 controls (healthy children N = 10, children with gastrointestinal symptoms similar to study patients N = 10, children with benign urinary abnormalities N = 7, and children with joint symptoms similar to study

patients N = 3) (26). Researchers measured the urinary excretion of stable nitric oxide (NO) metabolites (NO_3^- plus NO_2^-) and neopterin, inflammatory mediators released by phagocytosis of foreign material by macrophages. Mean levels of NO metabolites in the study patients were higher than those in controls, but significantly higher only when compared with levels in the subgroup of healthy children. Mean neopterin excretion in study patients was higher than each of the four control subgroups, but significantly so only in comparison to the healthy, gastrointestinal, and joint symptom subgroups. The investigators speculated that macrophage activation by silicone results in the release of NO and other substances with subsequent inhibition of esophageal peristalsis (26).

At follow-up (mean 2.1 years) of 11 children with esophageal dysmotility who had been breastfed by mothers with silicone breast implants, 7 had subjective clinical improvement in their symptoms (27). Esophageal sphincter pressures (both lower and upper) and percent of wave propagation into the distal esophagus following swallowing were statistically similar to the values obtained at initial manometric testing. Wave amplitude in the distal esophagus, however, did increase significantly. Urinary neopterin decreased significantly, whereas urinary nitrates (NO_3^- plus NO_2^-) decreased but not significantly. The data suggested that the dysmotility had become a chronic condition in this group of children (27).

In a 1998 study, silicon concentrations in milk and blood of 15 women with bilateral silicone gel-filled implants were compared with similar samples in 34 women with no implants, store-bought cow's milk, and 26 brands of commercially available infant formula (28). Silicon was used as a "proxy" measure for silicone. Mean milk and blood silicon levels were statistically similar in the implant group compared with women without implants: 55.45 and 79.29 ng/mL vs. 51.05 and 103.76 ng/mL, respectively. Much higher mean silicon concentrations were found in cow's milk (708.94 ng/mL) and commercial infant formula (4402.5 ng/mL) (28).

Two studies have described unusual signs and symptoms in children who had been breastfed by mothers with silicone breast implants. Follow-up studies by the same investigators suggested that these effects may have been caused by the transfer of maternal mutagenicity to silicone to the fetuses or infants during pregnancy or breastfeeding and that the pathogenesis in the offspring might be caused by macrophage activation. However, these conclusions are controversial (29–31) and have not been confirmed. Many experts recommend that women with silicone breast implants should be encouraged to breastfeed because the benefits of breastfeeding appear to far outweigh the potential, if

any, risk to the nursing infant. Mothers with silicone breast implants should be fully informed of the current state of knowledge so that they are actively involved in the decision whether to breastfeed. The American Academy of Pediatrics concluded that the available evidence does not justify classifying silicone implants as a contraindication to breastfeeding (32).

SIMETHICONE

Antiflatulent/Defoaming Agent

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Compatible

PREGNANCY SUMMARY

Simethicone is an over-the-counter nonabsorbable silicone product that is used as an antiflatulent. No published reports linking the use of this agent with congenital defects have been located.

FETAL RISK SUMMARY

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 248 newborns had been exposed to simethicone during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 14 (5.6%) major birth defects were observed (11 expected). Specific data were available for six defect categories, including (observed/expected) 6/2 cardiovascular defects, 0/0.5 oral clefts, 0/0 spina bifida, 2/1 polydactyly, 0/.5 limb reduction defects, and 1/0.5 hypospadias. Although the number of cardiovascular defects was more than expected, simethicone could not have caused them because the drug is not absorbed into the systemic circulation. Other factors, such as the mother's disease, concurrent drug use, and chance, are most likely involved. Thus, the drug can be classified as compatible in pregnancy.

BREASTFEEDING SUMMARY

No reports describing the use of simethicone during human lactation have been located. There is no risk to a nursing infant from maternal use of the drug as it is not absorbed.

SIMVASTATIN

Antilipemic Agent

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Based on the animal data and limited human experience, exposure to simvastatin during early pregnancy does not appear to present a significant risk to the fetus. However, because the interruption of cholesterol-lowering therapy during pregnancy should have no apparent effect on the long-term treatment of hyperlipidemia, simvastatin should not be used during pregnancy. Women taking this agent before conception should ideally stop the therapy before becoming pregnant and certainly on recognition of pregnancy. Accidental use of the drug during gestation, though, apparently has no known consequences for the fetus.

FETAL RISK SUMMARY

Simvastatin (a statin) is a lipophilic agent that is used to lower elevated levels of cholesterol. It has the same cholesterol-lowering mechanism (i.e., inhibition of hepatic 3-hydroxy-3-methylglutaryl-coenzyme A [HMG-CoA] reductase) as other agents available in this class, atorvastatin, fluvastatin, lovastatin, pitavastatin, pravastatin, and rosuvastatin (cerivastatin was withdrawn from the market in 2001). It is structurally similar to lovastatin and pravastatin.

Simvastatin was not teratogenic in rats and rabbits at doses up to three times the human exposure based on BSA (1). A decrease in fertility was observed in male rats dosed for 34 weeks at four times the maximum human exposure level based on AUC, but this effect was not observed when the study was repeated for 11 weeks (1). Male dogs given 10 mg/kg/day (about twice the human exposure based on AUC at 80 mg/day) demonstrated a drug-related testicular atrophy, decreased spermatogenesis, spermatocytic degeneration, and giant cell formation (1).

Shepard reviewed four studies involving the administration of simvastatin to pregnant rats and rabbits (2–5). Although maternal weight was reduced

compared with controls, no teratogenicity, adverse effects on fertility, or interference with postnatal behavior or fertility were observed.

Five cases of fetal loss were reported to the FDA in 1995, but additional data on these cases are not available (F. Rosa, personal communication, FDA, 1995).

A surveillance study of simvastatin and lovastatin exposures during pregnancy, conducted by the manufacturer, was reported in 1996 (6) and updated in 2005 (7). Of the 477 reports, all involving 1st trimester exposure, 386 were prospective (319 simvastatin, 67 lovastatin) and 91 were retrospective (53 simvastatin, 38 lovastatin). The pregnancy outcomes were known for 225 (58%) of the prospective reports. There were congenital defects in five liveborn and one stillborn, all involving simvastatin. The outcomes with defects were as follows (maternal dose and exposure in weeks from last menstrual period shown in parentheses): (i) postaxial polydactyly with small, boneless, outgrowth from hand (10 mg/day, 3–4 weeks); (ii) cleft lip (20 mg/day, 0–12 weeks); (iii) balanic hypospadias (10 mg/day, 2–6 weeks); (iv) trisomy 18, multiple malformations in a dead fetus, other twin normal (10 mg/day, 0–7 weeks); (v) duodenal atresia (20 mg/day, 0–8 weeks); and (vi) balanced translocation chromosomes I and II, baby reported to look and behave normally, mother also treated for hypertension (20 mg/day, 3–5 weeks). The cases of postaxial polydactyly, cleft lip, and hypospadias are relatively common birth defects. Only postaxial polydactyly has been associated with inborn errors of cholesterol metabolism. The trisomy and chromosomal abnormality were also dismissed as drug induced because there is no evidence that these defects could be caused by drugs. Other outcomes were 18 spontaneous abortions (SABs), 49 elective abortions (EABs), 4 fetal deaths, and 148 live births without defects. All of the outcomes, with the exception of fetal deaths, were similar to the population background rate. Although the number of fetal deaths was increased, there was no specific pattern to suggest a common cause. One death involved a nuchal cord and another was a trisomy 18. No congenital defects were reported in the SABs or EABs (7).

There were 13 cases of congenital defects in retrospective reports; 6 involving simvastatin and 7 with lovastatin (7). The details of the congenital defects after exposure to simvastatin were (daily dose and exposure in weeks from last menstrual period) as follows:

- (a) “major anomalies,” EAB (dose not reported, 1st trimester);
- (b) suspected triploidy, SAB (20 mg, 0–9 weeks);

- (c) unilateral cleft lip (10 mg, 2–6 weeks);
- (d) right lower limb aplasia of one tarsal bone, foot hypoplasia, equal shortening of the fibula and tibia (intercalary deficiency (20 mg, 0–4 weeks);
- (e) clubfoot (10 mg, 1st trimester);
- (f) features of VATER association (vertebral defects, anal atresia, tracheoesophageal fistula, esophageal atresia, radial limb reduction, and renal defect) with other abnormalities, EAB (10 mg, 2–12 weeks).

There were no specific patterns observed in the prospective or retrospective reports (7).

A 2004 report described the outcomes of pregnancy that had been exposed to statins and reported to the FDA (see Lovastatin).

Among 19 cases followed by a teratology information service in England, seven involved 1st trimester exposure to simvastatin (8). The pregnancy outcomes included two SABs; three healthy newborns; and two infants with congenital defects: sacral pit, intrauterine growth restriction (also exposed to enalapril, labetalol, and nifedipine); and mild positional talipes (8).

A 2005 case report described the pregnancy outcome of a 33-year-old woman treated with simvastatin in the first 8 weeks of an unplanned pregnancy (9). Diseases in the patient included hypercholesterolemia, hypertension, morbid obesity, and type 2 diabetes mellitus. Other drugs used by the woman were glimepiride, orlistat, ramipril, thiocolchicoside (a muscle relaxant), metformin, ciprofloxacin, and aspirin. When pregnancy was diagnosed at 8 weeks, all medications were stopped, and she was started on methyldopa and insulin. She gave birth at 38 weeks to a 3.470-kg female infant with Apgar scores of 5 and 7 at 1 and 5 minutes, respectively. No minor or major malformations were observed in the infant (9).

BREASTFEEDING SUMMARY

No published reports describing the use of simvastatin during lactation have been located. However, the passage of simvastatin into milk should be expected because at least two other similar agents (fluvastatin and pravastatin) appear in human milk. Because of the potential for adverse effects in the nursing infant, the drug should not be used during lactation.

SIROLIMUS

Immunologic Agent (Immunosuppressant)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Only a few reports of exposure to sirolimus in human pregnancy have been located. The animal reproduction data suggest a potential for toxicity, but not for teratogenicity. The in vitro study described suggests that sirolimus could affect growth of the fetal and neonatal heart. Although the clinical significance of the concentrations used in that study is unknown, there was no attempt to determine the no-effect concentration. The very limited human pregnancy experience prevents a full assessment of the risk. Reviews discussing transplantation in pregnancy are ambivalent regarding the use of sirolimus; with some not recommending its use (1) and others implying that it may be continued in pregnancy (2). Until human data are available, however, the safest course is to avoid the drug in pregnancy. If sirolimus is used in pregnancy, or in the event of inadvertent exposure, close monitoring of the embryo–fetus for developmental toxicity is warranted. The manufacturer recommends that women of childbearing potential use effective contraception before and during therapy, and for 12 weeks after therapy is stopped (3).

FETAL RISK SUMMARY

Sirolimus (rapamycin) is a distinct, oral immunosuppressant that is indicated for the prophylaxis of organ rejection in patients receiving renal transplants. It is recommended that it initially be used in combination with cyclosporine and corticosteroids. Chemically, the drug is a macrocyclic lactone produced by *Streptomyces hygroscopicus*. Sirolimus inhibits T-lymphocyte activation and proliferation induced by antigenic and cytokine (interleukin-2 [IL-2], IL-4, and IL-15) stimulation. Sirolimus is classified as a small-molecule immunosuppressant

agent (4). It is highly protein bound to plasma albumin and other proteins (about 92%) and has a mean terminal half-life in renal transplant patients of about 62 hours (3).

Reproduction studies have been conducted in rats and rabbits. In rats, doses about 0.2–0.5 times the human clinical dose based on BSA (HCD) were embryo–fetal toxic (death; reduced fetal weights with associated delays in skeletal ossification). However, structural defects were not observed. No effect on female rat fertility was observed at doses about 1–3 times the HCD. When combined with cyclosporine, increased embryo–fetal death compared with sirolimus alone was observed in rats. In pregnant rabbits, there were no effects on development at a maternal toxic dose about 0.3–0.8 times the HCD (3).

In carcinogenesis studies in mice and rats, there was a significant increase in malignant lymphoma at all doses tested (about 16–135 times the HCD). In mice, a lower dose (about 3–16 times the HCD) was associated with hepatocellular adenoma and carcinoma (males). In rats, a dose approximately equivalent to the HCD significantly increased the incidence of testicular adenoma. Sirolimus was not genotoxic in a variety of assays (3).

A 1998 in vitro study examined the effect of sirolimus on heart cell growth (5). Cardiac myocytes were isolated from 15-day-old fetal rats and exposed for 5 days in culture medium to various concentrations of sirolimus. (Note: The lowest concentration tested [0.5 ng/mL] was about 1.3% of the adult mean maximum concentration [37.4 ng/mL] obtained with a 5 mg/day dose). The exposed cells were then washed and grown in culture medium without sirolimus for an additional 5 days. Sirolimus inhibited both short-term and subsequent proliferation of cardiac myocytes. The investigators noted that fetal and neonatal heart growth occurs predominantly through myocyte proliferation (5).

It is not known if sirolimus crosses the human placenta. The molecular weight (about 914) is within the range for passive diffusion, and the elimination half-life will allow the drug to be present at the maternal:fetal interface for a long interval. However, the high protein binding should limit the amount of drug available to cross the placenta.

A 2003 report from the National Transplantation Pregnancy Registry briefly described four female kidney recipients who were treated during pregnancy with sirolimus and other immunosuppressants (6). The outcomes of the pregnancies were three live births (at 31, 36, and 38 weeks' gestation) and one spontaneous abortion (at 8 weeks' gestation). The only structural defect observed in the four cases was a cleft lip/palate and an ear deformity in a 1531-g infant delivered at 31 weeks' gestation. Immunosuppression during the

first 24 weeks consisted of mycophenolate mofetil, tacrolimus, and prednisone (6). Sirolimus, added at 24 weeks' gestation for biopsy-proven acute rejection, was not related to the anomalies.

A 2004 case report described the use of sirolimus in a 21-year-old woman who became pregnant 3 years after liver transplantation (7). At the time of conception, immunosuppression was maintained with sirolimus, tacrolimus, and corticosteroids (doses not specified). Pregnancy was diagnosed at 6 weeks' gestation and sirolimus was discontinued, but corticosteroids and tacrolimus were continued throughout pregnancy. At 39 weeks' gestation, a healthy, 2950-g female infant was delivered by cesarean section. The infant's physical development has been normal, and no unusual infections have been observed (7).

BREASTFEEDING SUMMARY

No reports describing the use of sirolimus during human lactation have been located. The molecular weight (about 914) and the prolonged half-life (about 62 hours) suggest that the drug will be excreted into breast milk. The effect of this potential exposure on a nursing infant is unknown, but consideration should be given to the carcinogenic properties of sirolimus, especially with long-term exposures. A 2002 review concluded that because of possible drug transfer into milk, women taking sirolimus should not breastfeed (1).

SITAGLIPTIN

Antidiabetic Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The animal reproduction data suggest low risk, but the very limited human pregnancy experience prevents a complete assessment of the embryo–fetal risk. No congenital anomalies attributable to sitagliptin (either alone or combined with metformin) have been reported.

Although the use of sitagliptin may help decrease the incidence of fetal and newborn morbidity and mortality in developing countries where the proper use of insulin is problematic, insulin still is the treatment of choice for this disease during pregnancy. Moreover, insulin does not cross the placenta and, this eliminates the additional concern that the drug therapy itself is adversely affecting the fetus. Carefully prescribed insulin therapy will provide better control of the mother’s blood glucose, thereby preventing the fetal and neonatal complications that occur with this disease. High maternal glucose levels, as might occur in diabetes mellitus, are associated with a number of maternal and fetal adverse effects, including fetal structural anomalies if the hyperglycemia occurs early in gestation. To prevent this toxicity, the American College of Obstetricians and Gynecologists recommends that insulin be used for types 1 and 2 diabetes occurring during pregnancy and, if diet therapy alone is not successful, for gestational diabetes (1,2). If a woman becomes pregnant while taking sitagliptin, changing the therapy to insulin should be considered.

The manufacturer maintains a pregnancy registry for women exposed to sitagliptin. Healthcare professionals are encouraged to report pregnancy exposures to the registry by calling the toll-free number 800-986-8999.

FETAL RISK SUMMARY

Sitagliptin is an orally active inhibitor of the dipeptidyl peptidase-4 (DPP4) enzyme. It is in the same antidiabetic subclass as linagliptin and saxagliptin. Sitagliptin is indicated as monotherapy as an adjunct to diet and exercise to improve glycemic control in patients with type 2 diabetes mellitus. It also is indicated in patients with type 2 diabetes mellitus to improve glycemic control in combination with metformin or a thiazolidinedione when the single agent alone, with diet and exercise, does not provide adequate glycemic control. In studies in healthy and diabetic subjects, sitagliptin did not lower blood glucose or cause hypoglycemia. Sitagliptin is partially metabolized with about 79% excreted in the urine as unchanged drug. The elimination half-life after a single dose was 12.4 hours. Plasma protein binding is low (38%) (3).

Reproduction studies have been conducted in rats and rabbits. In pregnant rats and rabbits, doses given during organogenesis that resulted in exposures about ≤ 30 and ≤ 20 times, respectively, the human exposure at the maximum recommended dose of 100 mg/day based on AUC (MRHD) were not teratogenic. At about 100 times the MRHD, an increased incidence of rib malformations was observed in offspring. A dose given to rats from gestation day 6 through lactation day 21 that resulted in exposures about 100 times the MRHD caused decreased body weight in offspring. No functional or behavioral toxicity was observed in the offspring (3).

Two-year carcinogenicity studies were conducted in male and female rats. An increased incidence of combined liver adenoma/carcinoma in males and females and of liver carcinoma in females was observed at an exposure about 60 times the MRHD. Liver tumors were not observed at about 20 times the MRHD. A similar study, performed in male and female mice with doses ≤ 70 times the MRHD, found no increase in the incidence of tumors in any organ. Sitagliptin was not mutagenic or clastogenic with or without metabolic activation in multiple assays. No impairment of fertility or fetal harm was observed in rats and rabbits given doses resulting in exposures that were about ≤ 12 times the MRHD (3).

Sitagliptin crosses the rat and rabbit placentas (3). Although it has not been studied, the drug probably crosses the human placenta. The molecular weight (about 505 for the phosphate salt), low metabolism and plasma protein binding, and prolonged elimination half-life suggest that the drug will cross to the embryo–fetus. However, the low lipid solubility might limit the exposure.

The Merck Pregnancy Registry for Januvia (sitagliptin) and Janumet (sitagliptin/metformin) covered the period August 4, 2006 through August 3, 2009 (4). During clinical trials, eight women were exposed to sitagliptin or

sitagliptin/metformin during the 1st trimester. The outcomes of these pregnancies were five healthy liveborn infants, two spontaneous abortions (SABs), and one fetal death (at 34 weeks' in a mother who took sitagliptin and metformin separately for the first 5 weeks of pregnancy). The outcomes of 16 prospectively enrolled pregnancies (exposures in the Registry are combined and do not distinguish between the two drugs) were nine live births (one set of twins), one SAB, five lost to follow-up, and two pregnancies pending. There were no congenital anomalies reported. There were six retrospectively enrolled pregnancies: two live births, three SABs, and one elective abortion at 19 weeks for encephalocele and intrauterine growth restriction (exposed to sitagliptin/metformin for 7 weeks during 1st trimester). In an internationally reported case, a woman took sitagliptin, insulin, metformin, and rosiglitazone for about 5 weeks in the 1st trimester. She gave birth at 33 weeks to a male infant with dysplastic left kidney, a missing kidney, severe hypospadias, a missing right testicle, and a poorly descended left testicle. The anomalies were consistent with diabetic embryopathy. A right inguinal hernia also was noted (4).

BREASTFEEDING SUMMARY

No reports describing the use of sitagliptin during human lactation have been located. The molecular weight (about 505 for the phosphate salt), low metabolism (about 21%) and plasma protein binding (about 38%), and prolonged elimination half-life (12.4 hours) suggest that the drug will be excreted into breast milk. The low lipid solubility might limit the exposure. The effect of this exposure on a nursing infant is unknown. Sitagliptin overdose (six times the maximum recommended human dose for 10 days) in healthy adults caused no dose-related adverse reactions (3). Thus, hypoglycemia in a nursing infant appears to be unlikely but should be monitored. The most common ($\geq 5\%$) adverse reaction in adults receiving monotherapy was nasopharyngitis (3).

SODIUM BICARBONATE

Nutrient/Antacid

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports of human 1st trimester use of sodium bicarbonate in pregnancy have been located. Animal studies have not suggested an increased risk for structural anomalies (1–5). Use of sodium bicarbonate (baking soda) for routine gastrointestinal ailments of pregnancy such as heartburn is typically not recommended due to the potential for fluid retention in pregnancy and subsequent complications and because alternatives are available (1). IV sodium bicarbonate therapy may be indicated for acute treatment of metabolic acidosis, certain drug intoxications, and severe diarrhea.

FETAL RISK SUMMARY

Sodium bicarbonate is an alkalinizing agent composed of sodium and bicarbonate ions. It is given as an IV solution to treat electrolyte disturbances resulting from severe metabolic acidosis that can occur in renal disease, uncontrolled diabetes, or severe dehydration. It also is used to treat overdoses of certain drugs such as barbiturates or salicylates. Sodium bicarbonate is used orally as an antacid to relieve symptoms of heartburn, indigestion, or stomach upset.

In animal studies, no teratogenic effect was noted among the offspring of rats given 40 to more than 4000 mg/kg/day of sodium bicarbonate during pregnancy (2–4). Similarly, no teratogenic effect was seen among the offspring of mice given 500 mg/kg/day of sodium bicarbonate during pregnancy (5).

Bicarbonate is a normal constituent of body fluids and plasma concentration is regulated by the kidney through acidification of the urine when there is a deficit or by alkalinization of the urine when there is an excess. In a healthy adult with normal kidney function, practically all the glomerular filtered

bicarbonate ion is reabsorbed; less than 1% is excreted in the urine. Treatment with exogenous sodium bicarbonate increases plasma bicarbonate, buffers excess hydrogen ion concentration, and raises blood pH (1).

Oral sodium bicarbonate is not recommended for the treatment of common complaints of heartburn and indigestion during pregnancy because of the potential for sodium-related fluid retention and edema that could contribute to other complications of pregnancy such as hypertension. Alternative treatments for chronic gastrointestinal complications of pregnancy that do not lead to fluid retention are preferred (1).

One human case report has been located (6). A woman who ingested 454 g of sodium bicarbonate a day between 29 and 31 weeks of pregnancy developed hypokalemic alkalosis, rhabdomyolysis, and hypertension. She subsequently gave birth to an apparently normal infant.

No studies of sodium bicarbonate and human fertility have been located. However, bicarbonate and carbon dioxide are common components in the secretions of the female reproductive tract, especially the oviduct (7). At physiologic concentrations, they are believed to play an important role in sperm hyperactivation and capacitation (8). An improvement of cervical mucus viscoelasticity and sperm penetration following vaginal douching with sodium bicarbonate has been reported (9).

BREASTFEEDING SUMMARY

Although sodium bicarbonate is known to be excreted into breast milk (1), no reports describing its use during human lactation have been located. However, chronic or indiscriminate use of the product as an antacid is not recommended during breastfeeding (1).

SODIUM IODIDE ^{131}I

Radiopharmaceutical/Antithyroid

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Hold Breastfeeding

PREGNANCY SUMMARY

Iodine-131-labeled sodium iodide (Na^{131}I) is a proven human teratogen. Because the effects of even small doses are not predictable, the use of the drug for diagnostic and therapeutic purposes should be avoided during pregnancy. A 1999 reference reviewed the effects of ^{131}I on the fetal thyroid after administration to the mother in early gestation (1).

FETAL RISK SUMMARY

Na^{131}I is a radiopharmaceutical agent used for diagnostic procedures and for therapeutic destruction of thyroid tissue. The diagnostic dose is approximately one-thousandth of the therapeutic dose. Like all iodides, the drug concentrates in the thyroid gland. ^{131}I readily crosses the placenta. The fetal thyroid is able to accumulate ^{131}I until after about 10–12 weeks of gestation (1–4). At term, the maternal serum:cord blood ratio is 1 (5).

As suggested by the above studies on the uptake of ^{131}I in fetal thyroids, maternal treatment with radioiodine early in the 1st trimester should not pose a significant danger to the fetus. Two reports describing Na^{131}I therapy at 4 and 8 weeks' gestation resulting in normal infants seemingly confirmed the lack of risk (6,7). However, a newborn, who was exposed to Na^{131}I at about 2 weeks' gestation, has been described as having a large head, exophthalmia, and thick, myxedematous-like skin (8). The infant died shortly after birth. In another early report, exposure to a diagnostic dose of Na^{131}I during the middle of the 1st trimester was considered the cause of anomalies observed in the newborn, including microcephaly, hydrocephaly, dysplasia of the hip joints, and clubfoot (9). Finally, Na^{131}I administered 1–3 days before conception was suggested as the cause of a spontaneous abortion at the end of the 1st trimester (10). All three of these latter reports must be viewed with caution because of the

uniqueness of the effects and the timing of the exposure. Factors other than radioiodine may have been involved.

Therapeutic doses of radioiodine administered near the end of the 1st trimester (12 weeks) or beyond usually result in partial or complete abolition of the fetal thyroid gland (11–21). This effect is dose-dependent, however, as one mother was treated at 19 weeks' gestation with 6.1 mCi of Na¹³¹I apparently without causing fetal harm (2). In the pregnancies terminating with a hypothyroid infant, Na¹³¹I doses ranged from 10 to 225 mCi (11–21). Clinical features observed at or shortly after birth in 10 of the 12 newborns were consistent with congenital hypothyroidism. One of these infants was also discovered to have hypoparathyroidism (21). In one child, exposed in utero to repeated small doses during a 5-week period (total dose 12.2 mCi), hypothyroidism did not become evident until 4 years of age (18). Unusual anomalies observed in another infant included hydrocephaly, cardiopathy, genital hypotrophy, and a limb deformity (16).

In a 1998 case report, a woman received 500 MBq of ¹³¹I in the 20th gestational week (22). Based on gamma camera examinations, the fetal thyroid gland uptake at 24 hours was estimated to be 10 MBq (2% of the dose) or an absorbed dose to the gland of 600 Gy (an ablative dose). The absorbed dose to the fetal body and brain was approximately 100 mGy, whereas the fetal gonads received about 40 mGy. At term, a hypothyroid, but otherwise healthy 3150-g male infant was delivered. Treatment with thyroxine was begun at 14 days of age. A neuropsychological examination at 8 years of age revealed normal mental performance, but with a low attention score and subnormal capacity regarding figurative memory. Plans were made for long-term surveillance of the infant because of the potential for thyroid cancer (22).

BREASTFEEDING SUMMARY

Na¹³¹I is concentrated in breast milk (23–26). Na¹²⁵I also appears in milk in significant quantities (27,28). Uptake of ¹³¹I contained in milk by an infant's thyroid gland has been observed (23). The time required for elimination of radioiodine from the milk may be as long as 14 days. For iodine-123 (¹²³I) and iodine-125 (¹²⁵I), radioactivity may be present in milk for up to 36 hours and 12 days, respectively (29). Since exposure to radioactive iodine may result in damage to the nursing infant's thyroid, including an increased risk of thyroid cancer, breastfeeding should be stopped until radioactivity is no longer present in the milk (29).

SODIUM OXYBATE

Psychotherapeutic (Miscellaneous)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

One report describing the use of sodium oxybate in human pregnancy has been located. The animal data suggest low risk, but the near absence of human pregnancy experience prevents a more complete assessment of the embryo–fetal risk. However, the indication suggests that the maternal benefit, under close medical supervision, may outweigh the unknown risk to the embryo–fetus.

FETAL RISK SUMMARY

Sodium oxybate, gamma hydroxybutyrate (GHB), is a CNS depressant that is available as an oral solution. It is indicated for the treatment of excessive daytime sleepiness and cataplexy in patients with narcolepsy. Because it is a known drug of abuse, sodium oxybate is only available through the Xyrem Success Program, using a centralized pharmacy. The drug is mainly eliminated by metabolism with <5% of unchanged drug appearing in the urine within 6–8 hours after dosing. Plasma protein binding is <1% and the half-life is 0.5–1 hour (1).

Reproduction studies have been conducted in rats and rabbits. Doses in these species that were about equal to and three times, respectively, the maximum recommended human dose based on BSA (MRHD) revealed no evidence of teratogenicity. In rats, a dose that was about equal to the MRHD given from day 6 of gestation through day 21 postpartum caused slight decreases in pup and maternal weight gains. No other drug effects on development were observed (1).

Sodium oxybate was not carcinogenic in long-term studies in male and female rats. A test for mutagenicity and a chromosomal aberration assay were

negative. Doses that were about equal to the MRHD did not impair fertility in rats (1).

It is not known if sodium oxybate, or its acid, cross the human placenta. The molecular weight of 4-hydroxybutyric acid (about 104) and the minimal plasma protein binding suggest that it will cross to the embryo–fetus, but the extensive, rapid metabolism and short half-life should limit the exposure.

A brief 2004 case report described a woman in labor who developed mild respiratory depression (2). The event was initially thought to be due to the opioid used for spinal–epidural analgesia. The depression was treated with face mask oxygen and 2 hours later she delivered a healthy newborn with a good Apgar score (scores not specified). Routine toxicology screening revealed the presence of GHB, also known as liquid ecstasy, and the mother admitted that she had used the drug (2).

BREASTFEEDING SUMMARY

No reports describing the use of sodium oxybate (GBH) during human lactation have been located, but such use is unlikely because of the drug’s rapid action. The molecular weight of the acid form (4-hydroxybutyric acid) (about 104) and the minimal plasma protein binding (<1%) suggest that it will be excreted into breast milk, but the extensive, rapid metabolism and short half-life (0.5–1 hour) should limit the amount excreted. The effect of this exposure on a nursing infant is unknown, but sedation and confusion are potential complications. However, because the drug is taken immediately before bedtime, nursing no sooner than 5 hours after a dose to just before the next dose should prevent clinically significant exposure of an infant.

SOLIFENACIN

Urinary Tract Agent (Antispasmodic)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of solifenacin in human pregnancy have been located. The animal data suggest moderate risk, but the absence of human pregnancy experience prevents a complete assessment of the embryo–fetal risk. However, there is no evidence that other anticholinergic drugs or agents in the subclass of urinary antispasmodics cause developmental toxicity. Nevertheless, until human pregnancy data are available, the safest course is to avoid solifenacin during pregnancy, especially in the 1st trimester. If inadvertent exposure in pregnancy does occur, the embryo–fetal risks probably are low.

FETAL RISK SUMMARY

The anticholinergic, solifenacin is a competitive antagonist of muscarinic receptors that are involved in cholinergic functions such as contractions of urinary bladder smooth muscle and stimulation of salivary secretion. Solifenacin is indicated for the treatment of overactive bladder with symptoms of urge urinary incontinence, urgency, and urinary frequency. It is in the same subclass as darifenacin, flavoxate, oxybutynin, and tolterodine, and trospium. Solifenacin is extensively metabolized by hepatic enzymes (mainly CYP3A4), but other metabolic pathways exist. One of the metabolites is active, but the concentration is low and is not thought to contribute significantly to clinical activity. Plasma protein binding is about 98%, primarily by α_1 -acid glycoprotein. The plasma elimination half-life with chronic dosing is 45–68 hours (1).

Reproduction studies have been conducted in mice, rats, and rabbits. In pregnant mice, doses ≥ 3.6 times the exposure at the maximum recommended human dose (MRHD) during organogenesis resulted in reduced fetal body

weights. When this dose was continued in pregnancy and during lactation, reduced peripartum and postnatal survival, reductions in body weight gain, and delayed physical development (eye opening and vaginal patency) were observed. A dose 7.9 times the MRHD during organogenesis was associated with increased incidences of cleft palate and a greater percentage of male offspring. No embryotoxicity was observed at 1.2 times the MRHD. No embryotoxicity was observed in rats and rabbits at doses that were <1 and 1.8 times the MRHD, respectively (1).

Solifenacin was not carcinogenic in mice and assays for mutagenicity were negative. The drug also had no effect on male and female fertility, reproductive performance, or early embryonic development in mice at a dose 13 times the MRHD, or in male and female rats at <1 and 1.7 times the MRHD, respectively (1).

It is not known if the solifenacin crosses the human placenta. The molecular weight (about 363 for the free base) and prolonged plasma elimination half-life suggest that the drug and/or its metabolites will cross to the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use of solifenacin during human lactation have been located. The molecular weight (about 363 for the free base) and prolonged plasma elimination half-life suggest that the drug and/or its metabolites will be excreted into breast milk. Although neonates are particularly sensitive to anticholinergics, two other agents in the anticholinergic class are classified by the American Academy of Pediatrics as compatible with breastfeeding (see Atropine and Scopolamine). The effect of solifenacin exposure in a nursing infant is unknown, but the risk of toxicity probably is low.

SOMATOSTATIN

Pituitary Hormone

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of somatostatin during human pregnancy have been located. (See also Octreotide.)

BREASTFEEDING SUMMARY

No reports describing the use of somatostatin during human lactation have been located. (See also Octreotide.)

SORAFENIB

Antineoplastic (Kinase Inhibitor)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of sorafenib in human pregnancy have been located. The animal reproduction data suggest risk, but the absence of human pregnancy experience prevents a more complete assessment of embryo–fetal risk. It should be noted, though, that sorafenib inhibits angiogenesis, a critical component of embryonic and fetal development. The manufacturer recommends that adequate contraception should be used during therapy and for at 2 weeks after completing therapy (1). However, renal cell carcinoma can be fatal, so if a woman requires sorafenib and informed consent is obtained, treatment should not be withheld because of pregnancy. If an inadvertent pregnancy occurs, the woman should be advised of the potential risk for severe adverse effects in the embryo and fetus.

FETAL RISK SUMMARY

Sorafenib is an oral multikinase inhibitor that decreases tumor cell proliferation, probably by reducing angiogenesis. There are several other antineoplastics in the same subclass (see Appendix). Sorafenib is indicated for the treatment of patients with advanced renal cell carcinoma. The mean plasma elimination half-life is 25–48 hours. After hepatic metabolism, at least eight metabolites have been identified, one of which has activity similar to the parent compound. Plasma protein binding is 99.5% (1).

Reproduction studies have been conducted in rats and rabbits. In these species, doses that were about 0.008 times the AUC in cancer patients taking the recommended human daily dose (RHDD) resulted in postimplantation loss, resorptions, skeletal retardations, and restricted fetal weight. A no-observed-adverse-effect-level (NOAEL) was not determined (1).

Studies for carcinogenicity have not been conducted with sorafenib. The drug

was clastogenic, in the presence of metabolic activation, in one test but was not mutagenic or clastogenic in other tests. An intermediate in the manufacturing process that also is present in the final product (<0.15%) was mutagenic when tested independently (1). Specific studies for fertility impairment have not been conducted, but sorafenib does adversely affect male and female reproductive organs. These effects, more pronounced in rats than in mice or dogs, included testicular atrophy and degeneration, oligospermia, degeneration of epididymis, prostate, and seminal vesicles, central necrosis of the corpora lutea, and arrested follicular development at doses that were about 0.3–0.5 times the RHDD (1).

It is not known if sorafenib crosses the human placenta. The molecular weight (433 for the free acid) and the long elimination half-life suggest that the drug will cross to the embryo and/or fetus.

BREASTFEEDING SUMMARY

No reports describing the use of sorafenib during human lactation have been located.

The molecular weight (433 for the free acid) and the long elimination half-life suggest that the drug will be excreted into breast milk. Because it is an acid, if excreted, the milk:plasma ratio should be <1. The effects of this exposure on a nursing infant are unknown, but severe toxicity may occur. In adults, hand–foot skin reaction and rash were the most common adverse events, but diarrhea, hemorrhage, and hypertension were also common.

SOTALOL

Antiarrhythmic

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

The use of sotalol in gestation appears to be low risk, but the pregnancy experience, especially in the 1st trimester, is limited. Several reviews have examined the use of β -adrenergic blockers in human pregnancy, concluding that these agents are relatively safe for the fetus (1–4). However, some β -blockers may cause intrauterine growth restriction (IUGR) and reduced placental weight, especially those lacking intrinsic sympathomimetic activity (ISA) (i.e., partial agonist). Sotalol has no ISA, but fetal growth restriction has not been reported. Typically, for β -blockers without ISA, continuous treatment beginning early in the 2nd trimester results in the greatest weight reductions, whereas treatment restricted to the 3rd trimester primarily affects only placental weight. IUGR and reduced placental weight may potentially occur with all agents within this class. Although IUGR is a serious concern, the benefits of maternal therapy with β -blockers, in some cases, might outweigh the risks to the fetus and must be judged on a case-by-case basis. Newborns exposed near delivery should be closely observed during the first 24–48 hours for signs and symptoms of β -blockade. Long-term effects of in utero exposure to this class of drugs have not been studied but warrant evaluation.

FETAL RISK SUMMARY

Sotalol is a sympatholytic agent indicated for the treatment of cardiac arrhythmias. The antiarrhythmic action of the drug includes both class II (β -adrenoreceptor blocking) and class III (cardiac action potential duration prolongation) properties. It has also been used for hypertension. Sotalol is a racemic mixture of the d- and l-isomers. Only the l-isomer exhibits β -adrenergic

blocking activity (without intrinsic sympathomimetic activity), but both isomers have Class III antiarrhythmic properties (5).

Sotalol was not teratogenic in rats and rabbits given doses 9 and 7 times the maximum recommended human dose based on BSA (MRHD), respectively, during organogenesis. In rabbits, a dose 16 times the MRHD, but not 8 times, resulted in a slight increase in fetal death that was thought to be related to maternal toxicity. Fetal resorptions were observed in rats at 18 times the MRHD, but not at 2.5 times (6).

In a 1996 study, the embryotoxicity of d-sotalol in rats was shown to be related to gestational age and resulted from dose-dependent bradycardia in in vitro (rat embryo culture) and in vivo (pregnant rat) experiments (7). In embryo cultures, the minimum effective concentration (15 mcg/mL) for causing significant bradycardia was about five times the human therapeutic plasma concentration (3 mcg/mL) achieved in pregnant women after a 400-mg oral dose. In nine pregnant rats, a single oral dose (1000 mg/kg) was administered on gestational day 13. No malformations were observed, but a resorption rate of almost 14% was noted (7).

The pharmacokinetics of sotalol in the 3rd trimester (32–36 weeks' gestation) of pregnancy and in the postpartum (at 6 weeks) period was reported in 1983 (8).

Sotalol crosses the placenta to the fetus (9–13). Twelve hypertensive pregnant women were prescribed sotalol (final daily dose 200–800 mg) beginning at 10–31 weeks' gestation (9). The mean gestational age at delivery was 37.7 weeks (range 32–40 weeks). The mean maternal plasma concentration of sotalol at delivery was 1.8 mcg/mL, nearly identical to the mean umbilical cord plasma level of 1.7 mcg/mL. In six women, the mean amniotic fluid concentration of sotalol was 7.0 mcg/mL. No data were provided on the time interval between the last sotalol dose and the collection of plasma samples (9). In a second study, eight women scheduled for elective cesarean section were given 80 mg of the drug orally 3 hours before the procedure (10). The mean maternal concentration of sotalol at surgery was 0.68 mcg/mL, compared with the mean umbilical vein concentration of 0.32 mcg/mL, a fetal:maternal ratio of 0.47 (10). A 1990 report described the use of sotalol, 80 mg twice daily, in one woman throughout gestation (11). A cesarean section was performed at approximately 37 weeks' gestation, 11 hours after the last dose. Maternal plasma and umbilical cord sotalol concentrations were 0.95 and 1.35 mcg/mL, respectively, a ratio of 1.42 (11). Maternal and cord serum concentrations of sotalol at delivery from a woman treated with 80 mg three

times daily throughout a 42 weeks' gestation were 0.77 and 0.65 mcg/mL (fetal:maternal ratio 0.84), respectively (12).

A 2003 study reported the use of sotalol in 18 pregnancies with fetal arrhythmias (9 with atrial flutter and 9 with supraventricular tachycardia [SVT]) (13). In the 17 surviving fetuses, one died, the mean birth weight was 3266 g. The mean fetal:maternal sotalol plasma concentration ratio was 1.1, and the mean amniotic fluid:fetal blood ratio was 3.2. These results suggested that sotalol accumulated in the amniotic fluid, but not in the fetus. In addition, there was no correlation between the effectiveness of sotalol therapy and maternal blood levels (13).

Sotalol was used in 12 pregnant women for the treatment of hypertension (details above) (9). No fetal adverse effects attributable to the drug were observed, but bradycardia (90–110 beats/minute), lasting up to 24 hours, was discovered in five of the six newborns with continuous heart rate monitoring (9). In a 1987 report, sotalol, in increasing doses up to 480 mg/day during a 12-day period, was combined with digoxin beginning at 31 weeks' gestation in an unsuccessful attempt to treat a hydropic fetus with SVT (14). Therapy was eventually changed to amiodarone plus digoxin with return of a normal fetal heart rate and resolution of the fetal edema. A normal infant was delivered at 38 weeks' gestation who was alive and well at 10 months of age (14).

A 23-year-old woman was treated throughout gestation with sotalol and flecainide for bursts of ventricular tachycardia (VT) and polymorphous ventricular premature complexes associated with an aneurysm of the left ventricle (11). A normal infant was delivered at approximately 37 weeks' gestation by cesarean section. No adverse effects of drug exposure, including bradycardia, were noted in the newborn, which was growing normally at 1 year of age (11).

A 1998 retrospective study reported the use of oral sotalol after the use of digoxin in 14 cases of fetal SVT (15). Treatment occurred at a median 28 weeks' gestation (range 24–36 weeks) with a median duration of 5 weeks (range 2–11 weeks). Two fetuses did not respond and two severely hydropic fetuses died 1 and 10 days, respectively, after starting sotalol. Of the surviving infants, 11 were doing well and 1 had cerebral atrophy, hypotonia, and developmental delay thought to be due to the arrhythmia and a thromboembolism (15).

A 2000 retrospective study evaluated the use of sotalol for fetal tachycardia in 21 pregnant women (16). The fetal arrhythmias were atrial flutter (AF) (N = 10), SVT (N = 10), and VT (N = 1). Hydrops fetalis was present in nine fetuses.

Sinus rhythm was established in eight fetuses with AF and six with SVT, but four deaths (19%) occurred (one with AF and three with SVT). Two newborns (one each with AF and SVT), both successfully converted to a sinus rhythm in utero, had significant neurological morbidity consisting of intracranial hemorrhage in one and cerebral hypoxic ischemia in the other. The authors concluded that sotalol was effective in AF, but the mortality and low conversion rate in fetuses with SVT indicated that the risks of sotalol outweighed the benefits in this group (16).

BREASTFEEDING SUMMARY

Sotalol is concentrated in human milk with milk levels three to five times those in the mother's plasma (9,11,12). Twenty paired samples of breast milk and maternal blood were obtained from 5 of the 12 women treated during and after pregnancy with sotalol for hypertension (dosage detailed above) (9). Specific details of dosage and the timing of sample collection in relationship to the last dose were not given. The mean concentrations in milk and plasma were 10.5 mcg/mL (range 4.8–20.2 mcg/mL) and 2.3 mcg/mL (range 0.8–5.0 mcg/mL), respectively. The mean milk:plasma ratio was 5.4 (range 2.2–8.8). No β -blockade effects were observed in the five nursing infants, including the one infant who had bradycardia at birth. The mother of this infant produced the highest concentrations of sotalol in milk (20.2 mcg/mL) observed in the study (9).

A woman treated throughout gestation with sotalol (80 mg twice daily) and flecainide was continued on these drugs during the postpartum period (11). The infant was not breastfed. Simultaneous milk and plasma samples were drawn 3 hours after the second dose of the day on the 5th and 7th postpartum days. The milk and plasma concentrations on day 5 were 5 and 1.4 mcg/mL, respectively, compared with 4.4 and 1.60 mcg/mL, respectively, on day 7. The two milk:plasma ratios were 3.57 and 2.75, respectively (11).

Sotalol, 80 mg three times daily, was taken by a woman throughout a 42 weeks' gestation and during the first 14 days of the postpartum period, at which time the dose was reduced to 80 mg twice daily (12). On the 5th postpartum day, milk and serum levels, approximately 6.5 hours after a dose (prefeeding), were 4.06 and 0.72 mcg/mL, respectively, a ratio of 5.6. A postfeeding milk sample collected 0.7 hour later yielded a concentration of 3.65 mcg/mL. The study was repeated on the 105th postpartum day, yielding prefeeding milk and serum concentrations 2.8 hours after the last dose of 2.36 and 0.97 mcg/mL (ratio 2.4), respectively. A postfeeding milk level 0.5 hour

later was 3.16 mcg/mL. The infant was consuming about 20%–23% of the maternal dose. No adverse effects were observed in the infant, who continued to develop normally throughout the study period (12).

Although symptoms of β -blockade, such as bradycardia and hypotension, were not observed in the nursing infants described above, these effects have been noted with other β -adrenergic blockers (see also Acebutolol, Atenolol, and Nadolol) and may occur with sotalol. Long-term effects of exposure to β -blockers from milk have not been studied but warrant evaluation. The American Academy of Pediatrics classifies sotalol as compatible with breastfeeding (17).

SPARFLOXACIN

[Withdrawn from the market. See 9th edition.]

SPECTINOMYCIN

[Withdrawn from the market. See 9th edition.]

SPINOSAD

Dermatological (Pediculicide)

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of spinosad in human pregnancy have been located. The animal reproduction is not relevant because oral doses were used and the drug is given topically in humans. Moreover, topical use of the drug suspension does not produce quantifiable amounts of spinosad in human plasma. Although the suspension contains an unspecified amount of benzyl alcohol, it is doubtful if sufficient amounts of the additive would be absorbed to cause embryo–fetal toxicity.

FETAL RISK SUMMARY

Spinosad is a pediculicide that is available as a suspension. It is indicated for the topical treatment of head lice infestations in patients 4 years or age or older. The drug has not been detected in the plasma (limit of quantitation 3 ng/mL) after topical use. The suspension contains a nonspecified amount of benzyl alcohol; plasma concentrations of this agent from use of the suspension have not been determined (1). (See also Benzyl Alcohol.)

Reproduction studies have been conducted in rats and rabbits. In these species, oral doses of 10–200 mg/kg/day given during organogenesis resulted in no teratogenic effects, but maternal toxicity was noted in rats at 200 mg/kg/day and, in rabbits, at 50 mg/kg/day. A two-generation dietary reproduction studied was performed in male and female rats with oral doses of 3–100 mg/kg/day from 10 to 12 weeks before mating and throughout mating, parturition, and lactation. No reproductive or developmental toxicity was observed up to 10 mg/kg/day. The 100 mg/kg/day dose was maternal toxic and adverse effects noted were increased dystocia in parturition, decreased gestation survival, litter size, pup body weight, and neonatal survival (1).

Comparisons with the human dose were not specified in any of these studies probably because plasma concentrations after topical use are below the level of quantification.

Two other published studies examining the effects in rats and rabbits from oral spinosad found results similar to those noted above (2,3).

Long-term carcinogenesis studies in mice and rats with oral spinosad were negative. Various assays for mutagenic or clastogenic potential also were negative. No effects of fertility were noted in rats (1).

It is not known if spinosad crosses the human placenta. Clinically significant exposure of the embryo–fetus is not expected because plasma concentrations of the drug after topical use are below the level of quantification.

BREASTFEEDING SUMMARY

No reports describing the use of spinosad during human lactation have been located. However, excretion of clinically significant amounts of the drug into breast milk is unlikely because plasma concentrations of the drug after topical use are below the level of quantification. Although an unspecified amount of benzyl alcohol also is present in the circulation, it is doubtful if sufficient amounts of the additive would be absorbed to cause toxicity in a nursing infant. Thus, use of the drug during breastfeeding appears to be compatible.

SPIRONOLACTONE

Diuretic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports linking spironolactone with human congenital defects have been located. Some have commented, however, that spironolactone may be contraindicated during pregnancy based on the known anti-androgenic effects in humans and the feminization observed in male rat fetuses (1). Other investigators consider diuretics in general to be contraindicated in pregnancy, except for patients with cardiovascular disorders, because they do not prevent or alter the course of toxemia and they may decrease placental perfusion (2–4). In general, diuretics are not recommended for the treatment of gestational hypertension because of the maternal hypovolemia characteristic of this disease.

FETAL RISK SUMMARY

Spironolactone is a potassium-conserving diuretic, an action that results from its antagonism of aldosterone in the distal convoluted renal tubule. The diuretic action results in an antihypertensive effect. Spironolactone also has progestational and anti-androgenic activity. The latter activity may result in apparent estrogenic adverse effects in humans (5).

Reproduction studies in mice at 20 mg/kg/day, a dose substantially below the maximum recommended human dose based on BSA (MRHD), revealed no embryo or fetal adverse effects. In rabbits dosed at 20 mg/kg/day (approximately the MRHD), an increased number of resorptions and lower number of live fetuses was observed. Because of spironolactone's anti-androgenic activity, feminization of male rat fetuses occurred at a dose of 200 mg/kg/day administered to the mothers during late embryogenesis and fetal development. In addition, rat offspring of both sexes exposed in utero in late

gestation to 50 or 100 mg/kg/day exhibited permanent dose-related changes in their reproductive tracts. It was also noted that spironolactone was tumorigenic in rats (5).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 31 newborns had been exposed to spironolactone during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Two (6.5%) major birth defects were observed (one expected), one of which was an oral cleft (none expected). No anomalies were observed in five other categories of defects (cardiovascular defects, spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available.

BREASTFEEDING SUMMARY

It is not known whether unmetabolized spironolactone is excreted in breast milk. Canrenone, the principal and active metabolite, was excreted with milk:plasma ratios of 0.72 at 2 hours and 0.51 at 14.5 hours (6). These amounts would provide an estimated maximum of 0.2% of the mother's daily dose to the infant (6). The effect on the infant from this ingestion is unknown, but the amounts appear to be clinically insignificant. The American Academy of Pediatrics classifies spironolactone as compatible with breastfeeding (7).

STAVUDINE

Antiviral

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo/Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

The animal and human data suggest that stavudine represents a low risk to the embryo–fetus. Theoretically, exposure to stavudine at the time of implantation could result in impaired fertility because of embryonic cytotoxicity, but this has not been studied in humans. Stavudine peak serum concentrations achievable in humans with therapeutic doses, however, are in the same range that has been found to inhibit postblastocyst development in mice. Mitochondrial dysfunction in offspring exposed in utero or postnatally to nucleoside reverse transcriptase inhibitors (NRTIs) has been reported (see Lamivudine and Zidovudine), but these findings are controversial and require confirmation. If indicated, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Stavudine (2',3'-didehydro-3'-deoxythymidine; d4T) inhibits viral reverse transcriptase and DNA synthesis. It is classified as an NRTI used for the treatment of HIV infection. Its mechanism of action is similar to that of five other nucleoside analogs: abacavir, didanosine, lamivudine, zalcitabine, and zidovudine. Stavudine is converted by intracellular enzymes to the active metabolite, stavudine triphosphate (1).

No evidence of teratogenicity was observed in pregnant rats and rabbits exposed to maximum plasma concentrations up to 399 and 183 times, respectively, of those produced by a human dose of 1 mg/kg/day. A dose-related increase in common skeletal variations, postimplantation loss, and early neonatal mortality was observed in one or both species (1).

Antiretroviral nucleosides have been shown to have a direct dose-related cytotoxic effect on preimplantation mouse embryos. A 1994 report compared

this toxicity among zidovudine and three newer compounds, stavudine, didanosine, and zalcitabine (2). Whereas significant inhibition of blastocyst formation occurred with a 1 $\mu\text{mol/L}$ concentration of zidovudine, stavudine and zalcitabine toxicity was not detected until 100 $\mu\text{mol/L}$, and no toxicity was observed with didanosine up to 100 $\mu\text{mol/L}$. Moreover, postblastocyst development was severely inhibited in those embryos that did survive exposure to 1 $\mu\text{mol/L}$ zidovudine. As for the other compounds, stavudine, at a concentration of 10 $\mu\text{mol/L}$ (2.24 mcg/mL), inhibited postblastocyst development, but no effect was observed with concentrations up to 100 $\mu\text{mol/L}$ of didanosine or zalcitabine. Although there are no human data, the authors of this study concluded that the three newer agents may be safer than zidovudine to use in early pregnancy.

Similar to other nucleoside analogues, stavudine appears to cross the human placenta by simple diffusion (3). The relatively low molecular weight (about 224) is in agreement with this. Stavudine also crosses the placenta in rats, resulting in a fetal:maternal ratio of approximately 0.5 (1). In near-term macaques, the steady-state fetal:maternal plasma ratio was approximately 0.8 (4). A related study found that zidovudine did not affect the placental transfer of stavudine in macaques (5). However, no reports in animals or humans have been located relating to the placental transfer of stavudine triphosphate (the active metabolite) or to the capability of the placenta or the fetus to metabolize stavudine.

Three experimental in vitro models using perfused human placentas to predict the placental transfer of NRTIs (didanosine, stavudine, zalcitabine, and zidovudine) were described in a 1999 publication (6). For each drug, the predicted fetal:maternal plasma drug concentration ratios at steady state with each of the three models were close to those actually observed in pregnant macaques. Based on these results, the authors concluded that their models would accurately predict the mechanism, relative rate, and the extent of in vivo human placental transfer of NRTIs (6).

The Antiretroviral Pregnancy Registry reported, for the period January 1989 through July 2009, prospective data (reported before the outcomes were known) involving 4702 live births that had been exposed during the 1st trimester to one or more antiretroviral agents (7). Congenital defects were noted in 134, a prevalence of 2.8% (95% confidence interval [CI] 2.4–3.4). In the 6100 live births with earliest exposure in the 2nd/3rd trimesters, there were 153 infants with defects (2.5%, 95% CI 2.1–2.9). The prevalence rates for the two periods did not differ significantly. There were 288 infants with birth defects among

10,803 live births with exposure anytime during pregnancy (2.7%, 95% CI 2.4–3.0). The prevalence rate did not differ significantly from the rate expected in a nonexposed population. There were 962 outcomes exposed to stavudine (771 in the 1st trimester and 191 in the 2nd/3rd trimesters) in combination with other antiretroviral agents. There were 25 birth defects (19 in the 1st trimester and 6 in the 2nd/3rd trimesters). In reviewing the birth defects of prospective and retrospective (pregnancies reported after the outcomes were known) registered cases, the Registry concluded that, except for isolated cases of neural tube defects (NTDs) with efavirenz exposure in retrospective reports, there was no other pattern of anomalies (isolated or syndromic) (7). (See Lamivudine for required statement.)

A 2000 case report described the adverse pregnancy outcomes, including NTDs, of two pregnant women with HIV infection who were treated with the anti-infective combination, trimethoprim/sulfamethoxazole, for prophylaxis against *Pneumocystis carinii*, concurrently with antiretroviral agents (8). Exposure to stavudine occurred in one of these cases. A 31-year-old woman presented at 15 weeks' gestation. She was receiving trimethoprim/sulfamethoxazole, didanosine, stavudine, nevirapine, and vitamin B supplements (specific vitamins and dosage not given) that had been started before conception. A fetal ultrasound at 19 weeks' gestation revealed spina bifida and ventriculomegaly. The patient elected to terminate her pregnancy. The fetus did not have HIV infection. Defects observed at autopsy included ventriculomegaly, an Arnold-Chiari malformation, sacral spina bifida, and a lumbo-sacral meningocele. The authors attributed the NTDs in both cases to the antifolate activity of trimethoprim (8).

A 1999 case report described a 26-year-old woman with a 5-year history of HIV infection (9). Two years before her current pregnancy, she had received monotherapy with zidovudine for 19 months, followed by 6 months of monotherapy with zalcitabine. She stopped therapy during the first 19 gestational weeks, then started stavudine and lamivudine that were continued until vaginal delivery at term of a healthy 3560-g female infant. The infant was not infected with HIV and was doing well at 9 months of age.

No data are available on the advisability of treating pregnant women who have been exposed to HIV via occupational exposure, but one author discourages this use (10).

Two reviews, one in 1996 and the other in 1997, concluded that all women currently receiving antiretroviral therapy should continue to receive therapy during pregnancy and that treatment of the mother with monotherapy should be

considered inadequate therapy (11,12). The same conclusion was reached in a 2003 review with the added admonishment that therapy must be continuous to prevent emergence of resistant viral strains (13). In 2009, the updated U.S. Department of Health and Human Services guidelines for the use of antiretroviral agents in HIV type 1 (HIV-1)-infected patients continued the recommendation that therapy, with the exception of efavirenz, should be continued during pregnancy (14). If indicated, stavudine should not be withheld in pregnancy because the expected benefit to the HIV-positive mother outweighs the unknown risk to the fetus. Updated guidelines for the use of antiretroviral drugs to reduce perinatal HIV-1 transmission also were released in 2010 (15). Women receiving antiretroviral therapy during pregnancy should continue the therapy but, regardless of the regimen, zidovudine administration is recommended during the intrapartum period to prevent vertical transmission of HIV to the newborn (15).

BREASTFEEDING SUMMARY

No reports describing the use of stavudine during lactation have been located. The molecular weight (about 224) suggests that stavudine will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown.

Reports on the use of stavudine during human lactation are unlikely because the antiviral agent is used in the treatment of HIV infection. HIV-1 is transmitted in milk, and in developed countries, breastfeeding is not recommended (11,12,14,16–18). In developing countries, breastfeeding is undertaken, despite the risk, because there are no affordable milk substitutes available. Until 1999, no studies had been published that examined the effect of any antiretroviral therapy on HIV-1 transmission in milk. In that year, a study involving zidovudine was published that measured a 38% reduction in vertical transmission of HIV-1 infection despite breastfeeding when compared with controls (see Zidovudine).

STEVIA

Dietary Supplement

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Although no reports describing the use of stevia during human pregnancy have been located, this dietary supplement is consumed extensively throughout the world. Exposure in pregnancy is inevitable, but the lack of reports prevents a thorough assessment of the embryo–fetal risk. In Brazil, South Korea, and Japan, stevioside and highly refined extracts are routinely used as a low-calorie sweetener (1). Such use in the United States started in 1995 (1). Animal reproduction studies have not shown evidence of developmental toxicity except at very high doses. The benefits of stevioside as a dietary supplement have been listed as its being a stable, noncaloric product that maintains good dental health by reducing the intake of sugar, and can be used by diabetic and phenylketonuria patients (1). Moreover, stevioside, the major sweetening compound in stevia, either is not absorbed into the systemic circulation or the absorption is very low. Information on the other compounds such as the rebaudiosides is lacking. Nevertheless, the moderate use of stevia or stevioside as sweeteners appears to represent a low risk to the embryo–fetus, if it exists at all.

FETAL RISK SUMMARY

The perennial shrub *Stevia rebaudiana* Bertoni (stevia) is indigenous to South America but is grown commercially in areas such as Central America, Israel, Thailand, and China. The leaves have been used as a low-calorie sweetener for hundreds of years. The largest use of stevia appears to be in Japan where it is used to replace aspartame and saccharin (2). Oral stevia is also used as a weight-loss aid; for contraception and lowering uric acid levels; for the treatment of diabetes, hypertension, and heartburn; and as a cardiogenic and

diuretic (3).

The sweetness of stevia is mainly due to stevioside, a sweet ent-kaurene glycoside that is 300 times sweeter than sucrose (0.4% solution). There also are several variants of rebaudioside, another ent-kaurene glycoside that is present in lower concentrations. Stevia leaves contain 6%–18% of stevioside. In addition to the glycosides, the leaves contain minor amounts of nonsweet sterols (stigmasterol, beta-sitosterol, and campesterol), vitamins (A, B, and C), electrolytes, minerals, and protein (1,2).

Reproduction and growth studies have been conducted with stevioside in male and female hamsters with daily oral doses up to 2.5 g/kg (4). No abnormalities in growth, fertility, or reproduction performance were observed through three generations. Moreover, histological examination of reproductive tissues revealed no evidence of stevia-induced abnormalities. The investigators briefly cited other studies that observed no toxic effects in mice and rats (4).

In a 2006 study, female rats before mating were given an aqueous extract of various mixtures of *Aegle marmelos* (6%), a Thai medicinal plant popularly consumed as a herbal tea, and stevia (0%–10%) (5). The rats then were mated with untreated males, and the effects on reproduction were examined at day 14 of pregnancy. Compared with untreated controls, there were no significant differences in terms of number of corpus lutea, implanted and dead fetuses, or fetal growth (5).

A 2003 review cited several other animal reproduction studies using stevia extracts that observed no developmental toxicity in chicken embryos, mice, rats, and hamsters (1). There also was no adverse effect on spermatogenesis or interstitial cell proliferation in male rats, except at very high doses.

A 1985 study found that stevioside was not mutagenic in *Salmonella typhimurium*, but that steviol, an aglycone metabolite of stevioside, was mutagenic when it was further metabolized (6). The clinical significance of this toxicity was unknown because the complete metabolic disposition of stevioside in humans had not been fully characterized. A review cited four studies that confirmed the mutagenicity but noted that the mutagenicity activity was low (1). In addition, the presence in blood of the steviol metabolites after feeding of stevioside has not been proven. Moreover, there is no evidence in animals or humans that stevioside is carcinogenic (1).

The pharmacology of stevia in animals and humans has been reviewed (1). The author concluded that the dietary supplement is safe when used as a sweetener. In humans, oral stevioside either is not absorbed or the uptake is extremely low. Even so, the European Commission refused to accept stevia or

stevioside as a novel food because of inadequate or controversial studies on its safety (1). For the same reason, the FDA classifies stevia as an “unsafe food additive” (3).

BREASTFEEDING SUMMARY

Although the dietary supplement stevia is used extensively as a natural, low-calorie sweetener, no reports describing its use during lactation have been located. Stevioside, the major sweetening compound in stevia, is either not absorbed into the systemic circulation or the absorption is very low. However, information on the other compounds, such as the rebaudiosides, is lacking. Nevertheless, the risk to the nursing infant from maternal intake of stevia, if it exists, appears to be low.

ST. JOHN'S WORT

Herb

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Two reports describing the use of St. John's wort (*Hypericum perforatum*) during human pregnancy have been located. Some of the animal studies apparently did not look for structural defects, but did not observe neurobehavioral deficits. Moreover, no mutagenicity was found with various tests involving mammalian cells. *Hypericum* has demonstrated human sperm toxicity in vitro, but no reports describing this adverse effect after ingestion of the drug have been located. Similarly, the uterotonic action observed in an in vitro animal experiment has not been reported in animals or humans following consumption. This lack of reported toxicity is reassuring. Moreover, because the use of St. John's wort is widespread and dates back thousands of years, it is doubtful that a major teratogenic action or other developmental toxicity would have escaped notice. More subtle or low-incidence effects, however, including structural and neurobehavioral toxicity, the induction of abortions, and infertility may have escaped detection, and further study is warranted.

FETAL RISK SUMMARY

Hypericum perforatum (St. John's wort) is an aromatic, aggressive perennial weed that is native to Europe but also grows throughout the United States and parts of Canada (1). The plant is harvested for medicinal purposes during July and August (1). A large number of chemical constituents have been isolated from the plant, including hypericin, pseudohypericin, flavonoids, glycosides, phenols, tannins, volatile oils, and other compounds (1–8). Hypericin and pseudohypericin are considered to be the primary orally active ingredients (1,5–8).

Preparations made from *H. perforatum* have been used for medicinal purposes for thousands of years. These uses have included the management of anxiety, depression, insomnia, inflammation, and gastritis. They have also been used as a diuretic and, topically, for the treatment of hemorrhoids and to enhance wound healing (1–5). More recently, hypericin has been investigated for activity against the HIV and other viruses (1,5,8). In addition, extracts and tinctures of hypericum have shown activity against gram-negative and gram-positive bacteria (1).

No data are available on the animal or human placental transfer of hypericin, pseudohypericin, or other constituents of St. John's wort.

The mechanism of antidepressant action is thought to be related to selected serotonin-reuptake inhibition, monoamine oxidase inhibitors, a combination of both, or other mechanisms (1–4,6–9). Adverse effects induced by hypericum preparations, relatively infrequent in nonpregnant humans but not studied in pregnant women, include gastrointestinal upset and constipation, allergic reactions, fatigue, dry mouth, dizziness, and confusion (1–10). Rare photosensitivity in fair-skinned individuals has also been observed.

Surprisingly, for a product that has been in use since ancient Greek and Roman times, only two reports have been located that described its consumption during human pregnancy (see below). Moreover, there are few animal reproductive studies available for evaluation of its embryo and fetal safety. Aqueous extractions of *H. perforatum* demonstrated weak uterine tonus-enhancing activity in experiments using isolated rabbit and guinea pig uterine horns (11). Uterotonic activity or abortions, however, have apparently not been reported after consumption of the herb by animals or humans.

In a randomized, placebo-controlled reproductive study, adult female mice were fed either hypericum (180 mg/kg/day) or placebo for 2 weeks before mating and then throughout gestation (12). The dose, which has antidepressant efficacy in adult mice, was equivalent to the human dose on a kg/ m² basis (12,13). The birth weights of all exposed pups were smaller than controls, but only the reduced birth weights of male pups reached statistical significance in comparison to controls (1.68 vs. 1.75 g, $p < 0.01$) (13). Moreover, successful performance on the negative geotaxis task, a measure of behavior during early development, was significantly lower in the exposed male pups (but not the female pups) on postnatal day 3 (13). Both the body weight and the negative geotaxis task performance were comparable to controls by postnatal day 5 (13). No differences, regardless of gender, were observed between the exposed and nonexposed pups in body length, head circumference, sexual

maturation, or the attainment of developmental milestones up to adulthood (12). Similarly, no differences were observed between the groups in pup–dam interactions, performance of locomotor, depression, and anxiety tasks during juvenile and adult periods, or in male sexual behavior and aggression. An evaluation of second-generation offspring found no differences between the groups in any measurement (12,13).

An aqueous ethanolic extract of hypericum was tested for mutagenic activity in a study published in 1990 (14). Using both in vitro and in vivo test systems (mice, hamsters, etc.), no evidence of mutagenic effects was observed.

In a sperm penetration assay, zona-free hamster oocytes were incubated for 1 hour with two concentrations of *H. perforatum*, 0.06 and 0.6 mg/mL, dissolved in HEPES-buffered synthetic human tubal fluid (modified HTF) (15). Fresh human donor sperm was suspended in the modified HTF and then mixed with the oocytes for 3 hours. Modified HTF served as the control. At the 0.06 mg/mL concentration, all the oocytes were penetrated, whereas at 0.6 mg/mL, zero penetration occurred. The decrease in penetration was not associated with a decrease in sperm motility (15). In the second part of the study, sperms were incubated with the herbal solutions for 7 days (15). Both concentrations caused significant sperm DNA denaturation concomitant with decreases in sperm viability compared with controls. The higher concentration showed point mutation of a selected sperm sentinel gene, the BRCA1 exon 11 gene (15). Extrapolation of these data to the reproductive risk of hypericum in males is difficult, in part because the concentration of hypericum in semen or sperm has not been studied (15). Moreover, although the doses used in this study are small fractions of the actual recommended human dose, usually expressed in grams of hypericin, there is no published evidence that the adverse effects observed have occurred in vivo.

Hypericum or placebo was given to mice 2 weeks before mating and throughout gestation (16). No differences between the groups were noted in gestational ages at birth and litter sizes. Offspring were followed from postnatal day 3 to adulthood. No differences between the groups were found in the increases of body weight and length, and head circumference, or in the times to reach physical milestones. There also was no effect on reproductive capability, perinatal outcomes, and growth and development of the second-generation offspring (16).

A brief 1998 case report described the use of St. John's wort by two pregnant women, but only one of the cases has outcome data (17). In the first case, a 38-year-old woman began taking St. John's wort, 900 mg/day, at 24

weeks' gestation for a major depressive disorder that had recurred during the 1st trimester. She continued the herbal medicine throughout the remainder of her pregnancy, taking her last dose 24 hours before delivery (gestational age not specified). Other than late-onset thrombocytopenia (platelet count 88,000), the pregnancy was unremarkable. The woman delivered a healthy, about 3400-g female infant with Apgar scores of 9 and 9 at 1 and 5 minutes. The physical examination and laboratory results were normal. Neonatal jaundice developed on day 5 but responded to brief phototherapy. Behavioral assessment at 4 and 33 days of age was normal. The second case involved a 43-year-old woman who had been taking fluoxetine and methylphenidate for a recurrent major depressive disorder (16). After an unexpected conception, she discontinued these medications because of concerns about potential adverse fetal effects and began self-medicating with St. John's wort, 900 mg/day. Apparently, this pregnancy was ongoing, because no outcome data were presented (17).

A 2009 study assessed the effects of the herb in pregnancy using a prospective, observational, controlled cohort design (18). Samples and controls were women who had contacted the Motherisk Program, a teratogen information service in Canada. The study group was 54 St. John's wort-exposed pregnancies, 39 (72%) of whom were taking the herb for depression. The two matched control groups included 56 women taking other agents for depression (disease comparator) and 56 healthy women not exposed to any known teratogens (healthy group). There was no statistical difference in the rates of major malformations in the three groups, 5%, 4%, and 0%, respectively. None of the other pregnancy outcomes differed statistically among the three groups. Although both the subject and disease comparator groups had higher rates of spontaneous abortions (SABs) than healthy controls (20.3% vs 12.5% vs 8.9% [ns], respectively) the authors cited references that women with depression had increased rates of SABs. Because the authors did not examine the offspring, the study could not determine if minor malformations were present (18).

Because standardization of any herbal product as to its constituents, concentrations, and the presence of contaminants is generally lacking, consumption of these preparations during pregnancy may result in fetal exposure to unintended chemicals and doses. Furthermore, pregnant women should be counseled on the risks to themselves and their pregnancies that may result from self-medication or discontinuing prescribed therapy without first consulting their healthcare provider.

BREASTFEEDING SUMMARY

One report describing the use of St. John's wort during human lactation has been located. A 38-year-old mother had taken 900 mg/day of St. John's wort from 24 weeks' gestation until delivery (16). (See case above.) She began breastfeeding her female infant after delivery and then resumed taking the herbal product 20 days after delivery. Neonatal jaundice was noted at 5 days of age but responded to brief phototherapy. Behavioral assessments of the nursing infant at 4 and 33 days of age were normal.

It is not known if any of the constituents and possible contaminants that may be found in preparations of St. John's wort are excreted into human milk or if exposure to them via the milk represents a risk to a nursing infant.

STREPTOKINASE

[Withdrawn from the market. See 9th edition.]

STREPTOMYCIN

Antibiotic (Aminoglycoside)

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Streptomycin may cause fetal ototoxicity, resulting in deafness in newborns. The risk of this toxicity is low if there is appropriate dose monitoring and the duration of fetal exposure is limited.

FETAL RISK SUMMARY

Streptomycin is an aminoglycoside antibiotic. The drug rapidly crosses the placenta into the fetal circulation and amniotic fluid, obtaining concentrations that are usually less than 50% of the maternal serum level (1,2). Early investigators, well aware of streptomycin-induced ototoxicity, were unable to observe this defect in infants exposed in utero to the agent (3–5). Eventually, ototoxicity was described in a 2-1/2-month-old infant whose mother had been treated for tuberculosis with 30 g of streptomycin during the last month of pregnancy (6). The infant was deaf with a negative cochleopalpebral reflex. Several other case reports and small surveys describing similar toxicity followed this initial report (7,8). In general, however, the incidence of congenital ototoxicity, cochlear or vestibular, from streptomycin is low, especially with careful dosage calculations and if the duration of fetal exposure is limited (9).

Except for eighth cranial nerve damage, no reports of congenital defects caused by streptomycin have been located. The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 135 of whom had 1st trimester exposure to streptomycin (10, pp. 297–301). For use anytime during pregnancy, 355 exposures were recorded (10, p. 435). In neither group was evidence found to suggest a relationship to large categories of major or minor malformations or to individual defects.

In a group of 1619 newborns whose mothers were treated for tuberculosis during pregnancy with multiple drugs, including streptomycin, the incidence of congenital defects was the same as in a healthy control group (2.34% vs.

2.56%) (11). Other investigators had previously concluded that the use of streptomycin in pregnant tuberculosis patients was not teratogenic (12).

The population-based data set of the Hungarian Case-Control Surveillance of Congenital Abnormalities, covering the period of 1980–1996, was used to evaluate the teratogenicity of aminoglycoside antibiotics (parenteral gentamicin, streptomycin, tobramycin, and oral neomycin) in a study published in 2000 (13). A case group of 22,865 women who had fetuses or newborns with congenital malformations were compared with 38,151 women who had no newborns with structural defects. A total of 38 cases and 42 controls were treated with the aminoglycosides. There was one case, but no controls, treated with streptomycin (odds ratio 5.0, 95% confidence interval 0.2–122.9). The investigators concluded that there was no detectable teratogenic risk for structural defects for any of the aminoglycoside antibiotics (13). They also concluded, although it was not investigated in this study, that the risk of deafness after in utero aminoglycoside exposure was small.

BREASTFEEDING SUMMARY

Streptomycin is excreted into breast milk. Milk:plasma ratios of 0.5–1.0 have been reported (14). Because the oral absorption of this antibiotic is poor, ototoxicity in the infant would not be expected. However, three potential problems exist for the nursing infant: modification of bowel flora, direct effects on the infant, and interference with the interpretation of culture results if a fever workup is required. The American Academy of Pediatrics classifies streptomycin as compatible with breastfeeding (15).

STREPTOZOCIN

Antineoplastic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Streptozocin is teratogenic or embryotoxic in several animal species and possesses mutagenic and carcinogenic effects. The potential for human embryo–fetal injury is a concern, but because the animal reproduction data lacks dosage and time of exposure information and other data, the degree of risk is unknown. One report has described the use of this drug during the latter half of gestation without apparent fetal harm. Until additional data are forthcoming, streptozocin should be considered a potential human teratogen if exposure occurs during organogenesis.

FETAL RISK SUMMARY

Streptozocin (streptozotocin) is an alkylating antineoplastic that is obtained from *Streptomyces achromogenes*. This nitrosourea agent belongs to the same group as carmustine (BCNU) and lomustine (CCNU). Streptozocin is indicated for the treatment of metastatic islet cell carcinoma of the pancreas and also is used in other cancers. It is rapidly cleared from the plasma and is distributed to tissues, primarily the kidneys, liver, intestines, and pancreas (1,2). Streptozocin undergoes extensive metabolism and, although it does not cross the blood–brain barrier, its metabolites are found in the cerebrospinal fluid (CSF) (1).

Streptozocin is mutagenic in bacteria, plants, and mammalian cells and is carcinogenic (renal, hepatic, stomach, and pancreatic tumors) in various animal species such as mice, rats, and hamsters (2). The drug also is diabetogenic in laboratory animals (3).

Reproduction studies with streptozocin have been conducted in pregnant rats and rabbits. Although the doses and administration times were not specified, streptozocin was teratogenic (types of defects not specified) in rats and had abortifacient effects in rabbits (2). No mention was made of maternal toxicity in

these studies.

Studies investigating the passage of streptozocin across the human placenta have not been located. The molecular weight (about 265) is low enough that exposure of the embryo or fetus should be expected. Moreover, in pregnant monkeys administered IV streptozocin, the agent appeared rapidly in the fetal circulation (2). However, the rapid clearance from the blood and the absence of the parent drug in the CSF suggest that the amount crossing the placenta, at least of unmetabolized drug, will be limited.

A 1984 report described a 21-year-old woman with diffuse histiocytic lymphoma treated before pregnancy with multiple courses of chemotherapy including cyclophosphamide, doxorubicin, vincristine, bleomycin, methotrexate, cytarabine, and etoposide, in addition to radiation therapy to the neck (4). Because of the failure of that therapy, she was changed to carmustine and procarbazine for 5 months before conception. The patient refused to terminate her pregnancy, and treatment with carmustine and procarbazine was continued during the first 24 weeks of pregnancy. Because of disease progression, her therapy was changed at 24 weeks' gestation to three courses of streptozocin, 800 mg IV/day for 3 days every 4 weeks. The last course was administered 2 weeks before delivery at 35 weeks' gestation. The normal-appearing male infant weighed 2.34 kg with a head circumference of 32.5 cm and a length of 51.5 cm. The Apgar scores were 7 and 9 at 1 and 5 minutes, respectively. Initial tests revealed normal hemoglobin, and white blood cell and platelet counts. All other clinical tests were within normal limits, including electrolytes, multiple chemistry, urinalysis, renal ultrasound, and chromosome studies (2).

BREASTFEEDING SUMMARY

No reports describing the use of streptozocin during human lactation have been located. The molecular weight (about 265) suggests that the drug will be excreted in breast milk. The effects of this exposure on a nursing infant are unknown. Because of the potential for serious toxicity, women receiving streptozocin should not nurse.

SUCCIMER

Antidote/Chelating Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Two reports have described the use of succimer during human pregnancy. The chelating agent has produced fetotoxicity and teratogenicity in mice and fetotoxicity in rats. These toxic effects often occurred at oral doses ≤ 10 times the human dose (weight basis). In addition, succimer-induced modulation of adult female rat immune function has been demonstrated. The exact mechanism of the animal developmental toxicity is unknown but appears to result from disturbances in mineral metabolism, especially that of zinc and copper. Therefore, if succimer is used in human pregnancy, the effects on maternal and fetal mineral metabolism—in particular, of zinc and copper—should be evaluated (1).

FETAL RISK SUMMARY

The heavy metal chelating agent succimer (meso-2,3-dimercaptosuccinic acid [DMSA]) is indicated for the treatment and prophylaxis of lead poisoning in pediatric patients (2). The drug has also been used as an antidote for the treatment of arsenic, mercury, and cadmium poisoning (3). Succimer has no significant effect on the urinary elimination of iron, calcium, or magnesium but doubles the excretion of zinc (2). After oral administration, approximately 60% is absorbed systemically from an initial dose of 30 mg/kg/day (1050 mg/m²/day) with an apparent elimination half-life of approximately 2 days.

In addition to the animal reproductive data provided by the manufacturer (2), a number of published animal studies have described the effect of succimer on the fetus (3–12). In pregnant rats, doses of 100–1000 mg/kg/day administered orally on gestational days 6–15 were not teratogenic but did produce maternal toxicity (decreased weight gain) (3). At pregnancy termination on day 20, fetal toxicity, characterized by increased early resorptions, postimplantation losses,

and reduced fetal body weight per litter, was evident at all doses. The no-observable-effect level (NOEL) was <100 mg/kg/day (3).

In another portion of the above study, the concentrations of five minerals (calcium, magnesium, zinc, copper, and iron) were measured in maternal and fetal tissues (4). Marked alterations were observed on the mineral concentrations in the fetuses. These effects suggested that the fetal toxicity noted was partially due to changes in mineral metabolism (4).

Succimer was teratogenic and fetotoxic when SC doses were given to pregnant mice during organogenesis (days 6–15 of gestation) at doses of 410–1640 mg/kg/day (2,5). At the maximum dose, maternal toxicity (reduced weight gain) was evident (5). Significant embryo and fetal toxicity, as evidenced by an increased incidence of resorptions and stunting, and a decrease in the number of live fetuses per litter, were observed at 1640 mg/kg/day. At 820 mg/kg/day, significant decreases in fetal weight and length were noted. A dose relationship was found for structural defects, including significant increases (compared with controls) in gross external defects (hematomas in the facial area, exencephaly, and micrognathia), internal soft tissue defects (hydrocephaly, small thoracic cavities, and brain defects), and skeletal variations (decreased ossification, hypoplasia of the mandible, and irregular-shaped ribs). The no-effect dose for defects was 410 mg/kg/day (5).

In continuation of the above study, pregnant mice were given oral succimer (200–800 mg/kg/day) from gestational day 14 through postnatal day 21 (weaning) (6). No maternal toxicity was observed at any dose. Adverse effects were observed only in the offspring exposed during lactation to the highest maternal dose. The effects observed in the nursing pups included significant decreases in body weight and a corresponding increase in relative brain weight (brain weight/body weight). The NOEL for adverse effects in the nursing pups was >400 mg/kg/day (6).

The type of developmental toxicity observed in mice suggested to some investigators that the toxicity may have been related to an interaction between succimer and zinc (5). However, in a subsequent report, no consistent changes could be demonstrated in mice fetal tissue levels of zinc, iron, calcium, or magnesium (7). Moreover, supplemental zinc did not protect the fetuses. Disturbance of maternal–fetal copper metabolism may have been related to the developmental toxicity because dose-dependent decreases in fetal liver copper levels were observed (7).

A 1991 report examined the efficacy of succimer to protect mice fetuses from the toxicity and teratogenicity of an intraperitoneal (IP) dose (12 mg/kg) of

sodium arsenite administered to pregnant mice on day 10 of gestation (8). In the dose-finding portion of the study, succimer SC doses of 80, 160, and 320 mg/kg were given immediately after sodium arsenite injection. An increasing protective effect was noted with an increasing succimer dose. The effect of the time interval between IP injection of sodium arsenite and injection of succimer was then studied. A single SC dose of succimer (320 mg/kg) was given to pregnant mice at various times up to 12 hours after a dose of sodium arsenite. Significant reductions in arsenite-induced embryo toxicity and teratogenicity were achieved only when succimer was administered within 1 hour of the arsenite dose (8).

Using a similar study design, the above investigators examined the effect of succimer in protecting fetal mice from the toxicity and teratogenicity of dibasic sodium arsenate (9). Sodium arsenate is the most common form of inorganic arsenic in the environment and is less fetotoxic than sodium arsenite (8,9). As in the above study, the investigators demonstrated a dose-related protective effect of succimer at SC doses of 37.5, 75, and 150 mg/kg administered at four successive time intervals (2, 24, 48, and 72 hours) after IP injection of dibasic sodium arsenate (45 mg/kg) (9).

A 1978 study in pregnant rats demonstrated that daily administration of succimer was effective in reducing methylmercury concentrations in neonatal rat brains (10). A 40-mg oral dose was more effective (70% reduction in methylmercury) than a 20-mg dose (50% reduction). In a later study with pregnant mice, a dose-related protective effect from methylmercury-induced embryo lethality and teratogenicity was demonstrated with the maximum protection achieved with an SC dose of 320 mg/kg/day (11).

The effect on the immune function of female rats exposed to succimer in utero was described in a 1999 report (12). Pregnant rats were administered lead acetate (250 ppm) in drinking water from 2 weeks before mating until parturition. Succimer (60 mg/kg/day), given orally from days 6–21 of gestation, significantly lowered the blood lead levels in both the dams and embryos. Several lead-induced changes in 13-week-old female offspring were reversed by the chelating agent (succimer-induced changes in parentheses), including body weight (increased), relative spleen weight (decreased), interferon γ (increased), and interleukin-4 (decreased). However, succimer alone affected immune function in the female offspring by decreasing the delayed-type hypersensitivity response and increasing interleukin-2 production. Therefore, succimer treatment during gestation did reverse some of the lead-induced immunotoxicity but also caused subsequent adult immunomodulation (12).

It is not known if succimer crosses the human placenta. The molecular weight (about 182) is low enough that fetal exposure should be expected. The studies cited above suggest that succimer crosses the placenta in mice and rats.

A 2001 case report described an 18-day course of oral succimer for lead poisoning at about 29–32 weeks' gestation (13). There was no effect on the woman's blood lead concentrations (44.0 mcg/dL before chelation and 43.9 mcg/dL after treatment). She gave birth at 37 weeks' to a 3.04-kg, female infant with Apgar scores of 8 and 9. At birth, the mother's blood lead level was 57.6 mcg/dL, whereas the cord blood lead concentration was 126 mcg/dL. The source of the lead in the mother was not found, even though an extensive search for the source was conducted. The infant was treated with chelation therapy and, although the concentrations remained elevated, her appearance and behavior were normal at 6.5 months of age (13).

One pregnant woman, in a series of seven, was treated with succimer for lead poisoning in a 2003 report (14). The source of the lead in most cases was the ingestion of pica (soil/clay-based substances). No lead-induced congenital defects were noted in the infants, but all received chelation therapy in the neonatal period (14).

BREASTFEEDING SUMMARY

No studies describing the use of succimer during lactation have been located. The molecular weight (about 182) suggests that the drug will be excreted into milk. The effects of this exposure on a nursing infant are unknown. However, because the use of succimer implies poisoning with lead, or other heavy metals, these substances might also be excreted into milk and cause toxicity in a nursing infant. Therefore, breastfeeding is contraindicated in women receiving succimer.

SUCCINYLCHOLINE

Skeletal Muscle Relaxant

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Succinylcholine is not embryotoxic or teratogenic in two animal species or, although the data are very limited, in humans. Succinylcholine has been routinely used in obstetric patients prior to delivery since the 1950s and no reports of fetal toxicity have been located. Partial or complete newborn paralysis, with resulting respiratory depression, has been reported when the drug was administered to women with the genetic trait for atypical cholinesterase. Prolonged newborn respiratory depression may occur when this trait has been inherited by the infant. The level of cholinesterase activity in the infant will determine the duration of paralysis. Women without the genetic trait for atypical cholinesterase rapidly metabolize the drug and, because clinically significant placental transfer is dependent on concentration, prevent toxicity in the newborn.

FETAL RISK SUMMARY

Succinylcholine is a depolarizing neuromuscular blocking agent that is used as an adjunct to general anesthesia, to facilitate tracheal intubation, and to provide skeletal muscle relaxation during surgery or mechanical ventilation. Approximately 90% of the drug is rapidly hydrolyzed by plasma cholinesterase to succinylmonocholine, a metabolite that is clinically inactive, and then more slowly to succinic acid and choline. The remaining 10% is excreted unchanged in the urine (1).

According to the manufacturer, reproduction studies in animals with succinylcholine have not been conducted (1). A 1984 source, however, stated that studies conducted in the 1950s in rabbits and dogs did not observe embryo or fetal toxicity or teratogenicity (2). Succinylcholine has no direct action on the uterus or other smooth muscles and, because it is highly ionized and has low

lipid solubility, does not readily cross the placenta (1).

A study published in 1961 noted the lack of quantitative data on the placental transfer of succinylcholine in animals and humans (3). Although published reports involving more than 1800 deliveries had shown the drug to be safe for the fetus and newborn, there were anecdotal reports of flaccid, apneic infants whose condition was attributed to succinylcholine (3). The authors cited two studies in which doses <100 mg in pregnant rabbits had no adverse effect on the newborns, but in dogs, paralysis was demonstrated in pups when a 400-mg dose was administered to the mother immediately before delivery (3). They then studied 14 patients delivered by cesarean section under general anesthesia, in which a single 100-mg IV dose of succinylcholine was followed by a continuous infusion of a 0.2% succinylcholine solution (3). The patients received a total dose (IV plus infusion) of 100–600 mg. Three of the newborn infants had Apgar scores <7 (time when determined was not specified). In an additional eight patients undergoing vaginal delivery, a single 100-mg IV dose was given within 4 minutes of birth. None of these infants had a depressed Apgar score. Of the total 22 newborns, no paralysis was observed. Placental transfer of succinylcholine as determined by a biologic test, however, could not be demonstrated in any of the cases (3).

In a second study by these same authors, pregnant rabbits at term were treated with a single IV dose of succinylcholine (0.25–570 mg/kg) with delivery of the fetuses 3–6 minutes later (4). A difference in vigor compared with that in controls was observed when the mother had received 340 mg/kg, about 600 times the human clinical dose based on weight. (The human clinical dose to facilitate tracheal intubation is 0.6 mg/kg IV, range 0.3–1.1 mg/kg [1]). At 540 mg/kg, all rabbit fetuses were alive but paralyzed. In the human part of this study, 13 women at term who were about to undergo vaginal delivery were given a single 200- to 500-mg rapid IV dose, 1–5.25 minutes before delivery (4). Maternal blood levels varied from 0 to 11.6 mcg/mL, whereas cord blood concentrations varied from 0 to 2.0 mcg/mL. Cord blood levels of 1.1–2.0 mcg/mL occurred in six of eight fetuses whose mothers had received doses of ≥300 mg/kg. No drug was found in the cord blood of five newborns after a 200-mg/kg maternal dose. None of the newborns appeared to be affected by succinylcholine, but all of the mothers were apneic at delivery and for periods up to 16 minutes.

The placental transfer of succinylcholine using radioactive tracers was studied in near-term monkeys, using IV doses of 2–3 mg/kg followed by repeated doses of 1.2 and 2 mg/kg (5). Rapid placental transfer occurred,

reaching a peak fetal plasma concentration approximately 30% of the maternal plasma level 5–10 minutes after the dose. Fetal metabolism of succinylcholine to inactive succinylmonocholine was demonstrated, albeit at a slower rate than that which occurred in the mother, an indication that fetal cholinesterase (pseudocholinesterase) activity was lower than that in the mother (5). The authors concluded that the amount of active drug transferred to the fetus produced a slight effect on skeletal muscle activity and was unlikely to depress respiration in the newborn (5).

Atypical cholinesterase is an autosomal dominant inherited condition with prevalence, for the dibucaine-resistant form, of 1:2000–1:4000 in various populations (6). The homozygote state is diagnosed by the onset of prolonged apnea (>10 minutes), in the absence of excessive amounts of other depressants, after succinylcholine (1–3 mg/kg) administration (6). Some of the anecdotal reports, mentioned in reference 3 of flaccid, apneic infants after succinylcholine administration may represent cases of this genetic trait. Four maternal cases of atypical cholinesterase, with probable atypical homozygote infants in three, are discussed below.

A study published in 1975 described respiratory depression and decreased muscular activity in a newborn whose mother had received succinylcholine, 80 mg IV followed by an IV infusion that delivered an additional 60 mg of drug, for cesarean section at term (7). Newborn ventilation support was required for 10 minutes after birth. Neuromuscular block in the mother continued for approximately 5.5 hours. Because the cholinesterase activity in the mother and that in the 2-day-old infant were 10% of normal, neither was able to rapidly metabolize the succinylcholine (7).

Low concentrations of plasma cholinesterase were thought to be responsible for transient respiratory depression in a newborn following the use of succinylcholine for cesarean section (8). The mother had received 200 mg thiamylal (a barbiturate similar to thiopental that is not currently available) and 100 mg succinylcholine IV for induction of general anesthesia 3 minutes prior to delivery. The onset of respiration and the development of an acceptable respiratory pattern in the newborn were slightly delayed with Apgar scores of 5 and 8 at 1 and 5 minutes, respectively. After recovery, the newborn did well. The mother required mechanical ventilation for 4 hours before return of spontaneous muscular activity and respiration (8). Cholinesterase activity in the mother was below the level of test sensitivity. Enzyme activity in the newborn was 410 U/L (normal 2436–4872 U/L) (8). Three months later, the infant's pseudocholinesterase activity had risen to 910 U/L. Enzyme concentrations in

the father (2420 U/L) were slightly low, normal in one sibling (2480 U/L), and markedly depressed in five other siblings (range 150–760 U/L).

A description of two mothers at term with atypical cholinesterase who were administered succinylcholine prior to elective cesarean section was reported in 1975 (9). The first mother received 100 mg of IV succinylcholine 5 minutes before delivery of a male infant. Apnea in the mother persisted for 2.5 hours after delivery before return of spontaneous respirations. Her infant was flaccid, apneic, and unresponsive to stimulation. Respiratory assistance was required for 6 hours before occurrence of full recovery. In the second mother, who also received succinylcholine 100 mg IV, recovery from paralysis required 2 hours. Her infant, delivered 10 minutes after the dose, cried immediately and had Apgar scores of 8 and 10 at 1 and 5 minutes, respectively. Analysis of serum cholinesterase activity and dibucaine numbers in the mothers and infants revealed that the mothers and the affected infant were atypical homozygotes, whereas the unaffected infant was a heterozygote (9).

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 26 of whom had 1st trimester exposure to succinylcholine (10). No congenital malformations were observed in any of the newborns.

BREASTFEEDING SUMMARY

The passage of succinylcholine into breast milk has not been studied. Because the drug is rapidly hydrolyzed by plasma cholinesterase (pseudocholinesterase) to an inactive metabolite, it is doubtful that clinically significant amounts of active drug are transferred into milk (11). Women with the genetic trait for atypical cholinesterase will have high concentrations of succinylcholine, but the effects of the drug on the mother will preclude nursing.

SUCRALFATE

Gastrointestinal Agent (Antisecretory)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Although the toxicity of aluminum has been well documented, there is no evidence that normal doses of aluminum-containing medications, such as sucralfate, present a risk to the fetuses of pregnant women with normal renal function. A study showing an association between in utero exposure to gastric acid-suppressing drugs and childhood allergy and asthma requires confirmation. Oral absorption of aluminum is poor, with only an average of 12% retained in one study of six normal subjects ingesting 1–3 g/day of aluminum (1). Moreover, no evidence has been found to suggest that aluminum is actively absorbed from the gastrointestinal tract (1). Because of these characteristics and the lack of reports of adverse fetal effects in humans or animals attributable to sucralfate, the risk to the fetus is probably nil. A 1985 review on the use of gastrointestinal drugs during pregnancy and lactation by the American College of Gastroenterology classified sucralfate as an agent whose potential benefits outweighed any potential risks (2).

FETAL RISK SUMMARY

Sucralfate is an aluminum salt of a sulfated disaccharide that inhibits pepsin activity and protects against ulceration. The drug is a highly polar anion when solubilized in strong acid solutions, which probably accounts for its poor gastrointestinal absorption. Its ulcer protectant and healing effects are exerted through local, rather than systemic, action (3). The small amounts that are absorbed, up to 2.2% of a dose in one study using healthy males (4), are excreted in the urine (3,4).

In mice, rats, and rabbits, sucralfate had no effect on fertility and was not teratogenic with doses up to 50 times those used in humans (3). Sucralfate is a

source of bioavailable aluminum (1,5). Each 1-g tablet of sucralfate contains 207 mg of aluminum (1). The potential fetal toxicity of this drug relates to its aluminum content.

When administered parenterally to pregnant animals, aluminum accumulated in the fetus, causing an increased perinatal mortality and impaired learning and memory (6,7). Teratogenic effects, however, were not observed (7). Prolonged exposure to the metal has caused neurobehavioral and skeletal toxicity (8). A 1985 review of aluminum described these toxic effects on the brain and bone tissue as dialysis encephalopathy in patients with renal failure and a unique form of osteodystrophy in uremic patients (1). Aluminum received from IV fluids may also be related to osteopenia in premature infants (9). A 1991 report described the results of a study of 88 pregnancies in women exposed to high amounts of aluminum sulfate that had been accidentally added to the city's water supply (10). Except for an increased rate of talipes (clubfoot) (four cases, one control; $p = 0.01$), there was no evidence that the exposure was harmful to the fetuses. Several theoretical explanations for the four cases of clubfoot were offered by the investigators, including the possibility that the observed incidence occurred by chance (10).

In patients with end-stage chronic renal failure, the use of sucralfate to bind phosphate resulted in serum aluminum levels comparable to those obtained from the antacid aluminum hydroxide (5). Administration of sucralfate to normal subjects did not increase plasma aluminum concentrations, but evidence of tissue aluminum loading was found in experiments with animals (1).

Analysis of 97 amniotic fluid samples, mostly from women undergoing amniocentesis for advanced maternal age, found a mean aluminum concentration of 93.4 mcg/L (range 37–149 mcg/L) (11). The authors of this study did not mention whether the women were consuming aluminum-containing medications, and the measured levels are apparently the normal baseline for the patient population studied.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 183 newborns had been exposed to sucralfate during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of five (2.7%) major birth defects were observed (eight expected). Specific data were available for six defect categories, including (observed/expected) 1/2 cardiovascular defects, 1/0 oral clefts, 0/0 spina bifida, 1/0.5 polydactyly, 0/0.5 limb reduction defects, and 1/0.5 hypospadias. These data do not support an association between the drug and congenital defects.

A population-based observational cohort study formed by linking data from three Swedish national healthcare registers over a 10-year period (1995–2004) was reported in 2009 (12). The main outcome measures were a diagnosis of allergic disease or a prescription for asthma or allergy medications. The drug types included in the study were gastric acid suppressors, including H₂-receptor antagonists, prostaglandins, proton pump inhibitors, combinations for eradication of *Helicobacter pylori*, and drugs for peptic ulcer and gastroesophageal reflux disease, such as sucralfate. Of 585,716 children, 29,490 (5.0%) met the diagnosis and 5645 (1%) had been exposed to gastric acid suppression therapy in pregnancy. Of these children, 405 (0.07%) were treated for allergic disease. For developing allergy, the odds ratio (OR) was 1.43 and the 98% confidence interval (CI) was 1.29–1.59, irrespective of the drug, time of exposure during pregnancy, and maternal history of allergy. For developing childhood asthma, but not other allergic diseases, the OR was 1.51 and the 95% CI was 1.35–1.69, irrespective of the type of acid-suppressive drug and the time of exposure in pregnancy. The authors proposed three possible mechanisms for their findings: (a) exposure to increased amounts of allergens could cause sensitization to digestion labile antigens in the fetus; (b) maternal Th₂ cytokine pattern could promote an allergy-prone phenotype in the fetus; and (c) maternal allergen-specific immunoglobulin E could cross the placenta and sensitize fetal immune cells to food and airborne allergens. Several limitations of the study that might have affected their findings were identified, including a general increase in childhood asthma but not necessarily an increase in allergic asthma (12). The study requires confirmation.

BREASTFEEDING SUMMARY

Minimal, if any, excretion of sucralfate into milk should be expected because only small amounts of this drug are absorbed systemically.

SUFENTANIL

Narcotic Agonist Analgesic

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 3rd Trimester

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The use of sufentanil during pregnancy with clinically used doses does not appear to present a significant risk to the fetus or newborn. Although no reports describing the use of the narcotic during the 1st trimester have been located, the lack of teratogenicity in animals and the general opinion that narcotic agents, in general, pose little risk of congenital malformations are reassuring. Sufentanil rapidly crosses the placenta to the fetus, even more so in the presence of fetal acidosis, and similar to all narcotics, dose-related depression of the fetus and newborn may occur. Both respiratory depression and adverse effects on neonatal neurobehavior are potential problems in the newborn. If sufentanil is used in pregnancy, healthcare professionals are encouraged to call the toll-free number (800-670-6126) for information about patient enrollment in the Motherisk study.

FETAL RISK SUMMARY

Sufentanil is a potent narcotic drug that is used as an analgesic adjunct to, or primary anesthetic agent during, general anesthesia and in combination with bupivacaine for epidural anesthesia during labor and vaginal delivery.

No evidence of teratogenicity has been observed in rats and rabbits, but the drug was embryocidal (most likely due to maternal toxicity) in both species when it was given for 10–30 days in a dose 2.5 times the upper human IV dose (1). No adverse reproductive (number of implantations and live fetuses, percent fetal wastage per litter, or mean fetal weight) or teratogenic effects (major or minor malformations) were observed in rats administered continuous infusions of sufentanil at doses of 10, 50, or 100 mcg/kg/day from day 5 through day 20 of pregnancy (2).

The placental transfer of sufentanil was studied in an experiment using the dual-perfused, single-cotyledon human placental model at doses of 1, 10, 20, and 100 ng/mL (3). Sufentanil was shown to rapidly cross the placenta by passive diffusion, but high maternal protein binding significantly reduced this transfer, whereas progressive fetal acidemia (reduction in pH from 7.4 to 6.8 in 0.2 increments) significantly increased transfer. Placental tissues appeared to bind sufentanil, but this accumulation apparently did not affect the overall net drug transfer to the fetus (i.e., the placenta accumulated sufentanil during periods of increasing maternal concentrations and then functioned as a source to sustain fetal drug levels when maternal concentrations declined) (3).

In another in vitro study, a single-pass (open) placental perfusion model was used to assess the placental transfer of sufentanil (1 and 100 ng/mL) and the effect of maternal plasma proteins, placental metabolism, and fetal pH (7.4–6.8) on the transfer (4). The conclusions of this study were identical to those of the study above, in that sufentanil rapidly crossed the placenta by passive diffusion, the placenta acted as a depot for the narcotic, maternal protein binding (not albumin) decreased transfer, and fetal acidosis increased the amount reaching the fetus (4). The authors also concluded that because of its low initial transfer (umbilical vein concentration only 2% of maternal concentration at 5 minutes), sufentanil may be the narcotic of choice if delivery is imminent (<45 minutes) (4).

Sufentanil crosses the placenta to the fetal circulation following maternal epidural anesthesia (5,6). In a 1991 double-blind study, 60 women undergoing elective cesarean section at term were randomized to receive epidural anesthesia consisting of 0.5% bupivacaine with epinephrine (1:200,000) alone (N = 20), sufentanil 20 mcg plus bupivacaine with epinephrine (N = 20), or sufentanil 30 mcg plus bupivacaine with epinephrine (N = 20) (6). The mean plasma concentrations of sufentanil in the mother and newborn in the 20-mcg group (14 subjects) were 0.030 and 0.025 ng/mL, respectively, whereas those in the 30-mcg group (15 subjects) were 0.056 and 0.042 ng/mL, respectively. The fetal:maternal ratios in the two groups were 0.83 and 0.75, respectively. To evaluate the safety of the epidural solutions for the newborn, the Neurological and Adaptive Capacity Score (NACS) was used to evaluate the infants at birth and between 1 and 2 hours. In each of the three groups, the percentage of neonates with a perfect score in each category of the NACS was statistically similar (6).

The placental transfer of sufentanil, fentanyl, and bupivacaine was studied in a double-blind, randomized trial involving 36 women at term who received

epidural anesthesia during labor prior to vaginal delivery (6). Patients received a 12-mL bolus of (a) bupivacaine 0.25% alone (N = 13), (b) bupivacaine 0.125% plus sufentanil 15 mcg (N = 9), or (c) bupivacaine 0.125% plus fentanyl 75 mcg (N = 14), followed by a 10 mL/hr infusion of bupivacaine 0.125% alone, bupivacaine 0.125% plus sufentanil 0.25 mcg/mL, or bupivacaine 0.125% plus fentanyl 1.5 mcg/mL. The mean umbilical vein:maternal vein (UV:MV) ratios for bupivacaine in the three groups were 0.29, 0.43, and 0.33, respectively. The mean UV concentrations of the narcotics for sufentanil and fentanyl were 0.016 and 0.18 ng/mL, respectively, whereas the mean MV concentrations were 0.019 and 0.52 ng/mL, respectively. The UV:MV ratios for sufentanil and fentanyl were 0.81 and 0.37, respectively. The NACS was used to assess the newborns in each group at delivery, 2 hours of age, and 24 hours of age (6). No statistical differences among the three groups were observed at delivery or at 2 hours of age, but at 24 hours, the bupivacaine-fentanyl group's NACS was significantly lower than that of the bupivacaine-sufentanil group, a result thought to reflect the continued presence of fentanyl in the neonate (6).

Intrathecal sufentanil (10 mcg), followed at least 1 hour later with bupivacaine epidural analgesia (N = 65), was compared with bupivacaine epidural analgesia alone (N = 64) in a 1996 report comparing the effects of the two analgesic regimens on fetal heart rate changes during labor (7). No statistical differences were observed between the groups in the incidence of clinically significant fetal heart rate tracing abnormalities (recurrent late decelerations and/or bradycardia) or in maternal hypotension within the 1st hour of administration (7). In addition, there were no differences between the groups in arterial or venous cord pH or the number of 5-minute Apgar scores <7. No abnormal fetal heart rate patterns were observed in an earlier study that compared intrathecal sufentanil (10 mcg) either alone (N = 20) or with 0.2 mg epinephrine (N = 20) (8). Epinephrine did not prolong analgesia but did increase the incidence of vomiting while decreasing the incidence and severity of pruritus. In a 1993 report, abnormal fetal heart rate changes were observed in 15% (11 of 73 tracings that were acceptable for analysis) among 108 women who received intrathecal sufentanil (10 mcg) during active labor (9). Of the 11 abnormal tracings, 5 were of moderate but transient variable decelerations, 4 were of mild nonrepetitive late decelerations, 1 was of a single episode of bradycardia, and 1 was of an episode of decreased variability. None of the 11 affected pregnancies required intervention for fetal compromise.

A number of studies have reported the successful use of sufentanil to produce adequate labor analgesia without fetal or newborn harm (10–19). A

1992 reference concluded that 10 mcg of sufentanil administered intrathecally produced faster and superior analgesia to that observed with epidural or IV administration of the same dose (10). Intermittent injections of intrathecal sufentanil (5 mcg) were compared with intermittent injections of intrathecal fentanyl (10 mcg) or meperidine (10 mg) in another 1992 report (11). In this study, meperidine provided better maternal analgesia once cervical dilation had progressed beyond 6 cm (11). No intergroup differences were observed in umbilical cord blood gases and none of the newborns had a 5-minute Apgar score <7. No significant differences were observed in Apgar scores, umbilical cord blood pH levels, or NACS at 2 and 24 hours in a study comparing epidural sufentanil plus bupivacaine (N = 30) to epidural fentanyl plus bupivacaine (N = 30) (12). During labor, the patients received epidural infusions at 12 mL/hr of either sufentanil (0.25 mcg/mL) or fentanyl (2.5 mcg/mL), both in 0.0625% bupivacaine. The total narcotic doses of sufentanil or fentanyl were 15.9 and 139.8 mcg, respectively. In seven other studies, spinal sufentanil either alone or combined with other various agents compared favorably with controls in efficacy and fetal and newborn safety (13–19).

A case of maternal respiratory depression following a 15-mcg dose of intrathecal sufentanil during labor was described in 1994 (20). A marked decrease (to 89%) in the patient's hemoglobin oxygen saturation was noted that was treated with tactile stimulation and oxygen via face mask. A healthy, 3905-g male infant was delivered 2.5 hours later with Apgar scores of 7 and 8 at 1 and 5 minutes, respectively. No adverse effects were observed in the neonate during routine hospital follow-up.

BREASTFEEDING SUMMARY

The use of sufentanil during lactation is unlikely because of its clinical indications. It is not surprising, therefore, that no reports describing the use of this agent during lactation have been located. The molecular weight (about 579) of sufentanil citrate, the commercial form of the drug, is low enough that passage into milk should be expected. The effects, if any, of this exposure on a nursing infant are unknown.

SULBACTAM

Anti-infective

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Sulbactam is always given in combination with ampicillin. It has caused no harm in animal reproduction studies, but reports of human exposure in early gestation are lacking. However, none of the penicillins has been shown to be teratogenic. Sulbactam readily crosses the human placenta to the fetus. Although no direct adverse effects of this exposure on the fetus or newborn have been reported, use of the antibiotic combination near delivery may result in superinfection with resistant bacteria in the newborn.

FETAL RISK SUMMARY

Sulbactam is a semisynthetic beta-lactamase irreversible inhibitor that is derived from the basic penicillin nucleus. When used alone, sulbactam does not have effective anti-infective activity (accept against the Neisseriaceae). However, sulbactam extends the activity of ampicillin when given in combination with this antibiotic (1).

Reproduction studies reported by the manufacturer involved mice, rats, and rabbits, but only with the combination of sulbactam and ampicillin (1). There was no evidence of impaired fertility or fetal harm in each species at doses up to 10 times the human dose. Pregnant rats given IV sulbactam at doses up to 500 mg/kg/day at various times, including before mating and throughout gestation, showed no evidence of adverse reproductive effects (2).

Sulbactam crosses the human placenta to the fetus at term (3,4). Placental transfer studies early in gestation have not been located. An abstract from a 1983 symposium reported a linear relationship between fetal and maternal serum sulbactam concentrations when sulbactam/ampicillin was given as a single dose (either 0.5 g/1 g or 1 g/1 g) just before cesarean section. The mean peak fetal serum level of sulbactam was <20 mcg/mL (3). In an in vitro experiment with bidirectional perfused human placental lobules, sulbactam was

demonstrated to cross by simple diffusion (4). The placental transfer is consistent with its low molecular weight (about 255).

A 1992 study compared the concentration of three antibiotics (sulbactam/ampicillin, ticarcillin/clavulanic acid, and cefotaxime) in maternal blood, placental tissue, and cord blood in 15 laboring women with chorioamnionitis at ≥ 37 weeks' gestation (5). Five of the women received the sulbactam/ampicillin combination. The mean concentrations of sulbactam in maternal blood, placental tissue, and cord blood were 7.25, 3.75, and 9.68 mcg/mL. The cord:maternal ratio was 1.3. The time interval between dosing and delivery and the dose used were not specified (5).

The pharmacokinetics of sulbactam at term were described in a 1993 study (6). The kinetics (area under drug vs. time curve, elimination rate constant, half-life, volume of distribution, and clearance) of a 0.5-g dose of sulbactam (combined with 1 g ampicillin) administered IV at cord clamping were not significantly different from those in nonpregnant patients. Changes were noted but did not reach statistical significance (6).

The combination of sulbactam and ampicillin has been used frequently in the 2nd and 3rd trimesters of pregnancy (7–15). These studies involved prophylaxis, as in cases of preterm premature rupture of the membranes, and therapy for established infections. No cases of fetal or newborn direct harm from exposure to the combination were reported. However, indirect harm to the newborn from antibiotic-related superinfection with resistant bacteria is a concern (15).

Inadvertent intrauterine infusion of sulbactam (1 g) plus ampicillin (2 g) was reported in a brief 2000 communication (16). The antibiotic combination was being given for prophylaxis of preterm premature rupture of the membranes at 30 weeks' gestation. Apparently the error occurred when the antibiotic was infused into an intrauterine catheter instead of the intended IV catheter. A 1690-g infant (sex not specified) was delivered by cesarean section the next day. No adverse effects of the error were observed.

BREASTFEEDING SUMMARY

Sulbactam is excreted into human breast milk. Sulbactam (0.5 or 1.0 g) was infused either with cephalothin or ampicillin in four postpartum women 2 days after cesarean section (17). The milk concentrations obtained 10–21 hours after a dose ranged from 0.13 to 1.2 mcg/mL (mean 0.52 mcg/mL). No sulbactam was found in one sample obtained at 49 hours. The investigators did not state whether the infants were allowed to nurse. The potential effects of

exposure to sulbactam on a nursing infant is unknown, but are probably similar to those that might occur with other antibiotics: modification of bowel flora, direct effects on the infant (e.g., allergy or sensitization), and interference with the interpretation of culture results if a fever workup is required. The American Academy of Pediatrics classifies sulbactam as compatible with breastfeeding (18).

SULCONAZOLE

Antifungal

PREGNANCY RECOMMENDATION: No Human Data—Potential Toxicity

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of sulconazole in human pregnancy have been located. When given orally, sulconazole was embryotoxic and prolonged gestation in one animal species, but the systemic exposures appeared to be far higher than those that could possibly be obtained after topical use. Sulconazole is partially absorbed with the amount reaching the plasma dependent on the dose and application site. The effects of this exposure are unknown. One study did find a significant increase (relative risk 1.4) in the risk of spontaneous abortion after vaginitis therapy with imidazole antifungals, clotrimazole and miconazole (1). A later study speculated that this effect might have been due to inhibition of the critical placental enzyme aromatase (2). There is no other evidence suggesting that similar topical imidazole-derivative antifungal agents cause embryo-fetal harm. However, sulconazole was a more potent inhibitor of aromatase than either of the two agents associated with the abortions (2). Until additional data are available, the best course is to avoid the use of sulconazole in the 1st trimester or the application of the antifungal to large areas of skin at any time in pregnancy.

FETAL RISK SUMMARY

Sulconazole is available as a 1% cream for topical application. It is in the same antifungal class of imidazole derivatives as butoconazole, clotrimazole, econazole, ketoconazole, miconazole, oxiconazole, sertaconazole, and tioconazole. Sulconazole is indicated for the treatment of tinea pedis (athlete's foot), tinea cruris, and tinea corporis caused by *Trichophyton rubrum*, *T. mentagrophytes*, *Epidermophyton floccosum*, *Microsporum canis*, and tinea versicolor (3).

In a 1988 study with seven adults, two applications (4.5 g/each) of the radiolabeled 1% cream were made on the abdominal skin at 0 and 12 hours (4). The site was then washed at 24 hours and then every 24 hours for 3 days. Radioactivity was detectable in the plasma from 8 to 96 hours, with a peak at 24 hours. The total percutaneous absorption was estimated to be 8.7%–11.3% of the total dose, the highest reported among imidazole derivatives (4).

Reproduction studies have been conducted in rats and rabbits. In rats, an oral dose 125 times the adult human dose based on body weight was embryotoxic. This dose also resulted in prolonged gestation and dystocia. No teratogenicity was observed in rats and rabbits given oral doses of 50 mg/kg/day (comparison to human dose not specified) (3).

It is not known if sulconazole crosses the human placenta. The molecular weight (about 461) suggests that exposure of the embryo–fetus will occur. However, the dose and application site will have a major role in determining the amount of drug available to cross the placenta.

A 2002 study evaluated azole antifungals commonly used in pregnancy for their potential to inhibit aromatase, a placental enzyme that is critical for the production of estrogen and for the maintenance of pregnancy (2). The authors speculated that the embryotoxicity observed in animals and humans (see also Clotrimazole and Miconazole) might be explained by inhibition of aromatase. They found that the most potent inhibitors of aromatase were (shown in order of decreasing potency) econazole, bifonazole (not available in the United States), sulconazole, clotrimazole, and miconazole. The potential plasma concentrations of sulconazole in humans were thought to be high enough to partially inhibit the enzyme (2). However, an earlier study reported a pregnancy that was maintained even when there was severe fetal and placental aromatase deficiency (<0.3% of that of controls) caused by a rare genetic defect (5). In this case, both the fetus and mother were virilized because of diminished conversion of androgens to estrogen. Because the pregnancy was maintained and the virilization, the case suggested that the main function of placental aromatase was to protect the mother and fetus from exposure to adrenal androgens (5).

BREASTFEEDING SUMMARY

No reports describing the use of sulconazole during human lactation have been located. The molecular weight (about 461) suggests that the drug will be excreted into breast milk. The drug is absorbed systemically (see above). The effect of this exposure on a nursing infant is unknown. Because the systemic

absorption was the highest known among similar agents, other imidazole antifungals might be more appropriate if a nursing woman requires topical antifungal therapy.

SULFASALAZINE

Gastrointestinal Agent/Immunologic Agent (Antirheumatic)

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Sulfasalazine is a compound composed of 5-aminosalicylic acid (5-ASA) joined to sulfapyridine by an azo-linkage (refer to Sulfonamides for a complete review of this class of agents). No evidence of developmental toxicity has been located. Although it has not been reported, there is a potential risk of neonatal jaundice if the drug is administered close to delivery. If sulfasalazine is used in pregnancy for the treatment of rheumatoid arthritis, healthcare professionals are encouraged to call the toll-free number (877-311-8972) for information about patient enrollment in the Organization of Teratology Information Specialists (OTIS) Rheumatoid Arthritis study.

FETAL RISK SUMMARY

Sulfasalazine is used for the treatment of ulcerative colitis, Crohn's disease, and rheumatoid arthritis. Reproduction studies in rats and rabbits at doses up to 6 times the human dose revealed no impairment of fertility or fetal harm (1).

No increase in human congenital defects or newborn toxicity has been observed from its use in pregnancy (2–12). However, three reports, involving five infants (two stillborn), have described congenital malformations after exposure to this drug (13–15). It cannot be determined whether the observed defects were related to the therapy, the disease, or a combination of these or other factors: bilateral cleft lip/palate, severe hydrocephalus, death (13); ventricular septal defect, coarctation of aorta (14); Potter-type IIa polycystic kidney, rudimentary left uterine cornu, stillborn (first twin) (14); Potter's facies, hypoplastic lungs, absent kidneys and ureters, talipes equinovarus, stillborn (second twin) (14); ventricular septal defect, coarctation of aorta, macrocephaly; gingival hyperplasia, small ears (both thought to be inherited)

(15).

Sulfasalazine and its metabolite, sulfapyridine, readily cross the placenta to the fetal circulation (6,7). Fetal concentrations are approximately the same as maternal concentrations. Placental transfer of 5-ASA is limited because only negligible amounts are absorbed from the cecum and colon, and these are rapidly excreted in the urine (16).

At birth, concentrations of sulfasalazine and sulfapyridine in 11 infants were 4.6 and 18.2 mcg/mL, respectively (7). Neither of these levels was sufficient to cause significant displacement of bilirubin from albumin (7). Kernicterus and severe neonatal jaundice have not been reported following maternal use of sulfasalazine, even when the drug was given up to the time of delivery (7,8). Caution is advised, however, because other sulfonamides have caused jaundice in the newborn when given near term (see Sulfonamides).

Sulfasalazine is a folic acid antagonist (dihydrofolate reductase inhibitor). In a 2000 case–control study, the effect of folic acid supplementation on the risks for certain congenital defects were examined (17). Supplementation reduced the teratogenic risk from sulfasalazine and similar acting folic acid antagonists. See Trimethoprim for details of this study.

Sulfasalazine may adversely affect spermatogenesis in male patients with inflammatory bowel disease (18,19). Sperm counts and motility are both reduced and require ≥ 2 months after the drug is stopped to return to normal levels (18).

BREASTFEEDING SUMMARY

Sulfapyridine is excreted into breast milk (6,16,20) (see also Sulfonamides). Milk concentrations were approximately 40%–60% of maternal serum levels. One infant's urine contained 3–4 mcg/mL of the drug (1.2–1.6 mg/24 hours), representing about 30%–40% of the total dose excreted in the milk. Unmetabolized sulfasalazine was detected in only one of the studies (milk:plasma ratio of 0.3) (6). Levels of 5-ASA were undetectable. No adverse effects were observed in the 16 nursing infants exposed in these reports (6,16,20). However, bloody diarrhea in an infant exclusively breastfed, occurring first at 2 months of age and then recurring 2 weeks later and persisting until 3 months of age, was attributed to the mother's sulfasalazine therapy (3 g/day) (21). The mother was a slow acetylator with a blood concentration of sulfapyridine of 42.4 mcg/mL (therapeutic range 20–50 mcg/mL). The acetylation phenotype of the infant was not determined, but his blood level of sulfapyridine was 5.3 mcg/mL. A diagnostic workup of the infant

was negative. The bloody diarrhea did stop, however, 48–72 hours after discontinuance of the mother's therapy. A repeat colonoscopy of the infant 1.5 months later was normal (21).

Based on the above report, the American Academy of Pediatrics classifies sulfasalazine as a drug that has been associated with significant effects in some nursing infants and should be given to nursing mothers with caution (22).

SULFONAMIDES

Anti-infective

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 3rd Trimester

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Taken in sum, sulfonamides, as single agents, do not appear to pose a significant teratogenic risk. One study has found associations with birth defects, but a causative association cannot be determined with this type of study and they may have been due to other factors, particularly if trimethoprim was combined with the sulfonamide. Confirmation is required. Because of the potential toxicity to the newborn, these agents should be avoided near term.

FETAL RISK SUMMARY

Sulfonamides are a large class of antibacterial agents. Although there are differences in their bioavailability, all share similar actions in the fetal and newborn periods, and they will be considered as a single group.

Sulfamethoxazole was teratogenic (primarily cleft palates) in rats given oral doses of 533 mg/kg (1). The highest dose that did not produce cleft palates was 512 mg/kg.

The sulfonamides readily cross the placenta to the fetus during all stages of gestation (2–10). Equilibrium with maternal blood is usually established after 2–3 hours, with fetal levels averaging 70%–90% of maternal levels. Significant levels may persist in the newborn for several days after birth when given near term. The primary danger of sulfonamide administration during pregnancy is manifested when these agents are given close to delivery. Toxicities that may be observed in the newborn include jaundice, hemolytic anemia, and, theoretically, kernicterus. Severe jaundice in the newborn has been related by several authors to maternal sulfonamide ingestion at term(11–16). Premature infants seem especially prone to development of hyperbilirubinemia (15).

However, a study of 94 infants exposed to sulfadiazine in utero for maternal prophylaxis of rheumatic fever failed to show an increase in prematurity, hyperbilirubinemia, or kernicterus (17). Hemolytic anemia has been reported in two newborns and in a fetus following in utero exposure to sulfonamides (11,12,16). Both newborns survived. In the case involving the fetus, the mother had homozygous glucose-6-phosphate dehydrogenase deficiency (16). She was treated with sulfisoxazole for a urinary tract infection 2 weeks before delivery of a stillborn male infant. Autopsy revealed an infant at 36 weeks' gestation with maceration, severe anemia, and hydrops fetalis.

Sulfonamides compete with bilirubin for binding to plasma albumin. In utero, the fetus clears free bilirubin by the placental circulation; however, after birth, this mechanism is no longer available. Unbound bilirubin is free to cross the blood–brain barrier and may result in kernicterus. Although this toxicity is well known when sulfonamides are administered directly to the neonate, kernicterus in the newborn following in utero exposure has not been reported. Most reports of sulfonamide exposure during gestation have failed to demonstrate an association with congenital malformations (10,11,18–24). Offspring of patients treated throughout pregnancy with sulfasalazine (sulfapyridine plus 5-aminosalicylic acid) for ulcerative colitis or Crohn's disease have not shown an increase in adverse effects (10,21,23) (see also Sulfasalazine). In contrast, a retrospective study of 1369 patients found that significantly more mothers of 458 infants with congenital malformations took sulfonamides than did mothers in the control group (25). A 1975 study examined the in utero drug exposures of 599 children born with oral clefts (26). A significant difference ($p < 0.05$), as compared with matched controls, was found with 1st and 2nd trimester sulfonamide use only when other defects, in addition to the clefts, were present.

As noted above, some sulfonamides are animal teratogens. Because of this, warnings of human teratogenicity have been published (27,28). In two reports, investigators associated in utero sulfonamide exposure with tracheoesophageal fistula and cataracts, but additional descriptions of these effects have not appeared (29,30). A mother treated for food poisoning with sulfaguanidine in early pregnancy delivered a child with multiple anomalies (31). The author attributed the defects to use of the drug, but a relationship is doubtful.

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 1455 of whom had 1st trimester exposure to sulfonamides (32, pp. 296–313). For use anytime during pregnancy, 5689 exposures were reported (32, p. 435). In neither group was evidence found to suggest a relationship to large

categories of major or minor malformations. Several possible associations were found with individual defects after anytime use, but independent confirmation is required: ductus arteriosus persistens (8 cases), coloboma (4 cases), hypoplasia of limb or part thereof (7 cases), miscellaneous foot defects (4 cases), urethral obstruction (13 cases), hypoplasia or atrophy of adrenals (6 cases), and benign tumors (12 cases) (32, pp. 485–486).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 131 newborns had been exposed to sulfisoxazole, 1138 to sulfabenzamide vaginal cream, and 2296 to the combination of sulfamethoxazole-trimethoprim during the 1st trimester (F. Rosa, personal communication, FDA, 1993). For sulfisoxazole, eight (6.1%) major birth defects were observed (six expected), two cardiovascular defects (one expected), and one oral cleft (none expected). No anomalies were observed in four other categories of defects (spina bifida, polydactyly, limb reduction defects, and hypospadias) for which data were available. For sulfabenzamide, 43 (3.8%) major birth defects were found (44 expected), including (observed/expected) 11/10 cardiovascular defects, 0/2 oral clefts, 0/0.5 spina bifida, 2/3 polydactyly, 1/2 limb reduction defects, and 1/3 hypospadias. The data for sulfisoxazole and sulfabenzamide do not support an association between the drug and congenital defects. In contrast, a possible association was found between sulfamethoxazole-trimethoprim and congenital defects (126 observed/98 expected; 5.5%) in general and for cardiovascular defects (37/23) in particular (see Trimethoprim for details).

A 2009 report from the National Birth Defects Prevention Study estimated the association between antibacterial agents and >30 selected birth defects (33). The authors conducted a population-based, multiple site, case–control study of women who gave birth to an infant with 1 of >30 selected defects. The outcomes were identified in a 10-state birth defect surveillance program and involved 13,155 cases and 4941 controls selected from the same geographical regions. Exposure to an antibacterial was determined by a detailed telephone interview conducted within 24 months after the estimated date of delivery. Women were considered exposed if they had used an antibacterial drug during the month before the estimated date of conception through the end of the 1st trimester (defined as the end of the 3rd month of pregnancy). Significant associations with multiple selected birth defects were found (total number of exposed cases/controls) with sulfonamides (145/42) (probably combined with trimethoprim) and nitrofurantoin (150/42). The adjusted odds ratios and 95% confidence intervals (in parentheses) for sulfonamides were anencephaly 3.4

(1.3–8.8), hypoplastic left heart syndrome 3.2 (1.3–7.6), coarctation of the aorta 2.7 (1.3–5.6), choanal atresia 8.0 (2.7–23.5), transverse limb deficiency 2.5 (1.0–5.9), and diaphragmatic hernia 2.4 (1.1–5.4). Significant associations (total number of exposed cases/controls; number of associations) also were found for penicillins (716/293; 1), erythromycins (202/78; 2), cephalosporins (128/47; 1), quinolones (42/14; 1), and tetracyclines (36/6; 1). The results for quinolones and tetracyclines, however, were based on small numbers of exposed cases and controls (33).

As with all retrospective case–control studies, the data can determine associations, but not causative associations (33). Moreover, several limitations were identified by the authors, including spurious associations caused by the large number of analyses, interviews conducted 6 weeks to 2 years after the pregnancy making recall difficult for cases and controls, recall bias, and inability to distinguish between drug-induced defects and defects resulting from the infection (33).

BREASTFEEDING SUMMARY

Sulfonamides are excreted into breast milk in low concentrations. Milk levels of sulfanilamide (free and conjugated) are reported to range from 6 to 94 mcg/mL (4,34–39). Up to 1.6% of the total dose could be recovered from the milk (34,37). Milk levels often exceeded serum levels and persisted for several days after maternal consumption of the drug was stopped. Milk:plasma ratios during therapy with sulfanilamide were 0.5–0.6 (38). Reports of adverse effects in nursing infants are rare. One author found reports of diarrhea and rash in breastfed infants whose mothers were receiving sulfapyridine or sulfathiazole (7). (See Sulfasalazine for another report of bloody diarrhea.) Milk levels of sulfapyridine, the active metabolite of sulfasalazine, were 10.3 mcg/mL, a milk:plasma ratio of 0.5 (10). Based on these data, the nursing infant would receive approximately 3–4 mg/kg/day of sulfapyridine, an apparently nontoxic amount for a healthy neonate (17). Sulfisoxazole, a very water-soluble drug, was reported to produce a low milk:plasma ratio of 0.06 (40). The conjugated form achieved a ratio of 0.22. The total amount of sulfisoxazole recovered in milk during 48 hours after a 4-g divided dose was only 0.45%. Although controversial, breastfeeding during maternal administration of sulfisoxazole seems to represent a very low risk for the healthy neonate (41,42).

In a 1993 cohort study, diarrhea was reported in 32 (19.3%) nursing infants of 166 breastfeeding mothers who were taking antibiotics (43). For the 12 women taking sulfamethoxazole-trimethoprim, no diarrhea was observed but 2

(17%) had poor feeding, an effect that was considered minor because it did not require medical attention (43).

Sulfonamide excretion into breast milk apparently does not pose a significant risk for the healthy, full-term neonate. Exposure to sulfonamides via breast milk should be avoided in ill, stressed, or premature infants and in infants with hyperbilirubinemia or glucose-6-phosphate dehydrogenase deficiency. With these latter precautions, the American Academy of Pediatrics classifies sulfapyridine, sulfisoxazole, and sulfamethoxazole (when combined with trimethoprim) as compatible with breastfeeding (44).

SULINDAC

Nonsteroidal Anti-inflammatory

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 1st and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Sulindac, a prostaglandin synthesis inhibitor, potentially could cause constriction of the ductus arteriosus in utero, as well as inhibition of labor, prolongation of pregnancy, and suppression of fetal renal function (1,2). Persistent pulmonary hypertension of the newborn should also be considered (3). Women attempting to conceive should not use any prostaglandin synthesis inhibitor, including sulindac, because of the findings in a variety of animal models that indicate these agents block blastocyst implantation (4,5). Moreover, as noted below, nonsteroidal anti-inflammatory drugs (NSAIDs) have been associated with spontaneous abortions (SABs) and congenital malformations. The absolute risk for these defects, however, appears to be low.

FETAL RISK SUMMARY

Sulindac is an NSAID prodrug that is converted in vivo to the biologically active sulfide metabolite. It is used for the relief of the signs and symptoms of rheumatoid arthritis, osteoarthritis, gouty arthritis, ankylosing spondylitis, and acute painful shoulder (6). Sulindac is in the same NSAID subclass (acetic acids) as diclofenac, indomethacin, and tolmetin. However, sulindac, a derivative of indomethacin, is seven times more cyclooxygenase (COX)-2 selective than indomethacin and is sometimes referred to as a COX-2 selective agent (7).

When administered to pregnant rats, similar to other NSAIDs, sulindac reduces fetal weight and pup survival (at doses ≥ 2.5 times than the usual maximum human daily dose), prolongs the duration of gestation, and may cause dystocia (6,8).

Consistent with the molecular weight (about 356), sulindac and its active metabolite cross the human placenta to the fetus. Nine women at a mean gestational age of 31.8 weeks (24.3–36.4 weeks) were given a single 200-mg oral dose of the drug a mean 5.5 hours (4.4–6.7 hours) before cordocentesis (9,10). Maternal serum was obtained at a mean 5.8 hours (3.5–7.3 hours) after the dose. The mean concentrations of sulindac in the mothers and fetuses were 0.59 and 0.98 mcg/mL, respectively, and of the sulfide metabolite 1.42 and 0.68 mcg/mL, respectively. The corresponding sulfide:sulindac ratios in the mother and fetal compartments were 2.32 and 0.53, respectively. The reduced amounts of metabolite in the fetus, compared with those in the mother, were thought to be caused by decreased placental transfer of the metabolite and slower metabolism of sulindac in the fetus (10). Because of these findings, the investigators theorized that, as a tocolytic, sulindac would be expected to cause less fetal toxicity than indomethacin.

Using a human term placental perfusion model, a 1999 study demonstrated that the sulfide metabolite reaches the fetus in higher concentrations than does sulindac or indomethacin (11). The fetal:maternal ratios after 2-hour perfusions were 0.34 (sulindac), 0.54 (sulfide metabolite), and 0.45 (indomethacin). Neither sulindac nor indomethacin was metabolized by the placenta (11).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 69 newborns had been exposed to sulindac during the 1st trimester (F. Rosa, personal communication, FDA, 1995). Three (4.3%) major birth defects were observed (three expected), including one cardiovascular defect (one expected). No anomalies were observed in five other categories of defects (oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available. For exposure during any trimester (102 newborns), two malformations of the eyeball (excluding oculomotor and ptosis) were observed (none expected), but no brain defects were recorded.

A combined 2001 population-based, observational cohort study and a case–control study estimated the risk of adverse pregnancy outcome from the use of NSAIDs (12). The use of NSAIDs during pregnancy was not associated with congenital malformations, preterm delivery, or low birth weight, but a positive association was discovered with SABs. A similar study, also published in 2001, failed to find a relationship, in general, between NSAIDs and congenital malformations, but did find a significant association with cardiac defects and orofacial clefts (13). In addition, a 2003 study found a significant association between exposure to NSAIDs in early pregnancy and SABs (14). (See

Ibuprofen for details on these three studies.)

A brief 2003 editorial on the potential for NSAID-induced developmental toxicity concluded that NSAIDs, specifically those with greater COX-2 affinity, had a lower risk of this toxicity in humans than aspirin (15).

An abstract and a full report, both published in 1992, described the use of sulindac in the treatment of preterm labor in comparison with indomethacin (16,17). The gestational ages at treatment for the groups were 29 and 30 weeks, respectively. The sulindac group (N = 18) received 200 mg orally every 12 hours for 48 hours, whereas those receiving indomethacin (N = 18) were given 100 mg orally once followed by 25 mg orally every 4 hours for 48 hours. Both groups received IV magnesium sulfate and some in both groups received SC terbutaline. The response to tocolysis was statistically similar for sulindac and indomethacin. However, the sulindac-treated women had significantly greater hourly fetal urine output, the deepest amniotic fluid pocket, and the largest amniotic fluid index. Patent ductus arteriosus (PDA) was observed in 11% vs. 22%, respectively, and intraventricular hemorrhage (IVH) in the newborn occurred in 11% of both groups. These differences were not significant. No cases of primary pulmonary hypertension in the newborns were observed (16,17).

A comparison between sulindac (200 mg orally every 12 hours for 4 days) and indomethacin (100 mg rectally on the 1st day, then 50 mg orally every 8 hours for 3 days) on fetal cardiac function was published in 1995 (18). Each group was composed of 10 patients with threatened premature labor at 28–32 weeks' gestation. Significant reductions in the mean pulsatility index of the fetal ductus arteriosus began 4 hours after the first indomethacin dose. The reduction increased with time and resolved 24 hours after the last dose. Other secondary changes in fetal cardiac function resulting from ductal constriction were also noted. In the sulindac group, a significant decrease in the mean pulsatility index, without secondary changes, was observed only at 24 hours (18).

A study comparing the fetal cardiovascular effects of sulindac (200 mg orally every 12 hours) and terbutaline (5 mg orally every 4 hours) for 68 hours at an approximate mean gestational age of 32 weeks was published in an abstract form in 1996 (19) and in a full report in 1999 (20). Significant ductal constriction was noted only in the sulindac group. In contrast to the study cited above, therapy was stopped because of severe constriction in 2 (one at 12 hours and the other at 24 hours) of the 10 patients. The constriction of the fetal ductus arteriosus occurred within 5 hours of receiving sulindac and resolved within 48

hours of discontinuing the drug (19,20).

A 1994 abstract reported that the tocolytic effect of a 7-day course of sulindac, 200 mg orally every 12 hours, following arrest of labor with IV magnesium sulfate, was no different from placebo and observation (21). The difference in prolongation of pregnancy between the sulindac (N = 13) and placebo (N = 15) groups (33 vs. 26 days, respectively) was not significant. No differences between the groups on days 0, 7, and 14 were found for hourly fetal urine production, amniotic fluid index, or ductus arteriosus velocity (21).

Two 1995 references from the same group of investigators, using a similar study design, concluded that sulindac did not reduce the rate of premature birth but did lengthen the interval to retocolysis in those patients who required retocolysis (22,23). No difference was found between sulindac and placebo in prolongation of pregnancy, delivery at >35 weeks' gestation, recurrent preterm labor, birth weight, or time spent in the neonatal intensive care unit. No adverse effects were observed in the exposed fetuses (22,23).

As demonstrated with other NSAIDs (see also Indomethacin), sulindac reduces amniotic fluid volume by decreasing fetal urine output in a dose-related manner (24). Sulindac, 200 mg twice daily, was given to the mothers of three sets of monoamniotic twins, diagnosed as having cord entanglement, beginning at 24, 27, and 29 weeks, respectively, and continued until elective cesarean section at 32 weeks' gestation. One of the twins had a preexisting heart defect (transposition of the great vessels and a ventricular septal defect). The dose was reduced in one patient to 200 mg/day to maintain an adequate amniotic fluid index. No significant changes in the umbilical artery or the ductus arteriosus Doppler waveforms were observed. All of the newborns had appropriate weights for gestation and normal renal function during the first week of life, and none required ventilation (24).

A 2000 abstract described a retrospective case-cohort study that compared the neonatal effects of sulindac with indomethacin (25). The infants (born between 1994 and 1999) had been exposed to antenatal sulindac (N = 25) or indomethacin (N = 66) and weighed <1500 g. Those exposed to both drugs or with congenital abnormalities were excluded. There were no significant differences between the indomethacin and sulindac groups in IVH (32% vs. 36%), grades III-IV IVH (14% vs. 12%), necrotizing enterocolitis (8% vs. 8%), serum creatinine >1.4 mg/dL (19% vs. 15%), PDA (17% vs. 28%), and mortality (12% vs. 12%), respectively. However, there was a significant increase in the risk for bronchopulmonary dysplasia after exposure to indomethacin (adjusted odds ratio 4.9, 95% confidence interval 1.01–23.44)

(25).

A 2003 review concluded that COX-2 selective drugs, such as sulindac, should only be used as tocolytics in randomized controlled trials (7). This conclusion was based on the uncertainty over whether the fetal toxicity observed with sulindac resulted from COX-2-dependent effects, or from fetal accumulation of drug levels sufficient to cause COX-1 inhibition (7).

BREASTFEEDING SUMMARY

No reports describing the use of sulindac during lactation have been located. The mean adult serum half-life of the biologically active sulfide metabolite is 16.4 hours (6). One reviewer concluded that because of the prolonged half-life, other agents in this class (diclofenac, fenoprofen, flurbiprofen, ibuprofen, ketoprofen, ketorolac, and tolmetin) were safer alternatives if an NSAID was required during nursing (26).

SUMATRIPTAN

Antimigraine

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Sumatriptan has caused toxicity and malformations in one animal species, but the drug does not appear to present a major teratogenic risk in humans. There was no consistent pattern among the reported birth defects to suggest a common cause. The studies, however, lack the sensitivity to identify minor anomalies because of the absence of standardized examinations. In one study, late-appearing major defects may also have been missed due to the timing of the questionnaires. Thus, although the data are generally reassuring, the number and follow-up of exposed pregnancies are still too limited to assess, with confidence, the safety of the agent or its teratogenic potential. However, a 2008 review of triptans in pregnancy found no evidence for teratogenicity, but the data did suggest a possible increase in the rate of preterm birth (1).

FETAL RISK SUMMARY

Sumatriptan (GR 43175) is a selective serotonin (5-hydroxytryptamine 1 [5-HT]) receptor subtype agonist used for the acute treatment of migraine headaches. It is available in oral tablets and as an SC injection. Sumatriptan has also been used for the treatment of cluster headaches. The drug is closely related to almotriptan, eletriptan, frovatriptan, naratriptan, rizatriptan, and zolmitriptan.

It is metabolized to inactive metabolites. Plasma protein binding is low (14%–21%) and the elimination half-life is about 2.5 hours (2).

Sumatriptan was embryolethal in rabbits when given in daily IV doses approximately equivalent to the maximum recommended single human SC dose of 6 mg based on BSA (MRHD). The doses were at or close to those

producing maternal toxicity. Fetuses of rabbits administered oral sumatriptan (at doses >50 times the MRHD) during organogenesis had an increased incidence of cervicothoracic vascular and skeletal anomalies. In contrast, embryo or fetal lethality was not observed in pregnant rats treated throughout organogenesis with IV doses approximately 20 times the MRHD. Moreover, no rat embryo–fetal lethality or teratogenicity was observed with daily SC doses before and throughout gestation (2). Shepard (3) described a study in which no fetal adverse effects were observed in rats given up to 1000 mg/kg orally during organogenesis.

No studies examining the placental transfer of sumatriptan in animals or humans have been located. The molecular weight (about 414), low plasma protein binding, and the elimination half-life suggest that exposure of the embryo and fetus should be expected.

Individual reports and data from Medicaid studies totaled 14 spontaneous abortions (SABs) with the use of sumatriptan during early pregnancy (F. Rosa, personal communication, FDA, 1996). Seven birth defect case reports received by the FDA included two chromosomal anomalies (both of which could have been exposed before conception), one infant with an ear tag, one case of a phocomelia, a reduction defect of the lower limbs (tibial aplasia), a case of developmental retardation, and one unspecified defect (some of these defects appear to be also included in data from the pregnancy registry cited below).

An interim report of the Sumatriptan/Naratriptan/Treximet Pregnancy Registry, covering the period January 1, 1996 through April 30, 2009, described the outcomes of 761 prospectively enrolled pregnancies exposed to sumatriptan: 578 outcomes (including 6 sets of twins and 1 set of triplets), 170 lost to follow-up, and 21 pending (4). Some of the data were also reported in a 1997 abstract (5). There were 494 outcomes with earliest exposure in the 1st trimester, 66 with earliest exposure in the 2nd trimester, 14 in the 3rd trimester, and 4 exposed at an unspecified time. In the 1st trimester group, there were 20 birth defects (16 live births, 1 fetal death, and 3 elective abortions [EABs]), whereas in the group with no birth defects reported, there were 427 live births, 4 fetal deaths, and 11 EABs. In the combined 1st trimester group, there were 32 SABs (<20 weeks' gestation). In the 66 outcomes with earliest exposure in the 2nd trimester, there were 3 live births with birth defects and 63 live births without defects. The 3rd trimester group had 14 live births without defects, and the unspecified group had 1 EAB with a birth defect and 3 live births without defects. Excluding fetal deaths and EABs without reported birth defects and all SABs, the observed proportion of birth defects in the 1st trimester group was

4.5% (95% confidence interval [CI] 2.8%–6.9%). For any trimester exposure, the proportion (with the same exclusions) was 4.5% (95% CI 3.0%–6.7%). The prevalence of birth defects in women with migraine has been estimated at 3.4%. The Registry noted the occurrence of ventricular septal defects in 4 of the 447 (0.89%) prospective 1st trimester exposures, 2 of which were clinically insignificant. There were three pregnancies exposed to Treximet (sumatriptan plus naproxen) prospectively enrolled and all are pending outcome (4).

Although retrospective reports (reported after the pregnancy outcome was known) are often biased (only adverse outcomes are reported), there were 26 birth defects reported to the Registry, 23 with earliest exposure in the 1st trimester, 1 with earliest exposure in the 2nd trimester, and 2 with unspecified trimester. Review of all birth defects from prospective and retrospective reports revealed no signal or consistent pattern to suggest a common etiology (4).

A 1998 report (first published in 1997 as an abstract [6]) described the prospectively determined pregnancy outcomes of 96 women exposed to sumatriptan (95 exposed during 1st trimester) (7). No difference in the rate of major birth defects was found between the study patients and nonteratogen-exposed controls or disease-matched controls. One major birth defect was reported in a sumatriptan-exposed infant: vesicoureteral reflux requiring bilateral reimplant (7).

A 1998 noninterventional observational cohort study described the outcomes of pregnancies in women who had been prescribed ≥ 1 of 34 newly marketed drugs by general practitioners in England (8). Data were obtained by questionnaires sent to the prescribing physicians one month after the expected or possible date of delivery. In 831 (78%) of the pregnancies, a newly marketed drug was thought to have been taken during the 1st trimester with birth defects noted in 14 (2.5%) singleton births of the 557 newborns (10 sets of twins). In addition, two birth defects were observed in aborted fetuses. However, few of the aborted fetuses were examined. Sumatriptan was taken during the 1st trimester in 35 pregnancies. The outcomes of these pregnancies included 4 SABs, 3 EABs, 5 pregnancies lost to follow-up, and 23 normal infants (2 premature) (8).

A 2004 case report described a 24-year-old woman who took sumatriptan (100 mg about once a week), naproxen (550 mg about twice a week), and bisoprolol (5 mg/day) for migraine headaches during the first 5 weeks of pregnancy (9). An elective cesarean section was performed at 37 weeks' for breech presentation to deliver a 3125-g male infant. The infant had a wide

bilateral cleft lip/palate, marked hypertelorism, a broad nose, and bilateral but asymmetric toe abnormalities (missing and hypoplastic phalanges) (9).

In an in vitro study, only high concentrations of sumatriptan were capable of increasing uterine contractions (10). The findings suggested that therapeutic concentrations of the drug would not induce preterm labor.

A second 2008 review of triptans in pregnancy concluded that sumatriptan appeared to be safe for use in the 1st trimester for the treatment of new-onset or worsened migraines (11). However, the data were insufficient to similarly classify other triptans.

Required statement (4): Sumatriptan: The number of exposed pregnancy outcomes accumulated to date represents a sample of insufficient size for reaching definitive conclusions regarding the possible teratogenic risk of sumatriptan. Specifically, the sample size to date remains too small for formal comparisons of the frequency of specific birth defects. If the baseline frequency of total birth defects is 3 in 100 live births, a sample size of 324 for 1st trimester exposure has an 80 percent chance (80% power) of correctly detecting at least a 1.9-fold increase from baseline in the frequency of birth defects. If the baseline frequency of specific birth defects is 1 in 1000 live births, a sample size of 324 for 1st trimester exposure has an 80 percent (80% power) of correctly detecting at least an 8.1-fold increase from baseline in the frequency of a specific birth defect.

Naratriptan: The data represent a sample of insufficient size for reaching definitive conclusions regarding the possible teratogenic risk of naratriptan. If the baseline frequency of total birth defects is 3 in 100 live births, a sample size of 31 for the 1st trimester exposure has an 80 percent chance (80% power) of correctly detecting at least a 4.6-fold increase from baseline in the frequency of total birth defects. If the baseline frequency for a specific birth defect is 1 in 1000 live births, a sample size of 31 for 1st trimester exposure has an 80 percent chance (80% power) of correctly detecting at least a 40.9-fold increase from baseline in the frequency of a specific birth defect.

The number of exposed pregnancy outcomes accumulated to date represents a sample of insufficient size for reaching definitive conclusions regarding the possible teratogenic risk of sumatriptan or naratriptan. It is expected that a teratogenic exposure in the 1st trimester would result in an increased frequency of one or a combination of individual defects or types of defects, but not necessarily in all defects.

As reporting of pregnancies to the Sumatriptan and Naratriptan Registry is voluntary, it is possible that even in prospectively reported pregnancies there could be bias in type of pregnancies reported. For example, differential reporting of low-risk or high-risk pregnancies may be a potential limitation to this type of registry. In addition, reporting of defects from maternal health care providers may limit detection of defects not immediately apparent at birth. Despite this, the Registry is intended both to supplement animal toxicology studies and other structured epidemiologic studies and clinical trial data, and to assist clinicians in weighing the risks and benefits of treatment for individual patients and circumstances.

BREASTFEEDING SUMMARY

Sumatriptan is excreted into human milk. Five women with a mean duration of lactation of 22.2 weeks (range 10.8–28.4 weeks) were administered a 6-mg SC dose of sumatriptan (12). Milk samples were obtained hourly for 8 hours by emptying both breasts of each subject with a breast pump. Frequent blood samples were also obtained from the women. The mean milk:plasma ratio was 4.9. The mean cumulative excretion of drug in milk during the 8-hour sampling

period was 12.6 mcg and, by extrapolation, a total recovery of only 14.4 mcg after a 6-mg dose. Using this latter value, the authors estimated that the mean weight-adjusted dose (mcg sumatriptan/kg of infant body weight as a percentage of the mother's dose in mcg/kg) for the infants would have been 3.5%. The investigators considered the risk to a nursing infant from this exposure to be not significant (12).

In adults, the mean oral bioavailability of sumatriptan is 14%–15% (range 10%–26%) (2,13), suggesting that absorption from the gastrointestinal tract is inhibited. Thus, although the oral absorption in infants may be markedly different from adults, the amount of sumatriptan reaching the systemic circulation of a breastfeeding infant is probably negligible. Discarding the milk for 8 hours after a dose, an interval during which about 88% of the amount excreted into milk can be recovered, would reduce even more the small amounts present in milk. The American Academy of Pediatrics classifies sumatriptan as compatible with breastfeeding (14).

SUNITINIB

Antineoplastic (Tyrosine Kinase Inhibitor)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of sunitinib in human pregnancy have been located. The animal reproduction data suggest risk, but the absence of human pregnancy experience prevents a more complete assessment. However, there are limited human pregnancy data for imatinib, a drug in the same subclass and with same mechanism of action as dasatinib. (See Imatinib.) Nevertheless, agents in this subclass inhibit angiogenesis, a critical component of embryonic and fetal development. Women of reproductive age should use effective contraception. However, gastrointestinal cancers can be fatal, so if a woman requires imatinib and informed consent is obtained, treatment should not be withheld because of pregnancy. If an inadvertent pregnancy occurs, the woman should be advised of the potential risk for severe adverse effects in the embryo and fetus.

FETAL RISK SUMMARY

Sunitinib is an oral tyrosine kinase inhibitor that inhibits tumor growth, pathologic angiogenesis, and metastatic progression of cancer. There are several other agents in this subclass (see Appendix). Sunitinib is indicated for the treatment of gastrointestinal stromal tumor after disease progression on or intolerance to imatinib. It is extensively metabolized by the liver. One of the metabolites is active and comprises 23%–37% of the total exposure. The terminal elimination half-lives of sunitinib and the active metabolite are 40–60 and 80–110 hours, respectively, whereas the binding to human plasma proteins is 95% and 90%, respectively. Elimination is primarily in the feces (1).

Reproduction studies have been conducted in rats and rabbits. In pregnant rats, doses producing systemic exposures that were about 5.5 times than the systemic exposure in humans from the recommended daily dose of 50 mg

based on AUC (SE-RDD) caused significant increases in the incidences of embryo death and structural anomalies (malformations of the ribs and vertebrae). The no-effect exposure in rats was 2.3 times the SE-RDD. In pregnant rabbits, an exposure about 2.7 times the SE-RDD caused a significant increase in embryo death and in cleft lips and palates. A lower exposure, about 0.3 times the SE-RDD, caused cleft lip only (1).

Studies for carcinogenicity have not been conducted with sunitinib. The drug did not cause genotoxicity in multiple tests. In a 3-month study in monkeys, with a dose producing systemic exposures that were about 5.1 times the SE-RDD, ovarian changes (decreased follicular development) were noted, while an exposure about 0.4 times the SE-RDD caused uterine changes (endometrial atrophy). When the study period was lengthened to 9 months, an exposure 0.8 times the SE-RDD caused vaginal atrophy, as well as the ovarian and uterine changes. A no-effect dose was not determined in the 3-month study but, in the 9-month study, it was about 0.2 times the SE-RDD. No effects on fertility were observed in male and female rats (1).

It is not known if sunitinib or its active metabolite crosses the human placenta. The molecular weight (about 399 for the free base) of the parent compound and the long elimination half-lives for sunitinib and the metabolite suggest that the agents will cross to the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use of sunitinib during human lactation have been located. The molecular weight (about 399 for the free base) of the parent compound and the long elimination half-lives for sunitinib and its active metabolite suggest that the agents will be excreted into breast milk. The risk to a nursing infant is unknown, but there is potential for severe toxicity affecting multiple systems.

T

TACROLIMUS

Immunologic Agent (Immunosuppressant)

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Tacrolimus has demonstrated abortifacient properties in three animal species and dose-related teratogenicity in one, but the use of this agent during human pregnancy has not been associated with either of these outcomes. The available human pregnancy experience continues to suggest that the embryo–fetal risk for congenital malformations is low. Common complications in infants, however, are hyperkalemia, which usually resolves untreated within 24–48 hours, renal toxicity, intrauterine growth restriction (IUGR), and premature delivery (because of hypertension, preeclampsia, and premature rupture of membranes). Based on one report, renal dysfunction is more common with cyclosporine than it is with tacrolimus. Moreover, IUGR and premature delivery are associated with the use of all immunosuppressant agents in pregnant transplant recipients. Because of the risk of cytomegalovirus infection in the mother and fetus, two reviews advised waiting at least 6 months before conception is attempted following transplantation and during periods of rejection when high doses of immunosuppressant agents may be used (i.e., the periods when infection with the virus is most likely) (1,2). Another report suggested waiting for 1 year to lower the risk of low birth weight and prematurity (3). Nevertheless, recent data suggest that the overall risk to the embryo–fetus is low. However, the long-term consequences of in utero exposure to tacrolimus, such as functional and/or neurobehavioral deficits, have not been studied.

FETAL FISK SUMMARY

Tacrolimus (FK506) is a macrolide immunosuppressant agent produced by *Streptomyces tsukubaensis* that acts similar to cyclosporine but is a more potent immunosuppressant. It is used either orally or IV for the prophylaxis of organ rejection in patients receiving various allogeneic organ transplants, such as kidney, liver, heart, and pancreas. The ointment is used for atopic dermatitis (4).

Reproduction studies have been reported in rats, rabbits, and mice (5,6). In pregnant rabbits, tacrolimus given in oral doses about 0.5–1 and 1.6–3.3 times the recommended human dose based on BSA (RHD) during organogenesis was associated with maternal toxicity and an increased incidence of abortions (5). At the higher dose, an increased incidence of malformations and developmental variations was also observed (type of defects was not specified). Pregnant rats dosed at 2.3–4.6 times the RHD exhibited maternal toxicity and an increase in late resorptions, decreased numbers of live births, and decreased pup weight and viability. Oral doses 0.7–1.4 and 2.3–4.6 times the RHD given after organogenesis and during lactation were associated with reduced pup weight (5).

Mice were treated with IM tacrolimus (0.17 or 1.37 mg/kg/day; relationship to human dose not specified), from day 1 through day 16 of gestation (6). No effects on maternal weight gain were observed in the low-dose group, but the number of resorptions was significantly increased over the number observed in controls. In contrast, none of the 13 pregnancies treated with high-dose tacrolimus was carried to term, and maternal weight gain was significantly less than that of controls. Except for the embryocidal action, low-dose tacrolimus, compared with untreated and saline controls, had no effect on mean placental or fetal weight and was not associated with an increase in malformations (6).

The molecular weight of tacrolimus (about 804) is low enough that the drug crosses the human placenta (5,7–9). In 12 pregnant women with liver transplants who were treated with tacrolimus (mean dose in 11 patients was about 10 mg/day; 1 patient treated with 48–64 mg/day), the mean cord:maternal plasma ratio was 0.49 (7). The placentas contained higher drug amounts (mean 4.30 ng/g) than that measured in maternal plasma (about 4 times) or cord plasma (2–56 times) and were thought to indicate a partial placental barrier to passage of the drug (7). A cord:maternal plasma ratio of 0.49 also was reported in another case (see below) (8). In two pregnancies (described below) under tacrolimus immunosuppression, the mothers were taking 15 and 10 mg/day, respectively (9). At delivery, umbilical cord blood

concentrations were 13.2 and 5.9 ng/mL, respectively, whereas the maternal venous blood concentrations were 11.8 and 31.2 ng/mL, respectively. The cord:maternal blood ratios were 1.12 and 0.19, respectively.

A number of reports have described the use of tacrolimus during human pregnancy. A 1993 letter reported a case of a woman with a liver transplant who was receiving tacrolimus (0.1 mg/kg/day with a target plasma level of <1.0 ng/mL) and who conceived about a year after her second transplant (8). At 28 weeks' gestation, a threatened acute graft rejection (tacrolimus plasma level <0.05 ng/mL) was successfully treated with bolus corticosteroids and an increase in the tacrolimus dose to 0.15 mg/kg/day. She delivered a healthy 2860-g male infant at 36 weeks' gestation that was doing well at 12 months of age. The tacrolimus cord blood and maternal plasma concentrations at birth were 0.24 and 0.49 ng/mL, respectively, a ratio of 0.49 (8).

A woman who had received a combined kidney and pancreaticoduodenal graft conceived while receiving tacrolimus (12 mg/day) and prednisolone (7.5 mg/day) (9). She also received furosemide and methyldopa for hypertension that was well controlled throughout gestation. Her pregnancy was complicated by hyperemesis gravidarum, septicemia (*Escherichia coli*), endocarditis, and esophagitis. At 38 weeks' gestation, she delivered a normal, 3410-g female infant with Apgar scores of 9 and 9 at 1 and 5 minutes, respectively. At delivery, the tacrolimus cord:maternal blood ratio was 1.12. In a second case, a woman conceived approximately 22 months after her second renal transplant. She received tacrolimus (10 mg/day), azathioprine (75 mg/day), and prednisolone (5 mg/day) for immunosuppression. Nifedipine and methyldopa were used to control her hypertension. Because of a possible placental abruption at 36 weeks' gestation, a normal 2400-g female infant was delivered by cesarean section. Her Apgar scores were 9 and 9 at 1 and 5 minutes, respectively. The tacrolimus cord:maternal blood ratio was 0.19. Both of the above infants were doing well at 3 months of age (9).

In a 1993 letter, the pregnancy outcomes of nine liver transplant recipients who had received tacrolimus (2–64 mg/day) immunosuppression throughout their gestation were detailed (10). Five of the women had also received corticosteroid therapy during pregnancy. None of the newborns was small for gestational age. Complications observed in the newborns included hyperkalemia in five (range 6.1–10.9 mEq/L; potassium levels measured in seven of the nine newborns), hypoxia in one who tested positive for cocaine (mother was taking cocaine), and anuria for 36 hours in one (thought to be secondary to high tacrolimus concentrations in the cord blood due to the

mother's renal impairment) who regained normal renal function in 1 week; death after delivery occurred in one at 22 weeks' gestation. In this latter case, the mother had conceived 1 month after transplantation and had cytomegalovirus in her blood and gastrointestinal tract that was being treated with ganciclovir. Of the eight surviving infants, all were alive and developing normally (10).

Some of the cases described in reference 10 above may have been included in a 1997 abstract that reported the outcomes of 14 pregnancies in 13 liver transplant recipients receiving various immunosuppressant agents, including tacrolimus (11). Although the agent used in each of the pregnancies was not specified, the complications included maternal renal insufficiency (N = 8), early hypertension (N = 5), preeclampsia (N = 4), worsening hypertension (N = 2), pyelonephritis (N = 2), anemia (N = 4), prolonged premature rupture of the membranes (N = 3), and cytomegalovirus infection (N = 3). The mean gestational age at delivery was 32.6 weeks, and the mean birth weight was 1913 g. Three newborns died; all three deaths were associated with cytomegalovirus infection and prematurity. No structural birth defects were mentioned (11).

A 1997 report detailed the outcomes of 27 pregnancies of 21 liver recipients who were treated with tacrolimus before and throughout gestation (7). The mean gestational age at delivery was 36.6 weeks, and the mean birth weight was 2638 g (50.2 percentile). Two infants died from prematurity after delivery at 23 and 24 weeks, respectively. The mean follow-up time of the infants was 39 months, and their mean growth weight percentile was 62. Unilateral nonfunctional cystic renal disease in one newborn was the only congenital anomaly observed in this series. In addition to the restricted growth and premature births in the total series, two other transient complications, noted among the first 13 infants born, were hyperkalemia in 10 and renal impairment in 7. Both adverse effects were thought to be caused by the drug (7).

Successful immunosuppression with tacrolimus following heart transplantation had been maintained for 2 years before conception occurred in a 39-year-old woman (12). She also took prophylactic trimethoprim–sulfamethoxazole before and throughout gestation, and her chronic hypertension was controlled with a long-acting calcium channel blocker (name not specified). Preeclampsia (rising blood pressure, proteinuria, and worsening renal impairment) was manifested between 26 and 31 weeks' gestation. An apparently normal, 2093-g female infant, who had Apgar scores of 9 and 9 at 1 and 5 minutes, respectively, was delivered by cesarean section at 33 weeks (12).

A 26-year-old renal transplant recipient was treated with tacrolimus (10

mg/day) and prednisolone (10 mg/day) throughout a 33.5-week pregnancy (13). Conception had occurred about 25 months after transplantation. The target blood concentration was 10 ng/mL. Symmetrical IUGR was discovered after 20 weeks' gestation. Because of spontaneous rupture of the membranes and breech presentation, a 1312-g female infant was delivered by cesarean section. A physical and ultrasonic examination found no congenital malformations. Complications other than IUGR noted in the newborn included mild hyperkalemia and a prolonged course of hyperbilirubinemia. Although not stated, the latter complication may have been secondary to prematurity (13).

A 1998 case report described the course and outcome of a pregnancy in a 32-year-old woman after renal transplantation (14). Tacrolimus, with a target plasma level of 5.0–11.5 ng/mL, was used alone throughout gestation after discontinuance of prednisolone (5 mg/day) early in gestation. Hypertension developed in the 22nd week of gestation which was treated with isradipine. A cesarean section was performed at 31 weeks' gestation because of severe hypertension, a progressive decline in graft function, and an abnormal Doppler assessment of blood velocity in the umbilical artery. No congenital malformations were noted in the 1140-g (3rd percentile) male infant who had Apgar scores of 8, 9, and 9 at 1, 5, and 10 minutes, respectively. The tacrolimus concentration in the umbilical vein was 8.1 ng/mL (maternal level at the time of delivery was not reported). At 2 days of age, the plasma drug level had decreased to 6.4 ng/mL, and at 8 days, the level was <5.0 ng/mL. Complications in the infant included mild hyperkalemia (6.4 mmol/L) on the 2nd day and transient renal impairment (serum creatinine 3.0 mg/dL at birth) that resolved completely over the next few weeks. A renal ultrasound examination was normal. Respiratory distress syndrome and a patent ductus arteriosus were successfully treated, and at a corrected age of 4 months, the healthy infant was developing normally (14).

A 1998 study examined the relationship between antenatal complications and various maternal factors in women who had undergone orthotopic liver transplantation (15). Of the 14 pregnancies studied, tacrolimus had been used in 5 (combined with prednisone in 3; with azathioprine and prednisone in 1), cyclosporine in 8 (combined with prednisone in 6; with azathioprine and prednisone in 2), and prednisone only in 1. Three of the complications—preeclampsia, worsening hypertension, and small for gestational age—occurred only in women with renal dysfunction (creatinine ≥ 1.3 mg/dL) at conception. Cyclosporine was more commonly associated ($p = 0.03$) with renal dysfunction than was tacrolimus (15).

A review of pregnancy outcomes after renal transplant was published in 1998 (16). The liveborn incidence among seven cases treated with tacrolimus was 71% (16).

In a 1998 report from the National Transplantation Pregnancy Registry (NTPR), the pregnancy outcomes of six women who were recipients of a lung transplant were described, one of whom was treated with tacrolimus (13–15 mg/day) throughout gestation (17). Her pregnancy was complicated by preterm labor at 24 weeks' gestation and a 1616-g infant (sex not specified) was delivered by cesarean section at 30 weeks'. The infant was successfully treated for respiratory distress syndrome and was healthy and doing well at 15 months of age (17). An updated report from the NTPR was published in 2005 (18). A total of 18 pregnancy outcomes were described from women who were recipients of kidney, liver, or heart transplants. In addition, two 2008 references (19,20) described the pregnancy outcomes of transplant recipients receiving tacrolimus in combination with mycophenolate (see Mycophenolate for details, in references 18–20).

In a 1999 case report, a woman who had a renal transplant was treated throughout gestation with tacrolimus (10–12 mg/day), prednisone, amlodipine, and labetalol (21). Azathioprine was also used during the first 10 weeks. At 32 weeks' gestation, she delivered twin male infants who developed severe respiratory distress syndrome and congestive heart failure. Echocardiograms showed dilated heart chambers in both infants and only twin B survived. Autopsy of twin A revealed thrombotic cardiomyopathy with degeneration of cardiac muscle. Because animal studies had shown that tacrolimus could cause vasculitis in the cardiac muscle of baboons and dogs, the authors concluded that the cardiomyopathy seen in the twins might have been caused by tacrolimus (21).

A 2000 reference described the outcomes of 100 pregnancies in 84 women who were receiving tacrolimus for autoimmune disease (Behcet's disease) (N = 1) or solid organ transplants (liver [N = 55], kidney [N = 22], heart [N = 3], kidney–pancreas [N = 1], pancreas [N = 1], and lung [N = 1]) (22). During pregnancy, the mean daily tacrolimus dose was 12.1–12.8 mg/day (range 1.0–64 mg/day). The outcomes of the pregnancies were 70 live births (2 neonates died in the perinatal period), 12 spontaneous abortions (SABs), 12 elective abortions (EABs), 1 stillbirth, 2 pregnancies ongoing, and 3 lost to follow-up. Gestational age at birth was known in 63 neonates, 37 (59%) of whom were premature. The birth weight was known in 64 cases with a mean weight of 2573 g (range 886–4346 g). The weight was appropriate for gestational age in

58 cases (90%). There were no malformations observed in the 24 aborted fetuses. However, four of the live births, all exposed to tacrolimus throughout the 1st trimester, had structural anomalies, one of which was alcoholic embryopathy. There was no pattern among the remaining three anomalies that suggested a single cause. The defects were meningocele, urogenital defects, and umbilical hernia; ear defect, cleft palate, and hypospadias; and multicystic dysplastic kidney and dimple without areola. The most common complications in the infants at birth were hypoxia, hyperkalemia, and renal dysfunction (22).

Two case reports, one in 2001 and the other in 2004, detailed the use of tacrolimus and mycophenolate during pregnancies that involved adverse outcomes (see Mycophenolate). A 2003 retrospective review detailed the outcomes of 38 pregnancies in 29 women who had undergone liver transplantation before pregnancy (23). Sixteen pregnancies (nine live births, seven elective abortions) had been exposed to tacrolimus combined with other agents. There were no fetal or neonatal deaths. Two tacrolimus-exposed infants had small membranous ventricular septal defects (23).

Another 2003 report described the pregnancy outcomes of 37 women, all after liver transplantation, who delivered 49 infants (all single gestations) (24). All mothers were treated with tacrolimus that was, in some cases, combined with other agents. In 47 infants, the mean gestational age was 36.4 weeks, but 2 infants were born at 23 and 24 weeks' gestation, respectively. Both of the very premature infants died, as did one infant from a mother with Alagille syndrome. The latter infant had a tracheoesophageal fistula and valvular heart disease. One of the surviving infants had a nonfunctional unilateral cystic kidney. The mean birth weight was 2797 g, with 78% of the infants weighing more than 2000 g (24).

The pregnancies of 38 renal allograft recipients were reported in a 2003 study (25). Four of the patients were treated with tacrolimus in combination with other agents. The outcomes of 73 pregnancies (48 live births) in the group were compared with 59 pregnancies (41 women; 48 live births) with primary renal disease not treated with immunosuppressive drugs. The study group had significantly more preterm deliveries, infants with intrauterine growth restriction, and infants requiring hospitalization in neonatal intensive care units. However, there was no statistical difference in the incidence of major (4.2% vs. 4.2%) and minor malformations (20.8% vs. 16.6%) (25).

In a 2004 report, the pregnancy outcomes of 13 mothers (19 babies) after kidney transplantation and 2 mothers (3 babies) after kidney–pancreas implantation, all under tacrolimus immunosuppression, were described (26).

One mother had a stillborn secondary to amniotic fluid leak and a small, ischemic placenta. The mean gestational age of the infants and their birth weight were 34.4 weeks and 2373 g, respectively. No congenital defects were detected (26).

A brief 2005 communication reported 16 women with 19 pregnancies after renal transplantation under tacrolimus (27). Appropriate birth weights and no malformations were observed in 10 successful pregnancies. The outcomes of the other nine cases were four SABs and five (EABs) (27).

There were 71 pregnancies among 45 women with liver transplantation in a 2006 report (3). Tacrolimus and cyclosporine were used in 42 and 29 of the pregnancies, respectively. The outcomes of the pregnancies were live births (29 vs. 21), SABs (7 vs. 6), EABs (5 vs. 1), molar pregnancy (1 vs. 0), and intrauterine death (0 vs. 1) (all ns). The median gestational age and birth weight were 37.5 vs. 37 weeks and 2660 vs. 2951 g, respectively (all ns). Pregnancies occurring within 1 year of transplantation had the highest incidence of prematurity and lowest birth weight. No congenital anomalies were observed (3).

Four successful pregnancies under tacrolimus in women with liver transplants were described in 2006 (28). The mean gestational age and birth weight were 34.4 weeks and 2302 g, respectively. No birth defects were detected in the infants.

A 2005 case report described the use of tacrolimus throughout pregnancy in a woman with refractory ulcerative colitis (29). She delivered a healthy 3500-g, height 51 cm, baby girl at 40 weeks' gestation with Apgar scores of 9, 10, and 10.

A 2007 short communication described the pregnancy outcome of a 35-year-old woman treated with tacrolimus after a liver transplant (30). The woman conceived 5 years after the transplant and remained on tacrolimus throughout the pregnancy. Except for hypertension (treated with methyldopa) and suspected chorioamnionitis, the pregnancy was uncomplicated. A cesarean section in the 38th week delivered a healthy 2780-g female infant. No additional information on the infant was provided (30).

Another 2007 reference described the outcomes of 16 pregnancies in renal transplant recipients that were exposed to tacrolimus combined with other immunosuppressive agents (13 with azathioprine and prednisone, 1 with azathioprine, and 2 with prednisone) (31). An additional 33 pregnancies (all in women after renal transplants) were treated with cyclosporine with azathioprine and/or prednisone and 3 pregnancies were treated with azathioprine and

prednisone alone. The mean patient age was 26.5 years (range 17–38 years). In the 52 pregnancies, preterm delivery occurred in 20 (38%) and fetal growth restriction in 16 (31%) (outcomes by specific drug exposure not provided). There was one fetal death due to extreme prematurity (26 weeks'). No congenital malformations in the offspring were observed (31).

In a 2007 case report, a 28-year-old woman became pregnant while taking tacrolimus (5 mg/day) and prednisolone (15 mg/day), 1.5 years after her second renal transplant (32). The pregnancy was uneventful and she gave birth vaginally to a healthy 3535-g male infant at term with Apgar scores of 9 and 10.

A 2012 case report described the use of tacrolimus (12 mg/day) throughout pregnancy in a woman with an intestinal transplant (33). Other medications used were prednisone (5 mg/day), esomeprazole (40 mg/day), diphenoxylate-atropine (2 tablets/day), tacrolimus (12 mg/day), ferrous sulfate (650 mg/day), ascorbic acid (1 g/day), prenatal vitamins (1/day), and magnesium supplementation. At 39 3/7 weeks, labor was induced and she had a spontaneous vaginal delivery of a healthy female infant (33).

BREASTFEEDING SUMMARY

Tacrolimus is excreted into breast milk. Ten colostrum samples were obtained from six women in the immediate postpartum period (0–3 days) with a mean drug concentration of 0.79 ng/mL (range 0.3–1.9 ng/mL) (7). The median milk:maternal plasma ratio was 0.5. The authors of this study did not mention if the women breastfed their infants.

In a 2003 report, a mother who had taken tacrolimus (0.1 mg/kg/day) throughout pregnancy because of liver transplantation continued the drug while breastfeeding her infant (34). From manually expressed samples, the highest and mean drug concentrations were 0.57 and 0.429 ng/mL, respectively. The milk:blood ratios before a dose and 1-hour postdose were 0.08 and 0.9, respectively. The estimated half-life, calculated on limited data, in milk was 12.85 hours. The estimated maximum dose the infant would absorb was 0.02% of the mother's weight-adjusted dose. The infant was developing normally at 2.5 months of age (34).

In a second case, a mother with a renal transplant was taking tacrolimus (4 mg/day) while exclusively breastfeeding her 3-month-old infant (35). The milk:blood ratio was 0.23, whereas the average tacrolimus milk concentration was 1.8 mcg/L (1.8 ng/mL). The estimated infant dose was 0.5% of the mother's weight-adjusted dose (35).

In a case described above, a mother took tacrolimus throughout pregnancy and continued the drug while breastfeeding her infant (33). The infant's tacrolimus level was <1.0 ng/mL at 1 week of age.

The absolute oral bioavailability of tacrolimus in healthy adults is 18%, but food, especially fat, markedly decreases the bioavailability (5). Based on the two cases above, breastfeeding during tacrolimus therapy does not appear to represent a significant risk to the infant. However, monitoring infant plasma levels is an option.

TAFLUPROST

Ophthalmic (Prostaglandin Agonist)

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of tafluprost in human pregnancy have been located. The animal data suggest moderate risk, but the amount appearing in the systemic circulation is very low. Moreover, the elimination half-life from plasma appears to be very fast. Although the absence of human pregnancy experience prevents a more complete assessment of embryo–fetal risk, the risk of harm appears to be low. Nevertheless, because the drug will be given daily for long periods, it may be best to use other antiglaucoma agents that have some human data (e.g., Latanoprost).

FETAL RISK SUMMARY

Tafluprost, a fluorinated analog of prostaglandin F_{2α}, is available as a 0.0015% ophthalmic solution that is given as single drop in the conjunctival sac of the affected eye(s) once daily. It is in the same class of prostaglandin agonists as bimatoprost, latanoprost, and travoprost. Tafluprost is indicated for reducing elevated intraocular pressure in patients with open-angle glaucoma or ocular hypertension. It is hydrolyzed within the eye to an active metabolite, tafluprost acid, that undergoes further metabolism to inactive metabolites. Very small amounts of tafluprost acid are absorbed into the systemic circulation. At a median 10 minutes postinstillation in each eye of healthy adults, mean plasma concentrations were 26–27 pg/mL. At 30 minutes postinstillation, mean plasma concentrations were below the limit of quantification (10 pg/mL) (1). This suggests an elimination half-life of about <17 minutes.

Reproduction studies have been conducted in rats and rabbits. When IV doses of tafluprost were given, increased postimplantation losses were observed in rats and rabbits and reduced fetal body weights in rats. The drug

also increased the incidence of vertebral skeletal defects in rats. In rats, the no-effect dose corresponded to maternal plasma levels of tafluprost acid that were 343 times the maximum clinical exposure based on the maximum plasma concentration (C_{max}). In a prenatal and postnatal study in rats, increased mortality of newborns, decreased body weights, and delayed pinna unfolding were noted in offspring. The no observed adverse effect level for these effects was at a tafluprost IV dose that was >3 times the maximum recommended clinical dose based on BSA. In rabbits, an increased incidence of skull, brain, and spine malformations was observed at maternal plasma levels of tafluprost acid during organogenesis that were about 5 times higher than the clinical exposure based on C_{max} . At the no-effect dose in rabbits, maternal plasma levels of tafluprost acid were below the level of quantification (20 pg/mL) (1).

In long-term studies, tafluprost was not carcinogenic in mice and rats, nor was it mutagenic or clastogenic in multiple assays. No adverse effects on mating performance or fertility were observed in given high IV doses of the drug (1).

It is not known if tafluprost acid crosses the human placenta. The molecular weight (about 453) is low enough, but the very small plasma concentrations of the drug are below the limit of quantification (10 pg/mL) 30 minutes postinstillation.

Prostaglandin F_{2α} has been used for pregnancy termination in humans via intrauterine extra-amniotic infusion to treat missed abortion or intrauterine death. However, there is no evidence that at doses given to reduce elevated ophthalmic pressure, an increased risk for uterine contractions would be seen (see Latanoprost).

BREASTFEEDING SUMMARY

No reports describing the use of tafluprost during human lactation have been located. The molecular weight (about 453) is low enough for excretion, but the very small plasma concentrations (26–27 pg/mL) of the drug are below the limit of quantification (10 pg/mL) 30 minutes postinstillation. It is unlikely that these brief concentrations would have any effect on a nursing infant.

TALIGLUCERASE ALFA

Endocrine/Metabolic Agent (Gaucher Disease)

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of taliglucerase alfa in human pregnancy have been located. The animal data suggest low risk, but the absence of human pregnancy experience prevents a more complete assessment of embryo–fetal risk. Although pregnancy may exacerbate existing Gaucher disease or result in new disease manifestations, the data for other agents in this subclass (e.g., see Imiglucerase) suggest that treatment may reduce the risk of spontaneous abortion and bleeding complications. If indicated, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Taliglucerase alfa, given as an IV infusion, is a recombinant active form of the lysosomal enzyme, β -glucocerebrosidase, that differs from the human enzyme by nine amino acids. It is a hydrolytic lysosomal glucocerebroside-specific enzyme produced by recombinant DNA technology using plant cell culture (carrot). Taliglucerase alfa is indicated for long-term enzyme replacement therapy for patients with a confirmed diagnosis of type 1 Gaucher disease. It is in the same pharmacologic subclass as alglucerase, imiglucerase, and velaglucerase alfa. The median terminal half-life is about 19–29 minutes (1).

Reproduction studies have been conducted in rats and rabbits. In these species, an IV dose that was about 5 times the recommended human dose of 60 units/kg based on BSA (RHD) in both species revealed no evidence of impaired fertility or fetal harm (1).

Studies to evaluate carcinogenic or mutagenic potential have not been conducted. In male and female rats, doses that were about 5 times the RHD did not cause any significant adverse effects on fertility parameters (1).

It is not known if taliglucerase alfa, a glycoprotein, crosses the human placenta. The high molecular weight (56,640) and short terminal half-life suggest that it will not cross to the embryo–fetus, at least early in pregnancy.

BREASTFEEDING SUMMARY

No reports describing the use of taliglucerase alfa during human lactation have been located. The molecular weight (56,640) and the short terminal half-life (19–29 minutes) suggest that clinically significant amounts of the drug will not be excreted into breast milk. In addition, there are limited data for two other agents in this class that support the use of the drug during breastfeeding (see Alglucerase and Imiglucerase). Moreover, if excretion does occur, the drug would most likely be digested in the infant’s gut and not absorbed systemically.

TAMOXIFEN

Antineoplastic/Antiestrogen

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Tamoxifen is an antiestrogen that has weak estrogenic activity in some tissues. Although tamoxifen is not considered an animal teratogen, it is carcinogenic in rodents and has been associated with intrauterine growth restriction, abortions, and premature delivery in some species. Uterine cancer has been reported in human adults treated with tamoxifen. Moreover, tamoxifen has produced toxic changes in the reproductive tracts of animals. Some of these changes were similar to those observed in humans exposed in utero to diethylstilbestrol (DES), but the risk of tamoxifen-induced clear cell adenocarcinoma of the vagina or cervix in exposed offspring is unknown because too few humans have been exposed during pregnancy or followed up long enough. Two adverse outcomes following inadvertent exposure to tamoxifen during gestation have been described. The relationship between tamoxifen and Goldenhar's syndrome in the first case is unknown, but, in the second case, a causal association between the drug and the ambiguous genitalia noted in the female infant appears to be more certain. In addition, several fetal and neonatal disorders and defects have been reported to the manufacturer, but it is not known whether this is the result of retrospective reporting. Because of the various toxicities noted in animals, the increased incidence of abortions noted in some patients when the drug was used for ovulation induction, and the possible human teratogenicity, the best course is to avoid use of tamoxifen during pregnancy. Moreover, because both the parent compound and the major metabolite have prolonged half-lives that may require ≤ 8 weeks to eliminate, women of childbearing age should be informed that a pregnancy occurring within 2 months of tamoxifen therapy may expose the embryo and/or fetus to the drug. If an inadvertent pregnancy does occur, the potential fetal and newborn risks must be discussed with the patient. Offspring who have been exposed to tamoxifen during pregnancy require

long-term (≤ 20 years) follow-up to assess the risk of carcinogenicity.

FETAL RISK SUMMARY

Tamoxifen, a triphenylethylene derivative that is structurally related to clomiphene, is a nonsteroidal, antiestrogen agent used in the treatment of breast cancer (1,2). In addition to its antiestrogen properties, it may also produce weak estrogenic and estrogenic-like activity at some sites. Unlabeled uses have included induction of ovulation and treatment of idiopathic oligospermia. Tamoxifen is thought to act by competing with estrogen for binding sites in target tissues (2). The parent drug has an elimination half-life of about 5–7 days (range 3–21 days) (1,2), whereas the elimination half-life of the major metabolite, N-desmethyltamoxifen, is approximately 9–14 days (1). Following prolonged treatment (e.g., 2–3 months), clearance of tamoxifen and its metabolites from the system may require 6–8 weeks (3).

Tamoxifen is carcinogenic, producing ovarian and testicular tumors in immature and mature mice and hepatocellular carcinoma in rats, at all doses tested (5, 20, and 35 mg/kg/day for up to 2 years) (2). The drug is also genotoxic in rat liver cells and in the human lymphoblastoid cell line. Tamoxifen, at a dose of 0.04 mg/kg/day (approximately 1/10th the human dose) for 2 weeks before conception through day 7 of pregnancy, impaired the fertility of female rats causing a decreased number of implantations and 100% fetal mortality (2).

In reproductive studies reported by the manufacturer, no teratogenicity was observed with rats, rabbits, and marmosets, but fetal toxicity was common (2). In rats, however, reversible, nonteratogenic developmental skeletal changes were observed at doses equal to or below the human dose (2). An increased fetal death rate occurred in pregnant rats when tamoxifen (0.16 mg/kg/day; human dose about 0.4–0.8 mg/kg/day) was administered from day 7 to day 17 (2). When this dose was given from day 17 of pregnancy to 1 day before weaning, an increased number of dead pups were noted and some of the surviving pups demonstrated slower learning behavior. Moreover, in utero growth restriction was evident in some of the pups (2). Tamoxifen (0.125 mg/kg/day) administered to pregnant rabbits during days 6 through 18 of pregnancy caused abortions and premature delivery (2). Higher doses produced fetal deaths. Abortions were observed in pregnant marmosets given 10 mg/kg/day either during organogenesis or in the last half of pregnancy (2).

A 1976 study administered oral tamoxifen (2 mg/kg/day) to rabbits starting at

either day 10 or day 20 of pregnancy (4). A significant increase in embryonic loss occurred in the first group, whereas treatment later in gestation resulted in premature delivery or abortion.

Several studies have described the effectiveness of tamoxifen as a postcoital contraceptive in animals (5–11). The action of tamoxifen as an antifertility agent appears to be a dose-related, antiestrogen effect that prevents implantation in the uterus. In one report, however, a single 5-mg/kg dose on day 4 after ovulation in macaques had no effect on fertility (12). No reports describing the use of tamoxifen as a contraceptive in humans have been located.

In rats and guinea pigs, tamoxifen produced significant, dose-related changes in the reproductive tract of the fetus and newborn (13–17). These changes, most pronounced in the guinea pig, involved trophic effects on the uterus and vagina similar to those produced by estrogens. Abnormalities in sexual differentiation of female offspring of guinea pigs have also been observed (18).

In a study published in 1987, the estrogenicity and potential teratogenicity of tamoxifen were demonstrated in genital tracts isolated from aborted 4- to 19-week-old human female fetuses grown for 1–2 months in mice (19). Some mice were used as controls, and others were treated with tamoxifen, clomiphene, or DES. In comparison with controls, abnormalities observed in the drug-treated mice included proliferation and maturation of the squamous vaginal epithelium; a decrease in the number of endometrial and cervical glands; impaired condensation and segregation of the uterine mesenchyme; and hyperplastic, disorganized epithelium and distorted mucosal plications in the fallopian tube. The abnormalities induced by tamoxifen and clomiphene were, in most instances, comparable to those of DES (19). A study published in 1979 examined the effects of tamoxifen administration on newborn female rats (5 mcg on days 1, 3, and 5), observing several abnormalities of reproductive development, including early vaginal opening, absence of cycles, atrophic ovaries and uteri, vaginal adenosis, and severe squamous metaplasia of the oviducts (20). Gonad and genitourinary tract abnormalities, including uterine hypoplasia and vaginal adenosis, were also observed in newborn female mice given tamoxifen for 5 days (21). A 1997 report compared the uterotrophic effects of tamoxifen (100 mcg), DES (1 mcg), or placebo administered SC daily to newborn female rat pups for 5 days (22). At postnatal day 6, both tamoxifen and DES produced significant epithelial hypertrophy and myometrial thickening, as well as other uterine changes that led the investigators to conclude that tamoxifen's estrogenic action on the developing uterus was

similar to that produced by DES (22).

The clinical significance of the above studies demonstrating developmental changes in animals, three of which involved neonatal exposure to tamoxifen, is presently unknown, but some of the alterations observed in experiments, especially vaginal adenosis, are similar to those observed in young women following in utero exposure to DES (2). Moreover, too few women have been exposed in utero to tamoxifen and followed sufficiently long (≤ 20 years) to determine whether the drug presents a risk of clear-cell adenocarcinoma of the vagina or cervix similar to DES (about 1 in 1000) (2) (see also Diethylstilbestrol). It should also be noted that long-term exposure of nonpregnant, adult humans to tamoxifen has been associated with an increased incidence of endometrial cancer (2).

Data pertaining to human fetal exposure to tamoxifen are limited. A 1993 letter cited a statement made by tamoxifen researchers that 85 women had become pregnant while receiving the drug and that no fetal abnormalities had been reported (23). A 1994 letter, however, citing data (oral and written) reported to the manufacturer, described the outcomes of 50 pregnancies associated with tamoxifen therapy (24). Of the total, there were 19 normal births, 8 elective abortions, 10 with a fetal or neonatal disorder (2 of which were congenital craniofacial defects), and 13 unknown outcomes. Although the number of adverse outcomes is suggestive of human teratogenicity, no mention was made whether the above cases represented prospective or retrospective reporting. The latter type frequently involves biased reporting in that adverse outcomes are much more likely to be communicated. Also included in this letter was the description of a case in which a 35-year-old woman, following breast cancer surgery, took tamoxifen (20 mg/day) throughout an approximately 27-week pregnancy (24). Because of premature labor, chorioamnionitis, and an abnormal lie, a cesarean section was performed to deliver an 896-g, karyotypically normal infant (sex not specified). Malformations noted in the infant, consistent with a diagnosis of Goldenhar's syndrome, included right-sided microtia, preauricular skin tags, and hemifacial microsomia (24). Other exposures, in addition to tamoxifen, were cocaine and marijuana smoking (1 or 2 times/week) during the first 6 weeks of gestation and a bone scan performed using technetium-99m medronate. The causal relationship between tamoxifen and the defects in the infant was unknown (24), but in some reports of familial cases, the patterns of inheritance of Goldenhar's syndrome (oculoauriculovertebral anomaly) have been described as consistent with an autosomal dominant, autosomal recessive, and multifactorial inheritance (25).

Ambiguous genitalia in a female newborn exposed in utero to tamoxifen during the first 20 weeks of pregnancy was reported in 1997 (26). The 35-year-old mother had been treated with tamoxifen (20 mg daily) for about 1 year for metastatic breast cancer. Because of the mother's deteriorating condition, the normal 46,XX karyotype, 1360-g infant was delivered at 29 weeks' gestation. Reproductive malformations included an enlarged, phallic-like clitoris (1.4 × 0.6 cm), a single perineal opening for the urethra and vagina, and fusion of the posterior portion of the rugated labioscrotal folds without palpable glands. An ultrasound examination revealed a normal uterus and ovaries without identifiable male structures. Congenital adrenal hyperplasia was excluded and a serum testosterone level was normal for a female infant. At 6 months of age, a reduction phalloplasty and vaginal reconstruction were performed without complications (26).

Two reports have described three successful pregnancies following chemotherapy with tamoxifen (27,28). In one of two cases described in a 1986 reference, a 26-year-old woman with a pituitary microadenoma and primary infertility was successfully treated with tamoxifen (20 mg/day) and bromocriptine (10 mg/day) (27). Combination therapy was used because she could not tolerate high-dose bromocriptine monotherapy. She ovulated and conceived approximately 7.5 months after combination therapy was begun. Tamoxifen was discontinued when pregnancy was confirmed (exact timing not specified), but bromocriptine was continued until 8 weeks' gestation. She delivered a normal 3240-g female infant at term. In the second case, a 25-year-old woman with a pituitary macroadenoma and primary infertility was treated for about 3 months with the same combination therapy as in the first case, again because of intolerance to monotherapy (27). Combination therapy was stopped when pregnancy was confirmed (exact timing not specified) and she delivered a normal 2600-g female infant at 37 weeks' gestation. The third pregnancy involved a 31-year-old woman with a diagnosis of well-differentiated adenocarcinoma of the endometrium who elected to receive 6 months of hormonal therapy with tamoxifen (30 mg/day) and megestrol acetate (160 mg/day) combined with repeated hysteroscopy and uterine curettage rather than undergo a hysterectomy (28). She was then placed on combination oral contraceptives for 3 months and conceived 1 month after they were discontinued. She eventually delivered a normal 3340-g male infant at term. In addition, two case reports have described the use of tamoxifen in combination with trastuzumab in pregnant women with breast cancer (see Trastuzumab).

Several studies have examined the efficacy of tamoxifen, often in direct

comparison with clomiphene, for ovulation induction in infertile women (29–35). Although no fetal anomalies were reported in these pregnancies following tamoxifen induction, a higher than expected occurrence of spontaneous abortion was noted in two studies (29,33). In contrast to clomiphene, however, tamoxifen induction did not appear to increase the frequency of multiple gestations (34).

In males, tamoxifen, like clomiphene, has been used for the treatment of idiopathic oligospermia (36–41). Tamoxifen appears to improve sperm density and the number of live spermatozoa, but conflicting results have been reported concerning the effect on sperm motility or morphology (37,40,41). A 1987 review, moreover, concluded that there was no convincing evidence that tamoxifen was effective in increasing the conception rate (41).

BREASTFEEDING SUMMARY

Tamoxifen has been shown to inhibit lactation (42,43). In a double-blind, placebo-controlled trial, tamoxifen started within 2 hours after delivery was effective in preventing milk secretion and breast engorgement (42). Two treatment courses were studied: 30 mg twice daily for 2 days, then 20 mg twice daily for 2 days, then 10 mg twice daily for 2 days (N = 50); and 10 mg twice daily for 14 days (N = 42). Two groups of control patients (N = 25 and N = 23) received similar placebo tablets. The 6-day treatment course was “superior” (statistical analysis was not done) to the 14-day treatment course with 43 (86%) vs. 31 (74%) of the women having a “good” response (i.e., either no milk in their breasts or only slight to moderate milk secretion) (42). Only six (13%) of the control patients had a “good” response. No adverse effects or rebound engorgement were observed in the women who had received tamoxifen.

In a second, placebo-controlled, single-blinded study, tamoxifen (N = 60, 10 mg 4 times daily) or placebo (N = 20) was started within 24 hours of delivery and continued for 5 days (43). Breast stimulation using a mechanical breast pump was used before the first dose, and then on days 3 and 5, followed by blood sampling for serum prolactin. By the 5th day, a significant decrease (compared with baseline) in serum prolactin concentration occurred in the tamoxifen group, but not in controls. Moreover, tamoxifen was effective in inhibiting lactation and preventing breast engorgement, and no rebound lactation was observed (43).

Because tamoxifen inhibits lactation and because of the adverse effects noted in newborn animals and human adults (see Fetal Risk Summary above)

given the drug directly, the drug is contraindicated during nursing.

TAMSULOSIN

Sympatholytic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of tamsulosin in human pregnancy have been located. The animal data suggest low risk, but the absence of human pregnancy experience prevents a more complete assessment of the embryo–fetal risk. Until such data are available, the safest course is to avoid use in pregnancy.

FETAL RISK SUMMARY

Tamsulosin is an antagonist of α_{1A} -adrenoceptors in the prostate. It is available as oral capsules and is indicated for the treatment of the signs and symptoms of benign prostatic hyperplasia (1). The drug is used off-label as adjunctive therapy in the management of ureteral stones (2,3). Tamsulosin is extensively metabolized and has an elimination half-life in the range of 9–15 hours. Plasma protein binding is 94%–99%, primarily to α_1 -acid glycoprotein (1).

Reproduction studies have been conducted in rats and rabbits. In pregnant rats, doses up to about 50 times the human therapeutic AUC exposure revealed no evidence of fetal harm. Similar results were observed in pregnant rabbits (1).

In carcinogenicity studies with male and female rats, no increase in tumor incidence was noted with the exception of a modest increase in the frequency of mammary gland fibroadenomas in female rats. In mice, there were no significant findings in males, but females had significant increases in the incidence of mammary gland fibroadenomas and adenocarcinomas. In both rats and mice, the increased incidences of mammary gland neoplasms were considered secondary to drug-induced hyperprolactinemia. Tamsulosin was not mutagenic in multiple assays. High doses of the drug resulted in reversible male

and female rat infertility (1).

It is not known if tamsulosin crosses the human placenta. The molecular weight (about 445) and moderately long elimination half-life suggest that the drug will cross to the embryo and/or fetus, but the extensive plasma protein binding should limit the amount crossing the placenta.

BREASTFEEDING SUMMARY

No reports describing the use of tamsulosin during human lactation have been located. The molecular weight (about 445) and moderately long elimination half-life (9–15 hours) suggest that the drug will be excreted into breast milk, but the extensive plasma protein binding (94%–99%) should limit the amount excreted. However, because antiadrenergic agents can cause hypotension, the safest course is to not breastfeed.

TAPENTADOL

Narcotic Agonist Analgesic

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of tapentadol in human pregnancy have been located. The drug caused significant embryo–fetal developmental toxicity in two animal species but always in the presence of maternal toxicity. In general, occasional use of narcotic agonist analgesics in pregnancy is considered low risk. However, tapentadol, as with other agents in this class, has the potential for abuse and such use could cause embryo–fetal harm. Respiratory depression of the newborn is a potential complication if the drug is used close to birth. A narcotic antagonist, such as naloxone, should be readily available to reverse neonatal respiratory depression if present.

FETAL RISK SUMMARY

Tapentadol is an oral centrally acting synthetic analgesic. It is indicated for the relief of moderate to severe acute pain in patients 18 years of age or older. Similar to other mu-opioid agonists, tapentadol has addictive properties and may be sought by drug abusers. The drug is extensively metabolized to inactive metabolites. Plasma protein binding is low (about 20%), whereas the average terminal half-life is 4 hours (1).

Reproduction studies have been conducted in rats and rabbits. No teratogenic effects were observed during organogenesis in rats given SC doses resulting in plasma exposures up to the plasma exposure at the maximum recommended human dose of 700 mg/day based on AUC (MRHD). The highest dose caused significant maternal toxicity and was associated with embryo–fetal toxicity that included transient delays in skeletal maturation (i.e., reduced ossification). Exposures up to 1.7 times the MRHD during late

gestation and early postnatal period did not influence physical or reflex development, the outcome of neurobehavioral tests or reproductive parameters. However, at maternal toxic exposures, treatment-related developmental delay was observed, including incomplete ossification, significant reductions in pup body weights and weight gains, and increased pup mortality (1).

During organogenesis, rabbits received SC doses resulting in plasma exposures that were 0.2–1.85 times the MRHD. At exposures ≥ 0.6 times the MRHD, embryo–fetal toxicity was observed that consisted of reduced fetal viability, skeletal delays and other variations, and multiple malformations (gastroschisis/thoracogastroschisis, amelia/phocomelia, and cleft palate). Malformations observed at exposures that were 1.85 times the MRHD were ablepharia, encephalopathy, and spina bifida. However, the exposures caused significant maternal toxicity and this may have caused the embryo–fetal toxicities, including malformations (1).

In 2-year studies for carcinogenicity, no increase in tumor incidence was observed in mice and rats. The drug was not mutagenic in several assays. A clastogenic effect was noted in one assay but was not confirmed in a repeat test or in vivo. In fertility tests in rats, plasma exposures up to 0.4 times the MRHD did not alter fertility at any dose level. However, maternal toxicity was observed at plasma exposures < 0.4 times the MRHD that resulted in a decreased number of implantations and live conceptuses, and increased preimplantation and postimplantation losses (1).

It is not known if tapentadol crosses the human placenta. The molecular weight (about 222 for the free base), low plasma protein binding, and the terminal half-life suggest that the drug will reach the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use of tapentadol during human lactation have been located. The molecular weight (about 222 for the free base), low plasma protein binding (about 20%), and the average terminal half-life (4 hours) suggest that the drug will be excreted into breast milk. As with all basic drugs, accumulation in the more acidic milk, as compared with plasma, should occur with continuous dosing and result in milk:plasma ratios > 1 . The effect of this exposure on a nursing infant is unknown, but respiratory depression and other narcotic effects are a potential complication.

TAZAROTENE

Dermatologic Agent

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Tazarotene is a retinoid that causes retinoid-like malformations in experimental animals. Because of this and the experience with other retinoids (e.g., see Isotretinoin), the drug is contraindicated in women who are or who may become pregnant. A negative pregnancy test should be obtained within 2 weeks before starting therapy with this agent, which should begin during a normal menstrual period (1).

FETAL RISK SUMMARY

Tazarotene is a retinoid prodrug that is rapidly converted in vivo to the active form, the cognate carboxylic acid of tazarotene (tazarotenic acid). The drug is indicated for the topical treatment of acne vulgaris and plaque psoriasis. The active drug is absorbed into the systemic circulation producing peak plasma levels up to approximately 2 ng/mL. In females treated for acne, doses applied to 15% of the BSA produced peak plasma levels 12 times higher than those from applications to only the face (1.2 vs. 0.1 ng/mL). Peak plasma levels occurred on day 15 of treatment and the highest observed level was 1.91 ng/mL (1).

Reproduction studies have been conducted in rats and rabbits (1). Topical doses resulted in reduced fetal body weights and reduced skeletal ossification in rats and single incidents of retinoid malformations, including spina bifida, hydrocephaly, and heart defects in rabbits. The systemic exposures resulting from the doses used in rats and rabbits were 1.2 and 13 times, respectively, the exposure resulting from treating a psoriatic patient with 0.1% cream over 35% of the BSA, and 4.0 and 44 times, respectively, the maximum systemic exposure of acne patients treated with 0.1% cream over 15% of the BSA (1). Oral administration of tazarotene caused developmental delays in rats, and

teratogenicity and resorptions in rats and rabbits at doses 1.1 and 26 times, respectively, the systemic exposure of a psoriatic patient and 3.5 and 85 times, respectively, the maximum systemic exposure of acne patients.

It is not known whether tazarotene or its active metabolite crosses the placenta to the fetus. The molecular weight (about 351) is low enough that transfer usually would be expected. However, the drug is highly bound to plasma protein (>99%) and maternal plasma concentrations are very low. Both of these factors should inhibit placental transfer.

The manufacturer has reports on nine pregnant women who were inadvertently exposed to tazarotene during clinical trials, two during studies involving acne patients and seven in other trials (1). One woman terminated her pregnancy, and healthy infants were delivered in the other eight cases. The timing of the exposures and the dosage used were not certain, so the significance of these findings is unknown (1).

BREASTFEEDING SUMMARY

Trace amounts of tazarotene are excreted into human milk (1). The risk to a nursing infant from this exposure is unknown.

TAZOBACTAM

Anti-infective

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Although the human data are very limited, the tazobactam–piperacillin combination appears to be relatively safe in pregnancy. No fetal harm in animals was observed at doses very close to those used in humans. Moreover, there is substantial experience with penicillins in human pregnancy that has shown this class of anti-infectives to be safe for the embryo–fetus. Because tazobactam is a derivative of the penicillin nucleus, it also probably is safe in pregnancy.

FETAL RISK SUMMARY

Tazobactam, a β -lactamase inhibitor, is combined with piperacillin to increase its antibacterial spectrum. It is not available as a single agent. Structurally, tazobactam is a derivative of the penicillin nucleus and is metabolized to an inactive metabolite. The plasma half-life ranges from 0.7 to 1.2 hours. Only 30% of tazobactam (and none of the metabolite) is bound to plasma proteins.

Reproduction studies with tazobactam have been conducted in mice and rats. No evidence of fetal harm was observed in these species at doses ≤ 6 and 14 times, respectively, the human dose based on BSA (HD). In rats, no effects on fertility were observed with doses 3 or fewer times the HD.

Consistent with its molecular weight (about 322) and its low protein binding, tazobactam crosses the human placenta. A 1998 report described the pharmacokinetics of piperacillin–tazobactam in six women with gestations of 25–32 weeks (2). Because of the increase in renal clearance and other factors, a marked decrease in maternal serum concentrations of both agents was observed. In one of the women (samples were inadequate in the other five), the fetal:maternal serum ratio of tazobactam was 2 approximately 3 hours after a

dose. In two other women, low concentrations of tazobactam, 2.3 and 3.7 mcg/mL, respectively, were measured in the amniotic fluid and, in two others, low concentrations in fetal urine, 8.2 and 12.4 mcg/mL, respectively.

BREASTFEEDING SUMMARY

Although specific details were lacking, the manufacturer states that tazobactam is excreted into breast milk in low concentrations (1). This is consistent with its molecular weight (about 322) and low protein binding (30%). Piperacillin also is excreted into milk (see Piperacillin). The effects of this low exposure on a nursing infant probably are not clinically significant, but three potential problems exist for the nursing infant: modification of bowel flora, direct effects on the infant, and interference with the interpretation of culture results if a fever workup is required.

TECHNETIUM Tc-99m

Diagnostic Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Limited data from two studies of technetium Tc-99m (Tc-99m) exposure in human pregnancy have not suggested an increased risk for the embryo or fetus. Although it is desirable to minimize ionizing radiation exposure during pregnancy, a radiopharmaceutical may be administered either in an unrecognized pregnancy or for urgent diagnostic reasons. In these situations, the radiation dose to the embryo–fetus is estimated to be well below the 5Gy limit of concern.

FETAL RISK SUMMARY

Tc-99m is a gamma-emitting metastable nuclear isomer of technetium-99. It is the most common radioisotope used in medical diagnostic procedures. It is available either in the pertechnetate soluble salt form or in complex with various other agents. These radiopharmaceuticals are administered orally, IV, or by inhalation to aid in diagnostic imaging and functional studies of the brain, myocardium, thyroid, lungs, liver, gallbladder, kidneys, skeleton, blood, and tumors. The physical half-life (decay through gamma emission) of Tc-99m is approximately 6 hours, and the biological half-life is approximately 24 hours (1).

Animal reproduction studies with Tc-99m have not been conducted. Studies for carcinogenicity or mutagenic potential have not been conducted for most Tc-99m products. No genotoxic activity was observed for the active metabolite of Tc-99m sestamibi in various tests. At cytotoxic concentrations (>20 mcg/mL), an increase in cells with chromosome aberrations was observed in the human lymphocyte assay. No genotoxic effects in the in vivo mouse micronucleus test were observed at a dose that caused systemic and bone marrow toxicity (9 mg/kg, >600 times the maximum human dose). Fertility

studies have not been conducted with Tc-99m (1).

Tc-99m is known to cross the placenta in animals and it is presumed that the same is true for the human placenta.

High-dose radiation exposure to the embryo or fetus is known to be associated with risks for intrauterine growth restriction, embryo–fetal loss, mental deficiency, and cancer. However, it is generally accepted that doses <5Gy to the embryo or fetus are not teratogenic. To evaluate potential risks for diagnostic procedures that utilize Tc-99m radiopharmaceuticals, estimates of the radiation dose available to the human embryo or fetus have been calculated under various scenarios, and these estimates are under the 5Gy limit. This suggests a low level of concern in situations where the diagnostic procedure is necessary in pregnancy or has been inadvertently performed in an unrecognized pregnancy (2–4).

In a 2009 study conducted by a German teratogen information service, 122 pregnancies were prospectively followed up in which the mothers were exposed sometime between the 2nd and 17th weeks of gestation to one of five Tc-99m radiopharmaceuticals for diagnosis of bone, thyroid, kidney, or lung conditions (5). Outcomes were compared with 366 unexposed pregnancies. No increased risks for growth deficiency, pregnancy loss, or major birth defects were noted in the exposed infants (5).

In a 1997 British study, data were abstracted from medical records for 82 pregnant women who had been evaluated for pulmonary embolism with either a Tc-99m perfusion or ventilation scan or both. Most scans were conducted late in pregnancy. No adverse pregnancy outcomes were reported, although no details were provided (6).

BREASTFEEDING SUMMARY

Tc-99m is excreted into breast milk. In a 1994 study, breast milk samples were obtained from 60 women who had been exposed to Tc-99m radiopharmaceuticals (7). Analysis found generally low radiation doses in breast milk across the samples, but there was distinct variability by specific radiopharmaceutical. Based on estimated dose, the recommendation for those products that produce the highest concentrations, such as Tc-99m pertechnetate, is to interrupt breastfeeding until activity in milk samples reaches a threshold concentration. For other products, no interruption in breastfeeding was considered necessary (8–10).

TEDUGLUTIDE

Gastrointestinal Agent (Glucagon-Like Peptide-2 Analog)

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of teduglutide in human pregnancy have been located. In the animal data, comparisons to the human dose were based on body weight. Even though such comparisons usually cannot be interpreted, the doses were up to 1000 times the human dose and might suggest low risk. Moreover, the drug is an analog of a naturally occurring peptide secreted by L-cells of the distal intestine (1). Consequently, if indicated the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Teduglutide, given as a daily SC injection, is a 33 amino acid analog of naturally occurring human glucagon-like peptide-2 that is known to increase intestinal and portal blood flow and inhibit gastric acid secretion. It is indicated for the treatment of adult patients with short bowel syndrome (SBS) who are dependent on parenteral support. It is metabolized to inactive components. The mean terminal half-life is about 2 hours in healthy subjects and 1.3 hours in SBS patients (1). However, information regarding plasma protein binding is apparently unknown.

Reproduction studies have been conducted in rats and rabbits. In these species, SC doses up to 1000 times the recommended human daily dose based on body weight (RHDD) did not reveal any evidence of fetal harm or impaired fertility. In addition, no evidence of adverse effects were observed in predevelopment and postdevelopment studies in rats with SC doses up to 1000 times the RHDD (1).

In a 2-year carcinogenicity rat study, teduglutide caused significant increases in the incidence of adenomas in the bile duct and jejunum of male rats. Studies

for mutagenicity were negative, as were studies of impaired fertility and reproductive performance in male and female rats (1).

It is not known if teduglutide crosses the human placenta. The molecular weight (about 3752) and the relatively short mean terminal half-life suggest that clinically significant amounts of the drug probably will not reach the embryo or fetus, at least early in gestation.

BREASTFEEDING SUMMARY

No reports describing the use of teduglutide during human lactation have been located. The molecular weight (about 3752) and the relatively short (1.3 hours) mean terminal half-life in SBS patients suggest that the drug will probably not be excreted into breast milk, at least in clinically significant amounts. Even if some excretion did occur, the peptide would probably be digested in the infant's gut. However, teduglutide is given as a daily SC injection and the manufacturer states that women receiving teduglutide should not breastfeed because of the tumorigenicity shown in rats (1).

TEGASEROD

[Withdrawn from the market. See 9th edition.]

TELAPREVIR

Antiviral Agent

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk (Contraindicated—3-Drug Combination)

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity (3-Drug Combination)

PREGNANCY SUMMARY

No reports describing the use of telaprevir in human pregnancy have been located. The animal data suggest low risk. However, the indication for telaprevir involves the combined use with ribavirin and peginterferon alfa. Although peginterferon alfa is probably compatible with pregnancy (see Interferon, Alfa), ribavirin is contraindicated because it has caused developmental toxicity in all animal species tested (see Ribavirin). The 3-drug combination should be avoided in pregnancy.

FETAL RISK SUMMARY

Telaprevir, a protease inhibitor, is a direct-acting antiviral agent against the hepatitis C virus. It is indicated, in combination with peginterferon alfa and ribavirin, for the treatment of genotype 1 chronic hepatitis C in adult patients with compensated liver disease, including cirrhosis, who are treatment-naive or who have previously been treated with interferon-based treatment, including prior null responders, and relapsers. Telaprevir is extensively metabolized to inactive metabolites. Plasma protein binding, primarily to α_1 -acid glycoprotein and albumin, is moderate (59%–76%). The mean elimination half-life after a single dose was 4.0–4.7 hours and 9–11 hours at steady state (1).

Reproduction studies with telaprevir alone have been conducted in mice and rats. The highest doses tested produced exposures that were 1.84 and 0.60 times, respectively, the human exposure at the recommended clinical dose (HERCD). No harm to the fetuses were observed at these exposures (1). However, ribavirin causes dose-related teratogenicity or embryo lethality in animals (see Ribavirin) and peginterferon alfa causes dose-related abortions in animals (see Interferon, Alfa).

The carcinogenic potential of telaprevir has not been studied. Multiple assays for genotoxicity were negative. However, the drug did have adverse effects on fertility parameters in rats. The no-observed-adverse-effect level for testicular toxicity was an exposure 0.17 times the HERCD. At exposures 0.30 times the HERCD, potential effects were decreased motile sperm and increased nonmotile sperm count. In female rats, there were minor increases in preimplantation loss in percent of dams with nonviable embryos, and percent of nonviable conceptuses per litter. These effects were probably related to testicular toxicity in males, but contributions of the female could not be ruled out (1).

It is not known if telaprevir crosses the human placenta. The molecular weight (about 680), moderate plasma protein binding, and long elimination half-life suggest that the drug will cross to the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use of telaprevir during human lactation have been located. The molecular weight (about 680), moderate plasma protein binding (59%–76%), and long elimination half-life (9–11 hours at steady state) suggest that the drug will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown. However, telaprevir is always combined with ribavirin and peginterferon alfa (see Ribavirin and Interferon, Alfa). The latter agent is known to be excreted into breast milk and ribavirin is probably excreted. If a woman taking this therapy is breastfeeding, her nursing infant could be exposed to all three agents. Thus, the best course of action is to not breastfeed.

TELAVANCIN

Antibiotic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of telavancin, a synthetic derivative of vancomycin, in human pregnancy have been located. The manufacturer interpreted the animal reproduction data as showing risk of limb and skeletal malformations. However, a presentation by Anthony Scialli, MD, Tetra Tech Sciences, at a public meeting of the FDA Advisory Committee on Antimicrobial Drugs, November 2008, did not support that interpretation. Among 654 rat and 156 rabbit fetuses, shortened limbs were observed in only three fetuses: two rats (one of which was not confirmed) and a rabbit. In minipigs, polydactyly was observed in controls and in all drug groups except the high-dose group, so inclusion of these results is questionable. Nevertheless, a better reason for not using this drug, at least until human pregnancy data are available, is that it does not appear to offer a clear advantage for its indication over other available antibiotics that do have pregnancy experience. A pregnancy registry has been established by the manufacturer to monitor pregnancy outcomes in women exposed to telavancin. Either the physician or the patient herself can register by calling 1-888-658-4228 (1).

FETAL RISK SUMMARY

Telavancin is a lipoglycopeptide antibacterial that is a synthetic derivative of vancomycin. It is given as an IV infusion. Telavancin is indicated for the treatment of adult patients with complicated skin and skin structure infections caused by susceptible isolates of the following gram-positive microorganisms: *Staphylococcus aureus* (including methicillin-susceptible and -resistant isolates), *Streptococcus pyogenes*, *Streptococcus agalactiae*, *Streptococcus anginosus*

group (includes *Streptococcus anginosus*, *Staphylococcus intermedius*, and *Streptococcus constellatus*), or *Enterococcus faecalis* (vancomycin-susceptible isolates only). The drug is partially metabolized. Binding to plasma proteins, primarily to albumin, is about 90%, and the elimination half-life is about 8 hours. The drug is highly lipophilic (1).

Reproduction studies have been conducted in rats, rabbits, and minipigs. In these species, IV doses resulting in exposures that were about 1–2 times the human exposure (AUC) at the maximum recommended clinical dose showed a potential to cause limb and skeletal malformations that included brachymelia (rats, rabbits), syndactyly (rats, minipigs), adactyly (rabbits), and polydactyly (minipigs) (see also above Summary). Other findings were flexed front paw and absent ulna (rabbits), misshapen digits and deformed front leg (minipigs), and an increase in the number of stillborn pups and decreased fetal body weights (rats) (1).

Long-term carcinogenicity studies have not been conducted. The drug was not mutagenic or clastogenic in multiple assays. Telavancin did not impair fertility or reproductive performance in male and female rats. When the drug was given for longer periods in male rats at doses resulting in exposures similar to those in humans, reversible altered sperm parameters were observed (1).

It is not known if telavancin crosses the human placenta. The molecular weight (about 1756 for the free base) and moderately high plasma protein binding may partially inhibit placental crossing, but the high fat solubility and long elimination half-life suggest that the drug will cross to the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use of telavancin during human lactation have been located. The molecular weight (about 1756 for the free base) and moderately high plasma protein binding (about 90%) may partially inhibit excretion into breast milk, but the high fat solubility and long elimination half-life (8 hours) suggest that some drug will cross into milk. Because telavancin is a weak base, ion trapping in the more acidic milk may occur that results in a milk:plasma ratio >1. The effect of this exposure on a nursing infant is unknown, but three potential problems exist: modification of bowel flora, direct effects on the infant (e.g., allergic response), and interference with the interpretation of culture results if a fever workup is required.

TELBIVUDINE

Antiviral

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

The human pregnancy experience with telbivudine is very limited. Although the animal reproduction data are encouraging, additional human pregnancy experience is required for a full assessment of the embryo–fetal risk. Theoretically, exposure to agents in this class at the time of implantation could impair fertility as a result of embryonic cytotoxicity. This toxicity was not observed with telbivudine in animal studies but has not been studied in humans. Mitochondrial dysfunction has been reported with two nucleoside reverse transcriptase inhibitors (see Lamivudine and Zidovudine). However, no appreciable mitochondrial toxicity was observed with telbivudine at concentrations much higher than those required to inhibit hepatitis B viral DNA synthesis (1). If indicated, the drug should not be withheld because of pregnancy. Physicians are encouraged to register exposed patients in the Antiretroviral Pregnancy Registry by calling 1-800-258-4263 (1).

FETAL RISK SUMMARY

Telbivudine is an oral synthetic thymidine nucleoside analog with antiviral activity against hepatitis B virus DNA polymerase. It has no activity against the HIV. It is phosphorylated to the active metabolite by cellular kinases. Telbivudine is indicated for the treatment of chronic hepatitis B in adult patients with evidence of viral replication and either evidence of persistent elevations in serum aminotransferases (alanine aminotransferase [ALT] or aspartate aminotransferase [AST]) or histologically active disease. The agent is in the same class of nucleoside reverse transcriptase inhibitors as abacavir, didanosine, emtricitabine, lamivudine, stavudine, tenofovir, and zidovudine. Plasma protein binding is very low (3%). The plasma terminal elimination half-

life is 40–49 hours and the drug is eliminated primarily by urinary excretion of unchanged drug (1).

Reproduction studies have been conducted in rats and rabbits. No evidence of fetal harm was observed in these species at exposures up to 6 and 37 times, respectively, the exposure levels from the human therapeutic dose of 600 mg/day (HTD). The drug crossed the placentas of both species (1).

Studies with telbivudine have found no evidence of carcinogenicity in mice and rats or genotoxicity in multiple assays (1,2). No evidence of impaired fertility was seen in male and female rats given doses that produced systemic exposures about 14 times the HTD (1).

It is not known if telbivudine crosses the human placenta. The low molecular weight (about 242) and plasma protein binding, and long elimination half-life suggest that the drug will reach the embryo and fetus.

The Antiretroviral Pregnancy Registry reported, for the period January 1989 through July 2009, prospective data (reported before the outcomes were known) involving 4702 live births that had been exposed during the 1st trimester to one or more antiretroviral agents (3). Congenital defects were noted in 134, a prevalence of 2.8% (95% confidence interval [CI] 2.4–3.4). In the 6100 live births with earliest exposure in the 2nd/3rd trimesters, there were 153 infants with defects (prevalence 2.5%, 95% CI 2.1–2.9). The prevalence rates for the two periods did not differ significantly. There were 288 infants with birth defects among 10,803 live births with exposure anytime during pregnancy (prevalence 2.7%, 95% CI 2.4–3.0). The prevalence rate did not differ significantly from the rate expected in a nonexposed population. There were six outcomes exposed to telbivudine (five in the 1st trimester and one in the 2nd/3rd trimesters) in combination with other antiretroviral agents. There were no birth defects. In reviewing the birth defects of prospective and retrospective (pregnancies reported after the outcomes were known) registered cases, the Registry concluded that, except for isolated cases of neural tube defects with efavirenz exposure in retrospective reports, there was no other pattern of anomalies (isolated or syndromic) (3) (see Lamivudine for required statement).

BREASTFEEDING SUMMARY

No reports describing the use of telbivudine during human lactation have been located. The molecular weight (about 242), plasma protein binding (3%), and long elimination half-life (40–49 hours) suggest that the drug will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown. Infants of mothers with hepatitis B are at high risk of chronic hepatitis B virus

infection when the maternal infection occurs perinatally or in early infancy (4). Hepatitis B immune globulin and hepatitis B virus vaccine given simultaneously to the infant at birth will prevent chronic infection in nearly all cases, regardless of whether the infant is breastfed (4). If the mother elects to breastfeed, the infant should be monitored closely for the most common telbivudine-induced toxicities observed in adults, such as upper respiratory infection, fatigue, malaise, abdominal pain, cough, fever, insomnia, rash, nausea, vomiting, diarrhea, and loose stools.

TELITHROMYCIN

Antibiotic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of telithromycin in human pregnancy have been located. The animal reproduction data suggest low risk, but the absence of human pregnancy experience prevents a more complete assessment. Although there are no other agents in the ketolide class, telithromycin is a chemical derivative of erythromycin, a macrolide anti-infective that is considered compatible in pregnancy. There is currently no evidence that macrolides are associated with developmental toxicity. However, telithromycin may cause severe hepatocellular hepatitis that can be fatal (1). The hepatotoxicity has special significance for pregnant women because liver toxicity sometimes occurs in pregnancy (e.g., viral hepatitis, fatty liver of pregnancy, preeclampsia, and HELLP [hemolysis, elevated liver enzymes, and low platelets] syndrome). Therefore, until there are human pregnancy data, the best course is to avoid the use of telithromycin in pregnancy.

FETAL RISK SUMMARY

Telithromycin, a ketolide, is a semisynthetic antibacterial agent that is a derivative of erythromycin. The chemical structure of telithromycin differs from the macrolide group.

The antibacterial is indicated for the treatment of community-acquired pneumonia (mild to moderate severity). Telithromycin is partially metabolized to inactive metabolites. Plasma protein binding is 60%–70%, primarily to albumin. The terminal elimination half-lives after single and multiple doses are about 7 and 10 hours, respectively (2).

Reproduction studies have been conducted in rats and rabbits. No evidence

of structural defects was found when doses that were about 1.8 and 0.49 times, respectively, the daily human dose based on BSA (DHD) were given to these species. No adverse effects on prenatal or postnatal development on rat pups were observed at 1.5 times the DHD. However, doses higher than 1.8 and 0.49 times, respectively, the DHD in rats and rabbits were associated with maternal toxicity and delayed fetal maturation (2).

Carcinogenicity studies have not been conducted, but tests for genotoxicity were negative. Doses that were about 0.61 times the DHD had no effect on fertility in rats. Higher doses, 1.8–3.6 times the DHD, did impair fertility but also caused toxicity in both male and female rats (2).

It is not known if telithromycin crosses the human placenta. The molecular weight (about 812), moderate plasma protein binding, and the long elimination half-life suggest that the antibacterial agent will cross to the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use of telithromycin during human lactation have been located.

The molecular weight (about 812), moderate plasma protein binding (60%–70%), and long elimination half-life (≤ 10 hours) suggest that telithromycin will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown. Although modification of the bowel flora, direct effects, and interference with the interpretation of culture results if a fever workup is required are potential effects, a closely related antibacterial, erythromycin is considered compatible with nursing. When taking this drug and nursing, a mother should observe her infant for the most common adverse effects reported in adults, such as diarrhea, nausea, vomiting, headache, and dizziness.

TELMISARTAN

Antihypertensive

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The antihypertensive mechanisms of action of telmisartan and angiotensin-converting enzyme (ACE) inhibitors are very close. That is, the former selectively blocks the binding of angiotensin II to AT₁ receptors, whereas the latter prevents the formation of angiotensin II itself. Therefore, use of this drug during the 2nd and 3rd trimesters may cause teratogenicity and severe fetal and neonatal toxicity that is identical to that seen with ACE inhibitors (e.g., see Captopril or Enalapril). Fetal toxic effects may include anuria, oligohydramnios, fetal hypocalvaria, intrauterine growth restriction, prematurity, and patent ductus arteriosus. Anuria-associated oligohydramnios may produce fetal limb contractures, craniofacial deformation, and pulmonary hypoplasia. Severe anuria and hypotension that are resistant to both pressor agents and volume expansion may occur in the newborn following in utero exposure to telmisartan. Newborn renal function and blood pressure should be closely monitored.

FETAL RISK SUMMARY

Telmisartan is a selective angiotensin II receptor blocker (ARB) that is used, either alone or in combination with other antihypertensive agents, for the treatment of hypertension. Telmisartan blocks the vasoconstrictor and aldosterone-secreting effects of angiotensin II by preventing angiotensin II from binding to AT₁ receptors (1).

Reproduction studies have been conducted in pregnant rats and rabbits. No teratogenicity was observed in either species at oral doses up to about 6.3 and 6.4 times the maximum recommended human dose of 80 mg based on BSA (MRHD), respectively, but embryoletality was noted at the highest dose in

rabbits. The highest doses were maternally toxic (reduced body weight gain and food consumption) in both species. In rats, an oral dose approximately 1.9 times the MRHD (also maternal toxic) during late gestation and lactation resulted in neonatal adverse effects, including reduced viability, low birth weight, delayed maturation, and decreased weight gain. The no-observed-effect doses for developmental toxicity in rats and rabbits were 0.64 and 3.7 times the MRHD, respectively. No adverse effects on reproductive performance were noted in male and female rats at a dose about 13 times the MRHD (1).

It is not known if telmisartan crosses the human placenta to the fetus. The drug is found in rat fetuses in late gestation (1). The molecular weight (about 515) is low enough that passage to the human fetus should be expected.

A 2003 case report described transient renal failure in a newborn secondary to maternal use of telmisartan (2). A 35-year-old woman with hypertension was treated with telmisartan throughout pregnancy. Oligohydramnios was diagnosed at 34 weeks' gestation and a 2.2-kg female infant was delivered by cesarean section. Apgar scores were 9, 10, and 10 at 1, 5, and 10 minutes, respectively. The infant was anuric until the third day of life, but renal function improved thereafter. Telmisartan plasma levels on day 10 and 13 were 20 and 13 ng/L, respectively. The infant's renal function had normalized by 1.5 months of age (2).

A 2012 review of the use of ACE inhibitors and ARBs in the 1st trimester concluded that there may be an elevated teratogenic risk, but the risk appeared to be related to other factors (3). The factors, that typically coexist with hypertension in pregnancy, included diabetes, advanced maternal age, and obesity.

BREASTFEEDING SUMMARY

No reports describing the use of telmisartan during human lactation have been located. The molecular weight (515) is low enough that excretion into human breast milk should be expected. The effect of this exposure on a nursing infant is unknown. The American Academy of Pediatrics, however, classifies ACE inhibitors, a closely related group of antihypertensive agents, as compatible with breastfeeding (see Captopril or Enalapril).

TEMAZEPAM

Hypnotic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Temazepam is a benzodiazepine that is used as a hypnotic for the short-term management of insomnia. Limited human data suggest an association between the drug and oral clefts, but confirming studies are required. Fetal death, possibly related to an interaction between temazepam and diphenhydramine, has been reported. The lethal interaction was apparently confirmed in an animal study.

FETAL RISK SUMMARY

Reproductive studies in rats revealed increased resorptions and an increased incidence of rudimentary ribs, which were considered skeletal variants (1). Exencephaly and fusion or asymmetry of ribs were observed in rabbits (1).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 146 newborns had been exposed to temazepam during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Six (4.1%) major birth defects were observed (six expected), including one cardiovascular defect (one expected) and two oral clefts (none expected). No anomalies were observed in four other categories of defects (spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available. Although the two oral clefts suggest a relationship with the drug, other factors, such as the mother's disease, concurrent drug use, and chance, may be involved.

A potential drug interaction between temazepam and diphenhydramine, resulting in the stillbirth of a term female infant, has been reported (2). The mother had taken diphenhydramine 50 mg for mild itching of the skin and approximately 1.5 hours later took 30 mg of temazepam for sleep. Three hours

later, she awoke with violent intrauterine fetal movements, which lasted several minutes and then abruptly stopped. The stillborn infant was delivered approximately 4 hours later. Autopsy revealed no gross or microscopic anomalies. In an experiment with pregnant rabbits, neither of the drugs alone caused fetal mortality but when combined, 51 (81%) of 63 fetuses were stillborn or died shortly after birth (2). No definite mechanism could be established for the apparent interaction.

BREASTFEEDING SUMMARY

Temazepam is excreted into breast milk. Ten mothers, within 15 days of delivery, were administered 10–20 mg of temazepam for at least 2 days as a bedtime hypnotic (3). Milk and plasma samples were obtained about 15 hours later corresponding to an infant feeding. Temazepam was detected (limit of detection 5 ng/mL) in the milk of only one woman with before- and after-feed levels of 28 and 26 ng/mL, respectively. The milk:plasma ratio in this patient was 0.12. Although no adverse effects were observed in the nursing, nursing infants of mothers consuming temazepam should be closely observed for sedation and poor feeding. The American Academy of Pediatrics classifies temazepam as a drug for which the effect on nursing infants is unknown but may be of concern (4).

TEMOZOLOMIDE

Antineoplastic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of temozolomide in human pregnancy have been located. The animal reproduction data suggest risk, but the absence of human pregnancy experience prevents a more complete assessment of embryo–fetal risk. The recommended first cycle of temozolomide is 42 days of consecutive therapy, followed by an increased dose for six cycles (5 consecutive days of therapy in each 4-week cycle). Thus, exposure could potentially occur throughout most of gestation. Women of childbearing age should employ adequate contraceptive methods to prevent pregnancy. However, if a woman requires temozolomide and informed consent is obtained, therapy should not be withheld because of pregnancy. If an inadvertent pregnancy occurs during therapy, the woman should be advised of the unknown, but potentially severe, risk for her embryo and/or fetus.

FETAL RISK SUMMARY

Temozolomide, an imidazotetrazine derivative, is an oral prodrug that undergoes rapid nonenzymatic conversion at physiologic pH to the reactive compound MTIC. The cytotoxic effect of MTIC is thought to be mainly due to alkylation of DNA. There are no other agents in this antineoplastic subclass. Temozolomide is indicated for the treatment of adult patients with newly diagnosed glioblastoma multiforme concomitantly with radiotherapy and then as maintenance treatment. It also is indicated for the treatment of adult patients with refractory anaplastic astrocytoma. Plasma protein binding of temozolomide is minimal (about 15%) and its elimination half-life is short (1.8 hours) (1).

Reproduction studies have been conducted in rats and rabbits. During organogenesis, rats and rabbits were given daily oral doses that were 0.375

and 0.75 times, respectively, the maximum recommended human dose based on BSA (MRHD) for 5 consecutive days. Numerous malformations were observed in both species, including defects of the external organs, soft tissues, and skeletons. Daily doses that were 0.75 times the MRHD also caused embryoletality (resorptions) (1).

Short-term studies for carcinogenicity have been conducted in rats. When rats were given a dose of temozolomide that was equal to the MRHD for 5 consecutive days every 28 days for three cycles, mammary carcinomas were found in males and females. When six cycles were given with doses that were 0.125, 0.25, or 0.625 times the MRHD, mammary carcinomas were observed at all doses. In addition, the highest dose was associated with multiple other tumors (1).

It is not known if temozolomide crosses the human placenta. The molecular weight of the parent compound (about 194) and the minimal plasma protein binding suggest that the drug will cross to the embryo and fetus. However, after absorption, temozolomide undergoes rapid hydrolysis to MTIC, and this compound also may cross the placenta.

BREASTFEEDING SUMMARY

No reports describing the use of temozolomide during human lactation have been located.

The molecular weight of the parent compound (about 194) and the minimal plasma protein binding (about 15%) suggest that the drug will be excreted into breast milk. Moreover, after absorption, temozolomide undergoes rapid hydrolysis to the active agent MTIC, so this compound also may be excreted into milk. The effect of these exposures on a nursing infant is unknown. In adults, the drug is rapidly and completely absorbed and may also be absorbed by a nursing infant. Thus, it is best that a woman receiving this agent does not breastfeed. If she chooses to do so, the infant should be closely monitored for the most common or serious adverse effects observed in adults. These effects include alopecia, nausea, vomiting, anorexia, headache, constipation, fatigue, thrombocytopenia, and convulsions (1).

Reference

1. Product information. Temodar. Schering, 2007.

TEMSIROLIMUS

Antineoplastic (Kinase Inhibitor)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of temsirolimus in human pregnancy have been located. The animal reproduction studies suggest risk, but the absence of human pregnancy experience prevents a full assessment of the embryo–fetal risk. The manufacturer recommends advising women of childbearing potential to avoid becoming pregnant during treatment and for 3 months after the last dose (1). The manufacturer also recommends that men be counseled on the potential effects of the drug on the fetus and sperm, and, if their partner is of childbearing potential, should use reliable contraception during treatment and for 3 months after the last dose (1). (See also Sirolimus.)

FETAL RISK SUMMARY

Temsirolimus is an antineoplastic agent indicated for the treatment of advanced renal cell carcinoma. It is a mTOR inhibitor (mammalian target of rapamycin) that is the same subclass as everolimus. Temsirolimus is given as an IV infusion over 30–60 minutes once weekly. The drug is metabolized to five metabolites. Sirolimus is the principal metabolite in humans. Plasma protein binding of sirolimus is about 92% but apparently is not known for the parent compound. The mean half-lives of temsirolimus and sirolimus are about 17 and 55 hours, respectively (1).

Reproduction studies have been conducted in rats and rabbits. Exposures after daily oral doses that produced embryo–fetal toxicity in rats and rabbits were about 0.04 and 0.12 times the AUC in cancer patients at the human recommended dose, respectively. Toxicity in the rat consisted of reduced fetal weight and reduced ossification, whereas in the rabbit it was reduced fetal weight, omphalocele, bifurcated sternabrae, notched ribs, and incomplete ossifications (1).

Carcinogenic studies have not been conducted with temsirolimus, but sirolimus was carcinogenic in mice and rats (see Sirolimus). Temsirolimus was not genotoxic in multiple assays. Fertility was impaired in male rats at doses that were about 0.2 times the human recommended IV dose (RHID). The effects observed were decreased number of pregnancies, decreased sperm concentration and motility, decreased reproductive organ weights, and testicular tubular degeneration. At about 2 times the RHID, fertility was absent. In female rats, an increased incidence of pre- and postimplantation losses was noted at an oral dose about 0.3 times the RHID (1).

It is not known if temsirolimus or sirolimus crosses the human placenta. The molecular weights of the two compounds, about 1030 and 914, respectively, are within the range for passive diffusion. In addition, the elimination half-lives will place the drug at the maternal–fetal interface for long periods.

BREASTFEEDING SUMMARY

No reports describing the use of temsirolimus during human lactation have been located. There also are no reports of the use of sirolimus, the active metabolite, during lactation (see Sirolimus). The molecular weights of the two compounds, about 1030 and 914, respectively, are low enough for excretion into breast milk. Moreover, the elimination half-lives, about 17 and 55 hours, respectively, suggest that both temsirolimus and sirolimus will be excreted. The effect of this exposure on a nursing infant is unknown. However, serious toxicity has been observed in adults, such as hypersensitivity reactions, including anaphylaxis, infections, interstitial lung disease, bowel perforation, renal failure, and abnormal wound healing.

TENECTEPLASE

Thrombolytic

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: Hold Breastfeeding

PREGNANCY SUMMARY

No reports describing the use of tenecteplase in human pregnancy have been located. The limited animal data do not suggest a direct risk. Moreover, fetal toxicity has not been observed with limited pregnancy exposure to another, similar glycoprotein enzyme, alteplase. Although maternal hemorrhage is a major risk, tenecteplase should not be withheld because of pregnancy if the maternal condition requires such therapy.

FETAL RISK SUMMARY

Tenecteplase is a modified form of human tissue plasminogen activator (tPA) that is produced by recombinant DNA technology using Chinese hamster ovary cells. It is a 527 amino acid glycoprotein that is indicated to reduce the mortality associated with acute myocardial infarction. Tenecteplase is cleared from the plasma with a half-life of 20–24 minutes, but the terminal phase half-life is 90–130 minutes (1).

In pregnant rabbits given multiple IV daily doses of 0.5, 1.5, and 5.0 mg/kg/day, vaginal hemorrhage resulted in maternal deaths. No fetal anomalies were observed. Single IV doses (the recommended human dose is a single bolus injection) in rabbits did not cause maternal or embryo toxicity. The no-observable-effect-level (NOEL) of a single IV dose was 5 mg/kg (about 8–10 times the human dose) (1).

It is not known if tenecteplase crosses the human placenta. Tenecteplase is a glycoprotein and, although some proteins do cross, the short plasma half-life will limit the exposure of the embryo–fetus to the enzyme.

BREASTFEEDING SUMMARY

No reports describing the use of tenecteplase during human lactation have been

located. It is not known whether the glycoprotein is excreted into human milk. Because of the nature of the indication for this agent and its very short plasma and terminal half-life, the opportunities for its use during lactation or the possible exposure of a nursing infant are minimal.

TENIPOSIDE

Antineoplastic

PREGNANCY RECOMMENDATION: Contraindicated—1st Trimester

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Teniposide, a podophyllin derivative, has been used in the 2nd and 3rd trimesters of one pregnancy (1). An apparently normal infant was delivered at 37 weeks' gestation.

FETAL RISK SUMMARY

Reproduction studies in rats given IV doses of 0.1–3 mg/kg (0.6–18 mg/m²) every second day from day 6 to day 16 postcoital revealed dose-related embryotoxicity and teratogenicity (2). Congenital malformations consisted of spinal and rib defects, deformed extremities, anophthalmia, and celosomia.

Long-term studies of growth and mental development in offspring exposed to antineoplastic agents during the 2nd trimester, the period of neuroblast multiplication, have not been conducted (3).

Occupational exposure of the mother to antineoplastic agents during pregnancy may present a risk to the fetus. A position statement from the National Study Commission on Cytotoxic Exposure and a research article involving some antineoplastic agents are presented in the monograph for cyclophosphamide (see Cyclophosphamide).

BREASTFEEDING SUMMARY

No reports describing the use of teniposide during human lactation have been located. Because of the potential for toxicity in a nursing infant, the safest course is not to breastfeed if this drug is administered.

TENOFOVIR

Antiviral

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Although the animal data are suggestive of risk (decreased growth), the limited human experience suggests that the embryo–fetal risk is low, at least for structural anomalies. If indicated, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Tenofovir is available as a prodrug, tenofovir disoproxil fumarate (PMPA), a fumaric acid salt of the ester derivative that is converted to tenofovir after oral administration. Tenofovir is an acyclic nucleoside analog reverse transcriptase inhibitor in the same antiviral class as abacavir, didanosine, emtricitabine, lamivudine, stavudine, zalcitabine, and zidovudine. It has activity against HIV types 1 and 2. Tenofovir is indicated in combination with other antiretroviral agents for the treatment of HIV-1. Less than 0.7% and 7% of tenofovir are bound to human plasma or serum proteins, respectively (1).

Reproduction studies have been conducted in rats and rabbits. In these species, doses up to 14 and 19 times the human dose based on BSA (HD), respectively, revealed no evidence of impaired fertility or fetal harm. There were no effects on fertility or mating performance, or early embryonic development in male and female rats given doses up to 10 times the HD for several weeks prior to mating and, in female rats, through the first 7 days of gestation (1).

Tenofovir crosses the placentas of gravid rhesus monkeys (2). Tenofovir was given to the monkeys at a dose of 30 mg/kg SC once daily starting early in the 2nd trimester (gestational day 80) and continuing until delivery at term (gestational day 157). The fetal:maternal blood levels (based on AUC mcg/hr) were 49.2/117.3 (ratio 0.42; gestational day 120) and 39.1/87.0 (ratio 0.45;

gestational day 140). Although normal fetal growth patterns were observed, the mean birth weight of tenofovir-exposed newborns was significantly less (about 381 vs. 467 g) than nonexposed controls. In addition, the crown-rump, humerus, and femur lengths were significantly reduced (2).

In a follow-up to the above study, investigators gave rhesus monkeys tenofovir (30 mg/kg) SC once daily from gestation days 20 to 150 (3). As in the study above, fetal development was normal but body weights and crown-rump lengths were significantly less than age-matched controls. In addition, fetal insulin-like growth factor was significantly reduced, as was fetal bone porosity, but alkaline phosphatase levels were increased. Transient alterations in maternal body weights and bone-related biomarkers and elevated alkaline phosphatase were observed during treatment (3).

The passage of tenofovir across the human placenta apparently has not been studied. The molecular weight (about 636 for the prodrug), and low plasma and serum protein binding, combined with the data from monkeys, suggest that the drug will cross to the human embryo–fetus.

The Antiretroviral Pregnancy Registry reported, for the period January 1989 through July 2009, prospective data (reported before the outcomes were known) involving 4702 live births that had been exposed during the 1st trimester to one or more antiretroviral agents (4). Congenital defects were noted in 134, a prevalence of 2.8% (95% confidence interval [CI] 2.4–3.4). In the 6100 live births with earliest exposure in the 2nd/3rd trimesters, there were 153 infants with defects (prevalence 2.5%, 95% CI 2.1–2.9). The prevalence rates for the two periods did not differ significantly. There were 288 infants with birth defects among 10,803 live births with exposure anytime during pregnancy (prevalence 2.7%, 95% CI 2.4–3.0). The prevalence rate did not differ significantly from the rate expected in a nonexposed population. There were 1217 outcomes exposed to tenofovir (756 in the 1st trimester and 461 in the 2nd/3rd trimesters) in combination with other antiretroviral agents. There were 26 birth defects (18 in the 1st trimester and 8 in the 2nd/3rd trimesters). In reviewing the birth defects of prospective and retrospective (pregnancies reported after the outcomes were known) registered cases, the Registry concluded that, except for isolated cases of neural tube defects with efavirenz exposure in retrospective reports, there was no other pattern of anomalies (isolated or syndromic) (4) (see Lamivudine for required statement).

Two reviews, one in 1996 and the other in 1997, concluded that all women currently receiving antiretroviral therapy should continue to receive therapy during pregnancy and that treatment of the mother with monotherapy should be

considered inadequate therapy (5,6). The same conclusion was reached in a 2003 review with the added admonishment that therapy must be continuous to prevent emergence of resistant viral strains (7). In 2009, the updated U.S. Department of Health and Human Services guidelines for the use of antiretroviral agents in patients infected with HIV-1 continued the recommendation that therapy, with the exception of efavirenz, should be continued during pregnancy (8). If indicated, tenofovir should not be withheld in pregnancy because the expected benefit to the HIV-positive mother outweighs the unknown risk to the fetus. Updated guidelines for the use of antiretroviral drugs to reduce perinatal HIV-1 transmission also were released in 2010 (9). Women receiving antiretroviral therapy during pregnancy should continue the therapy but, regardless of the regimen, zidovudine administration is recommended during the intrapartum period to prevent vertical transmission of HIV to the newborn (9).

BREASTFEEDING SUMMARY

No reports describing the use of tenofovir during human lactation have been located. The molecular weight (about 636 for the prodrug) and low plasma (about 1%) and serum (about 7%) protein binding suggest that the drug will be excreted into human breast milk. The effect of this exposure on a nursing infant is unknown.

Reports on the use of tenofovir during lactation are unlikely because the drug is indicated in the treatment of patients with HIV. HIV-1 is transmitted in milk, and in developed countries, breastfeeding is not recommended (5,6,8,10–12). In developing countries, breastfeeding is undertaken, despite the risk, because there are no affordable milk substitutes available.

TERAZOSIN

Sympatholytic (Antiadrenergic)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Terazosin is a peripherally acting α_1 -adrenergic blocking agent used in the treatment of hypertension and symptomatic benign prostatic hyperplasia. No reports describing the use of terazosin in human pregnancy have been located.

FETAL RISK SUMMARY

Reproduction studies in rats and rabbits at doses 280 and 60 times the recommended maximum human dose (RMHD), respectively, revealed no teratogenic effects, but an increased incidence of fetal resorptions occurred in both species (1). In addition, decreased fetal weight and an increased number of supernumerary ribs were observed in rabbit offspring. The embryo–fetal toxicity in both species was attributed to maternal toxicity (1). A significant increase in rat pup mortality was also seen at doses more than 75 times the RMHD in peri- and postnatal studies (1).

It is not known if terazosin crosses the human placenta. The molecular weight (about 388 for the nonhydrated free base) is low enough that exposure of the embryo–fetus should be expected.

BREASTFEEDING SUMMARY

No reports describing the use of terazosin during lactation have been located. The molecular weight (about 388 for the nonhydrated free base) is low enough that excretion into breast milk should be expected. The effect of this exposure on a nursing infant is unknown.

TERBINAFINE

Antifungal

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although the animal reproduction data are encouraging, the lack of human pregnancy experience does not allow a full assessment of the fetal risk from terbinafine. If possible, therefore, waiting to begin treatment until after a pregnancy has been concluded would be the safest course. If terbinafine is used in pregnancy, health care professionals are encouraged to call the toll free number 800-670-6126 for information about patient enrollment in the Motherisk study.

FETAL RISK SUMMARY

Terbinafine is a synthetic allylamine antifungal agent that is indicated for the treatment of onychomycosis of the toenail or fingernail due to dermatophytes (tinea unguium) (1). No studies evaluating the placental transfer of terbinafine in humans have been located. The molecular weight (about 328) is low enough that transfer to the embryo–fetus should be expected.

Reproduction studies have been conducted in rats and rabbits (1). Oral doses in rats up to about 12 times the maximum recommended human dose based on BSA (MRHD) had no effect on fertility or other reproductive parameters. In pregnant rabbits, intravaginal administration of terbinafine did not cause abortions, premature delivery, or affect fetal parameters. In pregnant rats and rabbits, no evidence of impaired fertility or fetal harm was seen with oral doses up to 12 and 9 times the MRHD, respectively (1).

BREASTFEEDING SUMMARY

Terbinafine is excreted into human milk. No specific details were given, but the milk:plasma ratio in nursing women was 7:1 (1). The effect of this exposure on

a nursing infant is unknown. Because the duration of therapy is usually prolonged (6 or 12 weeks for patients with fingernail or toenail onychomycosis, respectively), the potential for serious toxicity in a nursing infant may be increased. Based on the accumulation in milk and the prolonged exposure, women taking terbinafine probably should not breastfeed.

TERBUTALINE

Sympathomimetic/Bronchodilator

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Terbutaline is used as a tocolytic and as a bronchodilator in asthma and such use has been considered low risk. However, new data have suggested an association exists between continuous use (≥ 2 weeks) of terbutaline by any route and autism spectrum disorders. Short-term use, such as 48–72 hours to allow for corticosteroid use to improve fetal lung maturation, is probably safe, but there may be a subpopulation of mothers and fetuses at increased risk secondary to genetic predisposition. In addition, there is a report of an association between 1st trimester terbutaline exposure for asthma and cardiac defects. The risk magnitude for these toxicities requires confirmation. Because of these reports, avoiding β_2 -adrenergics early in gestation, except for quick relief of asthmatic symptoms with low inhaled doses, and continuous use in the 2nd/3rd trimesters appear to be warranted. If terbutaline is used in pregnancy for the treatment of asthma, health care professionals are encouraged to call the toll-free number 877-311-8972 for information about patient enrollment in an Organization of Teratology Information Specialists (OTIS) study.

FETAL RISK SUMMARY

Terbutaline is a β_2 -sympathomimetic indicated for the prevention and reversal of bronchospasm. During pregnancy, it is primarily used as a tocolytic agent in the late 2nd and early 3rd trimesters.

Reproduction studies in mice, rats, and rabbits at doses ≤ 1500 times the SC maximum recommended human daily dose of 0.1 mg/kg have revealed no evidence of impaired fertility or fetal harm (1).

A 2003 report described the effects of terbutaline given to rat pups (2). Because rats are altricial, the investigators gave the pups SC terbutaline 10 mg/kg/day in two different periods, one during the early postnatal period (days 2–5) and the other second spanning the time of eye opening (days 11–14). Hearts were examined for cardiac damage 24 hours after the last dose and on postnatal day 30. Compared with controls, neither treatment caused an increase in cardiac anomalies. However, there was a significant decrease in the number of cardiac nuclei in female pups (2).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 149 newborns had been exposed to terbutaline during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Seven (4.7%) major birth defects were observed (six expected), including three cardiovascular defects (two expected) and one oral cleft (none expected). No anomalies were observed in four other categories of defects (spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available. These data do not support an association between the drug and congenital defects.

Terbutaline rapidly crosses the placenta to the fetus (3). In seven women given 0.25 mg IV during the second stage of labor, cord blood levels 7–60 minutes after the dose ranged from 12% to 55% (mean 36%) of maternal serum.

Terbutaline has been used as a tocolytic agent since the early 1970s (4,5). The incidence of maternal side effects is usually low (e.g., $\leq 5\%$) but may be severe (4,6–10). A 1983 review listed the more serious side effects of parenteral β_2 -sympathomimetic therapy (e.g., terbutaline, ritodrine) as pulmonary edema, myocardial ischemia, cardiac arrhythmias, cerebral vasospasm, hypotension, hyperglycemia, and miscellaneous metabolic alterations (hypokalemia, increased serum lactate, and a decrease in measured hemoglobin concentration) (11). The more serious adverse effects are seen with continuous infusions of these drugs. Avoidance of this route of administration as well as careful selection of patients, appropriate dosing, and close monitoring of patient status may help to prevent serious maternal effects.

Terbutaline may cause fetal and maternal tachycardia (4,6–8). Fetal rates are usually <175 beats/minute (7). As mentioned previously, maternal hypotension may occur, especially in the bleeding patient (11). More commonly, increases in systolic pressure and decreases in diastolic pressure occur with no reduction in mean arterial pressure and, thus, do not adversely affect the fetus (8,11,12).

As with all β -mimetics, terbutaline may cause transient maternal hyperglycemia followed by an increase in serum insulin levels (4,13,14). Sustained neonatal hypoglycemia may be observed if maternal effects have not terminated before delivery (13). Maternal glucose intolerance was observed at 1 hour in 19 of 30 patients receiving oral terbutaline for at least 1 week (15). Although macrosomia was not observed, the birth weights (after adjustment for gestational age) of infants from terbutaline-treated mothers had a tendency to be greater than those of babies from comparable controls (15).

Sudden, unexplained intrapartum death in a fetus at 30 weeks' gestation occurred 5 hours after the start of an IV infusion of terbutaline for premature labor (16). No evidence of uterine, placental, or fetal anomalies was discovered.

Myocardial necrosis in a newborn was reported in 1991 (17). A continuous SC infusion of terbutaline (initial dose 0.5 mg/hr) was started at 25 weeks' gestation for premature labor in a 22-year-old woman with gestational diabetes. Therapy was continued until delivery at 37 weeks' of a 2850-g male infant. Tachypnea (80–100 breaths/minute) developed shortly after birth and chest radiography demonstrated mild cardiomegaly with increased pulmonary vascularity. A right ventricular biopsy obtained during cardiac catheterization showed marked myocardial fiber degeneration and focal bizarre nuclear dysmorphism. These findings were believed to be caused by catecholamine excess. Normal electrocardiogram and echocardiogram were found on examination at 1 month of age (17).

In a 1996 epidemiologic study that looked for correlations between drug exposure and major malformations, 1472 births with defects (cases) were compared with 9682 births without major or minor malformations (controls) (18). Overall, there was no significant association between β_2 -sympathomimetics (bronchodilators) and major malformations. When the malformations were divided into 10 organ categories, an association with cardiac defects (types not specified) was significant (odds ratio 5.8, 95% confidence interval 1.4–24) ($p = 0.05$) (18).

Maternal liver impairment was reported in a patient after 1 week of continuous IV administration of terbutaline (19). Therapy was stopped and 1 week later, a healthy newborn was delivered without signs of liver toxicity.

A paradoxical reaction to terbutaline was observed in a patient after 0.25 mg IV produced marked uterine hypertonus and subsequent severe fetal bradycardia (<50 beats/minute) (20). A healthy baby was delivered by emergency cesarean section.

Terbutaline has been used frequently to treat intrapartum fetal distress (21–25). The mechanism of the beneficial effects on fetal pH and heart rate are thought to be caused by relief of the ischemia produced by uterine contractions on the placental circulation.

Although maternal complications may occur, few direct adverse effects, other than transient tachycardia and hypoglycemia, and the single report of myocardial necrosis, have been observed in the fetus or newborn. In many studies, neonatal complications are minimal or nonexistent (26–30). Compared with controls, prophylactic terbutaline in low-risk patients with twin gestations has produced significant gains in birth weights caused by longer gestational times (29). In addition, terbutaline decreases the incidence of neonatal respiratory distress syndrome in a manner similar to other β -mimetics (31). Long-term evaluation of infants exposed to terbutaline in utero has been reported (32–34). No harmful effects in the infants (2–24 months) have been found.

A 26-year-old woman became pregnant with quadruplets after a gamete intrafallopian transfer procedure (35). Preterm labor began at 18 weeks' gestation and treatment was started with IV ritodrine for 2 weeks and then changed to SC terbutaline. She was maintained on terbutaline, except for a "24-hour rest period" every week, for 51 days. During this period, she received 200 mg of terbutaline. Labor progressed and a cesarean section was performed in the 28th week of gestation. Between 28 and 32 hours after birth, three of the four infants developed cardiovascular decompensation with bradycardia, metabolic acidosis, poor tissue perfusion, and decreased urine output. The conditions were resistant to standard interventions but responded to dobutamine. The infants required dobutamine for 3–9 days. The authors speculated that the prolonged β -sympathomimetic therapy led to downregulation of fetal β -receptors (35).

A study published in 2005 reported an association between continuous use of terbutaline for ≥ 2 weeks and increased concordance for autism spectrum disorders in dizygotic twins (36). The investigators concluded that genetic factors and over stimulation of β_2 -adrenergic receptors by terbutaline could affect developmental programs in the fetal brain leading to autism.

A 2009 report examined the evidence for the use and toxicity of β_2 -agonists in pregnancy, particularly for terbutaline and ritodrine as tocolytic agents and albuterol for asthma (37). Based on animal and human reports, the authors concluded that there was a biological plausible basis for associating prolonged in utero exposure to β_2 -agonists with functional and behavioral teratogenesis,

such as increased risks for autism spectrum disorders, psychiatric disorders, and poor cognitive, motor function, and school performance. There also were increased risks for elevated heart rate and hypertension. The mechanisms for these effects appeared to be a decrease in parasympathetic activity resulting in an increase in sympathetic activity. A genetic predisposition for the toxicity was supported by data. The available data suggested that short-term terbutaline use (2–3 days) was not associated with these toxicities, but prolonged use (≥ 2 weeks) was associated (37).

BREASTFEEDING SUMMARY

Terbutaline is excreted into breast milk. In two mothers with chronic asthma about 6–8 weeks postpartum, 5 mg 3 times daily produced mean maternal plasma levels of 1.9–4.8 ng/mL, whereas milk concentrations ranged between 2.5 and 3.8 ng/mL (38). The nursing infants ingested approximately 0.2% of the maternal dose, and the drug could not be detected in their plasma. In the second report, two mothers, both at 3 weeks postpartum and both with chronic asthma, were treated with 2.5 mg 3 times a day (39). Plasma levels varied between 0.97 and 3.07 ng/mL, whereas mean milk levels were 2.76–3.91 ng/mL. Peak milk concentrations occurred at about 4 hours. The milk:plasma ratios of 1.4–2.9 are indicative of ionic trapping in the milk. Concentrations of terbutaline were highest in the fat fraction of the milk. Based on calculations, the infants were ingesting approximately 0.7% of the maternal dose (39).

No symptoms of adrenergic stimulation were observed in the four infants and all exhibited normal development. Long-term effects of this exposure, however, have not been studied. The American Academy of Pediatrics classifies terbutaline as compatible with breastfeeding (40).

TERCONAZOLE

Antifungal

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Although no published reports describing the use of terconazole in human pregnancy have been located, the FDA database provided information on a large number of exposures. This pregnancy experience, combined with the animal data, suggest that the embryo–fetal risk is low. However, additional human studies are required for confirmation.

FETAL RISK SUMMARY

Terconazole is available as either a vaginal cream or suppositories. The antifungal agent is absorbed into the systemic circulation in humans after vaginal administration. Fetal exposure to the drug is also possible by direct transfer of terconazole across the amniotic membranes after vaginal administration (1). Terconazole is a triazole antifungal agent in the same class as fluconazole, itraconazole, posaconazole, and voriconazole.

No evidence of teratogenicity was found after oral and SC administration of terconazole to rats and rabbits, but some embryotoxicity was observed at high doses (1).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 1167 newborns had been exposed to terconazole during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 34 (2.9%) major birth defects were observed (48 expected). Specific data were available for six defect categories, including (observed/expected) 14/12 cardiovascular defects, 0/2 oral clefts, 0/0.5 spina bifida, 3/3 polydactyly, 1/2 limb reduction defects, and 1/3 hypospadias. These data do not support an association between the drug and congenital defects.

BREASTFEEDING SUMMARY

No reports describing the use of terconazole during lactation have been located.

TERFENADINE

[Withdrawn from the market. See 9th edition.]

TERIFLUNOMIDE

Immunologic Agent (Immunomodulator)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

One report cited a clinical trial that involved 43 pregnancies (1). Although no details of the exposures were provided, the report stated that there was no increased risk of spontaneous abortions, lower birth weights, lower gestational ages, or congenital malformations. The animal reproduction data suggest risk, including embryo malformations and fetal death. The manufacturer classifies the drug as contraindicated in pregnancy. If a woman conceives while taking this drug, or a woman a childbearing potential stops the drug, the 11-day procedure for accelerated elimination of teriflunomide is recommended because it takes on average 8 months, but possibly as long as 2 years, to reach plasma concentrations (<0.02 mg/mL) that are considered minimal risk (see package insert for procedure) (2). If exposure does occur in pregnancy, physicians are encouraged to enroll their patient in the manufacturer's pregnancy registry, or women can enroll themselves, by calling 1-800-745-4447, option 2.

FETAL RISK SUMMARY

Teriflunomide, an oral immunomodulator with anti-inflammatory properties, inhibits a mitochondrial enzyme involved in de novo pyrimidine synthesis. It is the principal active metabolite of leflunomide and is responsible for leflunomide's activity (see also Leflunomide). Teriflunomide is indicated for the treatment of patients with relapsing forms of multiple sclerosis. The drug is mainly distributed in plasma. It is metabolized to inactive metabolites. Plasma protein binding is high (>99%), and the dose-dependent elimination half-life is very long (18–19 days). The drug has been detected in human semen (2).

Reproduction studies with teriflunomide have been conducted in rats and rabbits. In rats given oral doses during organogenesis that were not maternal

toxic, high incidences of fetal defects, mainly craniofacial, and axial and appendicular skeletal defects, as well as embryo–fetal death were observed. The no-effect maternal plasma exposure for embryo–fetal developmental toxicity was less than that in humans at the maximum recommended human dose (MRHD). When nonmaternal toxic doses were administered during gestation and lactation, decreased growth, eye and skin abnormalities, and high incidences of limb defects and postnatal death were observed in the offspring. The no-effect maternal plasma exposure for prenatal and postnatal developmental toxicity in rats was less than that in humans at the MRHD. In rabbits given oral doses that caused minimal maternal toxicity, high incidences of defects (similar to those seen in rats) and embryo–fetal death, were observed. The maternal plasma exposure at the no-effect dose for prenatal and postnatal developmental toxicity in rabbits was less than that in humans at the MRHD (2).

No evidence of carcinogenicity was observed in mice and rats in lifetime studies. Both positive and negative results for mutagenic and clastogenic effects were noted in various assays. In studies with male rats, no adverse effect on fertility was noted, but a dose-related decrease in epididymal sperm count did occur. In female rats, oral doses before and during mating resulted in embryoletality, reduced fetal body weight, and malformations at all doses tested (2).

It is not known if teriflunomide crosses the human placenta. The molecular weight (about 270) and very long elimination half-life suggest that the drug will cross to the embryo–fetus, but the high plasma protein binding might limit the exposure.

A 2013 reference cited data from a clinical trial database that involved 43 pregnancies exposed to teriflunomide (1). Although no information was provided on the dose, timing of the exposures, or specific data on outcomes, the citation stated that no increased risk of spontaneous abortions, lower birth weights, lower gestational ages, or congenital malformations were observed (1).

BREASTFEEDING SUMMARY

No reports describing the use of teriflunomide during human lactation have been located. The molecular weight (about 270) and very long elimination half-life (about 18–19 days) suggest that the drug will be excreted into breast milk, but the high plasma protein binding (>99%) might limit the amount excreted. Because of the severe toxicity that has occurred in adults taking the drug (e.g., severe hepatotoxicity, bone marrow depression, immunosuppression), the drug

is best not used in women who are nursing an infant.

TERPIN HYDRATE

Respiratory Drug (Expectorant)

PREGNANCY RECOMMENDATION: Contraindicated (Significant Alcohol Content)

BREASTFEEDING RECOMMENDATION: Contraindicated (Significant Alcohol Content)

PREGNANCY SUMMARY

Terpin hydrate is available as a liquid preparation that contains a significant amount (about 42%) of ethanol. It should not be used in pregnancy.

FETAL RISK SUMMARY

Although no longer approved as an expectorant, this agent has been used for a number of years and may still be available for this indication. At one time it was combined with codeine as an expectorant–antitussive proprietary mixture. No animal reproductive studies of terpin hydrate have been located.

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 146 of whom had 1st trimester exposure to terpin hydrate (1, pp. 378–89). Congenital malformations were observed in 13 (standardized relative risk [SRR] 1.29) of the newborns. For use anytime in pregnancy, 1762 mother–child pairs were exposed (1, p. 442). Twenty-nine (30.6 expected) of the newborns had anomalies (SRR 0.95). Neither of the exposure periods indicates an increased fetal risk from the drug. Specific malformations or conditions identified following use of terpin hydrate anytime in pregnancy were any benign tumors 9 (SRR 1.9), clubfoot 11 (SRR 1.2), and inguinal hernia 34 (SRR 1.4) (1, p. 496). However, these data are uninterpretable without independent confirmation from other studies. Any positive or negative associations may have occurred by chance (1, p. 481). A 1964 study found no abnormalities in six infants exposed in utero to terpin hydrate (with or without codeine) during the 1st trimester (2). Neither of the above studies specified the doses consumed by the patients.

The recommended dose of terpin hydrate, which contains approximately 42% ethanol, is 5–10 mL 3–4 times daily. The maximum daily dose would therefore contain about 17 mL of absolute ethanol or about one-half of the amount that

has been shown to produce mild fetal alcohol syndrome (see Ethanol). Because the minimum amount of ethanol exposure required to produce fetal developmental toxicity is unknown, this product should be avoided during pregnancy.

BREASTFEEDING SUMMARY

No reports describing the use of terpin hydrate during lactation have been located. Because of the high ethanol content (about 42%) of terpin hydrate, frequent use of this product should be avoided during lactation (see also Ethanol).

TESAMORELIN

Growth Hormone Releasing Factor

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of tesamorelin acetate in human pregnancy have been located. Animal data suggest risk, but the absence of human pregnancy experience prevents an assessment of the embryo–fetal risk. However, during human pregnancy, visceral adipose tissue increases due to normal hormonal and metabolic changes. Altering these changes with tesamorelin offers no known benefit and could result in fetal harm. Therefore, tesamorelin is contraindicated in pregnancy.

FETAL RISK SUMMARY

Tesamorelin is given as a daily SC injection. It is a growth hormone releasing factor (GRF) analog indicated for the reduction of excess abdominal fat in HIV-infected patients with lipodystrophy. Tesamorelin binds and stimulates human GRF receptors with potency similar to endogenous GRF. Metabolism in humans has not been studied. The mean elimination half-life is 26 minutes in healthy subjects and 38 minutes in HIV-infected patients (1).

Reproduction studies have been conducted in rats and rabbits. In rats during organogenesis, doses that were about 2 and 4 times the human clinical dose based on AUC (HCD) resulted in hydrocephaly in offspring. Lower doses that were about 0.1–1 times the HCD during organogenesis caused delayed skull ossification. No adverse developmental effects were observed in rabbits at doses up to 500 times the HCD (1).

Carcinogenicity studies in rodents have not been conducted with tesamorelin. The drug was not genotoxic in multiple assays. There was no effect on fertility in male or female rats after doses approximately equal to the HCD for 28 days in males or 14 days in females. In a 26-week study, female rats given 16 and 25 times the HCD were more likely to be in diestrus (1).

It is not known if tesamorelin crosses the human placenta. The molecular

weight (about 5136 for the free base) and the short elimination half-life suggest that exposure of the embryo–fetus will be limited.

BREASTFEEDING SUMMARY

No reports describing the use of tesamorelin during human lactation have been located. The molecular weight (about 5136 for the free base) and the short elimination half-life (38 minutes for HIV-infected patients) suggest that excretion into milk will be limited. Moreover, any drug in breast milk would most likely be digested in the infant’s gut. However, tesamorelin is a weak base, and when used during lactation, accumulation in the milk may occur with concentrations significantly greater than corresponding plasma levels. Nevertheless, it is unlikely that tesamorelin will be used during breastfeeding because the drug is indicated for use in HIV-infected patients and breastfeeding is not recommended in this patient population.

TESTOSTERONE

Androgenic Hormone

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

First trimester in utero exposure of female fetuses to exogenous testosterone or its derivatives causes clitoral hypertrophy, fused or partial fused labia, and, possibly, absent vagina. These varying degrees of masculinization are referred to as nonadrenal female pseudohermaphroditism. Exposure to testosterone hormones at any gestational age is associated with clitoral hypertrophy (1). However, to cause labial–scrotal fusion, exposure must occur before the 10th or 11th fetal week when female differentiation of external genitalia is complete (1). Other than the genital abnormalities, testosterone and its derivatives do not appear to cause structural defects. Only one report of nongenital malformations after testosterone exposure has been published, but this association lacks confirmation. However, a study in monkeys has suggested that long-term potentially permanent changes in the central nervous system of female offspring may result from in utero testosterone exposure. Apparently, this has not been studied in humans. Testosterone and its derivatives are contraindicated at any time during pregnancy.

FETAL RISK SUMMARY

Testosterone is a natural hormone with androgenic and anabolic properties. Testosterone and its derivatives (e.g., methyltestosterone) are primarily indicated as replacement therapy in male hypogonadal disorders secondary to various causes. Preparations of testosterone products are available for oral, buccal, topical, and IM administration. About 80% of testosterone is bound to sex-hormone-binding globulin. Several metabolic pathways of testosterone have been identified, including aromatization to form estrogenic derivatives. The plasma elimination half-life of testosterone is in the range of 10–100 minutes (2). Testosterone rapidly crosses the human placenta to the embryo or fetus

(3).

In a 1987 study, testosterone exposure of female rhesus monkeys in utero appeared to have induced irreversible changes in the pattern of luteinizing hormone secretion in adult life (4). Seventeen female monkey pseudohermaphrodites (exposed in utero) and 24 normal females were studied at about 13–14 years of age. All subject and control animals demonstrated evidence of ovulatory menstrual cycles. The 17 monkeys with pseudohermaphroditism had been exposed in utero to testosterone that had resulted in external genital masculinization/obliteration of the external vaginal orifice or clitoromegally alone (degree of genital masculinization was dependent on the timing of exposure). Compared with controls, significant increases in the ratio of luteinizing hormone to follicle-stimulating hormone in the luteal and follicular phases of the ovulatory menstrual cycles were measured in the pseudohermaphrodites (4).

A 1957 report cited several animal studies published in the late 1940s and early 1950s that had demonstrated that administration of testosterone or its derivatives to pregnant animals resulted in masculinization of female fetuses (5). A later report also reviewed the animal data and specifically evaluated the dose and fetal age associated with masculinization of female fetuses (3).

Testosterone and its derivatives are contraindicated in pregnancy because they cause virilization of female fetuses (5–16). Two case reports, one in 1953 and another in 1955 (both in German), were the first to describe female pseudohermaphroditism in human infants after exposure to a testosterone derivative (methylandrostenediol; methandriol) (6) or testosterone/methyltestosterone/estradiol (7).

The first English language cases of nonadrenal human female pseudohermaphroditism secondary to maternal use of testosterone were published in 1957. A woman was treated with oral methyltestosterone 20 mg/day for alopecia starting in the 7th week of pregnancy and continuing irregularly until term (total dose 1.5 g) (5). During treatment, the woman noted a deepening voice, hirsutism, and a male-pattern of body hair, as well as partial resolution of her alopecia. Sex of the newborn, which initially appeared to be male, was not established until 7 months of age when the diagnosis of female pseudohermaphroditism was made (5). In the second case, a woman at 10 weeks' gestation was treated with two doses of testosterone (100 mg IM on day 1 and 3) and 51 days of oral methyltestosterone (30 mg/day) for nausea and vomiting of pregnancy (8). The therapy was discontinued because of the woman's deepening voice. A 3.4-kg infant was delivered at term who had

cyanosis and bradycardia of short duration. Although the sex was ambiguous (small penis, undescended testes), the infant was raised as a male. Detailed examination at 6 months of age revealed the infant to be a female (8).

Other cases have described nonadrenal female pseudohermaphroditism secondary to exposures to methyltestosterone or testosterone, sometimes in combination with estradiol or other estrogens, in the 1st trimester (9–16). In each of these cases, examination of the newborn infant usually revealed a hypoplastic penis, cryptorchidism, and hypospadias. The actual diagnosis of female sex with clitoral hypertrophy, with or without fused labia, and an occasionally absent vagina, was made weeks to months after birth. Surgery was usually required to correct the genital abnormalities. In two cases, the infants had been exposed to methyltestosterone or testosterone during the first 12 or 16 weeks of pregnancy (13,14). They were later diagnosed as females and the genital abnormalities were corrected surgically. In their early 20s, both had normal pregnancies and gave birth to healthy infants (14,15). In another case, the mother received daily oral methyltestosterone from the 14th week until term for breast engorgement (3). In addition, she was given four IM doses of testosterone (total dose 115 mg) between the 14th and 35th weeks of gestation. Except for clitoral hypertrophy, no other signs of virilization were observed in the infant or the mother (3).

The only report of structural defects, other than genital, associated with the use of testosterone appeared in a 1953 article (17). Three infants with limb anomalies had been exposed during the 1st trimester to a combination of testosterone and progesterone.

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 26 of whom were exposed to a group of miscellaneous hormones during the 1st trimester (18). Among the 26 cases, 3 were exposed to testosterone, 4 to methandrostenolone, and 1 each to methyltestosterone, fluoxymesterone, and an unspecified male hormone. There were no congenital malformations observed in the 26 exposures (18).

BREASTFEEDING SUMMARY

Testosterone, usually combined with an estrogen, has been used to suppress lactation and to treat postpartum breast pain and engorgement (19–29). Testosterone suppresses lactation apparently by prolactin inhibition (29). Although the amount of testosterone administered was very large, no cases of virilization or other adverse effects attributable to the androgen have been reported. The combination, however, is no longer used because the estrogen–

testosterone combination was associated with frequent rebound lactation and an increased incidence of postpartum thromboembolic disease (29).

Although testosterone inhibits prolactin, suckling or any breast manipulation may antagonize the inhibitory effect (21). This has been shown in cases where a mother has received the testosterone–estrogen combination, then changed her mind and breastfed her infant. The amounts of testosterone excreted into milk have apparently not been determined. The absence of reports of adverse effects in nursing infants probably indicates that the short-term exposure is benign. However, the effects from long-term maternal use of testosterone or its derivatives on a nursing infant have not been studied. Therefore, breastfeeding should be halted if these agents are required.

TETRABENAZINE

Antichorea

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

The very limited human pregnancy experience prevents an assessment of the embryo–fetal risk. However, tetrabenazine caused stillbirths and pup mortality in one animal species. Moreover, the drug rapidly distributes into the brain and reversibly depletes monoamines, such as dopamine, serotonin, norepinephrine, and histamine (1). Thus, it is best avoided in pregnancy.

FETAL RISK SUMMARY

Tetrabenazine, a reversible monoamine depletory, is indicated for the treatment of chorea associated with Huntington's disease. The drug undergoes rapid and extensive hepatic metabolism to two active metabolites resulting in plasma concentrations of the parent drug that are generally below the limit of detection. Plasma protein binding of the two metabolites is moderate, in the range of 59%–68%, and their half-lives are 4–8 hours and 2–4 hours, respectively (1).

Reproduction studies have been conducted in rats and rabbits. In rats, doses up to 3 times the maximum recommended human dose of 100 mg/day based on BSA (MRHD) from the beginning of organogenesis through the lactation period had no clear effects on embryo–fetal development. However, increases in stillbirths and postnatal mortality were observed at doses 1.5–3 times the MRHD, as well as delayed pup maturation at doses 0.5–3 times the MRHD. The no-effect dose for stillbirths and postnatal mortality was 0.5 times the MRHD. In rabbits, dose up to 12 times the MRHD during organogenesis had no effect on embryo–fetal development (1).

Neither carcinogenicity nor fertility impairment studies have been conducted. The parent drug and the active metabolites were negative in mutagenic studies,

but were clastogenic in two assays (1).

It is not known if tetrabenazine or its two active metabolites cross the human placenta. The molecular weight of the parent compound (about 317), and the plasma protein binding and half-lives of the metabolites suggest that all three compounds will cross to the embryo–fetus.

A woman with chorea gravidarum was treated with tetrabenazine starting late in the 2nd trimester (2). No drug-induced fetal or newborn effects were observed. The small ventricular septal defect in the infant was probably not related to tetrabenazine exposure (2).

BREASTFEEDING SUMMARY

No reports describing the use of tetrabenazine during lactation have been located. The molecular weight of the parent compound (about 317), and the plasma protein binding and half-lives of the two metabolites (see above) suggest that at least the metabolites will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown. However, common adverse effects observed in adults, such as sedation, somnolence, insomnia, depression, akathisia, and other toxicities, are potential complications.

TETRACAINE

Local Anesthetic

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

A 1988 review concluded that the available human pregnancy data for tetracaine were inadequate to estimate the embryo–fetal risk from use of the local anesthetic in pregnancy (1). Animal reproduction data also are very limited but did not indicate risk. However, the highest dose used was equal to the human dermal dose based on BSA. In addition, there are no studies regarding the amount of tetracaine reaching the systemic circulation after topical (other than the skin patch) or spinal administration. Nevertheless, based on very small numbers, tetracaine does not appear to represent a risk of embryo and/or fetal harm any greater than that of other local anesthetics (see also Lidocaine, Pramoxine, and Ropivacaine). Thus, although the combined data are inadequate, the risk of embryo–fetal harm from tetracaine is probably low.

FETAL RISK SUMMARY

Tetracaine is an ester type local anesthetic agent. Because of the potential for severe systemic toxicity, its use is restricted to topical anesthesia and spinal block. For some procedures, injectable lidocaine is considered to be a safer alternative (2). Tetracaine is available as topical preparations (concentrations) that include solutions (2%), gels (2%), creams (1% and 2%), and ointments (1%), ophthalmic solutions (0.5%), and formulations for spinal anesthesia (0.2%, 0.3%, and 1%). It is also available in equal combination (70 mg each) with lidocaine as a skin patch that is indicated for use on intact skin to provide local dermal anesthesia for superficial venous access and superficial dermatological procedures such as excision, electrodesiccation, and shave biopsy of skin lesions (3). Little, if any, tetracaine is absorbed from the skin

patch. Plasma levels of the anesthetic were not detectable (<0.9 ng/mL) at 30 and 60 minutes, whereas lidocaine was detectable in the plasma (<5 ng/mL) (3).

Reproduction studies have been conducted in rats and rabbits. In these species, SC doses up to the single dermal administration dose based on BSA (SDAD) were not teratogenic. In addition, no other reproductive or developmental toxicity was observed when tetracaine was given during gestation and lactation at a SC dose that was equal to the SDAD. Tetracaine has not been studied for carcinogenicity, but tests for mutagenicity were negative. The anesthetic agent had no effect on male and female rat fertility at SC doses up to the SDAD (3).

The low molecular weight (about 264) suggests that tetracaine crosses the human placenta, as does lidocaine and other local anesthetics (see Lidocaine). However, the amounts in the systemic circulation appear to be very low, at least from the skin patch, so the amount reaching the embryo and/or fetus will also be very low. Although the absorption of tetracaine into the blood from other formulations is unknown, it also is probably low.

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 23 of whom had exposure to tetracaine during the 1st trimester (4, pp. 358, 360). No evidence of an association with malformations was found.

A 1981 report described 53 women who received spinal anesthesia with tetracaine diluted to 0.5% (5). Prolongation of the induction-to-delivery interval had no effect on the Apgar scores or the neonatal acid-base values. However, when the uterine incision-to-delivery interval was more than 3 minutes, there were significantly lower mean pH and pO₂ values in the umbilical vein and artery, and significantly higher mean pCO₂ and base deficit results in the umbilical artery. Moreover, the prolonged interval was also associated with significantly more Apgar scores less than 7 at 1 and 5 minutes (5).

BREASTFEEDING SUMMARY

No reports describing the use of tetracaine during human lactation have been located. The low molecular weight (about 264) suggests that tetracaine will be excreted into human breast milk, as does lidocaine. (See Lidocaine.) However, the amount of tetracaine in the systemic circulation appears to be very low, at least from the skin patch, so the amount excreted into breast milk will also be very low. Although the absorption of tetracaine into the blood from other formulations is unknown, it also is probably low. Based on these estimates, the risk to a nursing infant from tetracaine given to the mother appears to be nil.

TETRACYCLINE

Antibiotic (Tetracycline)

PREGNANCY RECOMMENDATION: Contraindicated—2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Tetracyclines are a class of antibiotics that should be used with extreme caution, if at all, in pregnancy. These agents can cause significant maternal and fetal toxicity. The discussion below, unless otherwise noted, applies to all members of this class.

FETAL RISK SUMMARY

Problems attributable to the use of the tetracyclines during or around the gestational period can be classified into four areas:

- Adverse effects on fetal teeth and bones
- Maternal liver toxicity
- Congenital defects
- Miscellaneous effects

Placental transfer of a tetracycline was first demonstrated in 1950 (1). The tetracyclines were considered safe for the mother and fetus and were routinely used for maternal infections during the following decade (2–5). It was not until 1961 that an intense yellow-gold fluorescence was observed in the mineralized structures of a fetal skeleton whose mother had taken tetracycline just before delivery (6). Following this report, a 2-year-old child was described whose erupted deciduous teeth formed normally but were stained a bright yellow because of tetracycline exposure in utero (7). Fluorescence under ultraviolet light and yellow-colored deciduous teeth that eventually changed to yellow-brown were associated with maternal tetracycline ingestion during pregnancy by several other investigators (8–22). An increase in enamel hypoplasia and caries was initially suspected but later shown not to be related to in utero tetracycline exposure (14,15,22). Newborn growth and development were

normal in all of these reports, although tetracycline has been shown to cause inhibition of fibula growth in premature infants (6). The mechanism for the characteristic dental defect produced by tetracycline is related to the potent chelating ability of the drug (13). Tetracycline forms a complex with calcium orthophosphate and becomes incorporated into bones and teeth undergoing calcification. In the latter structure, this complex causes a permanent discoloration, because remodeling and calcium exchange do not occur after calcification is completed. Because the deciduous teeth begin to calcify at around 5 or 6 months in utero, use of tetracycline after this time will result in staining.

The first case linking tetracycline with acute fatty metamorphosis of the liver in a pregnant woman was described in 1963 (23), although two earlier papers reported the disease without associating it with the drug (24,25). This rare but often fatal syndrome usually follows IV dosing of >2 g/day. Many of the pregnant patients were being treated for pyelonephritis (24–37). Tetracycline-induced hepatotoxicity differs from acute fatty liver of pregnancy in that it is not unique to pregnant women and reversal of the disease does not occur with pregnancy termination (38). The symptoms include jaundice, azotemia, acidosis, and terminal irreversible shock. Pancreatitis and nonoliguric renal failure are often related findings. The fetus may not be affected directly, but as a result of the maternal pathology, stillborns and premature births are common. In an experimental study, increasing doses of tetracycline caused increasing fatty metamorphosis of the liver (39). The possibility that chronic maternal use of tetracycline before conception could result in fatal hepatotoxicity of pregnancy has been raised (36). The authors speculated that tetracycline deposited in the bone of a 21-year-old patient was released during pregnancy, resulting in liver damage.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, a large number of newborns had been exposed to the tetracycline group of antibiotics during the 1st trimester (F. Rosa, personal communication, FDA, 1993). For four tetracyclines (T, tetracycline; D, doxycycline; O, oxytetracycline; M, minocycline), specific data were available for six defect categories, including (observed/expected):

| | T | D | O | M |
|----------------------------------|-------|-------|-------|-------|
| Number of exposures | 1795 | 1795 | 26 | 181 |
| Number of major defects | 47 | 78 | 1 | 8 |
| Percent | 4.7% | 4.3% | 3.8% | 4.4% |
| Number of major defects expected | 46 | 76 | 1 | 7 |
| Cardiovascular defects | 12/10 | 20/18 | 0/0.3 | 2/2 |
| Oral clefts | 1/2 | 0/3 | 0/0 | 1/0.5 |
| Spina bifida | 0/0.5 | 2/1 | 0/0 | 0/0 |
| Polydactyly | 5/3 | 7/5 | 0/0 | 0/0.5 |
| Limb reduction defects | 1/2 | 0/3 | 0/0 | 0/0.5 |
| Hypospadias | 1/2 | 4/4 | 0/0 | 0/0.5 |

These data do not support an association between the drugs and the specific malformations evaluated.

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 341 of whom had 1st trimester exposure to tetracycline, 14 to chlortetracycline, 90 to demeclocycline, and 119 to oxytetracycline (40, pp. 297–313). For use anytime in pregnancy, 1336 exposures were recorded for tetracycline, 0 for chlortetracycline, 280 for demeclocycline, and 328 for oxytetracycline (40, p. 435). The findings of this study were as follows:

Tetracycline: Evidence was found to suggest a relationship to minor, but not major, malformations. Three possible associations were found with individual defects, but independent confirmation is required: hypospadias (1st trimester only) (5 cases); inguinal hernia (25 cases); and hypoplasia of limb or part thereof (6 cases) (40, pp. 472, 485).

Chlortetracycline: No evidence was found to suggest a relationship to large categories of major or minor malformations or to individual defects. However, the sample size is extremely small, and safety should not be inferred from these negative results.

Demeclocycline: No evidence was found to suggest a relationship to large categories of major or minor malformations, but the sample size is small (40, pp. 297–313). Two possible associations were found with individual defects, but independent confirmation is required: clubfoot (1st trimester only) (3 cases); and inguinal hernia (8 cases) (40, pp. 472, 485).

Oxytetracycline: Evidence was found to suggest a relationship to large categories of major and minor malformations (40, pp. 297–313). One possible association was found with individual defects, but independent confirmation is required: inguinal hernia (14 cases) (40, pp. 472, 485).

In 1962, a woman treated with tetracycline in the 1st trimester for acute bronchitis delivered an infant with congenital defects of both hands (41,42). The mother had a history of minor congenital defects on her side of the family and doubt was cast on the role of the drug in this anomaly (43). A possible association between the use of tetracyclines in pregnancy or during lactation and congenital cataracts has been reported in four patients (44). The effects of other drugs, including several antibiotics, and maternal infection could not be determined, and a causal relationship to the tetracyclines seems remote. An infant with multiple anomalies whose mother had been treated for acne with clomocycline daily during the first 8 weeks of pregnancy has been described (45). Some of the defects, particularly the incomplete fibrous ankylosis and bone changes, made the authors suspect this tetracycline as the likely cause.

Doxycycline has been used for 10 days very early in the 1st trimester for the treatment of Mycoplasma infection in a group of previously infertile women (46). Dosage was based on the patient's weight, varying from 100 to 300 mg/day. All 43 of the exposed liveborn were normal at 1 year of age. Bubonic plague occurring in a woman at 22 weeks' gestation was successfully treated with tetracycline and streptomycin (47). Long-term evaluation of the infant was not reported.

A 1997 report examined the question of doxycycline-induced teratogenicity in the large population-based dataset of the Hungarian Case–Control Surveillance of Congenital Abnormalities, 1980–1992 (48). Some mild defects were excluded, including hemangiomas and minor malformations. Moreover, although an extensive retrospective assessment of drug use during pregnancy was performed, a history of tobacco and alcohol exposure was not obtained because the accuracy of these data was believed to have low validity. Among the 32,804 women who had normal infants (controls), 63 (0.19%) had taken doxycycline, whereas 56 (0.30%) of the 18,515 women who delivered infants with congenital anomalies had taken the antibiotic ($p = 0.01$). A case–control pair analysis of exposures during the 2nd and 3rd months of gestation, however, did not show a significant difference among the groups in any of the malformation types (48).

A retrospective cohort study using data from Tennessee Medicaid included 30,049 infants born in 1985–2000 was published in 2009 (49). Infants with fetal exposures in the 1st trimester to four antibiotics recommended for potential bioterrorism attacks (doxycycline, amoxicillin, ciprofloxacin, and azithromycin) were compared to infants with no fetal exposure to any antibiotic. Erythromycin was included as a positive control. In the 1691 infants exposed to doxycycline

and no other antibiotics, the number of cases, risk ratios, and 95% confidence interval [CI] were: any malformation (42, 0.85, 0.59–1.23); cardiac (15, 0.86, 0.47–1.57); musculoskeletal (12, 0.94, 0.47–1.88); genitourinary (4, 0.45, 0.15–1.34); gastrointestinal (3, 0.35, 0.10–1.20); CNS (4, 0.87, 0.27–2.78); and orofacial (5, 2.96, 0.75–11.67). The authors concluded that the four antibiotics should not result in a greater incidence of overall major malformations (see also Amoxicillin, Azithromycin, and Ciprofloxacin) (49).

A 2000 report, using the same database as above, but now for the years 1980–1996, examined the relationship between oral oxytetracycline and congenital malformations (50). Of 22,865 women who had offspring with a congenital defect, 216 (0.9%) had been treated with oxytetracycline, whereas of 38,151 women with offspring without defects, 214 (0.6%) had been treated (odds ratio [OR] 1.7, 95% CI 1.4–2.0). Analysis of medically documented treatment in the 2nd/3rd months of gestation revealed significant associations with neural tube defects (NTD) (OR 9.7, 95% CI 2.0–47.1), cleft palate (OR 17.2, 95% CI 3.5–83.5), and multiple defects (mainly neural tube defects and cardiovascular malformations) (OR 12.9, 95% CI 3.8–44.3). However, these results were based on a very small number of cases: two NTD, two cleft palates, and four multiple defects. The number of cases, OR, and 95% CI occurring in the entire pregnancy for these outcomes were NTDs (7, 5.4, 2.4–12.1), cleft palate (3, 4.6, 1.4–15.0), and multiple defects (6, 3.3, 1.4–7.9) (50).

Under miscellaneous effects, two reports have appeared that, although they do not directly relate to effects on the fetus, do directly affect pregnancy. In 1974, a researcher observed that a 1-week administration of 500 mg/day of chlortetracycline to male subjects was sufficient to produce semen levels of the drug averaging 4.5 mcg/mL (51). He theorized that tetracycline overdose could modify the fertilizing capacity of human sperm by inhibiting capacitation. Finally, a possible interaction between oral contraceptives and tetracycline resulting in pregnancy has been reported (52). The mechanism for this interaction may involve the interruption of enterohepatic circulation of contraceptive steroids by inhibiting gut bacterial hydrolysis of steroid conjugates, resulting in a lower concentration of circulating steroids.

BREASTFEEDING SUMMARY

Tetracycline is excreted into breast milk in low concentrations. Milk:plasma ratios vary between 0.25 and 1.5 (4,53,54). In a 1996 case, black breast milk was reported in a woman taking minocycline, a semisynthetic derivative of

tetracycline (55). She had stopped breastfeeding 18 months before she was treated with minocycline 150 mg/day and topical clindamycin for acne. Within 4 weeks of starting minocycline, milk expressed from her breasts was black. No other abnormalities were found on a diagnostic workup. Analysis of the milk demonstrated black pigment particles within macrophages, as well as extracellular, that stained positive for iron. The milk contained a high iron concentration (11.9 $\mu\text{mol/g}$ wet weight) (55).

Theoretically, dental staining and inhibition of bone growth could occur in breastfed infants whose mothers were consuming tetracycline. However, this theoretical possibility seems remote, because tetracycline serum levels in infants exposed in such a manner were undetectable (<0.05 mcg/mL) (4). Three potential problems may exist for the nursing infant even though there are no reports in this regard: modification of bowel flora, direct effects on the infant, and interference with the interpretation of culture results if a fever workup is required. The American Academy of Pediatrics classifies tetracycline as compatible with breastfeeding (56).

THALIDOMIDE

Immunologic Agent (Immunomodulator)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Thalidomide is a potent human teratogen. The severe malformations induced by thalidomide may involve defects of the limbs, axial skeleton, head and face, eyes, ears, tongue, teeth, central nervous, respiratory, cardiovascular, and genitourinary systems, and the gastrointestinal tract. The neurological complications may include severe mental retardation secondary to sensory deprivation. The critical period of exposure is 34–50 days after the first day of the last menstrual period (LMP) (20–36 days after conception). The drug is contraindicated in pregnancy.

FETAL RISK SUMMARY

Thalidomide is an immunomodulatory agent used for the acute treatment of erythema nodosum leprosum, a cutaneous manifestation of Hansen's disease (leprosy) (1). The agent was recently approved for use in the United States for the first time, making its debut in 1999. Thalidomide was one of the first drugs that was clearly shown to be a human teratogen and probably has caused more known severe malformations in humans than any other drug.

A large number (>30) of animal (mice, rats, rabbits, and monkeys) reproduction studies conducted with thalidomide were reviewed in a 1976 reference (2). Embryoletality and teratogenicity (structural and/or functional abnormalities) were noted commonly in some species. Evidence of significant thalidomide teratogenicity was found in monkeys, but in mice and rats, limb reduction defects were not observed and, in some cases, there was no evidence of teratogenicity. Amelia and micromelia were noted in two mouse fetuses and a limb defect in another that closely resembled the defects observed in humans, but these reports were considered inconclusive (2). In a 1983 study with rats, however, increased rates of both embryoletality and

congenital defects involving the skeleton (ribs and spine) and eyes (ophthalmorrhhexis and microphthalmia) were observed (3). The authors speculated that the difference in outcome between their study and previous experimental work with rats was possibly due to hydrolysis of the drug before administration, the use of toxic solvents that masked the teratogenic effect of thalidomide, or the low solubility of thalidomide in the solvent that prevented delivery of an effective dose to the target site (3). Experiments in rabbits have consistently revealed fetal limb malformations that are very similar to those seen in human infants exposed in utero to thalidomide (4–8). Other anomalies noted in rabbit fetuses included hemangioma of the nose and defects of the skull, nostril, external genitalia, and tail (6). Another study with rabbits observed limb anomalies, arthrogyrosis, dysplasia of the kidneys and gallbladder, cleft palate, hernia, and gastric hypoplasia (8). Experiments with chick embryos demonstrated that thalidomide induced cardiovascular anomalies in this species (9).

Several reviews have described the various human systems affected by thalidomide-induced embryopathy (10–19). One of these reviews presented the pregnancy history of two children (twins), born in the United States, who had very different severity of thalidomide embryopathy (10). The first twin, 2211-g female, was born with duodenal atresia, a rectoperineal fistula, and hypoplastic, dislocated thumbs (right thumb worse than left). The other twin, a 2240-g male, had phocomelia of both upper extremities and a midline hemangioma on the forehead. Missing or hypoplastic digits were noted on both hands (10).

The critical period of fetal exposure to thalidomide is 34–50 days after the first day of the LMP (20–36 days after conception) (13,16–18). Congenital malformations that have been associated with approximate time periods within this 17-day interval include (days after LMP; when two ranges are shown, the references cited disagreed): anotia (34–38 days), microtia (39–43 days), thumb duplication (35–38 days), thumb aplasia (35–43 days), thumb hypoplasia (38–40 days), thumb triphalangism (46–50 days), eye defects (35–42 days), cardiovascular defects (ductus, conotruncal defects, and septal defects) (36–45 days), duplication of the vagina (35–39 days), cranial nerve palsy (35–37 days), amelia of the arms (38–43 days), phocomelia of the arms (38–47 or 49 days), dislocation of the hip (38–48 days), amelia of the legs (41–45 days), phocomelia of the legs (40 or 42–47 days), choanal atresia (43–46 days), duodenal atresia (40–47 days), anal atresia (41–43 days), aplasia of gallbladder (42–43 days), pyloric stenosis (40–47 days), duodenal stenosis

(41–48 days), rectal stenosis (49–50 days), ectopic kidney and hydronephrosis (38–43 days), other genitourinary defects (45–47 days), and abnormal lobulation of lungs (43–46 days) (13,17).

Perhaps the best description of the spectrum of congenital defects caused by thalidomide was written by Newman (16,17). The limb reduction defects are bilateral, usually grossly symmetric, and upper limb anomalies are commonly associated with lower limb defects. Shoulder and hip malformations occur with increasing severity of upper limb defects. Vertebral defects include an increased incidence of progressive ossification of the anterior spinal ligaments that converts the sacral and lumbar vertebral bodies into one bone mass, loss of distal segment of the sacrum, and spondylolisthesis. Spina bifida occulta and meningomyelocele occur with increased frequency. A nonspecific facial asymmetry may occur, as well as tooth hypoplasia and a deficiency in the number of teeth. There may be a hypoplastic nasal bridge with an expanded nasal tip, and choanal atresia can affect one or both nostrils. Laryngeal and tracheal anomalies and abnormal lobulation of the lungs have been observed. Ocular defects include refractive errors, pupillary abnormalities, muscle dysfunction, coloboma, microphthalmos, cataracts, and abnormalities of all three components of the oculomotor nerve. Ear defects are frequently associated with ocular malformations, as is facial nerve palsy. The defects of the ears include external, middle, and internal anomalies which are frequently associated with deafness (either conductive, neural, or both). A midline capillary hemangioma or nevus of the nose and philtrum have been described, but may fade as the child grows older. Cardiac defects, commonly of the conotruncal region, occur frequently and are a major cause of early death (30% at birth, 6% in survivors). Gastrointestinal tract defects include atresia and stenosis, and absence of the gallbladder and appendix. Inguinal hernias may be observed. Genitourinary malformations involve the kidneys (ectopic, horseshoe, hydronephrosis, and double ureter), double vagina, and cryptorchism (16,17).

Thalidomide was introduced into clinical medicine in West Germany in 1956 (20). Although a wide range of indications was promoted for the drug, it was primarily used as a sedative and tranquilizer. Because of the concern over birth defects, thalidomide was withdrawn from the market in most countries in late 1961 (21).

In 1961, two cases of congenital defects of the limbs were presented at a German pediatric meeting (22). At the meeting, Lenz (23) proposed that thalidomide was the cause of the defects. A brief 1961 correspondence, however, was the first published English language article to describe birth

defects that were suspected as being induced by thalidomide (24). McBride (24) had noted an approximate 20% incidence of polydactyly, syndactyly, and limb reduction defects consisting of abnormally short femora and radii in infants exposed in utero to thalidomide. In early 1962, Lenz (23) estimated that 2000–3000 thalidomide-exposed babies had been born in West Germany since 1959.

A number of communications have been published that describe the types of congenital malformations caused by thalidomide (10,15–19,23–81):

Thalidomide Embryopathy

Limb Defects

Upper and lower limbs (bilateral amelia or phocomelia; absence or hypoplasia of radius/ulna and/or tibia/fibula; femoral hypoplasia; preaxial aplasia of upper and lower limbs; absence of the fingers and/or toes; thumb defects such as duplication, hypoplasia, and triphalangism; duplication of big toe and triphalangism) (10,15–19,23–38,40,41,45–47,49–51,54–59,61–66,68,70,71,74–81)

Osteochondritis of femoral head (Legg-Calve-Perthes disease) (possibly a late complication that results from growth disturbance of the upper end of the femur; appeared in early childhood) (51)

Knee joints (laxity of cruciate ligaments) (16,17,61)

Other Skeletal Defects

Spine (ossification of sacral and lumbar vertebrae, loss of distal segment of sacrum, spondylolisthesis, scoliosis) (15–18,35–37,40,43,49,50,58,61,66,71,78,79)

Shoulder (hypoplasia/dysplasia of glenoid cavity, dysplasia of neck of scapula, altered humeral head) (16,17,19,61)

Hip/pelvis (dislocation, pelvic girdle hypoplasia) (16,17,19,35,51,59,61,66,78,79)

Jaw (69,74)

Craniofacial

Eye (refractive errors, pupil, motility, coloboma of the iris, uvea, lens, and choroid, microphthalmos, cataracts, glaucoma, crocodile-tear syndrome) (15–19,25,30,33,36,37,40,45–47,49,50,62,63,65,66,68,70–77)

Ear (anotia, microtia, low set, middle and internal ear, deafness) (15–19,23,25–27,29,30,33,35,37,39,41,43–45,48,53,56–58,61–68,70,73)

Face/skull (face—asymmetrical; skull—rhomboid shape) (16,17,58,69)

Tongue (dysplasias of lingual frenulum in the form of an ankyloglossia [tongue-tie] or a shortened, sinew-shaped frenulum; grooved point of

tongue [bifid tongue]) (16,69)

Nose (hypoplastic nasal bridge with expanded nasal tip) (16,17,19,58,66)

Choanal atresia (16–19,29,37,62,65,70,71,75)

Teeth (hypodontia, hyperdontia, malformed crown, enamel hypoplasia, discoloring, malocclusion, missing teeth) (16–18,58,60,69,75)

Midline hemangioma or nevus (nose, upper lip, frontal area) (10,16,17,23,25,30,33,35,45,46,57,58,60,65,66,71)

Central Nervous System

Facial nerve palsy (often associated with eye and ear anomalies) (15–19,35,39,43,61,63,68,71,73,75–77)

Hydrocephalus (37,57,65,73)

Spina bifida occulta (16,17,78,79)

Meningomyelocele (16,17,35)

Autism (18,77)

Epilepsy (15,16,76,77)

Marcus Gunn phenomenon or jaw winking syndrome (16,19)

Crocodile-tear syndrome (see **Eye**)

Major Organ Systems

Respiratory system (laryngeal and tracheal abnormalities, abnormal lobulation of lungs) (16,17,19,29,33,36,37,49,62,65,66,74,75)

Cardiovascular (ventricular septal defect, atrial septal defect, tetralogy of Fallot, cor triloculare, pericardial effusion, hypertrophy of atrium and ventricle, coarctation of aorta, systolic murmurs) (16–19,23,25,30,33,35–37,39,40,42,43,45,57,61,62,65,66,70,73,75,76)

Gastrointestinal tract

Esophageal atresia (23,29,30,37,74)

Duodenal atresia (10,16,19,23,29,30,33,35,37,49,61,62,66,70)

Common bile duct atresia (33,66)

Anal atresia (16,18,19,23,29,30,33,35,37,44,61,62,66,75)

Rectoperineal fistula (10)

Malrotation (25,30,33,35,66)

Stenosis (16–19,25,30,37,40,45,46,53,61,62,65,66,70,76)

Abnormal lobulation of liver (33,37)

Aplasia of appendix (16,17,19,23,29,30,33,37,40,46,52,53,59,65,66)

Aplasia of cecum (33)

Aplasia of gallbladder (16,17,19,23,30,33,36,49,57,65,66)

Rectoperineal fistula (10)

Genitourinary system

Unspecified (25,30,33,37,75)

Renal abnormalities
(16–19,29,35–37,46,57,59,61,62,65,66,70,74,75,81)

Defects and duplication of ureters (16,17,19,37,81)

Aplasia of fallopian tube (62)

Defects of uterus and/or vagina (16,17,19,33,37,55,62,65,66,80)

Penile maldevelopment (65)

Cryptorchism (16,17,19,25,36,61,65,66)

Other

Excessive sweating (52,54)

Inguinal hernias (16,17,19,61,66)

Cleft lip with or without cleft palate has occasionally been observed in newborns with thalidomide embryopathy (35,44,48,49,65,66,69–71), but it is not thought to be related to thalidomide exposure (19).

In 1962, Lenz and Knapp (62) reviewed the fetal effects of thalidomide that were known at the time. Of 293 cases known to the authors or from published reports, the approximate percentage of each defect was arms only (52%); arms and legs (28%); arms, legs, and ears (3%); arms and ears (6%); ears only (7%); legs only (2%); and other malformations (3%). The anomalies observed in the eight infants grouped as “other malformations” included one case each of a right polycystic kidney with aplasia of the left kidney, aplasia of left fallopian tube and left cornu of the uterus, multicystic kidneys, anal stenosis with hydronephrosis, fistula of the neck, congenital heart disease, choanal atresia, and anal atresia (62). In addition, malformations that accompanied those of the limbs and ears were pyloric stenosis, duodenal stenosis, duodenal atresia, cardiac defect, microphthalmos, anophthalmia, imperforate anus, and choanal atresia (62). Two additional review articles by Lenz, focusing on thalidomide-induced defects, appeared in 1966 (63) and 1971 (64), one with a commentary by Warkany (82).

In 1963, Japanese investigators reported phocomelia and other malformations in 10 cases (5 live infants and 5 stillbirths or early neonatal deaths) (65). Another investigator evaluated 160 cases of thalidomide embryopathy that occurred in Japan (66). Of the 160 cases, 99 had a well-documented history of thalidomide intake in early pregnancy. Of these, 70% had defects of the arms only; 14% of arms and legs; 5% of the arms, legs, and ears; 5% of the ears only; 3% of the arms and ears; and 3% of other organs

(66). In 41 of the cases with malformations of the limbs and ears, an autopsy found multiple other defects of various organ systems that were similar to those reported by Lenz and Knapp (see reference 62) (66).

The importance of early examinations for ear anomalies, especially for resulting hearing impairment, was emphasized in a study published in 1965 (67). The author had observed 14 cases of bilateral congenital meatal atresia in thalidomide-exposed infants at his center, but he was aware of 50 such cases throughout England. Eleven of the cases (three were unsuitable for operation) underwent either bilateral or unilateral surgery to construct a sound conducting mechanism. Gross malformations determined by x-ray and tomographic examinations in the 14 cases (28 ears) involved the ossicles (32%), middle ear (21%), and labyrinth (25%) (67).

A later study, published in 1976, evaluated the ear anomalies in 18 children, ages 12–16 years, who had thalidomide-induced malformations (68). Hearing impairment and vestibular hypofunction or absence of function were each found in 15 (83%) of the children. External and middle ear anomalies found in 11 of the 18 children included bilateral microtia (N = 5), bilateral microtia and bilateral atresia of the auditory canal (N = 5), and bilateral microtia and unilateral atresia of the auditory canal (N = 1). In one 13-year-old girl, surgical exploration revealed that the stapes and the oval and round windows had not developed, the long process of the incus was shaped like a string, and there was a nearly normal malleus. X-ray examination revealed inner ear malformations in 15 cases (83%) consisting of bilateral inner ear aplasia (N = 9), cystic deformity with the shape of the anterior semicircular canal (N = 4), large cystic defect of the inner ear (N = 1), and a narrow, internal auditory canal bilaterally (N = 1) (68). In addition to the ear defects, 12 children had eye-movement disturbances consisting of bilateral abducens palsy (N = 5), bilateral abducens palsy and bilateral adduction disturbance (N = 6), and unilateral abducens palsy (N = 1). Bilateral (N = 3) or unilateral (N = 3) facial palsy, and “crocodile-tear” syndrome (i.e., abnormal lacrimation that accompanies eating) (N = 7) were also observed (68).

A 1968 reference described the findings that resulted from clinical, orthodontic, and radiologic examinations of the face and jaws of children with thalidomide embryopathy (69). The findings in 127 children (approximate ages 4–6 years) with thalidomide embryopathy (group 1) were compared with 57 children with nonthalidomide-induced dysmelia (group 2), and 120 children without malformation of the limbs (group 3). Thalidomide exposure did not disturb either the shape or number of the deciduous or permanent teeth (69).

However, in the 103 children of group 1 with complete deciduous dentition, there was an increase in the frequency of abnormalities of the maxilla and/or mandible. The other important findings were malformation at the base of the skull, asymmetry of the skull, and dysplasia of the point of the tongue and the frenum (69).

One investigator categorized the malformations found in 154 children with thalidomide embryopathy using a classification system of principal defects that he had designed (70). The type of defects were the same as those listed above for thalidomide embryopathy. In eight groups, limb defects were dominant but other defects were often present, whereas in two groups, limb defects were absent or minimal. The defect classifications and the number and approximate percentage of children in each group were as follows: upper limb amelia or phocomelia with normal legs (N = 60, 39%); upper limb amelia or phocomelia with other leg defects (N = 18, 12%); forearm defects with normal legs (N = 17, 11%); four limb phocomelia (N = 15, 10%); anomalies of the ears (N = 16, 10%); severe lower limb defects with less severe upper limb defects (N = 10, 6%); other limb defects (N = 9, 6%); forearm defects with defects of the lower limbs (N = 5, 3%); lower limb defects with normal upper limbs (N = 3, 2%); and other anomalies (N = 1, <1%). A discussion of the disabilities caused by the defects in each group was also included in the text (70).

The focus of eight studies was on thalidomide-induced ocular malformations (18,46,47,71–75). Four children with ocular defects and typical thalidomide embryopathy were described in a 1964 report (46). The eye defects thought to be thalidomide related were as follows: left optic disc with a very deep physiologic cup; bilateral coloboma of the iris, unilateral coloboma of the choroid and retina involving the optic disc, and unilateral microphthalmos; unilateral coloboma of the choroid and retina; and bilateral coloboma of the iris, choroid, and retina, involving the optic disc on one side, and unilateral microphthalmos (46). At one ophthalmology center, minor ocular abnormalities were found in some children consisting of pigmentary retinopathy, a high refractive error, and reduced visual acuity (47). A 1963 study evaluated 20 children with known or suspected thalidomide-induced limb malformations for ocular anomalies (71). Of the children, 13 had anatomically normal eyes with apparently normal function and 7 (35%) had visual defects. Five of the seven had structural defects consisting of either unilateral or bilateral coloboma of the iris, choroid, or lens, sometimes involving the macular areas or the disc, and microphthalmos. The other two had anatomically normal eyes but abnormalities in visual function. The visual prognosis was rated as good in three cases, poor

in two, and uncertain in two (71). A 1966 study from Sweden examined 38 children for ocular malformations who had thalidomide-induced defects (72). Abducens paralysis was found in 17 children, bilateral in 13, and unilateral in 4. Bilateral oculomotor paralysis was present in two of these cases and unilateral in one (72). Other conditions, often concomitant with additional defects, included strabismus, unequal pupils (both reactive to light), nonreactive pupil, microphthalmos (both bilateral and unilateral), anophthalmos on one side and severe microphthalmos on the other, coloboma of the choroid, bilateral aplasia of macula with nystagmus, and bilateral epiphora (with free tear ducts and grossly normal drainage system) (72). Of note, more than half of the children had hearing impairment of varying severity. A 1967 report reviewed the previously published cases of ocular abnormalities induced by thalidomide and presented additional data on 21 Canadian children (ages 3–4.5 years) exposed in utero to the drug (73). Only four of these children had ocular malformations and none had a coloboma.

Ocular abnormalities associated with thalidomide embryopathy were reported in a 1991 study of 21 Swedish patients, ages 28–29 years (74). Horizontal incomitant strabismus, usually of the Duane syndrome type, was the most common ocular motility abnormality, but other motility abnormalities were also noted (74). Abnormal tearing, facial nerve (7th cranial nerve) palsy, and ear anomalies were also present in some cases. Citing previous studies, facial nerve palsy and ear anomalies were thought to have occurred from thalidomide exposure on days 20–29 after conception (74). This time period is consistent with the time intervals (34–43 days after LMP) given earlier. Two years later, these same authors reported the results of an ophthalmological study conducted in 86 of 100 Swedes with documented thalidomide embryopathy (75). The subjects, 49 males and 37 females, ranged in age from 27 to 30 years. Forty-six (54%) had one or more abnormal eye signs. The ocular abnormalities included the following: (a) motility defects (N = 43, 50%), including 37 with horizontal incomitant strabismus (26 with Duane syndrome, 4 with marked limitation of abduction, and 7 with gaze paresis), and 6 with horizontal comitant strabismus (all esotropia); (b) facial nerve palsy (N = 17, 20%); (c) abnormal lacrimation (N = 17, 20%); (d) coloboma of uvea and optic disc (N = 1, 1%) or optic disc only (N = 2, 2%); (e) microphthalmos (N = 2, 2%); and (f) one each of congenital glaucoma, conjunctival lipodermoid, and hypertelorism (75).

In a subsequent paper, the authors again reviewed the above ocular findings but also included the multiple other thalidomide-induced defects that were found

in the 86 subjects (18). The defects and the number of cases for each were (note that all cases had more than one defect): thumbs (triphalaengeal, absent, misplaced, hypoplastic, or extra digit) N = 70 (81%), upper limb excluding thumb N = 59 (69%), lower limb N = 21 (24%), ears/hearing N = 33 (38%), facial nerve palsy N = 17 (20%), kidney (absent, horseshoe, hydronephrosis, dysfunctional) N = 12 (14%), cardiovascular (ventricular septal defect [VSD], arrhythmia, ductus botalli, murmur) N = 7 (8%), chest/lung (cardiovascular defects, pulmonary atresia, enlarged chest wall or structural anomaly) N = 4 (5%), genitalia (absent uterus and vagina, double vagina) N = 3 (3%), anal atresia N = 4 (5%), choanal atresia N = 2 (2%), dental anomalies N = 4 (5%), mental retardation (moderate to severe) N = 5 (6%), and autism (all had mental retardation) N = 4 (5%) (18). The authors also expanded the type of ocular malformations listed in their previous study (reference 73) to include two cases of myelinated nerve fiber, two cases of ptosis, and one additional case each of coloboma (uveal or optic disc) and microphthalmos (18).

Neurologic complications of thalidomide embryopathy include epilepsy. In a study that appeared in 1976, the incidence of epilepsy was determined from a database that included all surviving children (N = 408) with documented thalidomide embryopathy in the United Kingdom (76). Seven children (1.7%) met established criteria for the diagnosis of epilepsy and were classified into two groups: (a) children with normal ears (four had upper limb defects, two had mental impairment, and one had ocular anomalies, facial palsy, and “high intelligence”) (N = 4); and (b) children with abnormal ears (in addition, one had ocular defects and facial palsy, one had defects of the thumbs, and one had facial palsy and bilateral sixth nerve palsies) (N = 3) (76). In a third group, those with cardiac abnormalities, the diagnosis of epilepsy was uncertain. The two children in this group also had other defects consisting of amelia of the upper limbs, pyloric stenosis, and ocular and ear defects in one, and upper limb defects in the other. These two cases were apparently excluded from the prevalence rate calculations below. The prevalence rates of epilepsy calculated for various ages were significant when compared with published rates in the population as a whole: active epilepsy—5 cases, 12.5/1000 vs. 2.7/1000 ($p < 0.01$); epilepsy between birth and 9 years of age—7 cases, 17.2/1000 vs. 2.42/1000 ($p < 0.0001$); and new cases in first 7 years of life—6 cases, 2.1/1000 vs. 0.43/1000 ($p < 0.01$) (76). The types of epilepsy in the first group (normal ears) were thought to be consistent with structural defects of the cerebral cortex (76). Moreover, two of the children in this group had severe refractory epilepsy, a prevalence of 5/1000 vs. 0.5/1000 in the general

population. The unlocalized or generalized seizures in the second group (abnormal ears) suggested abnormalities in the brain stem (76).

Five subjects, suspected of having a severe learning disorder (IQ scores <20 to 70–84), were identified from a group of 100 patients previously studied for ocular malformations (77). The five cases were then evaluated for the presence of autism. The ages of the subjects (three males, two females) ranged from 30 to 31 years. All had physical stigmata (i.e., ocular motility defects, other cranial nerve disorders, ear and upper-limb anomalies) characteristic of thalidomide embryopathy that had occurred from drug exposure approximately 20–24 days after conception (34–38 days after LMP). Four of the cases (two males, two females) met the criteria for autism. Based on an incidence of 4%, compared with a prevalence of about 0.08% in the general population, the investigators estimated that there was a 50 times higher rate of autism in those with thalidomide embryopathy (77).

A 1977 report evaluated the spinal deformities in 28 children, ages 10–14 years, who had thalidomide embryopathy (78). The children's spinal defects had been first studied at 4–8 years of age (79), and the current study was part of a continuing evaluation of their status. The initial group contained 32 cases, but 4 were either lost to follow-up or had died. All of the subjects had characteristic limb defects. In both studies, the spinal abnormalities were classified into five types. The initial and current (shown in italics) findings for each group were: (a) local anomalies of bone development (*spina bifida*, N = 3; fusion of adjacent spinous processes, N = 2), neural arch defect more obvious, increased number of minor changes; (b) scoliosis (N = 18), 20 children now had scoliosis; (c) wedge deformity of solitary vertebral bodies (N = 4), worsened in four cases; (d) disc space calcification (N = 3); and (e) end-plate and disc defects (N = 16), two additional cases of vertebral fusion, extension of fusion in two others, reduction in lumbar lordosis in 10 cases (78).

The pregnancy outcomes of women with thalidomide embryopathy were presented in a 1988 publication (80), and also discussed in 1989 (83). The pregnancy of one woman was described in detail (80). This case involved a 24-year-old primigravida with upper limb amelia and lower limb phocomelia. Although there were many technical difficulties (e.g., blood pressure determination, blood sampling, and obesity), she eventually delivered a term, 3.4-kg healthy female infant without any apparent abnormalities. The baby was doing well at the first postnatal check. During the cesarean section, a left rudimentary uterine horn was noted that did not communicate with the uterine cavity (80). Supplementing their case history, the authors described the

outcomes of 70 pregnancies in 35 women (includes the case history) who were living in England and who had thalidomide embryopathy (8 with absent upper and/or lower limbs; 27 with minor disabilities of the upper limbs and ears). Six miscarriages (9%) had occurred, but there were no congenital malformations in the 64 live births (80).

Renal failure complicated the fifth pregnancy of a 26-year-old woman with upper limb phocomelia and kidney and ureter malformations secondary to thalidomide (81). At 11 years of age, bilateral refluxing megaureters with dilated calices and thinning of the renal cortex were diagnosed because of chronic urinary tract infections and she underwent a bilateral antireflux procedure. Her first pregnancy, at 19 years of age, had been normotensive but complicated by proteinuria, hematuria, and premature labor thought to have been precipitated by a urinary tract infection. She had delivered a 660-g female infant who was currently alive and well. Her next three pregnancies resulted in a spontaneous abortion and two elective terminations. At 24 weeks' gestation in the index pregnancy, complications included normochromic normocytic anemia, hypertension, proteinuria, hematuria, urinary tract infection, and renal failure (creatinine clearance 11 mL/minute). A renal ultrasound revealed small kidneys with diffuse caliceal clubbing, a very thin parenchyma, and dilated ureters to the bladder (81). Peritoneal dialysis, in addition to antihypertensive, antibiotic, and iron therapy, was initiated with ritodrine tocolysis. Two weeks later, however, ultrasound confirmed that no fetal growth had occurred and her hypertension and renal failure had worsened. A cesarean section was performed to deliver a 460-g male infant who died 6 hours after birth. Because of her continued renal failure, the patient eventually received a kidney transplant (81).

The mechanism of thalidomide-induced malformations is unknown. The findings of many investigations have been discussed in reviews published in 1988 (84) and 2000 (85,86). Four other references (87–90) have developed additional hypotheses to explain how thalidomide causes structural defects.

A review published in 1988 listed 24 proposed mechanisms for thalidomide teratogenesis (84). Eight of the proposals were rejected by the author for various reasons. The remaining 16 proposed mechanisms were classified as those involving biochemical or molecular mechanisms (N = 9), cellular mechanisms (N = 2), or tissue-level mechanisms (N = 5) (84). The absence of solid experimental evidence for the proposed mechanisms, however, led the author to the conclusion that none of the proposals could adequately account for thalidomide teratogenicity (84).

The role of a toxic arene oxide metabolite was thought to be involved in

thalidomide teratogenicity according to a 1981 study (87). In an in vitro experiment, the human lymphocyte toxicity of a thalidomide metabolite was enhanced in the presence of epoxide hydrolase inhibitors and abolished by addition of the pure enzyme. The toxic thalidomide metabolite was not produced by rat liver microsomes, but was produced in hepatic preparations from maternal rabbits, and fetal rabbits, monkeys, and humans. These results were consistent with the lack of sensitivity to thalidomide teratogenesis in the rat vs. the sensitivity of rabbits, monkeys, and humans (87). A decrease in ascorbic acid (vitamin C) levels has been suggested as a mechanism of thalidomide teratogenesis (88). Two important consequences of ascorbic acid deficiency in the fetus would be inhibition of collagen synthesis and disruption of the development of nerve ganglia innervating limb buds (88).

A 1996 research study used developing chick embryos to test the hypothesis that elimination of the mesonephros, in the absence of scarring, would produce limb abnormalities similar to those observed with thalidomide (89). Tantalum foil barriers were used at various levels of the intermediate mesoderm to prevent caudal elongation of the mesonephros. Limb reduction defects were produced when the mesonephros was prevented from forming caudal to somite 14. The types and percentage of limb defects in the chick embryos were: upper limb only (57%), upper and lower limb (31%), and lower limb only (12%). In comparison, the corresponding percentages of limb reduction defects in 1252 human cases of thalidomide embryopathy were 64%, 34%, and 2%, respectively (89). Based on these results and previous studies, the investigators concluded that disruption of the mesonephros (or factors produced in the mesonephros) results in limb reduction defects and that the mechanism of thalidomide-induced limb anomalies probably also involves disruption of the mesonephros (89).

Whole embryo culture was used in a study directly comparing thalidomide-resistant rats and thalidomide-sensitive rabbits (90). Various concentrations of thalidomide were shown to significantly decrease the concentration of glutathione in rabbit visceral yolk sacs, but not in the rat. Cysteine concentrations were not affected in either species, but the cysteine levels in control rabbits were 65% lower than those in control rats. Thus, a possible role for glutathione was suggested by the results (90).

In a study published in 1996, a highly teratogenic derivative of thalidomide (EM12) was used in an experiment with nonhuman primates (marmosets) (91). EM12 was chosen because it is a more potent teratogen than thalidomide; it is more stable to hydrolysis and produces a teratogenic incidence close to 100%

in the marmoset. Moreover, the pattern of malformations produced in the marmoset is identical to those seen in humans after in utero exposure to thalidomide (91). The data indicated that thalidomide produced a statistically significant downregulation (in some cases, complete disappearance) of several surface adhesion receptors found on early limb bud cells and other organs. The adhesion receptors identified were receptors of the integrin family (β_1 -integrins, β_2 -integrins, and β_3 -integrins), the immunoglobulin family, and the selectin family. These receptors are involved in the development of the limbs, heart, head, and body. The downregulation of these receptors, which was most pronounced in those involved with limb development, was expected to alter cell–cell and cell–extracellular matrix interactions (91).

A 1998 communication proposed that the mechanism of limb reduction anomalies induced by thalidomide was related to the inhibition of mesenchymal proliferation in the limb bud (92). In the progress-zone model, the proximal and distal structures of the limb are specified sequentially by a continuous signal (thought to be fibroblast growth factor [FGF]) from the apical ectodermal ridge (92). The mesenchyme at the tip of the limb bud is respecified by FGF to produce distal structures, whereas those not receiving a continuous FGF signal develop into proximal structures. If thalidomide blocks mesenchymal cell growth, all of the progress-zone cells remain under the influence of FGF and are programmed to form the only distal most elements (i.e., a phocomelia) (92).

Two 2000 reviews by the same group of investigators evaluated 30 mechanistic hypotheses of thalidomide embryopathy (85,86). Of the proposals, 14 were rejected because they were either unsubstantiated or had not been proved to be viable. The 16 remaining hypotheses were grouped into 6 categories with thalidomide affecting: (a) DNA synthesis or transcription, synthesis and/or function of (b) growth factors (insulin-like growth factor and FGF); or (c) integrins (α subunit type v and β subunit type 3); (d) angiogenesis; (e) chondrogenesis; or (f) cell death or injury (85,86). The hypotheses were not thought to be necessarily mutually exclusive, but could eventually be fitted into a unified model (85,86). Citing evidence from the literature, they proposed that thalidomide, or a metabolite, intercalates into the DNA of specific promoter regions of genes that code for proteins involved in normal limb development. The binding of thalidomide would inhibit the transcription of these genes, resulting in interference with the development of new blood vessels and leading to truncation of the limb (85,86).

Although thalidomide was withdrawn from England and the European

markets in late 1961, the agent has continued to be available in 8 of 10 South American countries for the treatment of leprosy (56,93). Thalidomide is manufactured in Argentina and Brazil and is available either through pharmacies (Brazil) or government health agencies (Brazil and Argentina) (93). A 1987 case report from Brazil described a 17-week-old fetus that was diagnosed by prenatal ultrasound with malformations secondary to thalidomide (56). After pregnancy termination, an autopsy revealed upper limb phocomelia, absent tibiae and fibulae (both feet connected directly to the femora), missing toes on both feet, and absent external ears (56). This case was apparently the first to report a prenatal diagnosis of thalidomide syndrome (56). In a second report, 34 children with thalidomide embryopathy who were born in South America after 1965 were identified by the Latin American Collaborative Study of Congenital Malformations (ECLAMC) in endemic areas for leprosy (93). Specific details of the typical thalidomide-induced malformations in 11 of these cases (including the case in reference 56) were presented.

A study published in 1988 reviewed the history of thalidomide embryopathy and cited 4336 cases that had been identified in various countries (20). The number of cases was considered a minimal estimate, however, because stillborns and early deaths were underrepresented and the ascertainment of surviving cases in many countries was thought to be incomplete (20). The countries and the number of affected fetuses/infants are shown below. Note that none of the cases from the United States (resulting from thalidomide obtained elsewhere) were included.

| Country | Number of Affected Fetuses/Infants |
|----------------|------------------------------------|
| Australia | 26 |
| Austria | 7 |
| Belgium | 35 |
| Brazil | 99 |
| Canada | 122 |
| Denmark | 20 |
| Finland | 8 |
| Ireland | 51 |
| Italy | 86 |
| Japan | 299 |
| Mexico | 4 |
| Netherlands | 34 |
| Norway | 11 |
| Portugal | 8 |
| Spain | 5 |
| Sweden | 153 |
| Switzerland | 12 |
| Taiwan | 36 |
| United Kingdom | 271 |
| West Germany | 3049 |

Seventeen years before the above report, a review on the medicolegal implications of the thalidomide tragedy estimated that a total of 5000–6000 babies had been affected, about 4000 of these in West Germany (94).

The critical maternal dose is at least 100 mg (95). However, normal pregnancy outcomes have occurred, even when thalidomide was taken during the critical period (45,96). In addition, other causes of limb reduction defects and heart defects, such as Holt-Oram syndrome, may mimic thalidomide-induced malformations (19).

The risk of congenital malformations after exposure during the critical period has been estimated to be between 20% and 50% (17). The large degree of uncertainty in the estimated risk is a result of the lack of epidemiologic studies and any organized attempt to determine the number of normal, yet exposed

children (17). Just as uncertain, because it is based on only four reports, the frequency of specific malformations is thought to be in the following order: arms only > arms and legs > ears only > arms and ears ≥ arms, legs, and ears > legs only (62,66,70,89). The frequencies of the other malformations associated with thalidomide are unknown, partially because many of them were determined at autopsy, were only recognized later in life or in specialized groups, or have not been fully analyzed.

Although thalidomide had not been approved for use in the United States when thalidomide embryopathy was discovered, at least 17 such cases were delivered in this country, apparently from women who had received the drug elsewhere (10,94). Fortunately, thalidomide did not receive approval in the United States because of the alertness of the FDA (94,97). Thalidomide is indicated (FDA approved) for the treatment of a leprosy skin complication (erythema nodosum leprosum) (1), but it may also have eventual application in other serious conditions, such as chronic graft-versus-host disease, rash due to systemic lupus erythematosus, Behcet's syndrome, inflammatory bowel disease, prostate cancer, metastatic breast cancer, rheumatoid arthritis, uremic pruritus, severe atopic erythroderma, weight loss in tuberculosis, and in the complications of acquired immunodeficiency syndrome (aphthous ulcers, microsporidiosis diarrhea, macular degeneration, wasting, Kaposi's sarcoma, and HIV replication) (85,98,99). The mechanism of action of thalidomide teratogenesis is unknown, but recent investigations have suggested that it involves disruption of specific genes involved in normal limb development. If the mechanism can be fully understood, development of nonteratogenic derivatives, that retain the ability to treat disease, may be possible (85,86).

Thalidomide is contraindicated during pregnancy and in women of childbearing age who are not receiving two reliable methods of contraception for 1 month prior to starting therapy, during therapy, and for 1 month after stopping therapy (1). In addition, it is contraindicated in women who do not meet the specific requirements of the STEPS program (System for Thalidomide Education and Prescribing Safety). The STEPS program was developed by the manufacturer to limit the prescribing and use of thalidomide to tightly controlled situations and to prevent inadvertent exposure of pregnant women (1,99). Any suspected fetal exposure to thalidomide should be reported to the FDA (Medwatch Program at 1-800-FDA-1088) and/or to the manufacturer (1).

BREASTFEEDING SUMMARY

No reports describing the use of thalidomide during lactation have been located.

The molecular weight (about 258) is low enough that excretion into milk should be expected. Moreover, nothing is known about the excretion of thalidomide metabolites into breast milk. Women who are taking thalidomide should not nurse because the effect on an infant from exposure to thalidomide and its metabolites in breast milk is unknown.

THEOPHYLLINE

Respiratory Drug (Bronchodilator)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Theophylline is the bronchodilator of choice for asthma and chronic obstructive pulmonary disease in the pregnant patient (1–6). No published reports linking the use of theophylline with congenital defects have been located.

FETAL RISK SUMMARY

Reproduction studies in mice and rats at oral doses up to about 2 and 3 times, respectively, the recommended human dose based on BSA (RHD) revealed no evidence of teratogenicity (7). At a slightly lower dose (about 2.5 times the RHD) in rats, embryo toxicity, but not maternal toxicity, was observed.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 1240 newborns had been exposed to theophylline and 36 to aminophylline during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 68 (5.5%) major birth defects were observed (53 expected) with theophylline and 1 (2.8%) major defect (2 expected) with aminophylline. For theophylline, specific data were available for six defect categories, including (observed/expected) 20/12 cardiovascular defects, 5/1 oral clefts, 2/0.5 spina bifida, 5/4 polydactyly, 0/2 limb reduction defects, and 2/3 hypospadias. Three of the defect categories, cardiovascular, oral clefts, and spina bifida, suggest an association with the drug, but other factors, such as the mother's disease, concurrent drug use, and chance, may be involved. For aminophylline, the single defect was a polydactyly.

The Collaborative Perinatal Project monitored 193 mother–child pairs with 1st trimester exposure to theophylline or aminophylline (8). No evidence was found for an association with malformations.

Theophylline crosses the placenta, and newborn infants may have

therapeutic serum levels (9–13). Transient tachycardia, irritability, and vomiting have been reported in newborns delivered from mothers consuming theophylline (9,10). These effects are more likely to occur when maternal serum levels at term are in the high therapeutic range or above (therapeutic range 8–20 mcg/mL) (11). Cord blood levels are approximately 100% of the maternal serum concentration (12,13).

In patients at risk for premature delivery, aminophylline (theophylline ethylenediamine) was found to exert a beneficial effect by reducing the perinatal death rate and the frequency of respiratory distress syndrome (14,15). In a nonrandomized study, aminophylline 250 mg IM every 12 hours up to a maximum of 3 days was compared with betamethasone, 4 mg IM every 8 hours for 2 days (15). Patients in the aminophylline group were excluded from receiving corticosteroids because of diabetes (4 patients), hypertension (10 patients), and ruptured membranes for more than 24 hours (4 patients). The aminophylline and steroid groups were comparable in length of gestation (32.5 vs. 32.1 weeks), male:female infant sex ratio (10:8 vs. 8:8), Apgar score (7.6 vs. 7.7), birth weight (1720 vs. 1690 g), and hours between treatment and delivery (73 vs. 68). Respiratory distress syndrome occurred in 11% (2 of 18) of the aminophylline group compared with 0% (0 of 16) of the corticosteroid group (ns). A significant difference ($p = 0.01$) was found in the incidence of neonatal infection with 8 of 16 (50%) of the betamethasone group having signs of infection and none in the aminophylline group. The mechanism proposed for aminophylline-induced fetal lung maturation is similar to that observed with betamethasone: enhancement of tissue cyclic adenosine monophosphate (AMP) by inhibition of cyclic AMP phosphodiesterase and a corresponding increased production and/or release of phosphatidylcholine (15).

An IV infusion of aminophylline has been tested for its tocolytic effects on oxytocin-induced uterine contractions (16). A slight decrease in uterine activity occurred in the first 15 minutes, but this was related to the effect on contraction intensity, not frequency. The author concluded that aminophylline was a poor tocolytic agent. However, a more recent in vitro study examined the effect of increasing concentrations of aminophylline on pregnant human myometrium (17). Aminophylline produced a dose-related decrease in contraction strength and a nondose-dependent lengthening of the period of contraction. In this study, the authors concluded that aminophylline may be a clinically useful tocolytic agent (17).

A reduction in the occurrence of preeclampsia among pregnant asthmatic women treated with theophylline has been reported (18). Preeclampsia

occurred in 1.2% (1 of 85) of patients treated with theophylline compared with 8.8% (6/68) ($p < 0.05$) of asthmatic patients not treated with the drug. Although the results were significant, the small numbers indicate that the results must be interpreted cautiously (18). The authors proposed a possible mechanism for the protective effect, if indeed it does occur, involving the inhibition of platelet aggregation and the altering of vascular tone, two known effects of theophylline (18).

Concern over the depressant effects of methylxanthines on lipid synthesis in developing neural systems has been reported (19). Recent observations that infants treated for apnea with theophylline exhibit no overt neurologic deficits at 9–27 months of age are encouraging (20,21). However, the long-term effects of these drugs on human brain development are not known (19).

Frequent, high-dose asthmatic medication containing theophylline, ephedrine, phenobarbital, and diphenhydramine was used throughout pregnancy by one woman who delivered a stillborn girl with complete triploidy (22). Although drug-induced chromosomal damage could not be proven, theophylline has been shown in in vitro tests to cause breakage of chromosomes in human lymphocytes (23). However, the clinical significance of this breakage is doubtful.

Theophylline withdrawal in a newborn exposed throughout gestation has been reported (12). Apneic spells developed at 28 hours after delivery and they became progressively worse over the next 4 days. Therapy with theophylline resolved the spells.

The pharmacokinetics of theophylline during pregnancy has been studied (24,25). One report suggested that plasma concentrations of theophylline fall during the 3rd trimester because of an increased maternal volume of distribution (24). However, a more recent study found a significantly lower clearance of theophylline during the 3rd trimester, ranging in some cases between 20% and 53% (25). Two women had symptoms of toxicity requiring a dosage reduction.

BREASTFEEDING SUMMARY

Theophylline is excreted into breast milk (26,27). A milk:plasma ratio of 0.7 has been measured (27). Estimates indicate that <1% of the maternal dose is excreted into breast milk (26,27). However, one infant became irritable secondary to a rapidly absorbed oral solution of aminophylline taken by the mother (26). Because very young infants may be more sensitive to levels that would be nontoxic in older infants, less rapidly absorbed theophylline

preparations may be advisable for nursing mothers (10,28). Except for the precaution that theophylline may cause irritability in the nursing infant, the American Academy of Pediatrics classifies the drug as compatible with breastfeeding (29).

THIABENDAZOLE

[Withdrawn from the market. See 9th edition.]

THIAMINE

Vitamin

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Thiamine is compatible with pregnancy, but doses above the RDA should be avoided.

FETAL RISK SUMMARY

Thiamine (vitamin B₁), a water-soluble B-complex vitamin, is an essential nutrient required for carbohydrate metabolism (1). The National Academy of Sciences' recommended dietary allowance (RDA) for thiamine in pregnancy is 1.5 mg (1).

Thiamine is actively transported to the fetus (2–5). As with other B-complex vitamins, concentrations of thiamine in the fetus and newborn are higher than in the mother (4–11).

Maternal thiamine deficiency is common during pregnancy (11,12). Supplementation with multivitamin products reduces the thiamine hypovitaminemia only slightly (9). Since 1938, several authors have attempted to link this deficiency to toxemia of pregnancy (13–16). A 1945 paper summarized the early work published in this area (14). All of the reported cases, however, involved patients with poor nutrition and pregnancy care in general. More recent investigations have failed to find any relationship between maternal thiamine deficiency and toxemia, fetal defects, or other outcomes of pregnancy (8,17).

No association was found between low birth weight and thiamine levels in a 1977 report (7). One group has shown experimentally, however, that the characteristic intrauterine growth restriction of the fetal alcohol syndrome may be caused by ethanol-induced thiamine deficiency (18).

Thiamine has been used to treat hyperemesis gravidarum, although pyridoxine (vitamin B₆) was found to be more effective (see Pyridoxine) (19–21). In one early report, thiamine was effective in reversing severe

neurologic complications associated with hyperemesis (19). A mother treated with frequent injections of thiamine and pyridoxine, 50 mg each/dose, for hyperemesis during the first half of two pregnancies delivered two infants with severe convulsions, one of whom died within 30 hours of birth (21). The convulsions in the mentally slow second infant were eventually controlled with pyridoxine. Pyridoxine dependency–induced convulsions are rare. The authors speculated that the defect was caused by in utero exposure to high circulating levels of the vitamin. Thiamine was not thought to be involved (see Pyridoxine).

An isolated case report described an anencephalic fetus whose mother was under psychiatric care (22). She had been treated with very high doses of vitamins B₁, B₆, C, and folic acid. The relationship between the vitamins and the defect is unknown. Also unproven is the speculation by one researcher that an association exists between thiamine deficiency and Down's syndrome (trisomy 21) or preleukemic bone marrow changes (23).

BREASTFEEDING SUMMARY

Thiamine (vitamin B₁) is excreted into breast milk (24–27). One group of investigators supplemented well-nourished lactating women with a multivitamin preparation containing 1.7 mg of thiamine (24). At 6 months postpartum, milk concentrations of thiamine did not differ significantly from those of control patients not receiving supplements. In a study of lactating women with low nutritional status, supplementation with thiamine (0.2–20.0 mg/day) resulted in mean milk concentrations of 125–268 ng/mL (25). Milk concentrations were directly proportional to dietary intake. A 1983 English study measured thiamine levels in pooled human milk obtained from preterm (26 mothers: 29–34 weeks) and term (35 mothers: 39 weeks or longer) patients (26). Milk obtained from preterm mothers rose from 23.7 ng/mL (colostrum) to 89.3 ng/mL (16–196 days), whereas milk from term mothers increased during the same period from a level of 28.4 to 183 ng/mL.

In Asian mothers with severe thiamine deficiency, including some with beriberi, infants have become acutely ill after breastfeeding, leading in some cases to convulsions and sudden death (28–31). Pneumonia was usually a characteristic finding. One author thought the condition was related to toxic intermediary metabolites, such as methylglyoxal, passing to the infant via the milk (28). Although a cause-and-effect relationship has not been proven, one report suggested that thiamine deficiency may aggravate the condition (29). Indian investigators measured very low thiamine milk levels in mothers of children with convulsions of unknown cause (32). Mean milk thiamine

concentrations in mothers of healthy children were 111 ng/mL, whereas those in mothers of children with convulsions were 29 ng/mL. The authors were unable to establish an association between the low thiamine content in milk and infantile convulsions (see Pyridoxine for correlation between low levels of vitamin B₆ and convulsions).

A 1992 case described the features of “Shoshin beriberi” in a 3-month-old breastfed infant (33). Both the infant and the mother had biochemical evidence of thiamine deficiency. Clinical features in the infant included cardiac failure with vasoconstriction, hypotension, severe metabolic acidosis, and atypical grand-mal seizures. He responded quickly to thiamine and made an unremarkable recovery.

The National Academy of Sciences’ RDA for thiamine during lactation is 1.6 mg (1). If the diet of the lactating woman adequately supplies this amount, maternal supplementation with thiamine is not needed (27). Supplementation with the RDA for thiamine is recommended for those women with inadequate nutritional intake. The American Academy of Pediatrics classifies thiamine as compatible with breastfeeding (34).

THIETHYLPERAZINE

[Withdrawn from the market. See 9th edition.]

THIOGUANINE

Antineoplastic

PREGNANCY RECOMMENDATION: Human and Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Thioguanine is a purine analog that interferes with nucleic acid biosynthesis. It is classified as an antimetabolite in the same antineoplastic subclass of purine analogs and related agents as cladribine, clofarabine, fludarabine, pentostatin, and mercaptopurine. The drug is potentially mutagenic, carcinogenic, and teratogenic (1).

FETAL RISK SUMMARY

Reproduction studies in rats at a dose 5 times the human dose caused resorptions and malformed or stunted offspring (1). Malformations observed included generalized edema, cranial defects, general skeletal hypoplasia, hydrocephalus, ventral hernia, situs inversus, and limb defects (1).

The use of thioguanine in pregnancy has been reported in 26 patients, 4 during the 1st trimester (2–19). An elective abortion, resulting in a normal fetus, was performed at 21 weeks' gestation in one pregnancy after 4 weeks of chemotherapy (17). Use in the 1st and 2nd trimesters has been associated with chromosomal abnormalities in one infant (relationship to antineoplastic therapy unknown), trisomy group C autosomes with mosaicism (2), and congenital malformations in another, two medial digits of both feet missing and distal phalanges of both thumbs missing with hypoplastic remnant of right thumb (3). In a third case, a fetus, who was not exposed to antineoplastic agents until the 23rd week, long after development of the affected extremity, was delivered at 42 weeks' gestation with polydactyly (six toes on the right foot), a condition that had occurred previously in this family (18).

Two cases of intrauterine fetal death have occurred after antineoplastic therapy with thioguanine and other agents (15,18). In one case, a mother, whose antileukemic chemotherapy was initiated at 15 weeks' gestation, developed severe pregnancy-induced hypertension in the 29th week of

pregnancy (15). Before this time, fetal well-being had been continuously documented. One week after onset of the preeclampsia, intrauterine fetal death was confirmed by ultrasound. In the second case, a woman, with a history of two previous 1st trimester spontaneous abortions, was treated for acute myeloblastic leukemia and ulcerative colitis beginning at 15 weeks' gestation (18). Intrauterine fetal death occurred at 20 weeks. No congenital abnormalities were found at autopsy in either of the fetuses.

Data from one review indicated that 40% of the infants exposed to anticancer drugs were of low birth weight (20). This finding was not related to the timing of exposure. Long-term studies of growth and mental development in offspring exposed to thioguanine during the 2nd trimester, the period of neuroblast multiplication, have not been conducted (21). However, individual children have been followed for periods ranging from a few months to 5 years and, in each case, normal development was documented (14,15,17,18).

Although abnormal chromosomal changes were observed in one aborted fetus, the clinical significance of this observation and the relationship to antineoplastic therapy are unknown. In two other newborns, karyotyping of cultured cells did not show anomalies (2,5). Paternal use of thioguanine with other antineoplastic agents before conception has been suggested as a cause of congenital defects observed in three infants: anencephalic stillborn (22), tetralogy of Fallot with syndactyly of the first and second toes (22), and multiple anomalies (23). However, confirmation of these data has not been forthcoming, and any such relationship is probably tenuous at best. Exposed men have also fathered normal children (23,24).

Occupational exposure of the mother to antineoplastic agents during pregnancy may present a risk to the fetus. A position statement from the National Study Commission on Cytotoxic Exposure and a research article involving some antineoplastic agents are presented in the monograph for cyclophosphamide (see Cyclophosphamide).

BREASTFEEDING SUMMARY

No reports describing the use of thioguanine during human lactation have been located. It is not known if the drug is excreted into breast milk. Because of the potential for severe toxicity, including tumors, in a nursing infant, women receiving thioguanine should not breastfeed.

THIORIDAZINE

Antipsychotic

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although occasional reports have attempted to link various phenothiazine agents with congenital malformations, most of the evidence suggests that these drugs are low risk for the embryo–fetus (see Chlorpromazine).

FETAL RISK SUMMARY

Thioridazine is a piperidyl phenothiazine. The drug is not teratogenic in animals (species not specified) (1).

Phenothiazines readily cross the placenta (2). Extrapyramidal symptoms were seen in a newborn exposed to thioridazine in utero, but the reaction was probably caused by chlorpromazine (3).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 63 newborns had been exposed to thioridazine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Two (3.2%) major birth defects were observed (three expected), one of which was a cardiovascular defect (one expected). No anomalies were observed in five other categories of defects (oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available.

A case of a congenital heart defect was described in 1969 (4). However, one investigator found no anomalies in the offspring of 23 patients exposed throughout gestation to thioridazine (5). Twenty of the infants were evaluated for up to 13 years.

A brief 1993 report described a 31-year-old woman with depression, panic disorder, and migraine headaches who was exposed to a number of drugs in the first 6 weeks of pregnancy, including thioridazine, dihydroergotamine,

citalopram, buspirone, and etilefrin (a sympathomimetic agent) (6). An elective abortion at 12 weeks' gestation revealed a normal fetus.

BREASTFEEDING SUMMARY

No reports describing the use of thioridazine during human lactation have been located. It is not known if the drug is excreted into breast milk. However, other phenothiazines are present in milk and have caused toxicity (see Chlorpromazine). Sedation is a possible effect in nursing infants.

THIOTEPA

Antineoplastic

PREGNANCY RECOMMENDATION: Contraindicated—1st Trimester

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing embryo–fetal harm caused by thiotepa have been located. However, the drug is a polyfunctional cytotoxic agent that is related chemically and pharmacologically to nitrogen mustard (mechlorethamine), an alkylating antineoplastic. Moreover, the animal reproduction data suggest risk.

FETAL RISK SUMMARY

Thiotepa impairs fertility and is carcinogenic, mutagenic, and teratogenic in animals (1). Reproduction studies in mice and rats at intraperitoneal doses one-eighth and one times, respectively, the maximum recommended human dose based on BSA (MRHD) revealed teratogenicity in both species. Embryoletality was noted in rabbits at a dose twice the MRHD (1).

It is not known if thiotepa crosses the human placenta. The molecular weight (about 189) is low enough that passage to the embryo–fetus should be expected.

Thiotepa has been used during the 2nd and 3rd trimesters in one patient without apparent fetal harm (2). Long-term studies of growth and mental development in offspring exposed to antineoplastic agents during the 2nd trimester, the period of neuroblast multiplication, have not been conducted (3).

Occupational exposure of the mother to antineoplastic agents during pregnancy may present a risk to the fetus. A position statement from the National Study Commission on Cytotoxic Exposure and a research article involving some antineoplastic agents are presented in the monograph for cyclophosphamide (see Cyclophosphamide).

BREASTFEEDING SUMMARY

No reports describing the use of thiotepa during lactation have been located.

The molecular weight (about 189) is low enough that excretion into breast milk should be expected. Because of the potential for severe toxicity, including tumors, in a nursing infant, women receiving thiotepa should not breastfeed.

THIOTHIXENE

Antipsychotic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Thiothixene, a phenothiazine derivative, is structurally and pharmacologically related to trifluoperazine and chlorprothixene (see Trifluoperazine). Although occasional reports have attempted to link various phenothiazines with congenital malformations, most of the evidence suggests that these drugs are low risk for the embryo–fetus.

FETAL RISK SUMMARY

No published reports, other than the one study below, describing the use of the drug in human pregnancy have been located. The drug is not teratogenic in mice, rats, rabbits, and monkeys (1–3).

It is not known if thiothixene crosses the human placenta. The molecular weight (about 444) is low enough that passage to the embryo–fetus should be expected.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 38 newborns had been exposed to thiothixene during the 1st trimester (F. Rosa, personal communication, FDA, 1993). One (2.6%) major birth defect (two expected), a cardiovascular defect (0.5 expected), was observed. No anomalies were observed in five other categories of defects (oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available.

BREASTFEEDING SUMMARY

No reports describing the use of thiothixene during lactation have been located. The molecular weight (about 444) is low enough that excretion into breast milk

should be expected. The effect on a nursing infant from exposure to the drug in milk is unknown. However, other phenothiazines are present in milk and have caused toxicity (see Chlorpromazine). Sedation is a possible effect in nursing infants.

THIPROPAZATE

[Withdrawn from the market. See 8th edition.]

THYROGLOBULIN

Thyroid

See Thyroid.

THYROID

Thyroid

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Thyroid contains the two thyroid hormones levothyroxine (T4) and liothyronine (T3) plus other materials peculiar to the thyroid gland. It is used during pregnancy for the treatment of hypothyroidism. Congenital defects have been reported with the use of thyroid but they are thought to be caused by maternal hypothyroidism or other factors (see Levothyroxine and Liothyronine).

FETAL RISK SUMMARY

Neither T4 nor T3 crosses the placenta when physiologic serum concentrations are present in the mother (see Levothyroxine and Liothyronine). In one report, however, two patients, each of whom had produced two cretins in previous pregnancies, were given huge amounts of thyroid, up to 1600 mg/day or more (1). Both newborns were normal at birth even though one was found to be athyroid. The authors concluded that sufficient hormone was transported to the fetuses to prevent hypothyroidism.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 44 newborns had been exposed to thyroid during the 1st trimester (F. Rosa, personal communication, FDA, 1993). One (2.3%) major birth defect (two expected), a cardiovascular defect (0.5 expected), was observed.

Combination therapy with thyroid–antithyroid drugs was advocated at one time for the treatment of hyperthyroidism but is now considered inappropriate (see Propylthiouracil).

BREASTFEEDING SUMMARY

See Levothyroxine and Liothyronine.

THYROTROPIN

Thyroid

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Thyrotropin (thyroid-stimulating hormone; TSH) does not cross the placenta (1). No correlation exists between maternal and fetal concentrations of TSH at any time during gestation (2).

BREASTFEEDING SUMMARY

No reports describing the excretion of thyrotropin in human milk have been located. Serum levels of this hormone have been measured and compared in breastfed and bottlefed infants (3–7). Breast milk does not provide sufficient levothyroxine (T4) or liothyronine (T3) to prevent the effects of congenital hypothyroidism (see Levothyroxine and Liothyronine). As a consequence, serum levels of TSH in breastfed hypothyroid infants are markedly elevated (3,4). In euthyroid babies, no differences in TSH levels have been discovered between breastfed and bottlefed groups (5–7).

TIAGABINE

Anticonvulsant

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Tiagabine was not teratogenic or embryo–fetal toxic in experimental animals at doses that did not cause maternal toxicity. However, the no–observed-effect levels were much <10 times the MRHD. The human data are too limited to determine the risk magnitude this agent represents to the embryo–fetus. Of concern, however, metabolism of tiagabine results in epoxide metabolites. As noted above, these intermediate arene oxide metabolites from other anticonvulsants have been associated with human teratogenicity. Therefore, the safest course is to avoid tiagabine, if possible, during the 1st trimester, but there is no evidence that exposure during organogenesis or at any other time during gestation will result in fetal harm. If tiagabine is required, monotherapy using the lowest effective dose is preferred, but because of its status as adjunctive therapy, this may not be possible. In addition, folic acid 4–5 mg/day should be taken with tiagabine.

FETAL RISK SUMMARY

The oral anticonvulsant tiagabine enhances the activity of γ -aminobutyric acid, the major inhibitory neurotransmitter, in the central nervous system. It is not known if this relates to its anticonvulsant activity. Tiagabine is indicated as adjunctive therapy in the treatment of partial seizures. Its elimination half-life is 7–9 hours, but is decreased to 4–7 hours in patients who are concurrently receiving hepatic enzyme-inducing anticonvulsants (e.g., carbamazepine, phenytoin, primidone, and phenobarbital). A 1996 review stated that the elimination half-life was 4–13 hours (mean 7 hours) and decreased to 2–3 hours when combined with enzyme-inducing anticonvulsants (2). In plasma,

96% is bound to albumin and α_1 -acid glycoprotein (1,2). Although not all of the metabolites have been identified, at least one is inactive (1). Of particular interest, a 1996 review stated that metabolism of tiagabine (based on data from a manufacturer) results in arene oxide metabolites (3). These intermediate free radicals have been associated with human teratogenicity (see Carbamazepine, Phenytoin, and Valproic Acid).

Reproduction studies with tiagabine have been conducted in rats and rabbits. In pregnant rats treated during organogenesis, maternal toxic (weight loss/reduced weight gain) doses approximately 16 times the maximum recommended human dose based on BSA (MRHD) were associated with an increased incidence of fetal malformations (craniofacial, appendicular, and visceral defects) and growth restriction. When this dose was given during late gestation and throughout parturition and lactation, maternal toxicity (decreased weight gain), stillbirths, and decreased postnatal offspring viability and growth were observed. No maternal or fetal adverse effects were observed at 3 times the MRHD. In pregnant rabbits, a dose 8 times the MRHD caused maternal toxicity (decreased weight gain), embryo death, and fetal variations. The no-effect dose for maternal, embryo, and fetal toxicity was approximately equivalent to the MRHD (1).

In rats, high doses (36–100 times the plasma exposure [AUC] obtained with the maximum recommended human dose of 56 mg/day) for 2 years were carcinogenic (hepatocellular adenomas in females and Leydig cell tumors of the testis in males). In an in vitro test, tiagabine, in the absence of metabolic activation, caused increased structural chromosome aberration frequency in human lymphocytes. This toxicity, however, was not observed in the assay in the presence of metabolic activation. Similarly, no genetic toxicity was observed in several other in vitro or in vivo assays (1).

It is not known if tiagabine crosses the human placenta. The molecular weight (376 for the free base) is low enough that exposure of the embryo–fetus should be expected. The moderately long elimination half-life will result in prolonged concentrations of the drug at the maternal blood–placenta interface, thus increasing the opportunity for embryo–fetal exposure.

A 1996 report described the outcomes of 23 human pregnancies exposed to tiagabine (3). Among the pregnancies exposed in a preclinical trial, there was one maternal death (unrelated to therapy), four spontaneous abortions (SABs), eight elective abortions (EABs) (including one blighted ovum and one ectopic pregnancy), eight normal outcomes, and one infant with unspecified malformations (also receiving other unspecified anticonvulsants). Specific data

relating to the exposures (e.g., dose, duration, timing) were not provided.

In a 1999 analysis of 53 clinical trials involving tiagabine, 2531 epileptic patients were treated, including 22 pregnancies (4). Some data from this report also might have been reported in the above reference. The pregnancy outcomes were: four SABs, seven EABs (includes one blighted ovum and one ectopic pregnancy), eight normal outcomes, one infant with hip displacement related to a breech presentation, and one ongoing pregnancy. In the last case, the mother, who had taken tiagabine only during the first 2 months of pregnancy, had a seizure and drowned in her bathtub. Autopsy revealed a normal fetus with growth consistent to the gestational age (4).

The Lamotrigine Pregnancy Registry, an ongoing project conducted by the manufacturer, was first published in January 1997. The final report was published in July 2010 (5). The Registry is now closed. In five prospectively enrolled pregnancies exposed in the 1st trimester to tiagabine and lamotrigine, with or without other anticonvulsants, the outcomes were four live births without birth defects and one SAB (5).

The effect of tiagabine on folic acid levels and metabolism is unknown (3). Although not specifically referring to tiagabine, a 2003 review recommended that to reduce the risk of birth defects from anticonvulsants, women should start multivitamins with folic acid before conception (6). Although the recommendation did not specify the amount of folic acid, a recent study found that multivitamin supplements with folic acid (typically 0.4 mg) did not reduce the risk of congenital malformations from four first-generation anticonvulsants (see Carbamazepine, Phenytoin, Phenobarbital, or Primidone). Therefore, until further information is available, the best course is to start folic acid supplementation before conception. Although a specific dosage recommendation has not been determined for patients receiving anticonvulsants, 4 mg/day appears to be reasonable.

BREASTFEEDING SUMMARY

No studies describing the use of tiagabine during human lactation have been located. The molecular weight (about 376 for the free base) and the moderately long elimination half-life (as long as 13 hours) suggest that excretion into breast milk should be expected. The effect on the nursing infant from exposure to tiagabine in milk is unknown.

TICAGRELOR

Hematologic (Antiplatelet)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of ticagrelor in human pregnancy have been located. The animal data suggest risk, but the absence of human pregnancy experience prevents a more complete assessment of the embryo–fetal risk. However, if indicated, the benefits to the mother might be greater than the risks to the embryo–fetus and must be evaluated on a case-by-case basis.

FETAL RISK SUMMARY

Ticagrelor is an oral reversible inhibitor of platelet activation and aggregation. It is indicated to reduce the rate of thrombotic cardiovascular events in patients with acute coronary syndrome (unstable angina, non-ST elevation myocardial infarction, or ST elevation myocardial infarction). Ticagrelor is metabolized to an approximately equipotent metabolite. Both the parent drug and metabolite are highly bound (>99%) to plasma proteins and mean half-lives are about 7 and 9 hours, respectively (1).

Reproduction studies have been conducted in rats and rabbits. Rats were given oral doses that were about 1–16.5 times the maximum recommended human dose of 90 mg twice daily for a 60-kg human (MRHD) based on BSA (MRHD-BSA) during organogenesis. Adverse outcomes in the offspring caused by the highest dose were supernumerary liver lobe and ribs, incomplete ossification of sternebrae, displaced articulation of pelvis, and misshapen misaligned sternebrae. When rats were given a dose that was about 10 times the MRHD-BSA during late gestation and lactation, pup deaths and effects on pup growth were observed. Minor effects such as delays in pinna unfolding and eye opening occurred at doses that were about 0.5–3.2 times the MRHD-BSA.

In rabbits, an oral dose that was 6.8 times the MRHD-BSA given during organogenesis resulted in delayed gall bladder development and incomplete ossification of the hyoid, pubis, and sternbrae (1).

In studies in mice and rats, no carcinogenic effects were noted in mice or male rats. In female rats, doses that were 29 times the MRHD based on AUC (BSA-AUC) were associated with uterine carcinomas, uterine adenocarcinomas, and hepatocellular adenomas. A lower dose that was about 8 times the MRHD-AUC was not carcinogenic. Neither the parent drug nor active metabolite were mutagenic in multiple assays. In fertility studies, ticagrelor had no effect on male rats, but an increased incidence of irregular duration of estrus cycles was observed in female rats (1).

It is not known if ticagrelor or its active metabolite cross the human placenta. The molecular weight (about 523) of the parent drug and moderately long half-lives suggest that both agents will cross to the embryo–fetus. However, the high plasma protein binding should limit the exposure.

BREASTFEEDING SUMMARY

No reports describing the use of ticagrelor during human lactation have been located. The molecular weight (about 523) of the parent drug and moderately long half-lives of the parent drug (7 hours) and its approximately equipotent metabolite (9 hours) suggest that both agents will be excreted into breast milk. However, the high (>99%) plasma protein binding of both agents should limit the exposure. The effects of the exposure on a nursing infant are unknown. If the drug is used during breastfeeding, the infant should be monitored for the most common adverse reactions observed in adults (bleeding and dyspnea).

TICARCILLIN

Antibiotic (Penicillin)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No reports linking the use of ticarcillin with congenital defects have been located. Although the reported pregnancy experience is limited, all penicillins are considered low risk in pregnancy.

FETAL RISK SUMMARY

Ticarcillin is a penicillin antibiotic. Reproduction studies in mice and rats have revealed no evidence of impaired fertility or fetal harm (1).

Ticarcillin rapidly crosses the placenta to the fetal circulation and amniotic fluid (2). Following a 1-g IV dose, single determinations of the amniotic fluid from six patients, 15–76 minutes after injection, yielded levels of 1.0–3.3 mcg/mL. Similar measurements of ticarcillin in cord serum ranged from 12.6 to 19.2 mcg/mL. In a study using in vitro perfused human placentas, the fetal:maternal ratio of ticarcillin was 0.91 (3).

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 3546 of whom had 1st trimester exposure to penicillin derivatives (4, pp. 297–313). For use anytime during pregnancy, 7171 exposures were recorded (4, p. 435). In neither group was evidence found to suggest a relationship to large categories of major or minor malformations or to individual defects.

BREASTFEEDING SUMMARY

Ticarcillin is excreted into breast milk in low concentrations. After a 1-g IV dose given to five patients, only trace amounts of drug were measured at intervals up to 6 hours (2). Although these amounts are probably not significant, three potential problems exist for the nursing infant: modification of bowel flora, direct effects on the infant (e.g., allergic response), and interference with the interpretation of culture results if a fever workup is required. The American Academy of Pediatrics classifies ticarcillin as compatible with breastfeeding (5).

TICLOPIDINE

Hematological Agent (Antiplatelet)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Ticlopidine is not teratogenic in experimental animals, but the human pregnancy experience is too limited to assess the potential risk to the embryo or fetus. Three case reports have described the use of ticlopidine in human pregnancy, one of which ended in a spontaneous abortion (SAB). Ticlopidine may cause life-threatening blood dyscrasias, including neutropenia/agranulocytosis, thrombotic thrombocytopenia purpura, and aplastic anemia (1). The peak incidence for these disorders is in the first 3 months of therapy. The adverse effects are not predictable by any known demographic or clinical characteristics (1). Theoretically, if ticlopidine crossed the placenta, the fetus or newborn could also be at risk, as well as the mother. Therefore, because other antiplatelet agents are available, ticlopidine should be used during pregnancy only if other agents are judged to be less effective for the mother's condition.

FETAL RISK SUMMARY

Ticlopidine is a direct, irreversible inhibitor of adenosine diphosphate (ADP)–induced platelet aggregation. The drug has at least 20 metabolites, all of which appear to be inactive. Reversible protein binding is extensive (98%), primarily to albumin and lipoproteins, but some (15%) also is bound to α_1 -acid glycoprotein. Ticlopidine is indicated to reduce the risk of thrombotic stroke in patients who have stroke precursors and in patients who have had a completed thrombotic stroke (1).

Reproduction studies have been conducted in mice, rats, and rabbits at doses up to 200, 400, and 200 mg/kg/day, respectively (1). There was no evidence of teratogenicity at these doses, but maternal and fetal toxicity was

observed at 200, 400, and 100 mg/kg/day, respectively. In male and female rats, however, no effects on fertility were observed at the highest dose. The maximum doses in mice and rats were approximately 29 and 56 times, respectively, the human clinical dose (HCD), or 3 and 8 times, respectively, the HCD on a BSA basis. Ticlopidine was not carcinogenic in mice or rats, or mutagenic in in vitro or in vivo assays (1).

Whether ticlopidine crosses the placenta is not known, but the molecular weight (about 300) is low enough that transfer to the fetus should be expected. Of interest, a platelet aggregation study was conducted on cord blood from a term pregnancy of a woman who had been receiving ticlopidine and aspirin for 2 weeks (2). Complete inhibition of platelet aggregation to 20 micromoles of ADP was demonstrated.

A 1998 case report described the treatment of an acute myocardial infarction in a 30-year-old woman at 38 weeks' gestation (2). Her condition did not improve with aspirin, heparin, nitrates, or balloon angioplasty, so a stent was placed in the partially occluded left anterior descending coronary artery during abciximab (an antiplatelet agent) infusion. Adequate flow was re-established in the artery. Postoperatively, she was treated with ticlopidine, aspirin, and an unspecified β -blocker. Two weeks later, she delivered vaginally a healthy baby boy with a normal ductus arteriosus (no other details were provided). No excessive maternal bleeding was observed (2).

A woman with a history of essential thrombocytopenia and an anterior wall myocardial infarction was treated with chemotherapy (details not specified) to normalize her platelet count (3). After cardiac bypass surgery, she conceived while taking ticlopidine (500 mg/day) and aspirin (300 mg/day). An SAB occurred in the 2nd trimester, 6 months after surgery. The woman's therapy was changed to clopidogrel and intermittent low-molecular-weight heparin, and she eventually had a normal pregnancy. The relationship between the abortion and the ticlopidine/aspirin combination is unknown (3).

A 24-year-old woman with a history of aortic valve replacement with a 21-mm St. Jude Medical mechanical valve and two SABs was treated before and through the 36th week of pregnancy with ticlopidine (300 mg/day), dipyridamole (300 mg/day), and aspirin (81 mg/day) (4). At that time, oral therapy was replaced with continuous IV heparin until delivery of a healthy baby (sex not specified) by an elective cesarean section at 38 weeks' gestation. No maternal or fetal thrombotic or bleeding complications were observed. Other than being healthy, no other information was given about the newborn (4).

BREASTFEEDING SUMMARY

No reports describing the use of ticlopidine during human lactation have been located. The molecular weight (about 300) is low enough that excretion into breast milk should be expected. The effect of this exposure on a nursing infant is unknown. However, the life-threatening hematological adverse reactions that have been reported with this drug (see above), especially in the first 3 months of therapy, suggest that ticlopidine should not be used by the lactating woman.

TIGECYCLINE

Antibiotic (Tetracycline)

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of tigecycline in human pregnancy have been located. In one animal species, exposures close to those obtained in humans that did not cause maternal toxicity did result in reduced fetal weight and minor skeletal anomalies. Moreover, tigecycline crosses the placentas of rats and rabbits and enters fetal tissues, including fetal bony structures (1). Similar to tetracyclines, tigecycline can permanently discolor the teeth if used in the second half of pregnancy (1). Inadvertent or planned use in the 1st trimester probably does not represent a major risk to the embryo or fetus, but use in later trimesters should be avoided.

FETAL RISK SUMMARY

Tigecycline is a glycylicycline, broad-spectrum antibacterial agent with bacteriostatic activity that is given by IV infusion. It is structurally related to the tetracycline class of antibiotics and may have similar adverse effects. Tigecycline undergoes partial metabolism. The elimination half-life after a single IV dose is about 27 hours, whereas after multiple dosing the half-life is about 42 hours. The primary route of elimination is by biliary excretion. The in vitro plasma protein binding ranges from about 71% to 89% (1).

Reproduction studies have been conducted in rats and rabbits. No teratogenic effects were observed in either species at exposures about 5 times and equal to, respectively, the human daily dose based on AUC (HDD). However, these exposures were associated with slight reductions in fetal weights and an increased incidence of minor skeletal anomalies (delays in bone ossification). The exposure in rabbits was maternally toxic and was associated with an increased incidence of fetal loss (1).

Studies for carcinogenicity have not been conducted with tigecycline, but tests for mutagenicity and clastogenicity were negative. No effects on reproductive performance or fertility were observed in male and female rats given doses resulting in exposures that were 5 times the HDD (1).

Tigecycline crosses the placentas of animals (1). However, it is not known if the drug crosses the human placenta. The molecular weight (about 586), prolonged elimination half-life, and wide distribution in tissues suggest that the antibiotic will cross to the embryo–fetus. Moreover, tetracycline is known to cross the human placenta resulting in fetal toxicity.

BREASTFEEDING SUMMARY

No reports describing the use of tigecycline during human lactation have been located. The molecular weight (about 586), prolonged elimination half-life, and wide distribution in tissues suggest that the antibiotic will be excreted into breast milk. However, the oral bioavailability of tigecycline is such that there might be little or no systemic exposure. Even if the oral bioavailability in infants is negligible, the presence of the antibiotic in milk could cause three potential problems: modification of bowel flora, direct effects on the infant’s gut, and interference with the interpretation of culture results if a fever workup is required.

TILUDRONATE

Bisphosphonate

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of tiludronate in human pregnancy have been located. Developmental toxicity (growth restriction, structural anomalies, and death) at doses close to those used in humans was observed in three animal species, but the maternal toxicity evident in two of the species prevents a better assessment of the animal embryo–fetal toxicity. The complete lack of human pregnancy experience with tiludronate and the very limited human data for the bisphosphonate class prevent further assessment of the risk. The amount of drug retained in bone and eventually released back into the systemic circulation is directly related to the dose and duration of treatment. Because tiludronate probably crosses the placenta, treatment of the mother before conception could result in continuous exposure of the embryo and fetus to an unknown amount of drug. Therefore, the use of tiludronate is not recommended in women who may become pregnant or during pregnancy. There is a theoretical risk of fetal harm (e.g., skeletal and other abnormalities) (1), but the magnitude of this risk cannot be estimated at the present time. Infants exposed in utero to tiludronate should be monitored for hypocalcemia during the first few days after birth.

FETAL RISK SUMMARY

Tiludronate is a bisphosphonate in the same class as alendronate, etidronate, ibandronate, pamidronate, risedronate, and zoledronic acid. It is indicated for the treatment of Paget's disease of bone (osteitis deformans). Tiludronate undergoes little, if any, metabolism. The plasma elimination half-life is about 150 hours, but the elimination rate from bone is unknown (1).

Reproduction studies have been conducted in mice, rats, and rabbits. In mice during organogenesis, a dose 7 times the 400 mg/day human dose based on BSA (HD) caused maternal toxicity (decreased body weight gain) and embryo–fetal developmental toxicity (increased postimplantation loss, decreased number of fetuses per dam, and decreased fetal body weight). A low incidence of malformations of the paw (shortened or missing digits, blood blisters between or in place of digits) was seen in one litter. Similar effects, including maternal toxicity but not fetal malformations, were observed in rats dosed at 10 times the HD. When rats were given doses 2 times the HD from day 15 of gestation to day 26 postpartum, protracted parturition and maternal death, presumably due to hypocalcemia, were observed. In rabbits during organogenesis, doses 2 and 5 times the HD caused dose-related scoliosis that was thought to be attributable to the pharmacologic properties of the drug (1).

Tiludronate was not genotoxic in several assays. The drug also had no effect on male or female rat fertility at doses up to twice the HD (1).

It is not known if tiludronate crosses the human placenta. The molecular weight (about 326 for the free acid), prolonged plasma elimination half-life (150 hours), and lack of metabolism suggest that active drug will cross to the embryo–fetus.

A 2008 review described 51 cases of exposure to bisphosphonates before or during pregnancy: alendronate (N = 32), pamidronate (N = 11), etidronate (N = 5), risedronate (N = 2), and zoledronic acid (N = 1) (2). The authors concluded that although these drugs may affect bone modeling and development in the fetus, no such toxicity has yet been reported.

BREASTFEEDING SUMMARY

No reports describing the use of tiludronate during lactation have been located. The molecular weight (about 326 for the free acid), prolonged plasma elimination half-life (150 hours), and lack of metabolism suggest that active drug will be excreted into breast milk. Although the oral bioavailability in infants differs from that of adults, the very low adult oral bioavailability (<1% with food) and the binding of tiludronate by the calcium in milk suggest that the amount absorbed by the infant will be clinically insignificant. Thus, breastfeeding is probably compatible with tiludronate treatment.

TIMOLOL

Sympatholytic (Antihypertensive)

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Systemic use of some β -blockers may cause intrauterine growth restriction (IUGR) and reduced placental weight, especially those lacking intrinsic sympathomimetic activity (ISA) (i.e., partial agonist). Treatment beginning early in the 2nd trimester results in the greatest weight reductions, whereas treatment restricted to the 3rd trimester primarily affects only placental weight. Timolol does not possess ISA. However, IUGR and reduced placental weight may potentially occur with all agents within this class. Although IUGR is a serious concern, the benefits of maternal therapy with β -blockers, in some cases, might outweigh the risks to the fetus and must be judged on a case-by-case basis.

The systemic use near delivery of some agents in this class has resulted in persistent β -blockade in the newborn (see Acebutolol, Atenolol, and Nadolol). Thus, newborns exposed in utero to timolol should be closely observed during the first 24–48 hours after birth for bradycardia and other symptoms. The long-term effects of in utero exposure to β -blockers have not been studied but warrant evaluation.

FETAL RISK SUMMARY

Timolol is a nonselective β -adrenergic blocking agent used for the treatment of hypertension, after myocardial infarction, for the prophylaxis of migraine headache, and topically for the treatment of glaucoma.

Reproductive studies in mice, rats, and rabbits at doses up to about 40 times the maximum recommended daily human dose based on patient weight of 50 kg (MRHD) found no evidence of teratogenicity (1). However, fetotoxicity (resorptions) was observed in rabbits at this dose and in mice exposed to 830

times the MRHD (a maternal toxic dose).

A study using an in vitro perfusion system of human placental tissue demonstrated that timolol crossed to the fetal side of the preparation (2). The placental transfer is consistent with the molecular weight of the compound (about 433 for timolol maleate).

A woman with glaucoma was treated throughout gestation with topical timolol (0.5%) two drops in each eye, pilocarpine, and oral acetazolamide (3). Within 48 hours of delivery at 36 weeks' gestation, the infant developed hyperbilirubinemia, hypocalcemia, hypomagnesemia, and metabolic acidosis. The toxic effects, attributed to the carbonic anhydrase inhibitor, acetazolamide (see Acetazolamide), quickly resolved on treatment. Mild hypertonicity was observed on examinations at 1, 3, and 8 months of age (3).

In a 1998 case report, a 37-year-old woman at 21 weeks' gestation was referred because of fetal bradycardia (74 beats/minute [bpm]) with irregularity (4). There were no cardiac structural anomalies and no fetal hydrops. The mother had been taking timolol eye drops 0.5%, one drop in each eye once daily, for glaucoma for 3 years. Because no other cause of the bradycardia could be found, the dose was reduced to 0.25% in each eye once daily at about 25 weeks' gestation. Three days later, the fetal heart rate increased to 96 bpm, and then to 120 bpm 1 week later. After consulting with an ophthalmologist, timolol was stopped completely at about 30 weeks, and 3 days later the fetal heart rate was around 130 bpm. At term, a 3025-g female infant was delivered with Apgar scores of 8 and 10 at 1 and 5 minutes, respectively. After birth, a cardiac arrhythmia developed that was diagnosed as right ventricle tachycardia (200 bpm) with atrial extra systole. The condition required digitalization. The baby was doing well at 2 months of age (4).

A case report published in 1986 described the pregnancy of a 24-year-old woman at 30 weeks' gestation who was treated for recurrent pheochromocytoma with a combination of timolol, prazosin (an α_1 -adrenergic blocker), and metyrosine (a tyrosine hydroxylase inhibitor) (5). Hypertension had been noted at her first prenatal visit at 12 weeks' gestation. Because of declines in fetal breathing, body movements, and amniotic fluid volume that began 2 weeks after the start of therapy, a cesarean section was conducted at 33 weeks. The 1450-g female infant had Apgar scores of 3 and 5 at 1 and 5 minutes, respectively. Mild metabolic acidosis was found on analysis of umbilical cord blood gases. Multiple infarcts were noted in the placenta but no evidence of metastatic tumor. The growth-restricted infant did well and was discharged home on day 53 of life (5).

BREASTFEEDING SUMMARY

Timolol is excreted into breast milk (6,7). In nine lactating women given 5 mg orally 3 times daily, the mean milk concentration of timolol 105–135 minutes after a dose was 15.9 ng/mL (6). When a dose of 10 mg 3 times daily was given to four patients, mean milk levels of 41 ng/mL were measured. The milk:plasma ratios for the two regimens were 0.80 and 0.83, respectively.

A woman with elevated intraocular pressure applied ophthalmic 0.5% timolol drops to the right eye twice daily, resulting in excretion of the drug in her breast milk (7). Maternal timolol levels in milk and plasma were 5.6 and 0.93 ng/mL, respectively, about 1.5 hours after a dose. A milk sample taken 12 hours after the last dose contained 0.5 ng/mL of timolol. Assuming that the infant nursed every 4 hours and received 75 mL at each feeding, the daily dose would be below that expected to produce cardiac effects in the infant (7).

In a 2008 report, milk concentrations of timolol were measured from a woman with open-angle glaucoma who had been administering timolol 0.5% eye drops twice daily to her right eye for 6 months (8). Four milk samples were collected over 6 days. The mean timolol concentration in milk was 0.12 ng/mL (range 0–0.37 ng/mL). The theoretical maximum relative infant dose expressed as a percentage of the mother's weight-adjusted dose was 0.012%. Even doubling the dose to reflect the standard practice of treating both eyes would only have raised the relative dose to 0.024%. These infant exposures were thought to be clinically insignificant (8). Comments on this study and a reply also have been published (9,10).

No adverse reactions were noted in the nursing infants described in the above reports. However, infants exposed to timolol via breast milk should be closely observed for bradycardia and other signs or symptoms of β -blockade. Long-term effects of exposure to β -blockers from milk have not been studied but warrant evaluation. The American Academy of Pediatrics classifies timolol as compatible with breastfeeding (11).

TINIDAZOLE

Anti-infective (Antiprotozoal)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: Hold Breastfeeding (Single Dose)
Limited Human Data—Potential Toxicity (Divided Dose)

PREGNANCY SUMMARY

The human pregnancy experience with tinidazole is very limited. Although there was a slight increase in fetal deaths in one animal species at a dose close to that used in humans, no other evidence of developmental toxicity was noted in animal studies. Tinidazole is chemically related to metronidazole, and there is no convincing evidence of embryo or fetal harm with that anti-infective. Nevertheless, it would be prudent to choose metronidazole for those infections where both agents are recommended. Tinidazole could be used in cases where metronidazole therapy has failed to eradicate the infection. However, until more human data are available, avoidance of the 1st trimester should be considered.

FETAL RISK SUMMARY

Tinidazole is an oral synthetic antiprotozoal agent that chemically is a second-generation 5-nitroimidazole. It is closely related structurally to metronidazole. Tinidazole is indicated for the treatment of trichomoniasis caused by *Trichomonas vaginalis*, giardiasis caused by *Giardia duodenalis*, and amebiasis caused by *Entamoeba histolytica*. Oral bioavailability is 100%. It is partially metabolized and has a plasma half-life of about 12–14 hours. Plasma protein binding of tinidazole is about 12% (1).

Reproduction studies have been conducted in mice and rats. In pregnant mice, no evidence of embryo or fetal harm was observed with doses up to about 6.3 times the maximum human therapeutic dose based on BSA (MHTD). In pregnant rats, a slightly higher incidence of fetal death was noted with a dose 2.5 times the MHTD. No biologically relevant neonatal developmental effects were noted in rat pups after maternal doses as high as 3 times the

MHTD (1).

Long-term studies for carcinogenic effects have not been conducted with tinidazole. A closely related agent, metronidazole, has been studied and found to be associated with tumors in mice and rats (1) (see also Metronidazole). Assays for mutagenicity with tinidazole have resulted in both positive and negative results (1).

Decreased fertility and testicular histopathology occurred in male rats given doses that were about 3 times the MHTD for 60 days. Spermatogenic effects were noted at doses that were about ≥ 1.5 times the MHTD. The no-observed-adverse-effect level for testicular and spermatogenic effects was about half the MHTD. These findings are characteristic of agents in the 5-nitroimidazole class (1).

Tinidazole crosses the human placenta. A single 500-mg IV infusion was given over 20 minutes to 11 women undergoing a 1st trimester abortion (2). Sixty minutes after the start of the infusion, the uterus was evacuated. The mean concentrations of tinidazole in the maternal serum, fetal tissue, and placental tissue were 13.2 mcg/mL, 7.6 mcg/g, and 4.9 mg/g, respectively. The fetal tissue level was 58% of the maternal serum concentration (2).

The large population-based dataset of the Hungarian Case–Control Surveillance of Congenital Abnormalities was used to evaluate the effect of oral tinidazole (1–2 g/day for 6–7 days) on pregnancy outcomes in terms of congenital defects (3). Among the 22,843 cases with congenital anomalies, 10 (0.04%) had taken tinidazole, whereas in 38,151 controls, 16 (0.04%) had been exposed to the drug. The exposures had occurred in the 1st trimester in six cases and six controls. Although the data are very limited, there was no suggestion that tinidazole exposures resulted in a higher rate of congenital anomalies (3).

A 2006 review of the treatment of trichomoniasis concluded that single, 2-g oral dose of either metronidazole or tinidazole were first-line therapy (4). If a decision was made to treat a pregnant woman, metronidazole was preferred because of the greater amount of data related to pregnancy.

According to the CDC's 2006 Sexually Transmitted Diseases Treatment guidelines, recurrent and persistent urethritis was best treated with single, 2-g oral dose of either metronidazole or tinidazole (5). No special consideration was made for pregnancy. A similar recommendation was made for trichomoniasis. In this case, however, the limited human pregnancy experience with tinidazole was mentioned (5).

BREASTFEEDING SUMMARY

Tinidazole is excreted into breast milk. In a 1972 report, four women had milk:serum ratios as high as 1.62 after 7 days of treatment with tinidazole (6). A 1983 investigation studied the milk excretion of the drug in 24 women (7). After cord clamping, an IV infusion of tinidazole 500 mg was given to the mother over 20 minutes. Milk (colostrum) and blood samples were collected at 12, 24, 48, 72, and 96 hours after the end of the infusion. Mean maternal serum concentrations (mcg/mL) in the five samples were 6.1, 3.7, 1.2, 0.1, and 0, respectively. Milk samples at 12 and 24 hours were mixed samples, whereas the samples at 48, 72, and 96 hours were collected as fore- and hind-milk. The mixed milk concentrations were 5.8 and 3.5 mcg/mL, respectively. At the three other times, the concentrations (fore-milk/hind-milk) were 1.28/1.20, 0.32/0.30, and trace/trace, respectively. It was not stated if the infants were allowed to breastfeed (7).

In a 1985 study, five women undergoing a cesarean section received a single IV dose of tinidazole 1600 mg infused within 1.5 hours immediately after cord clamping (8). Blood and milk samples were collected at 8- and 4-hour intervals, respectively, for 96 hours. The average half-life of tinidazole in serum was 11.4 hours. The milk:serum ratios ranged from 0.62 to 1.39 with milk concentrations highly related to serum concentrations ($r = 0.969$). By 72 hours, only one woman had a milk concentration greater than 0.5 mcg/mL. The infants were not allowed to breastfeed. It was estimated that at 72 hours, the maximum daily dose for a nursing infant would be 0.1 mg/kg (assuming 3.5 kg body weight and 400 mL of milk consumed), and that breastfeeding then could commence (8).

The effect of exposure to tinidazole in breast milk is unknown because none of the above mothers breastfed their infants. Because of the close similarity between tinidazole and metronidazole, the American Academy of Pediatrics classifies both drugs as agents whose effect on nursing infants is unknown but may be of concern (9). If single-dose therapy is given, discontinuing breastfeeding for 12–24 hours to allow excretion of the drug was recommended.

TINZAPARIN

[Withdrawn from the market. See 9th edition.]

TIOCONAZOLE

Antifungal

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Although the animal reproduction data suggest low risk, there was no comparison with the recommended human dose. Only very small amounts of tioconazole are absorbed systemically from the human vagina and comparison with the oral doses used in the animal studies would have little meaning. The limited human data also suggest low risk, but the failure to specify the gestational ages and other data limits the assessment of embryo–fetal risk. The use of intravaginal tioconazole during pregnancy does not appear to represent a major risk, but more commonly used agents such as clotrimazole, miconazole, or nystatin should be considered the antifungals of choice during pregnancy.

FETAL RISK SUMMARY

Tioconazole is a topical antifungal agent that is indicated for the local treatment of vulvovaginal candidiasis (moniliasis). In the United States, it is available only as a single-dose, 300-mg (6.5% ointment) for intravaginal administration. Systemic absorption of tioconazole after intravaginal administration of a 300-mg dose is negligible (1–3). Six women with vaginal candidosis were treated with intravaginal 2% tioconazole cream (100 mg tioconazole in 5 g) for 14 consecutive days. The drug was not detected in blood samples drawn before and 2, 4, and 8 hours after the first and last doses (2). In another study, a 300-mg dose was given to 10 nonpregnant women. The mean plasma concentration was 21.2 ng/mL 8 hours after a dose and was undetectable (detection limit 10 ng/mL) at 24 hours in 9 of the 10 women. In contrast, the mean concentration in vaginal fluid was 21,400 ng/mL (3).

Reproduction studies have been performed in rats and rabbits. No adverse

effects on fetal viability or growth and no major structural anomalies were observed in pregnant rats given 55–165 mg/kg/day orally during organogenesis. An increase in the incidence of dilated ureters, hydroureters, and hydronephrosis in fetuses was not evident in pups raised to 21 days of age. These effects were not observed when a 2% tioconazole cream (about 10 mg/kg/day) was given intravaginally. Similar to other azole antimycotic agents, when treatment was extended through parturition in rats, tioconazole caused dystocia, prolongation of pregnancy, embryo–fetal deaths, and impaired pup survival. The no-effect dose for this toxicity was about 20 mg/kg/day orally and about 9 mg/kg/day intravaginally. In pregnant rabbits, there was no evidence of embryo toxicity or teratogenicity with oral doses \leq 165 mg/kg/day or daily intravaginal application of about 2–3 mg/kg from a 2% cream during organogenesis. No effects on parturition occurred in rabbits at 50 mg/kg/day orally (1).

It is not known if tioconazole crosses the human placenta. The molecular weight (about 388) is low enough, but systemic absorption of the drug from the vagina is negligible. Thus, exposure of the embryo–fetus to clinically significant concentrations is unlikely.

In an open 1987 study, 45 pregnant women with intractable vaginal candidosis were treated with a single-dose 300-mg tioconazole vaginal ovule (4). In addition, they applied a tioconazole 1% cream intra-anally, and rubbed the cream onto the perianal and vulva regions once daily for 7 days. The gestational ages of the women were not specified. All 45 women had spontaneous vaginal deliveries of normal healthy infants (gestational age at delivery and status of the newborn not specified). At 6-week follow-up, the infants were in satisfactory condition (4).

BREASTFEEDING SUMMARY

No reports describing the use of tioconazole during human lactation have been located. The molecular weight (about 388) is low enough for excretion into breast milk. However, systemic absorption of the drug from the vagina is negligible and detectable concentrations in milk are unlikely. Moreover, a 1% tioconazole cream has been used safely in neonates and infants to treat candidal diaper rash (5). Thus, the effect of maternal use of intravaginal tioconazole on a nursing infant appears to be nil.

TIOTROPIUM

Respiratory Drug (Bronchodilator)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of tiotropium during human pregnancy have been located. The approved indication for the drug suggests that such experience will be rare, but its use in asthmatic patients is possible. Although the animal data suggest low risk, the absence of pregnancy data prevents a full assessment of human risk. There are human pregnancy data for ipratropium, which is the preferred inhaled anticholinergic bronchodilator in pregnancy. However, because its long elimination half-life, use of tiotropium immediately before the diagnosis of an inadvertent pregnancy would most likely result in the exposure of a portion of organogenesis. Therefore, if a nonpregnant woman has shown a good response to inhaled tiotropium, it would be reasonable to continue her on this drug during pregnancy. If the maternal condition warrants starting tiotropium in pregnancy, avoidance of the 1st trimester should be considered.

FETAL RISK SUMMARY

Tiotropium is a parasympatholytic (anticholinergic), quaternary ammonium compound that has specificity for muscarinic receptors. It is formulated as capsules that contain a powder given by oral inhalation. Tiotropium is indicated for the long-term maintenance treatment of bronchospasm associated with chronic obstructive pulmonary disease (COPD), including chronic bronchitis and emphysema. As expected, the majority of the dose is deposited in the gastrointestinal tract, but oral bioavailability is poor (2%–3%). The absolute bioavailability of an inhaled dose, primarily from the lung, is about 20%. The terminal elimination half-life after inhalation is 5–6 days (1,2).

Reproduction studies have been conducted with tiotropium in experimental

animals. Long-term studies in rats revealed no evidence of tumorigenicity, mutagenicity, or clastogenicity. In pregnant rats and rabbits, inhalation doses up to about 660 and 6 times, respectively, the maximum recommended human daily dose based on BSA (MRHD) revealed no evidence of structural anomalies. In rats, however, a dose about 35 times the MRHD resulted in fetal toxicity (resorptions, litter loss, decreased number of live pups at birth, decreased mean birth weight, and a delayed pup sexual maturation) and, in a fertility study, decreased number of corpora lutea and percentage of implants. In rabbits an increase in postimplantation loss was noted at about 360 times the MRHD. The no-observed-effect level (NOEL) for these toxicities in rats and rabbits was about 4 and 80 times the MRHD, respectively. However, these dose multiples may be over-estimated because of the difficulties in measuring deposited doses in animal inhalation studies (1,2).

It is not known if tiotropium crosses the placenta. The drug's molecular weight (about 490 for the bromide monohydrate salt) is low enough to cross. The peak plasma concentrations at steady state are very low (17–19 pg/mL), thus limiting the amount of drug at the maternal–fetal interface.

BREASTFEEDING SUMMARY

No reports describing the use of tiotropium during human lactation have been located. Because of the very low amounts in plasma (steady state peak plasma levels of 17–19 pg/mL) and the poor oral bioavailability (about 2%–3%), maternal use of the drug during lactation probably would have no effect on a nursing infant. However, close monitoring of the infant for anticholinergic effects (e.g., dry mouth, constipation, urinary retention, and increased heart rate) is warranted.

TIPRANAVIR

Antiviral

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

The very limited human pregnancy experience during the 1st trimester does not allow a prediction as to the risk of tipranavir during gestation. The animal data suggest low risk, but the obtainable systemic exposures were very low. If indicated, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Tipranavir is a nonpeptide inhibitor of HIV type 1 (HIV-1) protease. Tipranavir is indicated, in combination with ritonavir 200 mg, for combination antiretroviral treatment of adults infected with HIV-1 with evidence of viral replication, who are highly treatment-experienced or have HIV-1 strains resistant to multiple protease inhibitors. Tipranavir and ritonavir are combined because tipranavir is primarily metabolized by CYP3A and ritonavir inhibits CYP3A, thereby markedly increasing the plasma concentrations of tipranavir (darunavir and lopinavir also are combined with ritonavir for the same reason). Metabolism in the presence of ritonavir is minimal. Tipranavir is extensively bound to plasma proteins (>99.9%), both albumin and α_1 -acid-glycoprotein. In HIV-infected adults, the mean terminal elimination half-life is about 6 hours when combined with ritonavir (1).

Reproduction studies have been conducted in rats and rabbits. In pregnant rats, no effect on early embryonic development was observed at tipranavir exposures about equal to the human exposure from the recommended dose of 500/200 mg tipranavir/ritonavir given twice daily. No teratogenicity was observed in rats or rabbits with tipranavir doses up to 1.1 and 0.1 times, respectively, the human exposure (AUC) of tipranavir at the recommended dose (HE). At about 0.8 times the HE or higher in rats, fetal toxicity (decreased

sternbrae ossification and body weights) was observed. In rats and rabbits, fetal toxicity was not observed at exposures (AUC) that were about 0.2 and 0.1 times, respectively, the HE. In pre- and postdevelopment studies in rats, dose levels about 0.8 times the HE caused growth inhibition in pups and maternal toxicity. The no-adverse-effect level was about 0.2 times the HE (1).

Long-term carcinogenicity studies have not been completed with tipranavir and tipranavir/ritonavir. No evidence of mutagenicity or clastogenicity was observed in a variety of assays. There also was no evidence of impaired fertility in rats at tipranavir exposures about equal to the human exposure from the recommended dose of 500/200 mg tipranavir/ritonavir given twice daily (1).

It is not known if tipranavir crosses the human placenta. The molecular weight (about 603), minimal metabolism, and elimination half-life suggest that the drug will cross, but the high plasma protein binding will be limiting factor.

A 33-year-old woman with drug-resistant HIV presented to a treatment center at 27 weeks' gestation (2). The woman's current therapy was stavudine, tenofovir, and lopinavir/ritonavir, but the response to this combination had been poor, as had been her compliance. Her therapy was changed to zidovudine, lamivudine, abacavir, tenofovir, enfuvirtide, and tipranavir/ritonavir. The patient was hospitalized. High-dose zidovudine was given at 34 weeks' gestation and a cesarean section delivered a healthy infant (sex not specified). No evidence of HIV was found in the infant on the day of birth and at 6 and 26 weeks of age (2).

In 1998, a public health advisory was issued by the FDA on the association between protease inhibitors and diabetes mellitus (3). Because pregnancy is a risk factor for hyperglycemia, there was concern that these antiretroviral agents would exacerbate this risk. The manufacturer's product information also notes the potential risk for new-onset diabetes, exacerbation of preexisting diabetes, and hyperglycemia in HIV-infected patients receiving protease inhibitor therapy (1). An abstract published in 2000 described the results of a study involving 34 pregnant women treated with protease inhibitors compared with 41 controls that evaluated the association with diabetes (4). No association between protease inhibitors and an increased incidence of gestational diabetes was found.

The Antiretroviral Pregnancy Registry reported, for the period January 1989 through July 2009, prospective data (reported before the outcomes were known) involving 4702 live births that had been exposed during the 1st trimester to one or more antiretroviral agents (5). Congenital defects were noted in 134, a prevalence of 2.8% (95% confidence interval [CI] 2.4–3.4). In the 6100 live

births with earliest exposure in the 2nd/3rd trimesters, there were 153 infants with defects (prevalence 2.5%, 95% CI 2.1–2.9). The prevalence rates for the two periods did not differ significantly. There were 288 infants with birth defects among 10,803 live births with exposure anytime during pregnancy (prevalence 2.7%, 95% CI 2.4–3.0). The prevalence rate did not differ significantly from the rate expected in a nonexposed population. There were five outcomes exposed to tipranavir (four in the 1st trimester and one in the 2nd/3rd trimesters) in combination with other antiretroviral agents. There were no birth defects. In reviewing the birth defects of prospective and retrospective (pregnancies reported after the outcomes were known) registered cases, the Registry concluded that, except for isolated cases of neural tube defects with efavirenz exposure in retrospective reports, there was no other pattern of anomalies (isolated or syndromic) (5) (see Lamivudine for required statement).

Two reviews, one in 1996 and the other in 1997, concluded that all women currently receiving antiretroviral therapy should continue to receive therapy during pregnancy and that treatment of the mother with monotherapy should be considered inadequate therapy (6,7). The same conclusion was reached in a 2003 review with the added admonishment that therapy must be continuous to prevent emergence of resistant viral strains (8). In 2009, the updated U.S. Department of Health and Human Services guidelines for the use of antiretroviral agents in HIV-1-infected patients continued the recommendation that the therapy, with the exception of efavirenz, should be continued during pregnancy (9). If indicated, therefore, protease inhibitors, including tipranavir, should not be withheld in pregnancy because the expected benefit to the HIV-positive mother outweighs the unknown risk to the fetus. Pregnant women taking protease inhibitors should be monitored for hyperglycemia. Updated guidelines for the use of antiretroviral drugs to reduce perinatal HIV-1 transmission also were released in 2010 (10). Women receiving antiretroviral therapy during pregnancy should continue the therapy but, regardless of the regimen, zidovudine administration is recommended during the intrapartum period to prevent vertical transmission of HIV to the newborn (10).

BREASTFEEDING SUMMARY

No reports describing the use of tipranavir during lactation have been located. The molecular weight (about 603), minimal metabolism, an elimination half-life (6 hours) suggest that the drug will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown.

Reports on the use of tipranavir during human lactation are unlikely because

the antiviral agent is used in the treatment of HIV infection. HIV-1 is transmitted in milk, and in developed countries, breastfeeding is not recommended (6,7,9,11–13). In developing countries, breastfeeding is undertaken, despite the risk, because there are no affordable milk substitutes available. Until 1999, no studies had been published that examined the effect of any antiretroviral therapy on HIV-1 transmission in milk. In that year, a study involving zidovudine was published that measured a 38% reduction in vertical transmission of HIV-1 infection despite breastfeeding when compared with controls (see Zidovudine).

TIROFIBAN

Antiplatelet Agent

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: Hold Breastfeeding

PREGNANCY SUMMARY

Only one report describing the use of tirofiban in human pregnancy has been located. The pregnancy was still ongoing at the time of the report. The animal data are reassuring but human pregnancy experience is required to assess the risk this agent presents to the embryo–fetus. The primary risk, however, appears to be from maternal hemorrhage during drug administration. If this is adequately controlled, the benefits of the drug to the mother appear to far outweigh the unknown risks to the fetus.

FETAL RISK SUMMARY

Tirofiban, a nonpeptide antagonist of the platelet glycoprotein IIb/IIIa receptor, is an inhibitor of platelet aggregation. It is given by continuous IV infusion for up to 108 hours depending on the indication. Tirofiban is in the same subclass of antiplatelet agents as abciximab and eptifibatide. It is indicated, in combination with heparin, for the treatment of acute coronary syndrome, including patients who are to be managed medically and those undergoing percutaneous transluminal coronary angioplasty (PTCA) or atherectomy. The metabolism of the agent is limited and about 65% is bound to plasma proteins. The half-life is about 2 hours (1).

Reproduction studies have been conducted in rats and rabbits. In these species, IV doses up to 5 and 13 times, respectively, the maximum recommended human dose based on BSA (MRHD) revealed no harm to the fetus (1).

Studies evaluating the carcinogenic potential of tirofiban have not been conducted. Multiple assays for mutagenicity and chromosomal aberration were negative. Fertility and reproductive performance were not affected in male and female rats given IV doses up to about 5 times the MRHD (1).

It is not known if tirofiban crosses the human placenta. The drug does cross the placenta in rats and rabbits. The molecular weight (about 441 for the nonhydrated free base), limited metabolism, and moderate plasma protein binding suggest that the drug will cross to the embryo–fetus. Moreover, the drug is given as a continuous IV infusion for periods up to 108 hours, thus allowing for prolonged contact at the maternal–fetal interface.

A 43-year-old woman, with a history of diabetes and hypertension, was in her sixth pregnancy when she had an acute myocardial infarction at 20 weeks' gestation (2). She was treated with aspirin, nitroglycerin, and then tirofiban with heparin for PTCA and intracoronary stenting. She was discharged home, 5 days after the procedure, on aspirin, clopidogrel, and metoprolol (doses not specified). The pregnancy was ongoing at the time of the report (2).

BREASTFEEDING SUMMARY

No reports describing the use of tirofiban during human lactation have been located. The molecular weight (about 441 for the nonhydrated free base), limited metabolism, and moderate plasma protein binding (65%) suggest that the drug will be excreted into breast milk. Moreover, the drug is given as a continuous IV infusion for periods up to 108 hours. The drug is commonly combined with heparin and sometimes with aspirin. The effect of this exposure on a nursing infant is unknown, as is its oral bioavailability. However, the safest course is to hold breastfeeding during the infusion.

TIZANIDINE

Skeletal Muscle Relaxant

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of tizanidine in human pregnancy have been located. The animal data suggest toxicity but not congenital defects. The absence of human pregnancy experience prevents an assessment of the embryo–fetal risk. However, dose-related hypotension has been observed in humans and this could be a potentially serious adverse effect in pregnant women. Single doses of the recommended dose (8 mg) have caused a 20% reduction in either the systolic or the diastolic blood pressure in two-thirds of patients. This effect may be minimized by titration of the dose, but close monitoring of the maternal blood pressure is required. In addition, if the drug must be used in pregnancy, avoidance in the 1st trimester is recommended.

FETAL RISK SUMMARY

Tizanidine is a centrally acting α_2 -adrenergic agonist structurally related to clonidine that is used for the management of spasticity. Based on animal studies, tizanidine has no direct effect on skeletal muscle fibers or the neuromuscular junction. Although, in animals the drug has a small fraction (2%–10%) of the potency of clonidine in lowering blood pressure, dose-related hypotension has been observed in humans. The terminal elimination half-life is about 2.5 hours (1).

Reproduction studies have been conducted in rats and rabbits. In rats, a dose equal to the maximum recommended human dose based on BSA (MRHD) revealed no evidence of teratogenicity. At doses up to 8 times the MRHD, increased duration of gestation, increased prenatal and postnatal pup mortality and slow development were noted. In rabbits, no evidence of structural defects

was evident at a dose 16 times the MRHD. However, postimplantation loss was increased at a dose equal to or greater than 0.5 times the MRHD (1).

It is not known if tizanidine crosses the human placenta. The relatively low molecular weight (about 254 for the free base) and lipid solubility suggest that passage to the embryo or fetus should be expected.

BREASTFEEDING SUMMARY

No reports describing the use of tizanidine during human lactation have been located. The molecular weight (about 254 for the free base) and lipid solubility suggest that excretion into breast milk will occur. The effect of this exposure on a nursing infant is unknown, but serious toxicity (e.g., sedation, hypotension, liver injury, and hallucinations/psychotic-like symptoms as seen in adults) is a potential complication. Because of these potential adverse effects, breastfeeding is not recommended.

TOBRAMYCIN

Antibiotic (Aminoglycoside)

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No reports linking the use of tobramycin with congenital defects have been located. The antibiotic is not teratogenic in two animal species (1). Ototoxicity, which is known to occur after tobramycin therapy, has not been reported as an effect of in utero exposure. However, eighth cranial nerve toxicity in the fetus is well known following exposure to other aminoglycosides (see Kanamycin and Streptomycin) and may potentially occur with tobramycin.

FETAL RISK SUMMARY

Tobramycin is an aminoglycoside antibiotic. Renal toxicity was observed in pregnant rats and their fetuses after maternal administration of high doses of tobramycin (30 or 60 mg/kg/day) for 10 days, during organogenesis. The dose-related fetal renal toxicity consisted of granularity and swelling of proximal tubule cells, poor glomerular differentiation, and increased glomerular density (2).

Tobramycin crosses the placenta into the fetal circulation and amniotic fluid (3,4). Studies in patients undergoing elective abortions in the 1st and 2nd trimesters indicate that tobramycin distributes to most fetal tissues except the brain and cerebrospinal fluid (3). Amniotic fluid levels generally did not occur until the 2nd trimester. The highest fetal concentrations were found in the kidneys and urine (3). In a woman undergoing surgical termination of an ovarian gestation in a 22-week heterotopic pregnancy (intrauterine and ovarian), a single 2 mg/kg IV dose of tobramycin was administered for 10 minutes, 5.6 hours before cesarean section (4). Tobramycin was found in all fluids and tissues of the 260-g ovarian fetus, with the highest concentrations occurring in the fetal spleen (1.53 mcg/mL) and kidney (2.98 mcg/mL). The intrauterine fetus developed normally and a healthy 2900-g girl was eventually delivered at

38 weeks' gestation. Reports measuring the passage of tobramycin in the 3rd trimester or at term are lacking.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 81 newborns had been exposed to tobramycin during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of three (3.7%) major birth defects were observed (three expected), one of which was a cardiovascular defect (one expected). No anomalies were observed in five other categories of defects (oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available.

The population-based dataset of the Hungarian Case–Control Surveillance of Congenital Abnormalities, covering the period of 1980–1996, was used to evaluate the teratogenicity of aminoglycoside antibiotics (parenteral gentamicin, streptomycin, tobramycin, and oral neomycin) in a study published in 2000 (5). A case group of 22,865 women who had fetuses or newborns with congenital malformations were compared with 38,151 women who had newborns with no structural defects. A total of 38 cases and 42 controls were treated with aminoglycosides. There were two cases and four controls treated with tobramycin (odds ratio 0.8, 95% confidence interval 0.2–3.9). The investigators concluded that there was no detectable teratogenic risk for structural defects for any of the aminoglycoside antibiotics. They also concluded, although it was not investigated in this study, that the risk of deafness after in utero aminoglycoside exposure was small (5).

A potentially serious drug interaction may occur in newborns treated with aminoglycosides who were also exposed in utero to magnesium sulfate (see Gentamicin).

BREASTFEEDING SUMMARY

Tobramycin is excreted into breast milk. Following an 80-mg IM dose given to five patients, milk levels varied from a trace to 0.52 mcg/mL over 8 hours (6). Peak levels occurred at 4 hours after injection. Because oral absorption of this antibiotic is poor, ototoxicity in the infant would not be expected. However, three potential problems exist for the nursing infant: modification of bowel flora, direct effects on the infant, and interference with the interpretation of culture results if a fever workup is required.

TOCAINIDE

[Withdrawn from the market. See 9th edition.]

TOCILIZUMAB

Immunologic Agent (Immunomodulator)

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Outcomes in 31 human pregnancies including 10 live births and 1 newborn death have been reported with no teratogenic effects noted. Teratogenicity was not observed in cynomolgus monkeys, but compared with controls, an increased risk of fetal death was observed at the two highest doses. No other forms of developmental toxicity were observed in the monkey model or in a mouse analog. If tocilizumab is used in pregnancy, patients should be informed of the lack of adequate human pregnancy experience. The manufacturer maintains a pregnancy registry (1). Physicians are encouraged to register patients and patients can register themselves by calling 1-877-311-8972.

FETAL RISK SUMMARY

Tocilizumab is a recombinant humanized IgG1κ monoclonal antibody against the human interleukin-6 receptor (IL-6). It is indicated for the treatment of adult patients with moderately to severely active rheumatoid arthritis who have had inadequate response to other therapies, and for the treatment of patients with juvenile idiopathic arthritis who are 2 years of age or older. The terminal elimination half-life in adult patients is up to 11 days for doses of 4 mg/kg and up to 13 days for doses of 8 mg/kg given by IV infusion every 4 weeks (1).

Reproduction studies have been conducted in pregnant cynomolgus monkeys who received daily doses of 0 (control), 2, 10, and 50 mg/kg given by IV infusion from gestation day 20 to 50. The comparability of these doses to the human dose of 8 mg/kg given every 2 to 4 weeks is unclear; however, there was no evidence of teratogenicity at any dose. An increase in embryo–fetal deaths was observed at the 10 and 50 mg/kg doses (embryo–fetal losses of

10%, 10%, 20%, and 30%, respectively, for the 0, 2, 10, and 50 mg/kg/day groups) (1,2).

In other studies in rats, rabbits, and mice no evidence of teratogenicity was noted. In addition, no effects on postnatal development including functional performance or immune competence were observed in mice. In rabbits, at the intermediate dose of 5 mg/kg, an increase in fetal mortality was noted, but effects were thought to be secondary to maternal toxicity (1,2).

The carcinogenic potential of tocilizumab has not been evaluated. Tocilizumab was negative for mutagenicity in two assays. No impairment of fertility was noted in male or female mice analog studies (1).

It is not known if tocilizumab crosses the human placenta, but the antibody does cross the cynomolgus monkey placenta (1,2). Although the molecular weight is high (about 148,000), the prolonged elimination half-life (up to 13 days) may allow the protein to cross the human placenta. Similar to other immune globulin antibodies, placental transfer should be expected late in gestation (1,2).

Thirty-three human pregnancies with known outcomes occurring in 32 patients with rheumatoid arthritis have been reported in abstract (3). Thirteen pregnancies ended in elective termination; 7 spontaneously aborted (5 of whom were also exposed to methotrexate); and 10 pregnancies resulted in healthy newborns. One additional liveborn infant died of respiratory distress after intrapartum fetomaternal hemorrhage due to placenta previa. No congenital malformations were reported (3).

In another study of 10 pregnant patients with preterm premature rupture of the membranes, the regulation of matrix metalloproteinase (MMP) expression by inflammatory cytokines in human amnion cells was investigated. Treatment with IL-6 increased secretion of selected MMPs, whereas treatment with 1 mcg/mL tocilizumab inhibited the IL-6-induced secretion (4).

BREASTFEEDING SUMMARY

No reports describing the use of tocilizumab during human lactation have been located. The high molecular weight (about 148,000) suggests that the antibody will not be excreted into breast milk, but the prolonged elimination half-life (up to 13 days) may allow some excretion.

Because maternal antibodies are excreted into breast milk, especially early in lactation, the presence of tocilizumab in milk should be expected. The effect of this exposure on a nursing infant is unknown.

TOFACITINIB

Immunologic Agent (Antirheumatic)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk (Contraindicated if Combined with Methotrexate)

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity (Contraindicated if Combined with Methotrexate)

PREGNANCY SUMMARY

No reports describing the use of tofacitinib in human pregnancy have been located. Animal reproduction data suggest risk, but the absence of human pregnancy experience prevents a more complete assessment of the embryo–fetal risk. The drug should not be used in pregnancy if combined with methotrexate. Women who are either pregnant or of reproductive age should be informed of the potential risk of this drug if taken in pregnancy. Either physicians or pregnant women themselves are encouraged to register in the manufacturer’s pregnancy registry for tofacitinib by calling 1-877-311-8972.

FETAL RISK SUMMARY

Tofacitinib is an inhibitor of Janus kinases that are intracellular enzymes. It is indicated for the treatment of adult patients with moderately to severely active rheumatoid arthritis who have had an inadequate response or intolerance to methotrexate. The drug may be used as monotherapy or in combination with methotrexate or other nonbiologic disease-modifying antirheumatic drugs. Tofacitinib is partially metabolized to inactive metabolites. Plasma protein binding to albumin is about 40% and the elimination half-life is about 3 hours (1).

Reproduction studies have been conducted in rats and rabbits. In rats, the drug was teratogenic at exposure levels about 146 times the maximum recommended human dose based on AUC (MRHD) at oral doses of 100 mg/kg/day (MRHD-100). Defects included external and soft-tissue malformations of anasarca and membranous ventricular septal defects, respectively, and skeletal malformations or variations (absent cervical arch;

bent femur, fibula, humerus, radius, scapula, tibia, and ulna; sternoschisis; absent rib; misshapen femur; branched rib; fused rib; fused sternebra; and hemicentric thoracic centrum). Early and late abortions also were observed as was decreased fetal weight and postnatal survival. The no-observed-effect exposure level (NOEL) for developmental toxicity was about 58 times the MRHD at oral doses of 30 mg/kg/day (MRHD-30). In rabbits, exposure levels about 13 times the MRHD-30 caused teratogenic effects consisting of thoracogastroschisis, omphalocele, membranous ventricular septal defects, and cranial/skeletal malformations (microstomia, microphthalmia), mid-line and tail defects. An increase in abortions also was observed. No developmental toxicity was observed at exposure levels about 3 times the MRHD at oral doses of 10 mg/kg/day (1).

In long-term studies, tofacitinib was not carcinogenic in mice but was carcinogenic in monkeys (lymphomas) and in rats (benign Leydig cell tumors, hibernomas, and benign thymomas). The drug was not mutagenic in multiple assays but was clastogenic in one assay. Reduced fertility due to increased postimplantation loss was seen in some rat studies but this effect was not observed when lower doses were used. Doses that were about 133 times the MRHD-100 had no effect on male fertility, sperm motility, or sperm concentrations (1).

It is not known if tofacitinib crosses the human placenta. The molecular weight (about 312 for the free base), moderate plasma protein binding, and elimination half-life suggest that the drug will cross to the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use of tofacitinib during human lactation have been located. The molecular weight (about 312 for the free base), moderate plasma protein binding (about 40%), and elimination half-life (about 3 hours) suggest that the drug will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown. However, because tofacitinib has been associated with severe adverse effects in adults, including infections that have resulted in death, the drug is best avoided during breastfeeding.

TOLAZAMIDE

Antidiabetic Agent

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 3rd Trimester

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although the use of tolazamide during human gestation does not appear to be related to structural anomalies, insulin is still the treatment of choice for this disease. Oral hypoglycemics might not be indicated for the pregnant diabetic. Moreover, insulin, unlike tolazamide, does not cross the placenta and, thus, eliminates the additional concern that the drug therapy is adversely affecting the fetus. Carefully prescribed insulin therapy will provide better control of the mother's blood glucose, thereby preventing the fetal and neonatal complications that occur with this disease. High maternal glucose levels, as may occur in diabetes mellitus, are closely associated with a number of maternal and fetal adverse effects, including structural anomalies if the hyperglycemia occurs early in gestation. To prevent this toxicity, the American College of Obstetricians and Gynecologists recommends that insulin be used for types 1 and 2 diabetes occurring during pregnancy and, if diet therapy alone is not successful, for gestational diabetes (1,2). If tolazamide is used during pregnancy, therapy should be changed to insulin and tolazamide discontinued before delivery (the exact time before delivery is unknown) to lessen the possibility of prolonged hypoglycemia in the newborn.

FETAL RISK SUMMARY

Tolazamide is a sulfonylurea used for the treatment of adult-onset diabetes mellitus. It is not indicated for the pregnant diabetic.

No reports describing the placental transfer of tolazamide have been located. The molecular weight (about 311) suggests that transfer to the fetus probably occurs (see Chlorpropamide).

A 1991 report described the outcomes of pregnancies in 21 noninsulin-dependent diabetic women who were treated with oral hypoglycemic agents (17 sulfonylureas, 3 biguanides, and 1 unknown type) during the 1st trimester (3). The duration of exposure ranged from 3 to 28 weeks, but all patients were changed to insulin therapy at the first prenatal visit. Forty noninsulin-dependent diabetic women matched for age, race, parity, and glycemic control served as a control group. Eleven (52%) of the exposed infants had major or minor congenital malformations compared with six (15%) of the controls. Moreover, ear defects, a malformation that is observed, but uncommonly, in diabetic embryopathy, occurred in six of the exposed infants and in none of the controls (1). One of the infants with an ear defect (thickened curved pinnae and malformed superior helices) was exposed in utero to tolazamide during the first 12 weeks of gestation. Sixteen live births occurred in the exposed group compared with 36 in controls. The groups did not differ in the incidence of hypoglycemia at birth (53% vs. 53%), but three of the exposed newborns had severe hypoglycemia lasting 2, 4, and 7 days even though the mothers had not used oral hypoglycemics (none of the three was exposed to tolazamide) close to delivery. The authors attributed this to irreversible β -cell hyperplasia that may have been increased by exposure to oral hypoglycemics. Hyperbilirubinemia was noted in 10 (67%) of 15 exposed newborns compared with 13 (36%) controls ($p < 0.04$), and polycythemia and hyperviscosity requiring partial exchange transfusions were observed in 4 (27%) of 15 exposed vs. 1 (3.0%) control ($p < 0.03$) (1 exposed infant was not included in these data because the infant was delivered after completion of the study) (3).

BREASTFEEDING SUMMARY

No reports describing the use of tolazamide during human lactation have been located. The molecular weight (about 311) is low enough that excretion in milk should be expected (see Chlorpropamide). The effect of exposure to the drug in milk on the nursing infant is unknown, but hypoglycemia is a potential toxicity.

TOLAZOLINE

[Withdrawn from the market. See 9th edition.]

TOLBUTAMIDE

Antidiabetic Agent

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 3rd Trimester

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although the use of tolbutamide during human gestation does not appear to be related to structural anomalies, insulin is still the treatment of choice for diabetes. Oral hypoglycemics might not be indicated for the pregnant diabetic. Moreover, insulin, unlike tolbutamide, does not cross the placenta and, thus, eliminates the additional concern that the drug therapy itself is adversely affecting the fetus. Because tolbutamide crossed the placenta, prolonged hypoglycemia occurred in a premature infant. Carefully prescribed insulin therapy will provide better control of the mother's blood glucose, thereby preventing the fetal and neonatal complications that occur with this disease. High maternal glucose levels, as may occur in diabetes mellitus, are closely associated with a number of maternal and fetal adverse effects, including fetal structural anomalies if the hyperglycemia occurs early in gestation. To prevent this toxicity, the American College of Obstetricians and Gynecologists recommends that insulin be used for types 1 and 2 diabetes occurring during pregnancy and, if diet therapy alone is not successful, for gestational diabetes (1,2). If tolbutamide is used during pregnancy, therapy should be changed to insulin and tolbutamide discontinued before delivery to lessen the possibility of prolonged hypoglycemia in the newborn. The timing when therapy should be changed to insulin is not certain but at least 4 days before delivery appears reasonable based on one case.

FETAL RISK SUMMARY

Tolbutamide is a sulfonylurea used for the treatment of adult-onset diabetes mellitus. It is not the treatment of choice for the pregnant diabetic patient.

Shepard (3) reviewed four studies that had reported teratogenicity in mice and rats, but not in rabbits. In a study using early-somite mouse embryos in whole-embryo culture, tolbutamide produced malformations and growth restriction at concentrations similar to therapeutic levels in humans (4). The defects were not a result of hypoglycemia. In a similar experiment, but using tolbutamide concentrations 2–4 times the human therapeutic level, investigators concluded that tolbutamide had a direct embryotoxic effect on the rat embryos (5).

When administered near term, the drug crosses the placenta (6,7). Neonatal serum levels are higher than corresponding maternal concentrations. In one infant whose mother took 500 mg/day, serum levels at 27 hours were 7.2 mg/dL (maternal 2.7 mg/dL) (7).

An abstract (8), and later full report (9), described the in vitro placental transfer, using a single-cotyledon human placenta, of four oral hypoglycemic agents. As expected, molecular weight was the most significant factor for drug transfer, with dissociation constant (pK_a) and lipid solubility providing significant additive effect. The cumulative percent placental transfer at 3 hours of the four agents and their approximate molecular weight (shown in parenthesis) were tolbutamide (270) 21.5%, chlorpropamide (277) 11.0%, glipizide (446) 6.6%, and glyburide (494) 3.9%.

Although teratogenic in animals, an increased incidence of congenital defects, other than those expected in diabetes mellitus, has not been found with tolbutamide in a number of studies (10–20). Four malformed infants have been attributed to tolbutamide but the relationship is unclear: right-sided preauricular skin tag, accessory right thumb, thrombocytopenia (nadir 19,000/mm³ on fourth day) (7); hand and foot anomalies, finger and toe syndactyly, external ear defect, atresia of external auditory canal, gastrointestinal, heart, and renal anomalies (21); grossly malformed (22); and severe talipes, absent left toe (23). The neonatal thrombocytopenia, persisting for about 2 weeks, was thought to have been induced by tolbutamide (7).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 4 newborns had been exposed to tolbutamide during the 1st trimester (F. Rosa, personal communication, FDA, 1993). One (25%) major birth defect was observed (none expected), but specific information on the defect is not available. No anomalies were observed in six categories of defects (cardiovascular defects, oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias).

A 1991 report described the outcomes of pregnancies in 21 noninsulin-

dependent diabetic women who were treated with oral hypoglycemic agents (17 sulfonylureas, 3 biguanides, and 1 unknown type) during the 1st trimester (24). The duration of exposure ranged from 3 to 28 weeks, but all patients were changed to insulin therapy at the first prenatal visit. Forty noninsulin-dependent diabetic women matched for age, race, parity, and glycemic control served as a control group. Eleven (52%) of the exposed infants had major or minor congenital malformations compared with six (15%) of the controls. Moreover, ear defects, a malformation that is observed, but uncommonly, in diabetic embryopathy, occurred in six of the exposed infants and in none of the controls. None of the infants with defects was exposed to tolbutamide. Sixteen live births occurred in the exposed group compared with 36 in controls. The groups did not differ in the incidence of hypoglycemia at birth (53% vs. 53%), but three of the exposed newborns had severe hypoglycemia lasting 2, 4, and 7 days even though the mothers had not used oral hypoglycemics (none of the three was exposed to tolbutamide) close to delivery. The authors attributed this to irreversible β -cell hyperplasia that may have been increased by exposure to oral hypoglycemics. Hyperbilirubinemia was noted in 10 (67%) of 15 exposed newborns compared with 13 (36%) of controls ($p < 0.04$), and polycythemia and hyperviscosity requiring partial exchange transfusions were observed in 4 (27%) of 15 exposed vs. 1 (3.0%) control ($p < 0.03$) (1 exposed infant was not included in these data because the infant was delivered after completion of the study) (24).

A case of prolonged hypoglycemia in a premature infant whose mother was treated with tolbutamide for gestational diabetes was reported in 1998 (25). The mother was treated with tolbutamide starting from 23 weeks' gestation until delivery at 34 weeks. The male infant's weight and length were 3200 g and 49 cm, respectively, both values above 1 standard deviation of the mean for gestational age. Hypoglycemia was diagnosed 1 hour after birth and IV 20% glucose was required for the first 3 days of life. Subcutaneous octreotide was also administered for first 9 days of life. Serum tolbutamide concentrations decreased from 38 mcg/mL (140.6 μ mol/L) at 3 hours after birth to 2 mcg/mL (7.4 μ mol/L) at 90 hours. The decline in serum concentration showed zero-order kinetics with an initial half-life of 46 hours that declined to 6 hours. The change in tolbutamide elimination suggested immaturity of hepatic elimination during the first 2 days of life. The infant displayed normal psychomotor development without seizures and normal glucose values at 3 months of age (25).

BREASTFEEDING SUMMARY

Tolbutamide is excreted into breast milk. Following long-term dosing with 500 mg orally twice daily, milk levels in two patients averaged 3 and 18 mcg/mL 4 hours after a dose (26). Milk:plasma ratios were 0.09 and 0.40, respectively. The effect on an infant from these levels is unknown, but hypoglycemia is a potential toxicity. The American Academy of Pediatrics, although noting the possibility of jaundice in the nursing infant, classifies tolbutamide as compatible with breastfeeding (27).

TOLCAPONE

Antiparkinson Agent

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of tolcapone in human pregnancy have been located. Because the drug is always used concomitantly with levodopa/carbidopa, the increased incidence of fetal anomalies and reduced fetal weight observed in rats treated with combination therapy resulting in plasma exposures of tolcapone only one-half of the expected human exposure is noteworthy. Embryo and/or fetal toxicity were also observed in rats and rabbits with tolcapone doses ranging from less than to slightly above the typical human dose. The complete lack of human pregnancy experience, however, prevents an assessment of the potential embryo and fetal risk from tolcapone. The low incidence of Parkinson's disease in women of reproductive age and the risk of potentially fatal, acute fulminant liver failure should markedly limit the use of tolcapone in this patient population.

FETAL RISK SUMMARY

Tolcapone is used as an adjunct to levodopa/carbidopa for the treatment of Parkinson's disease. The agent is a selective and reversible inhibitor of catechol-O-methyltransferase (COMT), an enzyme involved in the metabolism of levodopa. Inhibition of COMT by tolcapone allows for more sustained plasma levels of levodopa resulting in greater beneficial effects on the signs and symptoms of Parkinson's disease. Because the drug may cause potentially fatal, acute fulminant liver failure, it is recommended that it should be used only in patients who are not appropriate candidates for other adjunctive therapies (1). Tolcapone is nearly completely metabolized to inactive metabolites before excretion in the urine. It has an elimination half-life of 2–3 hours with no

evidence of accumulation after repeat dosing (1).

Reproduction studies with tolcapone alone have been conducted in rats and rabbits. In rats, doses up to 5.7 times the recommended human clinical dose of 600 mg/day based on BSA (RHCD) had no effect on fertility or general reproductive performance. There was no evidence of teratogenicity with these doses during organogenesis, but the highest dose was associated with maternal toxicity (decreased weight gain, death). When tolcapone was given to rats in late gestation and throughout lactation, decreased litter size, and impaired growth and learning performance were observed in female pups. Because the initial dose (4.8 times the RHCD) was associated with a high rate of maternal mortality, the dose was reduced during late gestation to 2.9 times the RHCD (1).

Treatment of rabbits during organogenesis with doses up to 15 times the RHCD revealed no evidence of teratogenicity, but an increased rate of abortion was observed at 3.7 times the RHCD (plasma exposure half the expected human exposure based on AUC). Maternal toxicity was evident at the highest dose (15 times the RHCD) (1). Pregnant rabbits were also treated with a combination of tolcapone (half the expected human exposure based on AUC) and levodopa/carbidopa (6 times the expected human therapeutic exposure of levodopa based on AUC) during organogenesis. The three-drug regimen (tolcapone, levodopa, and carbidopa) resulted in an increased incidence of fetal anomalies, primarily external and skeletal digit defects, compared with levodopa/carbidopa alone. The combination of levodopa–carbidopa is known to cause visceral and skeletal malformations in rabbits. The three-drug regimen in pregnant rats with tolcapone (0.5 times the expected human exposure or higher based on AUC) and levodopa/carbidopa (levodopa exposures 21 times the human exposure or higher) was associated with reduced fetal body weights. However, no effect on fetal body weight was observed when tolcapone (1.4 times the expected human exposure based on AUC) was used alone (1).

It is not known if tolcapone crosses the human placenta. The molecular weight (about 273) is low enough that embryo–fetal exposure should be expected. The nearly complete metabolism and relatively short elimination half-life should limit the amount of active parent drug available for distribution to the fetus.

BREASTFEEDING SUMMARY

No reports describing the use of tolcapone during human lactation have been located. The molecular weight (about 273) is low enough that excretion into

breast milk should be expected. The nearly complete metabolism and relatively short elimination half-life should limit the amount of active drug available for passage into milk. The effect on a nursing infant from exposure to tolcapone from milk is unknown. Because of the potential for severe toxicity (e.g., potentially fatal, acute fulminant liver failure as seen in adults), lactating women who are taking tolcapone should not breastfeed.

TOLMETIN

Nonsteroidal Anti-inflammatory

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 1st and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Constriction of the ductus arteriosus in utero is a pharmacologic consequence arising from the use of prostaglandin synthesis inhibitors during pregnancy (see also Indomethacin) (1). Persistent pulmonary hypertension of the newborn may occur if these agents are used in the 3rd trimester close to delivery (1,2). These drugs also have been shown to inhibit labor and prolong pregnancy, both in humans (3) (see also Indomethacin) and in animals (4). Women attempting to conceive should not use any prostaglandin synthesis inhibitor, including tolmetin, because of the findings in a variety of animal models that indicate these agents block blastocyst implantation (5,6). Moreover, as noted above, nonsteroidal anti-inflammatory drugs (NSAIDs) have been associated with spontaneous abortions (SABs) and congenital malformations. The absolute risk for these defects, however, appears to be low.

FETAL RISK SUMMARY

Tolmetin is an NSAID used for the relief of the signs and symptoms of rheumatoid arthritis, juvenile arthritis, and osteoarthritis. It is in the same subclass (acetic acids) as three other NSAIDs (diclofenac, indomethacin, and sulindac).

Tolmetin is not teratogenic in rats and rabbits (7,8). The doses used in some of the studies were up to 1.5 times the maximum clinical dose based on a body weight of 60 kg (8).

It is not known if tolmetin crosses the human placenta. The molecular weight of the sodium salt (about 315) is low enough that passage to the fetus should be expected.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 99 newborns had been exposed to tolmetin during the 1st trimester (F. Rosa, personal communication, FDA, 1993). One (1.0%) infant had a major birth defect (four expected) consisting of a cardiovascular defect (one expected) and polydactyly (none expected).

A combined 2001 population-based observational cohort study and a case–control study estimated the risk of adverse pregnancy outcome from the use of NSAIDs (9). The use of NSAIDs during pregnancy was not associated with congenital malformations, preterm delivery, or low birth weight, but a positive association was discovered with SABs. A similar study, also published in 2001, failed to find a relationship, in general, between NSAIDs and congenital malformations, but did find a significant association with cardiac defects and orofacial clefts (10). In addition, a 2003 study found a significant association between exposure to NSAIDs in early pregnancy and SABs (11). (See Ibuprofen for details on these three studies.)

A brief 2003 editorial on the potential for NSAID-induced developmental toxicity concluded that NSAIDs, and specifically those with greater COX-2 affinity, had a lower risk of this toxicity in humans than aspirin (12).

BREASTFEEDING SUMMARY

Tolmetin is excreted into breast milk (8,13). In the 4 hours following a single 400-mg oral dose, milk levels varied from 0.06 to 0.18 mcg/mL with the highest concentration occurring at 0.67 hour. Milk:plasma ratios were 0.005–0.007. The clinical significance of these levels to the nursing infant is unknown. The American Academy of Pediatrics classifies tolmetin as compatible with breastfeeding (14).

TOLTERODINE

Urinary Tract Agent (Antispasmodic)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of tolterodine in human pregnancy have been located. The limited animal data suggest low risk, but the complete lack of human pregnancy experience prevents an assessment of embryo–fetal risk. The safest course is to avoid the 1st trimester, but inadvertent exposure in early pregnancy does not appear to represent a major risk.

FETAL RISK SUMMARY

Tolterodine is a competitive muscarinic receptor antagonist that is indicated for the treatment of overactive bladder with symptoms of urge urinary incontinence, urgency, and frequency. It is in the same subclass as darifenacin, flavoxate, oxybutynin, solifenacin, and trospium. Tolterodine is metabolized in the liver to a major active metabolite that has the same potency as tolterodine. Metabolism is mediated by the cytochrome P450 2D6 (CYP2D6). After multiple dosing, the elimination half-life is 2.2 hours in extensive metabolizers. In those lacking CYP2D6 (poor metabolizers; about 7% of the population), metabolism (to an inactive metabolite) is mediated by CYP3A4 and the elimination half-life of tolterodine is 9.6 hours. About 96% of tolterodine is bound in the plasma, primarily to α_1 -glycoprotein, but the binding of the active metabolite is only 64% (1).

Reproduction studies have been conducted in mice and rabbits. In pregnant mice, oral doses producing systemic exposures about 14 times the human exposure (HE) revealed no evidence of teratogenicity. At doses 20–25 times the HE, embryoletality, reduced fetal weight, and increased incidences of intra-abdominal hemorrhage and malformations (cleft palate and digital and various skeletal abnormalities) were seen. In pregnant rabbits, SC doses

producing systemic exposures about 3 times the HE did not cause embryotoxicity or teratogenicity. Tolterodine is neither carcinogenic nor mutagenic in experimental systems (1).

Tolterodine crosses the placenta in mice (2). It is not known if tolterodine or its active metabolite crosses the human placenta. The molecular weight of tolterodine tartrate (about 476) is low enough that exposure of the embryo–fetus should be expected.

BREASTFEEDING SUMMARY

No reports describing the use of tolterodine during human lactation have been located. The molecular weight of the parent compound (about 476) is low enough that excretion into breast milk should be expected. Moreover, tolterodine has an equipotent metabolite that also might be excreted into milk. The effect of this exposure in a nursing infant is unknown.

TOLVAPTAN

Vasopressin Receptor Antagonist

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of tolvaptan in human pregnancy have been located. The animal reproduction data suggests low risk because all of the toxic effects occurred in the presence of maternal toxicity and at doses that were much greater than 10 times the human dose. Although human pregnancy experience is needed for a better risk assessment, there does not appear to be a reason to withhold the drug in pregnancy if indicated.

FETAL RISK SUMMARY

Tolvaptan is an oral selective vasopressin receptor antagonist. It is in the same class as conivaptan. Tolvaptan is indicated for the treatment of clinically significant hypervolemic and euvoletic hyponatremia (serum sodium <125 mEq/L or less marked hyponatremia that is symptomatic and resisted correction with fluid restriction), including patients with heart failure, cirrhosis, and syndrome of inappropriate antidiuretic hormone. The drug is metabolized to inactive metabolites. Tolvaptan is highly plasma protein bound (99%) and has a terminal phase half-life of about 12 hours (1).

Reproduction studies have been conducted in rats and rabbits. In rats during organogenesis, decreased fetal body weights and delayed ossification were observed at the highest dose that was 162 times the maximum recommended human dose based on BSA (MRHD). Maternal toxicity (reduced body weight gain and food consumption) were noted at ≥ 16 times the MRHD. In rabbits during organogenesis, maternal toxicity (reduced body weight and food consumption) occurred with doses that were ≥ 32 times the MRHD and abortions at ≥ 97 times the MRHD. Increased rates of embryo–fetal death, microphthalmia, open eyelids, cleft palate, brachymelia and skeletal

malformations occurred at doses that were 324 times the MRHD (1).

Tolvaptan was not carcinogenic in 2-year studies in rats and mice. Tests also were negative for genotoxicity. No effect on fertility was noted in male rats but, in female rats a dose that was 162 times the MRHD caused significantly fewer corpora lutea and implants than controls (1).

It is not known if tolvaptan crosses the human placenta. The molecular weight (about 449) and long terminal phase half-life suggest that the drug will cross, but the high plasma protein binding should limit the embryo–fetal exposure.

BREASTFEEDING SUMMARY

No reports describing the use of tolvaptan during human lactation have been located. The molecular weight (about 449) and long terminal phase half-life (about 12 hours) suggest that it will be excreted into breast milk, but the high plasma protein binding (99%) should limit the amount. The effect of this exposure on a nursing infant is unknown. However, because the drug promotes urinary water excretion, dehydration and hypovolemia are potential complications.

TOPIRAMATE

Anticonvulsant

PREGNANCY RECOMMENDATION: Human and Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

A 2012 review concluded that the use of topiramate during pregnancy was associated with a two- to threefold increased risk of malformations, largely due to an increased risk for cleft lip with or without cleft palate (1). Another 2012 study found significant effects on cognitive functions and other matters (see below) (2). Consistent with previous anticonvulsants studies, the risk of birth defects appears to be increased when topiramate is combined with other antiepileptics. Topiramate does not produce epoxide metabolites (3). Because these intermediate arene oxide metabolites have been associated with teratogenicity (see Carbamazepine, Phenytoin, and Valproic Acid), this may indicate a lower risk of teratogenicity compared with other agents. The effect of topiramate on folic acid levels or metabolism is unknown (3). Until this information is available, the safest course is to start folic acid supplementation (4–5 mg/day) before conception, as is done with other antiepileptic agents. Topiramate should be avoided, if possible, during the 1st trimester but, if required, monotherapy with the lowest effective dose is preferred. The risk for neonatal hypocalcemic seizures following in utero exposure to topiramate requires further study.

FETAL RISK SUMMARY

Topiramate, a sulfamate-substituted monosaccharide, is an antiepileptic agent indicated as adjunctive therapy in patients with partial onset seizures, primary generalized tonic-clonic seizures, and seizures associated with Lennox-Gastaut syndrome. The drug undergoes partial metabolism to six metabolites, none of which constitutes more than 5% of the dose, with approximately 70% of the dose eliminated unchanged in the urine. Only 13%–17% is bound to human

plasma proteins and the mean plasma elimination half-life is 21 hours. Topiramate is a weak carbonic anhydrase inhibitor, but this activity is not thought to be a major contributing factor to its antiepileptic action (4).

Reproduction studies with topiramate have been conducted in mice, rats, and rabbits. In pregnant mice, oral doses, 0.2–5 times the recommended human dose (400 mg/day) based on BSA (RHD), administered during organogenesis increased the incidence of fetal malformations at all doses. The primary anomalies were craniofacial defects. At the highest dose (5 times the RHD), reduced fetal body weights and ossification were evident, but this dose also caused maternal toxicity (decreased body weight gain) (4).

Topiramate at doses of 0.005–12.5 times the RHD was administered to pregnant rats during organogenesis. At ≥ 10 times the RHD, the frequency of limb malformations (ectrodactyly, micromelia, and amelia) was increased. In addition, in the postnatal portion of the study, pups exposed to topiramate during organogenesis exhibited delayed physical development (doses 10 times the RHD) and persistent reductions in body weight gain (doses ≥ 1 times the RHD). The teratogenic dose (≥ 10 times the RHD) produced clinical signs of maternal toxicity. At ≥ 2.5 times the RHD, reduced maternal weight gain was evident. However, fetotoxicity (reduced fetal body weight and increased incidence of structural variations) was observed at half the RHD. Pregnant rats also were treated during the latter part of gestation and throughout lactation with doses ranging from 0.005 to 5 times the RHD. No drug-related effects on gestation length or parturition were observed at any studied dose. At ≥ 0.05 times the RHD, reductions in pre- and/or postweaning body weight gain were observed. At 5 times the RHD, offspring exhibited decreased viability and delayed physical development (4).

Pregnant rabbits were administered oral doses during organogenesis that were approximately 0.6–11 times the RHD. At ≥ 2 times the RHD, embryo and fetal mortality was observed, but maternal toxicity (decreased body weight gain, clinical signs, and/or mortality) also were evident. At 6 times the RHD, teratogenic effects, primarily rib and vertebral malformations, were observed (4).

Topiramate crosses the placenta to the fetus with cord and maternal plasma drug levels approximately equivalent at term (5,6). Diffusion across the placenta to the embryo early in gestation has not been studied. The molecular weight (about 339), the relatively lack of protein binding and low metabolism, and the prolonged plasma elimination half-life favor transfer of the drug to the embryo and fetus.

Postmarketing experience has been reported by the manufacturer (4). Without providing specific details, the manufacturer stated that cases of hypospadias had been observed in male infants exposed in utero to the drug, with or without other anticonvulsants. A causal relationship with topiramate has not been established (4).

A 2003 reference cited details from pregnancy exposure during clinical trials (5). Among 28 pregnancies, all involving polytherapy (other anticonvulsants not specified), there was “one malformation and two children with anomalies.” In addition, the outcomes of 139 pregnancies identified during postmarketing surveillance were 87 live births, 23 elective abortions, and 29 lost to follow-up. The patient’s anticonvulsant therapy was not specified. Five cases of hypospadias were observed, presumably in the live births (5).

In cases reported in a 2002 publication, five women were treated with topiramate (100–400 mg/day) combined with either carbamazepine (four cases) or valproic acid (one case) throughout gestation (6). All five newborns were healthy, normal infants. Birth weights of three infants ranged from 3520 to 3855 g, whereas the other two, both delivered from smoking mothers, had lower weights: 3160 g (6 cigarettes/day) and 2720 g (10 cigarettes/day), respectively. Cord blood levels of topiramate (average 8.1 microM) were nearly equivalent to the maternal plasma concentration at delivery (average 8.4 microM) (6).

A 2002 review cited a case of a pregnant patient who had been treated with topiramate (1400 mg/day) monotherapy throughout gestation (7). The growth-restricted newborn had several minor anomalies, including generalized hirsutism, a third fontanelle, short nose with anteverted nares, blunted distal phalanges and nails, and fifth nail hypoplasia. The similarity of some of these anomalies to those observed with other anticonvulsants suggested to the authors that genetic factors might have been involved (7).

A 2006 report from the United Kingdom Epilepsy and Pregnancy Register provided information on 35 pregnancies treated with topiramate for epilepsy, 28 of which involved monotherapy (8). Two newborns, both exposed to monotherapy, had major congenital malformations (rate 7.1%, 95% confidence interval [CI] 2.0%–22.6%); one with cleft lip–palate and the other with hypospadias.

A second report from the above Register described the outcomes of 203 pregnancies exposed to topiramate (70 monotherapy and 133 polytherapy) (9). The outcomes of this prospective (enrolled before the outcome was known) observational study were 18 spontaneous abortions (SABs), 5 elective

abortions, 2 stillbirths, and 178 live births (62 monotherapy and 116 polytherapy). The mean topiramate dose in the two groups was 245 mg (range 50–800 mg) and 299 mg (range 25–1000 mg), respectively, whereas the mean gestational age at delivery and the birth weight was 39.2 and 38.8 weeks, and 3168 and 3062 g, respectively. Three (4.8%, 95% CI 1.7%–18.2%) major anomalies were observed in the monotherapy group (daily dose): cleft lip and bilateral cleft palate (200 mg); hypospadias (400 mg); and cleft lip and palate (600 mg). There also were five (8.1%) infants with minor malformations who had been exposed to doses of 50–750 mg/day. Among the 116 live births exposed to polytherapy, 13 (11.2%, 95% CI 6.7%–18.2%) had major defects (daily dose): left hydronephrosis, dysmorphic (800 mg); pyloric stenosis (3 cases) (75, 150, 800 mg); hernia and hydrocele (250 mg); anal atresia (175 mg); tracheoesophageal fistula (150 mg); hypospadias (50 mg); cleft palate, crossed toes (500 mg); bilateral dislocated hips (400 mg); Harold type II talipes, plagiocephaly (350 mg); congenital dislocated hip (500 mg); and left cleft lip and palate (250 mg). The other anticonvulsants were carbamazepine, clobazam, ethosuximide, lamotrigine, levetiracetam, phenobarbital, sodium valproate, and vigabatrin. Minor defects, including two infants with glandular or mild hypospadias, were observed in 10 (8.6%) infants exposed to polytherapy. In the combined groups, four oral clefts (2.2%, 95% CI 0.9%–5.6%) were observed, and among 78 male infants, 4 had hypospadias (5.1%, 95% CI 0.2%–10.1%). The rate of oral clefts was 11 times the background rate (9).

A teratogen information service (TIS) in Israel reported the outcomes of 52 pregnancies that were exposed to topiramate including in the 1st trimester (10). Compared with 212 controls not exposed to teratogens, there were statistically significant differences in SABs (11.3% vs. 2.8%, $p = 0.017$), birth weight (2932 vs. 3300 g, $p = 0.024$), and birth weight of single term infants (3084 vs. 3356 g, $p = 0.001$). After adjustment of the abortion data for gestational age when the TIS was called, maternal age, previous miscarriages, and smoking, regression analysis revealed that gestational age at initial TIS contact was a significant predictor and did not support a drug effect. The total number of major birth defects (4/41, 9.8%) was not statistically different from controls (7/206, 3.4%) ($p = 0.090$), but the possibility of a small increased risk could not be excluded because of the sample size. However, two of the anomalies were genetic in origin and were not caused by drugs. The other cases were pulmonary artery stenosis (topiramate 475 mg/day) and multiple brain cysts with neonatal seizures (topiramate 50 mg/day plus valproic acid 800 mg/day and clonazepam 1 mg/day). The reason for the low birth weight was unknown (10).

In the 2007 report from the Australian Registry of Antiepileptic Drugs in Pregnancy, no malformations were observed in the offspring of 15 pregnancies treated with topiramate monotherapy in the 1st trimester (11).

The Lamotrigine Pregnancy Registry, an ongoing project conducted by the manufacturer, was first published in January 1997. The final report was published in July 2010 (12). The Registry is now closed. Among 54 prospectively enrolled pregnancies exposed to topiramate and lamotrigine, with or without other anticonvulsants, 48 were exposed in the 1st trimester resulting in 40 live births, 2 birth defects, 3 SABs, and 3 EABs. There were six exposures in the 2nd/3rd trimesters resulting in five live births and one birth defect (12).

A 2007 report described two siblings that developed hypocalcemic seizures shortly after birth from a mother taking topiramate throughout pregnancy (13). The mother had developed seizures during her first pregnancy at age 20 and had been treated with valproic acid. Following that pregnancy, her anticonvulsant therapy had been changed to topiramate, 200 mg twice daily. Seven years later she became pregnant a second time and gave birth to a normal appearing, 3153-g male infant that was formula fed. Seizures began on day 3 of life and were associated with hypocalcemia, hypomagnesemia, and hyperphosphatemia but normal parathyroid hormone concentrations. Other laboratory parameters were within normal limits. He was treated with IV calcium and a low-phosphorus formula, and was discharged home at age 14 days on phenobarbital. At age 6 months, phenobarbital was discontinued. His development and neurologic examination were normal at 1 year of age. The mother subsequently delivered a normal baby girl (weight not specified) at term that was formula fed. During this pregnancy, her third, she had taken topiramate 100 mg twice daily. Seizures were noted at age 7 days and were associated with the same electrolyte and hormone abnormalities as in the first case. The infant was treated with IV calcium, magnesium, phenobarbital, and a change in the formula. No further seizures occurred after age 8 days, and she was discharged home on short-term courses of oral calcium and phenobarbital. Her neurological examination was normal at 2 months of age. Because there was no identifiable biochemical etiology for the seizures in the two infants, the seizures were attributed to hypocalcemia caused by hypoparathyroidism. It was proposed that in utero exposure to topiramate led to hypoparathyroidism and subsequent hypocalcemia via effects on protein kinase A signaling (13).

In a 2012 study, 9 children of preschool age (3–7 years) exposed during pregnancy to topiramate were compared with 18 children not exposed (2). The

two groups were compared on developmental measures of visual, fine and gross motor function, and behavior and cognitive functions. The exposed group performed significantly worse than controls in almost all measures, including verbal, nonverbal, and general IQ scores (2).

A dose-related interaction between topiramate and a combined oral contraceptive (ethinylestradiol 35 mcg/northethindrone 1 mg) has been reported (4,14). At a dose of 400 mg/day, peak levels of the estrogen were decreased. At 800 mg/day, estrogen bioavailability was reduced and clearance increased. Norethindrone clearance was also increased at 800 mg/day. The concurrent use of these agents could reduce the efficacy of the contraceptive, possibly requiring a higher-dose contraceptive combination (14).

Topiramate is known to induce hepatic enzymes and may increase the incidence of early hemorrhagic disease of the newborn by depleting fetal vitamin K stores. Although vitamin K₁ (see Phytonadione) does not readily cross the placenta, 10 mg/day of the vitamin may be given orally to the mother in the last 4 weeks of pregnancy. In addition, 1 mg of vitamin K₁ should be given IV or IM to the infant at birth (15).

BREASTFEEDING SUMMARY

Topiramate is excreted into breast milk. This is consistent with the low molecular weight (about 339), protein binding (13%–17%), and metabolism (about 30%), and the prolonged plasma elimination half-life (21 hours).

Three women who had been treated with topiramate throughout pregnancy (see above) and continued during nursing were studied (6). The daily doses were 150, 200, and 200 mg/day. The mean milk:plasma ratio 3 weeks after delivery was 0.86 (range 0.67–1.1). In one case, 3 months after delivery, the ratio was 0.69. The minimum weight-adjusted infant doses, based on 150 mL/kg of milk per day, were about 0.1–0.7 mg/kg/day or 3%–23% of the maternal doses. Plasma concentrations of topiramate in two infants at 3 weeks of age, before and after nursing, were 1.4 and 1.3 microM, and 1.6 and 1.9 microM, respectively. The latter infant had a topiramate plasma concentration of 2.1 microM at 3 months of age. (Note: Possible antiepileptic effects of topiramate on cultured neurons are concentration-dependent within the range of 1 to 200 microM [3]). Plasma levels in the third infant were undetectable at 2 and 4 weeks postdelivery. The elimination half-life in the infants was estimated to be about 24 hours compared with 20–30 hours among healthy adult controls. No adverse effects of the exposure were observed (6).

In pediatric patients (ages 2–16 years), common adverse effects (most

occurred twice as often or more than those in placebo-treated patients) associated with topiramate were fatigue, somnolence, difficulty with concentration/attention, aggressive reaction, confusion, difficulty with memory, ataxia, purpura, epistaxis, infections (viral and pneumonia), and anorexia and weight decrease (4). (Patients also were receiving one or two other anticonvulsants.) The potential for these or other adverse effects in a nursing infant cannot be assessed with the available data. Therefore, nursing women who are being treated with topiramate, particularly those receiving high doses, should be advised to monitor their infants for signs of toxicity and for changes in alertness, behavior, and feeding habits.

TOPOTECAN

Antineoplastic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of topotecan in human pregnancy have been located. The animal reproduction data suggest risk, but the absence of human pregnancy experience prevents a more thorough assessment of the embryo–fetal risk. Because of the potential for embryo and fetal harm, women of childbearing potential should employ adequate contraceptive methods to prevent pregnancy. However, all of the indications for topotecan involve potentially fatal cancers, so if informed consent is obtained, treatment should not be withheld because of pregnancy. If an inadvertent pregnancy occurs during therapy, the woman should be advised of the unknown, but potentially severe risk for her embryo–fetus.

FETAL RISK SUMMARY

The DNA topoisomerase I-inhibitor, topotecan, is a semi-synthetic derivative of camptothecin that is given as an IV infusion. It is in the same antineoplastic subclass as irinotecan. Topotecan is indicated as secondary therapy for metastatic carcinoma of the ovary, small-cell lung cancer, and, in combination with cisplatin, recurrent or persistent carcinoma of the cervix. The cytotoxicity of topotecan is thought to involve the inhibition of the enzyme responsible for the repair of normally occurring single-strand breaks in DNA. Topotecan undergoes partial metabolism in the liver. Binding to plasma proteins is about 35% and the terminal elimination half-life is 2–3 hours (1).

Reproduction studies have been conducted in the rat and rabbit. In rats, a daily dose about equal to the clinical dose based on BSA (CD) given for 14 days before mating through gestation day 6 caused preimplant loss, fetal resorption, and microphthalmia. The dose also produced mild maternal toxicity. A lower daily dose, about 0.5 times the CD, given on gestation days 6–17

caused increased postimplantation mortality and fetal malformations. The most frequent malformations involved the eye (microphthalmia, anophthalmia, rosette formation of the retina, coloboma of the retina, and ectopic orbit), brain (dilated lateral and third ventricles), skull, and vertebrae. In pregnant rabbits, a daily dose about equal to the CD given on gestation days 6–20 caused maternal toxicity, embryo death, and decreased fetal body weight (1). The route of drug administration in the above animal studies was not specified.

Studies for carcinogenicity have not been conducted. However, topotecan is known to be genotoxic in mammalian cells and is probably a carcinogen (1). The drug also is mutagenic and clastogenic, with or without metabolic activation (1).

It is not known if topotecan crosses the human placenta. The molecular weight (about 422 for the free base), low metabolism and plasma protein binding suggest that the drug will cross to the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use of topotecan during human lactation have been located.

The molecular weight (about 422 for the free base), low metabolism and plasma protein binding (35%) suggest that the drug will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown, but may be severe. It is best that a woman receiving this agent does not breastfeed. However, if she chooses to do so, the infant should be closely monitored for the most common or serious adverse effects observed in adults. These effects include bone marrow suppression (primarily neutropenia), headache, nausea, vomiting, diarrhea or constipation, abdominal pain, alopecia, and hepatic toxicity (1).

TORSEMIDE

Diuretic

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of torsemide in human pregnancy have been located. Fetotoxicity was observed in animal studies but only with maternal toxic doses. In general, exposure to diuretics in early pregnancy has not been associated with structural anomalies, but the lack of human pregnancy experience with torsemide prevents a better assessment of the embryo–fetal risk. Diuretics do not prevent or alter the course of toxemia but may decrease placental perfusion (see also Chlorothiazide) because of maternal hypovolemia characteristic of this disease.

FETAL RISK SUMMARY

Torsemide is a loop diuretic in the same pharmacologic class as bumetanide, ethacrynic acid, and furosemide. The drug can be given orally or IV. Torsemide is indicated for the treatment of edema associated with congestive heart failure, renal disease, or hepatic disease. It is also indicated for the treatment of hypertension alone or in combination with other antihypertensive agents. Torsemide undergoes hepatic metabolism to primarily inactive metabolites. Plasma protein binding is >99% and the elimination half-life is about 3.5 hours (1).

Reproduction studies have been conducted in rats and rabbits. In these species, doses up to 10 and 1.7 times, respectively, the human dose of 20 mg/day based on BSA caused no fetotoxicity or teratogenicity. Doses that were 5 (rats) and 4 (rabbits) times larger caused maternal toxicity (decreased average body weight) and fetal toxicity (increased resorptions and delayed ossification) (1).

No overall increase in tumor incidence was noted when torsemide was given

to rats and mice throughout their lives. In addition, no mutagenic activity was noted in a variety of assays and no adverse effects were noted on the reproductive performance of male and female rats (1).

It is not known if torsemide crosses the human placenta. The molecular weight (about 348) and moderate elimination half-life suggest that the drug will cross, but the high plasma protein binding may limit the amount available for transfer.

BREASTFEEDING SUMMARY

No reports describing the use of torsemide during human lactation have been located. The molecular weight (about 348) and moderate elimination half-life (about 3.5 hours) suggest that the drug will be excreted into breast milk, but the high plasma protein binding (>99%) should limit the amount in milk. The effect of this exposure on a nursing infant is unknown, but no adverse effects in nursing infants exposed to diuretics in milk have been reported. Of note, however, thiazide diuretics have been used to suppress lactation (see Chlorothiazide).

TRAMADOL

Central Analgesic

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

The National Birth Defects Prevention Study discussed below found evidence that opioid use during organogenesis is associated with a low absolute risk of congenital birth defects. Neonatal withdrawal is a potential complication after continuous use in the mother. The long-term effects on the neurobehavior of offspring are unknown but warrant study.

FETAL RISK SUMMARY

Tramadol is a synthetic, centrally acting, analgesic analog of codeine that has the potential to cause physical dependence similar to, but much less than, that produced by opiates. Because of its low addiction potential, tramadol is not classified as a controlled substance. The drug is available only as an oral tablet in the United States but has been used both parenterally and rectally in other countries. The drug is extensively metabolized to active and inactive metabolites. The active metabolite (M1) is a more potent analgesic than the parent drug. Plasma protein binding of tramadol is about 20%. The plasma elimination half-lives of tramadol and M1 are about 6–7 hours (1).

Reproduction studies in mice, rats, and rabbits at doses that were 1.4, ≥ 0.6 , and ≥ 3.6 times the maximum daily human dose based on BSA (MDHD) were embryotoxic, fetotoxic, and maternally toxic, but not teratogenic. Embryo and fetal toxicity consisted of decreased fetal weights, skeletal ossification, and increased supernumerary ribs. In perinatal and postnatal studies in rats, doses that were ≥ 1.2 times the MDHD resulted in decreased pup weights and survival. Transient delays in developmental or behavioral parameters were seen in rat pups (1). Shepard described a reproductive study using oral and SC tramadol in mice and rats with no observed teratogenic effects (2).

Tramadol has a molecular weight of about 300 and crosses the placenta to

the fetus. In 40 women given 100 mg of tramadol during labor, the mean ratio of drug concentrations in the umbilical cord and maternal serum was 0.83 (3).

Several studies outside of the United States, some of which were reviewed in 1993 (4) and 1997 publications (3), have compared the use of tramadol with meperidine or morphine for labor analgesia (5–13). In five of these studies (5–9), the use of tramadol was associated with less neonatal respiratory depression than meperidine, but no difference was observed in four studies in comparison with meperidine or morphine (10–13). Tramadol also has been combined with bupivacaine for epidural during labor (14).

The effects of tramadol and meperidine (100 mg IV), for each drug, were compared in laboring patients in a study conducted in Thailand (8). A second or third dose of 50 mg IV was given at 30-minute intervals if requested. A significant increase in the incidence of neonatal respiratory depression was observed in the offspring of the meperidine group, if delivery occurred 2–4 hours after the last dose. The respiratory depressant effects of meperidine are known to be time- and dose-related, increasing markedly after 60 minutes (see Meperidine).

A study from Singapore found that 100 mg IM of tramadol was equivalent in analgesic effect to 75 mg IM of meperidine for the control of labor pain (9). Meperidine was associated with a significantly higher frequency of adverse effects (nausea, vomiting, fatigue, drowsiness, and dizziness) in the mothers and a significantly lower respiratory rate in the newborns. However, the injection–delivery interval in the patients was 7–8 hours.

In a 1997 case report, a male infant developed withdrawal symptoms between 24 and 48 hours after birth (15). Symptoms consisted of trembling, tachypnea, tachycardia, hypertonic muscle tone, signs of tetany when touched, and a single mild convulsion. The mother admitted to taking tramadol 300 mg/day for 4 years. The infant was treated with diazepam and/or phenobarbital for 13 days until the symptoms had fully resolved. No long-term follow-up of the infant was reported. The authors concluded that the drug's estimated elimination half-life of 36 hours in the infant was consistent with the course of the withdrawal syndrome (15).

Four other reports, involving seven infants, have described neonatal abstinence syndrome after long-term use of tramadol (200–800 mg/day) in pregnancy (16–19). Withdrawal symptoms in the infants occurred on the second day of life and persisted for up to about 2 weeks.

Results of a National Birth Defects Prevention Study (1997–2005) were published in 2011 (20). This population-based case–control study examined the

association between maternal use of opioid analgesics and >30 types of major structural birth defects. In 17,449 case mothers, therapeutic opioid use was reported by 454 (2.6%) compared with 134 (2.0%) of 6701 control mothers. Indications for use of opioid analgesics were surgical procedures (41%), infections (34%), chronic diseases (20%), and injuries (18%). Dose, duration, or frequency were not evaluated. The exposure period evaluated was from 1 month before to 3 months after conception. Limiting the exposure period to the first 2 months after conception produced similar results. Infants with >1 defect were included in multiple birth defect categories. The following opioids were included (number of cases for each agent not specified): codeine, hydrocodone, hydromorphone, fentanyl, meperidine, methadone, morphine, oxycodone, pentazocine, propoxyphene, and tramadol. The birth defect, total number, number exposed, and the adjusted odds ratio (aOR) with 95% confidence interval (CI) were as follows:

| Birth Defect | Total | Cases | aOR (95% CI) |
|--|-------|-------|---------------|
| Spina bifida | 718 | 26 | 2.0 (1.3–3.2) |
| <i>Any heart defect (20 types)</i> | 7724 | 211 | 1.4 (1.1–1.7) |
| Atrioventricular septal defect | 175 | 9 | 2.4 (1.2–4.8) |
| Teratology of Fallot | 672 | 21 | 1.7 (1.1–2.8) |
| Conotruncal defect | 1481 | 41 | 1.5 (1.0–2.1) |
| Conoventricular septal defect | 110 | 6 | 2.7 (1.1–6.3) |
| Left ventricular outflow tract obstruction defect | 1195 | 36 | 1.5 (1.0–2.2) |
| Hypoplastic left heart syndrome | 357 | 17 | 2.4 (1.4–4.1) |
| Right ventricular outflow tract obstruction defect | 1175 | 40 | 1.6 (1.1–2.3) |
| Pulmonary valve stenosis | 867 | 34 | 1.7 (1.2–2.6) |
| Atrial septal defect (ASD) | 511 | 17 | 2.0 (1.2–3.6) |
| Ventricular septal defect + ASD | 528 | 17 | 1.7 (1.0–2.9) |
| Hydrocephaly | 301 | 11 | 2.0 (1.0–3.7) |
| Glaucoma/anterior chamber defects | 103 | 5 | 2.6 (1.0–6.6) |
| Gastroschisis | 726 | 26 | 1.8 (1.1–2.9) |

The authors speculated that the activity of opioids and their receptors as growth regulators during development of the embryo might be a mechanism to

explain the above findings. The exposure data were obtained by retrospective maternal self-report; the authors acknowledged that recall bias and misclassification might have affected their results. They concluded that the absolute risk was a modest absolute increase above the baseline risk for birth defects (20).

A 2012 review of tramadol in pregnancy and lactation found no clear evidence of fetal or neonatal harm, but concluded that the drug should be avoided during conception and the 1st trimester because of lack of data during these periods (21). The above study was not cited in the review.

BREASTFEEDING SUMMARY

Both tramadol and its pharmacologic active metabolite (M1) are excreted into human milk (1). After a single 100-mg IV dose, the cumulative amounts of the parent drug and M1 excreted into milk within 16 hours were 100 and 27 mcg, respectively (1). The recommended dose of tramadol is 50–100 mg every 4–6 hours up to a maximum of 400 mg/day. Moreover, the mean absolute bioavailability of a 100-mg oral dose is 75%. Thus, ingestion of the recommended dose may produce drug amounts in breast milk that could exceed those reported above. The effect of this exposure on a nursing infant is unknown.

In a 2008 study, 75 breastfeeding mothers were taking tramadol (100 mg every 6 hours) on days 2–4 after cesarean section (22). Samples were collected after four or more doses. On the study date, 49% of the subjects and 100% of the controls also took other opiate analgesics (mostly oxycodone) while 61% of the subjects and 58% of the controls also took nonsteroidal anti-inflammatory agents (mostly diclofenac). The mean milk:plasma ratio was 2.2 for tramadol and 2.8 for M1. For tramadol, the estimated absolute and relative infant doses were 112 mcg/kg/day and 0.64%, respectively, whereas for M1 the doses were 30 mcg/kg/day and 2.24%, respectively. Compared with controls not taking tramadol, there were no significant behavioral adverse effects (22).

A 2012 review of tramadol in pregnancy and lactation concluded that the use of tramadol during early breastfeeding was unlikely to cause harm in healthy term infants (21).

TRANDOLAPRIL

Antihypertensive

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The fetal toxicity of trandolapril in the 2nd and 3rd trimesters is similar to other angiotensin-converting enzyme (ACE) inhibitors. The use of this drug during the 2nd and 3rd trimesters may cause teratogenicity and severe fetal and neonatal toxicity. Fetal toxic effects may include anuria, oligohydramnios, fetal hypocalvaria, intrauterine growth restriction (IUGR), prematurity, and patent ductus arteriosus. Stillbirth or neonatal death may occur. Anuria-associated oligohydramnios may produce fetal limb contractures, craniofacial deformation, and pulmonary hypoplasia. Severe anuria and hypotension, which is resistant to both pressor agents and volume expansion, may occur in the newborn following in utero exposure. Newborn renal function and blood pressure should be closely monitored.

FETAL RISK SUMMARY

The prodrug, trandolapril, is rapidly metabolized to the active drug, trandolaprilat. It is indicated in the management of hypertension either alone, or in combination with other antihypertensives (e.g., hydrochlorothiazide). Trandolapril is also indicated in the management of stable patients with heart failure or left-ventricular dysfunction after myocardial infarction. The active metabolite, trandolaprilat, is an ACE inhibitor, thus preventing the conversion of angiotensin I to angiotensin II (1).

Reproduction studies have been conducted in rats, rabbits, and cynomolgus monkeys. No teratogenicity was observed in the three species at doses that were 2564, 3, and 108 times, respectively, the maximum projected human dose based on BSA (1).

It is not known if trandolapril or trandolaprilat cross the human placenta. The

molecular weights (about 431 for trandolapril; about 403 for trandolaprilat) are low enough that transfer to the fetus should be expected.

A retrospective study using pharmacy-based data from the Tennessee Medicaid program identified 209 infants, born between 1985 and 2000, who had 1st trimester exposure to ACE inhibitors (2). Infants of mothers with evidence of diabetes, either before or during pregnancy, were excluded, as were those exposed to angiotensin-receptor antagonists (ARBs), ACE inhibitors, or other antihypertensives beyond the 1st trimester, and exposure to known teratogens. Two comparison groups, other antihypertensives (N = 202) and no antihypertensives (N = 29,096), were formed. The number of major birth defects in each of the three groups was 18 (8.6%), 4 (2%), and 834 (2.9%), respectively. Compared with the no antihypertensives group, exposure to ACE inhibitors was associated with a significantly increased risk of major defects (relative risk [RR] 2.71, 95% confidence interval [CI] 1.72–4.27). When the analysis was conducted by the type of defect, the highest rates were with cardiovascular defects, 9, 2, and 294, respectively, RR 3.72, 95% CI 1.89–7.30, and with CNS defects, 3, 0, and 80, respectively, RR 4.39, 95% CI 1.37–14.02. The major defects observed in the subject group were: atrial septal defect (N = 6) (includes three with pulmonic stenosis and/or three with patent ductus arteriosus [PDA]), renal dysplasia (N = 2), PDA alone (N = 2), and one each of ventricular septal defect, spina bifida, microcephaly with eye anomaly, coloboma, hypospadias, intestinal and choanal atresia, Hirschsprung disease, and diaphragmatic hernia (2). In an accompanying editorial, it was noted that neither previous reports of 1st trimester exposure to ACE inhibitors nor the animal studies had observed an increased risk of birth defects (3). It also was noted that no mechanism for ACE inhibitor-induced teratogenicity was known. A subsequent communication raising concerns about the validity of the study in terms of adequate exclusion of diabetes, charting and coding errors in busy medical practices, and the effects of maternal obesity (4) was addressed by the investigators (5).

Trandolapril and other ACE inhibitors are human teratogens when used in the 2nd and 3rd trimesters, producing fetal hypocalvaria and renal defects. The cause of the defects and other toxicity is probably related to fetal hypotension and decreased renal blood flow. The compromise of the fetal renal system may result in severe, and at times fatal, anuria, both in the fetus and in the newborn. Anuria-associated oligohydramnios may produce pulmonary hypoplasia, limb contractures, persistent PDA, craniofacial deformation, and neonatal death (6,7). IUGR, prematurity, and severe neonatal hypotension may also be

observed. Two reviews of fetal and newborn renal function indicated that both renal perfusion and glomerular plasma flow are low during gestation and that high levels of angiotensin II may be physiologically necessary to maintain glomerular filtration at low perfusion pressures (8,9). Trandolapril prevents the conversion of angiotensin I to angiotensin II and, thus, may lead to in utero renal failure. Because the primary means of removal of the drug is renal, the impairment of this system in the newborn prevents elimination of the drug resulting in prolonged hypotension. Newborn renal function and blood pressure should be closely monitored. If oligohydramnios occurs, stopping trandolapril may resolve the problem but may not improve infant outcome because of irreversible fetal damage (6). In those cases in which trandolapril must be used to treat the mother's disease, the lowest possible dose should be used combined with close monitoring of amniotic fluid levels and fetal well-being. Guidelines for counseling exposed pregnant patients have been published and should be of benefit to health professionals faced with this task (6,10).

The observation in Tennessee Medicaid data of an increased risk of major congenital defects after 1st trimester exposure to ACE inhibitors raises concerns about teratogenicity that have not been seen in other studies (3). Medicaid data are a valuable tool for identifying early signals of teratogenicity, but are subject to a number of shortcomings and their findings must be considered hypotheses until confirmed by independent studies.

A 2012 review of the use of ACE inhibitors and ARBs in the 1st trimester concluded that there may be an elevated teratogenic risk, but the risk appeared to be related to other factors (11). The factors, that typically coexist with hypertension in pregnancy, included diabetes, advanced maternal age, and obesity.

BREASTFEEDING SUMMARY

No reports describing the use of trandolapril in human lactation have been located. The molecular weights (about 431 for trandolapril; about 403 for trandolaprilat) suggest that excretion into breast milk should be expected. The effect of this exposure on a nursing infant is unknown. However, other ACE inhibitors are excreted into breast milk and are considered compatible with breastfeeding by the American Academy of Pediatrics (see Captopril and Enalapril).

TRANEXAMIC ACID

Hemostatic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

No adverse effects attributable to use of tranexamic acid during pregnancy, in either animals or humans, have been reported in the fetus or newborn. The drug crosses the placenta to the fetus, but its reported lack of effect on plasminogen activator activity in the vascular wall (1,2) (vs. its known effect in the peripheral circulation) may protect the fetus and newborn from potential thromboembolic complications.

FETAL RISK SUMMARY

This hemostatic agent, a competitive inhibitor of plasminogen activation, is used to reduce or prevent hemorrhage in hemophilia and in other bleeding disorders. The drug blocks the action of plasminogen activators (e.g., tissue plasminogen activator [alteplase; t-PA], streptokinase, and urokinase) by inhibiting the conversion of plasminogen to plasmin (3).

No adverse fetal effects were observed in reproductive toxicity testing in mice, rats, and rabbits (3,4). Both Schardein (5) and Shepard (6) cited a 1971 study in which doses up to 1500 mg/kg/day were given to mice and rats during organogenesis without causing adverse fetal effects.

Tranexamic acid crosses the human placenta to the fetus (7). Twelve women were given an IV dose of 10 mg/kg just before cesarean section. Cord serum and maternal blood samples were drawn immediately following delivery, a mean of 13 minutes after the dose of tranexamic acid. The mean drug concentrations in the cord and maternal serum were 19 mcg/mL (range <4–31 mcg/mL) and 26 mcg/mL (range 10–53 mcg/mL), respectively, a ratio of 0.7 (7).

Twelve women with vaginal bleeding between 24 and 36 weeks' gestation

were treated with 7-day courses of tranexamic acid, 1 g orally every 8 hours (8). Additional courses were given if bleeding continued (number of patients with repeat courses not specified). Four women underwent cesarean section (placenta previa in three, breech in one) and the remainder had vaginal deliveries. One of the newborns was delivered at 30 weeks' gestation, but the gestational ages of the other newborns were not specified. All of the newborns were alive and well. Two of the mothers were receiving treatment at the time of delivery, and the drug concentrations in the cord blood were 9 and 12 mcg/mL (8).

A pregnant woman with fibrinolysis was treated with tranexamic acid and fibrinogen for 64 days until spontaneous delivery of a normal 1400-g girl at 30 weeks' gestation (9). No adverse fetal or newborn effects attributable to the drug were reported. Tranexamic acid was used in a woman with abruptio placentae during her third pregnancy (10). She had a history of two previous pregnancy losses because of the disorder. Treatment with tranexamic acid (1 g IV every 4 hours for 3 days, then 1 g orally 4 times daily) was begun at 26 weeks' gestation and continued until 33 weeks' gestation, at which time a cesarean section was performed because of the risk of heavier bleeding. A healthy 1430 g male infant was delivered (10).

The use of tranexamic acid in a woman with Glanzmann's thrombasthenia disease was described in an abstract published in 1981 (11). Treatment was started at 24 weeks' gestation and continued until spontaneous delivery at 42 weeks' gestation of a healthy boy. A study published in 1980 described the use of tranexamic acid in 73 consecutive cases of abruptio placentae, 6 of which were treated for 1–12 weeks (1). Six (8.2%) of the newborns were either stillbirths (N = 4) or died shortly after delivery (N = 2), a markedly reduced mortality rate compared with the expected 33%–37% at that time (10). None of the deaths was attributed to the drug. No cases of increased hemorrhage, thromboses, or maternal deaths were observed (1).

Tranexamic acid (4 g/day) was used in a 21-year-old primigravida at 26 weeks' gestation for the treatment of vaginal bleeding (12). She also received terbutaline and betamethasone for premature labor. Tranexamic acid was administered as a single dose on admission, and 6 days later a 10-day course was initiated for continued bleeding. Acute massive pulmonary embolism occurred at the termination of tranexamic acid, and following 2–3 days of treatment with heparin and streptokinase, a preterm 1140-g male infant was spontaneously delivered. No adverse effects in the fetus or newborn attributable to the drug therapy were noted (12).

A retrospective study published in 1993 examined the question of whether tranexamic acid was thrombogenic when administered during pregnancy (2). In the period 1979–1988 in Sweden, among pregnant women with various bleeding disorders, 256 had been treated with tranexamic acid (mean duration 46 days), whereas 1846 had not been treated (controls). Two patients (0.78%) in the treated group had pulmonary embolism compared with four (0.22%) (three deep vein thromboses, one pulmonary embolism) (odds ratio 3.6, 95% confidence interval [CI] 0.7–17.8) in the control group. In the subgroups of those patients who were delivered by cesarean section (168 treated, 439 controls), the rates of thromboembolism were 1 (0.60%) and 4 (0.91%) (odds ratio 0.65, 95% CI 0.1–5.8), respectively. Thus, no evidence was found indicating that the use of tranexamic acid during gestation was thrombogenic. Although the purpose of this study did not include examining the effects of the therapy on the fetus or newborn, the authors concluded that in the absence of a thrombogenic risk, there was no reason to change the indications for its use during pregnancy (2).

BREASTFEEDING SUMMARY

Tranexamic acid is excreted into human milk. One hour after the last dose following a 2-day treatment course in lactating women, the milk concentration of the agent was 1% of the peak serum concentration (13). In adults, approximately 30%–50% of an oral dose is absorbed (1). The amount a nursing infant would absorb is unknown, as is the effect of the small amount of drug present in milk.

TRANLYCYPROMINE

Antidepressant

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Tranlycypromine is a monoamine oxidase inhibitor used in the treatment of major depressive episode without melancholia. Other agents in this subclass are iproniazid, isocarboxazid, nialamide, and phenelzine. Although risk was suggested in consecutive pregnancies from one woman, the human pregnancy experience is too limited to assess adequately the embryo–fetal risk.

FETAL RISK SUMMARY

Relevant animal reproduction data have not been located. However, the drug crosses the rat placenta (1).

The Collaborative Perinatal Project monitored 21 mother–child pairs exposed to monoamine oxidase inhibitors during the 1st trimester, 13 of whom were exposed to tranlycypromine (2). Three of the 21 infants had malformations (relative risk 2.26). Details of the 13 cases with exposure to tranlycypromine were not specified.

A brief 2000 abstract described two consecutive adverse pregnancy outcomes in a woman treated with tranlycypromine (3). In the first pregnancy, the 41-year-old woman with severe depression was treated with tranlycypromine (100 mg/day), pimozide (1 mg/day), and diazepam (5–10 mg/day). The woman delivered a stillborn fetus at 31 weeks' gestation. Examination of the macerated female fetus revealed hypertelorism, a large atrioventricular septal defect, single coronary ostium, and right pulmonary isomerism. The placenta had multiple infarcts that were considered significant factors in the fetal death. In her second pregnancy (other drugs and doses not specified), an ultrasound at 19 weeks' revealed a fetus with a head described

as “lemon-shaped.” A female infant (normal karyotype) was delivered at 38 weeks’ because of poor growth (weight not specified). The infant had multiple defects, including hypertelorism, low-set overfolded ears, cleft palate, micrognathia, marked distal phalangeal hypoplasia, agenesis of the corpus callosum, and an atrioventricular septal defect (first detected at 26 weeks’). The outcomes of both pregnancies were attributed to tranylcypromine, possibly due to reduced uterine and placental blood flow (3).

It is not known if tranylcypromine crosses the human placenta. The molecular weight (about 365) is low enough that exposure of the embryo–fetus should be expected.

BREASTFEEDING SUMMARY

No reports describing the use of tranylcypromine during lactation have been located. The molecular weight (about 365) is low enough that excretion into breast milk should be expected. The effect of this exposure on a nursing infant is unknown.

TRASTUZUMAB

Antineoplastic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

The human pregnancy experience with trastuzumab is limited to six cases, three of which involved 1st trimester exposure. No congenital malformations were noted in the infants and all were developing normally. However, fetal renal toxicity, as evidenced by oligohydramnios or anhydramnios, was observed in four cases. The toxicity might have been secondary to inhibition of epidermal growth factor receptor 2 (HER2) in the fetal kidneys but additional study is required. The toxicity appears to be reversible when trastuzumab is stopped. Although the action of this receptor in human fetal development requires study, HER2 protein expression is high in many embryonic tissues, such as cardiac and neural tissues, and blocking this expression may be harmful. Trastuzumab has a very long elimination half-life and could be present in the maternal system for ≤ 5 months after the last dose.

FETAL RISK SUMMARY

Trastuzumab, a recombinant DNA-derived humanized monoclonal antibody (an IgG₁ kappa), selectively binds with high affinity to the extracellular domain of the human epidermal growth factor receptor 2 (HER2) protein. It is indicated, either alone or in combination with paclitaxel, for the treatment of patients with metastatic breast cancer whose tumors overexpress the HER2 protein. Trastuzumab is administered as an IV infusion. The mean elimination half-life, after a 4 mg/kg loading dose followed by a weekly maintenance dose of 2 mg/kg, was 5.8 days (range 1–32 days) (1).

No evidence of impaired fertility or fetal harm were observed in female cynomolgus monkeys administered doses up to 25 times the weekly human

dose of 2 mg/kg. However, HER2 protein expression is high in many embryonic tissues, such as cardiac and neural tissues. Early death was observed in embryos of mutant mice that lacked this protein. Trastuzumab was not mutagenic in multiple assays or clastogenic in one test (1).

It is not known if trastuzumab crosses the human placenta. The antibody does cross the placentas of cynomolgus monkeys in both early (gestational days 20 and 50) and late (gestational days 120 and 150) pregnancy. The presence of trastuzumab in the serum of infant monkeys had no adverse effect on growth or development from birth to 3 months of age (1).

Six case reports have described the use of trastuzumab during pregnancy (2–7). A 28-year-old woman had undergone bilateral mastectomy for breast cancer, followed by chemotherapy with cyclophosphamide, doxorubicin and paclitaxel, and then radiation therapy (2). She then received trastuzumab 580 mg every 3 weeks. Pregnancy was diagnosed at 23 weeks' gestation, 3 weeks after the last dose of trastuzumab. Anhydramnios was present with normal appearing fetal kidneys and an estimated fetal weight of 475 g. The anhydramnios slowly resolved and a normal 2950-g female infant was delivered vaginally at 37.5 weeks' with Apgar scores of 8 and 9, at 1 and 5 minutes, respectively. The placenta pathology was unremarkable with normal fetal membranes. The infant had normal renal function at birth and no evidence of pulmonary hypoplasia. The 6-month-old child was doing well with growth at the 75th percentile (2).

In another 2005 case report, a 26-year-old woman with breast cancer was treated with trastuzumab, paclitaxel, fluorouracil, epirubicin, and cyclophosphamide, followed by a left mastectomy and radiation therapy (3). Fourteen months later, in the 27th week of pregnancy, multiple hepatic metastases were detected. She was treated with trastuzumab (4 mg/kg loading dose, then 2 mg/kg every week) and vinorelbine (25 mg/m² weekly for 3 weeks followed by a week of rest) until 34 weeks' gestation. Oligohydramnios was noted during therapy. Because of decreased fetal movement, labor was induced at 34 weeks' gestation and a healthy 2.6-kg male infant was delivered vaginally with Apgar scores of 9, 9, and 10 at 1, 5, and 10 minutes, respectively. At 6 months of age, the infant was healthy and developing normally (3).

A 30-year-old woman with breast cancer was treated with epirubicin, cyclophosphamide, fluorouracil, a bilateral mastectomy, and radiation therapy (4). She was enrolled in a clinical trial and was randomized to receive trastuzumab 736 mg as a loading dose and then 523 mg every 3 weeks for the

first year. Conception occurred 3 days after her second cycle. A third cycle was apparently given before she was withdrawn from the study. She delivered a normal female infant at term (no other details provided) (4).

A 38-year-old woman at 17 weeks' in her second pregnancy had spinal-cord compression secondary to metastatic disease 7 years after undergoing treatment for breast cancer (5). Treatment had consisted of surgery, six cycles of fluorouracil, methotrexate, and cyclophosphamide, radiotherapy, and then 5 years of tamoxifen. She was given radiotherapy to the cervical vertebrae, with lead shielding of the uterus to protect the fetus. At about 26 weeks' gestation, she received trastuzumab 8 mg/kg and paclitaxel 175 mg/m². A second cycle of trastuzumab (6 mg/kg) and paclitaxel was given 3 weeks later. At 26–32 weeks', fetal abdominal circumference stopped growing and amniotic fluid decreased to near anhydramnios. At the end of this period, the volume of both fetal kidneys was below the 5th percentile and the fetal bladder was barely visible. Corticosteroids were given for fetal lung maturity and a cesarean section delivered a growth-restricted 1.460-kg (10th percentile) male infant. Complications in the newborn included bacterial sepsis with hypotension, transient renal failure, and respiratory failure. The renal impairment resolved within 14 days. The infant was discharged home at 6 weeks weighing 2.335 kg and was developing normally at 12 weeks of age. Although the cause of the fetal renal impairment was not known with certainty, it was noted that epidermal growth factor receptors are expressed in the kidney during fetal development and blocking these receptors may have prevented normal kidney growth and development (5).

A 2007 case report described a woman treated during the first 24 weeks of pregnancy with trastuzumab (6). The patient had a history of breast cancer with multiple metastases that had been treated with surgery, paclitaxel, carboplatin, trastuzumab, and radiation. She had been on trastuzumab exclusively for a year when pregnancy was diagnosed at 5 weeks' gestation. Trastuzumab was continued until 24 weeks' at which time it was stopped because of reversible, asymptomatic maternal heart failure (low ejection fraction). At 37 weeks', a healthy 2.6-kg female infant was delivered by cesarean section with Apgar scores of 9 and 10 at 1 and 5 minutes, respectively. At 2 months of age, the infant's weight, height, and head circumference were 4.4 kg (25th percentile), 55 cm (25th percentile), and 40 cm (50th percentile), respectively. No abnormalities were found on physical and neurological examination and her development was within normal limits for age (6).

Another 2007 case report described a 28-year-old woman with a history of

radical mastectomy, chemotherapy, and radiotherapy 1 year before pregnancy (7). Because of metastases, she was treated with docetaxel and trastuzumab at 23 and 26 weeks' gestation, trastuzumab alone at 27 weeks', and docetaxel alone at 30 weeks'. Trastuzumab was omitted at 30 weeks' because an ultrasound revealed anhydramnios and fetal growth at the 5th percentile. The anhydramnios was thought to be due to trastuzumab. At 33 weeks', oligohydramnios was noted. An elective cesarean section was conducted at 36 weeks' to deliver a 2.23-kg male infant with Apgar scores of 7 and 9 at 1 and 5 minutes, respectively. No evidence of positional deformations or respiratory abnormalities from the prolonged low amniotic fluid was noted and the neonatal urine output was normal. The development of the infant also was normal (7).

Because of the unknown potential for embryo–fetal harm, two reviews recommended that the use of trastuzumab in pregnancy should be avoided or limited until adequate human pregnancy experience is available (8,9). However, as noted in one review, compared with standard chemotherapy, the use of trastuzumab could improve the pregnancy outcome for both the mother and her fetus (8).

BREASTFEEDING SUMMARY

No reports describing the use of trastuzumab during human lactation have been located.

Human immunoglobulin G also is excreted into breast milk (1,7). The effect of this exposure on a nursing infant is unknown. In adults, adverse effects include left ventricular dysfunction and congestive failure, anemia, leucopenia, diarrhea, and an increased incidence of infection. The manufacturer recommends that women should not breastfeed while receiving trastuzumab and for 6 months after the last dose (1).

TRAVOPROST

Ophthalmic (Prostaglandin Agonist)

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of travoprost in human pregnancy have been located. The animal data suggest moderate risk, but the amount appearing in the systemic circulation is very low. Moreover, the elimination half-life from plasma is very fast. Although the absence of human pregnancy experience prevents a more complete assessment of embryo–fetal risk, the risk of harm appears to be low. Nevertheless, because the drug will be given daily for long periods, it may be best to use other anti-glaucoma agents that have some human data (e.g., Latanoprost).

FETAL RISK SUMMARY

Travoprost is a synthetic prostaglandin F analog that acts as a selective FP prostanoid receptor agonist to reduce intraocular pressure by increasing uveoscleral outflow. It is available as an 0.004% ophthalmic solution that is given as one drop in the affected eye(s) once daily. It is in the same class of prostaglandin agonists as bimatoprost, latanoprost, and tafluprost. Travoprost is indicated for the reduction of elevated intraocular pressure in patients with open-angle glaucoma or ocular hypertension. It is hydrolyzed in the eye to the active free acid and systemically to inactive metabolites. In most nonpregnant subjects, plasma concentrations were below the quantification limit (0.01 ng/mL) of the assay. In subjects with quantifiable plasma levels, the mean plasma maximum concentration was 0.018 ng/mL and the elimination half-life was estimated to be 45 minutes (range 17–86 minutes) (1).

Reproduction studies have been conducted in mice and rats. In rats, a daily IV dose up to 250 times the maximum recommended human ocular dose (MRHOD) was associated with an increase in the incidence of skeletal

malformations and external and visceral defects (fused sternebrae, domed head, and hydrocephaly). Teratogenicity was not observed with daily IV doses up to 75 times the MRHOD in rats or in mice with daily SC doses up to 25 times the MRHOD. Travoprost caused an increase in postimplantation losses and a decrease in fetal viability in rats at daily IV doses up to 75 times the MRHOD or in mice with daily SC doses up to 7.5 times the MRHOD. When rats received a daily SC dose that was 3 times the MRHOD from day 7 of pregnancy to lactation day 21 there was an increased incidence of postnatal mortality and decreased neonatal body weight gain. Neonatal development also was affected as evidenced by delayed eye opening, pinna detachment, preputial separation, and decreased motor activity (1).

No evidence of carcinogenicity was observed in 2-year studies in mice and rats with SC doses. Most assays for mutagenicity were negative but a slight increase in mutant frequency was observed in one assay. No effect on mating or fertility was observed in male or female rats, but at the highest dose (250 times the MRHOD), the mean number of corpora lutea was reduced and postimplantation losses were increased (1).

It is not known if travoprost free acid crosses the human placenta. The molecular weight of the parent drug (about 501) is low enough but the short elimination half-life and very low plasma concentrations suggest that clinically significant amounts of the drug will not cross to the embryo–fetus.

Prostaglandin F_{2α} has been used for pregnancy termination in humans via intrauterine extra-amniotic infusion to treat missed abortion or intrauterine death. However, there is no evidence that at doses given to reduce elevated ophthalmic pressure, an increased risk for uterine contractions would be seen (see Latanoprost).

BREASTFEEDING SUMMARY

No reports describing the use of travoprost during human lactation have been located. The molecular weight of the parent drug (about 501) is low enough but the short elimination half-life (45 minutes) and very low plasma concentrations suggest that clinically significant amounts of the drug will not be excreted into breast milk.

TRAZODONE

Antidepressant

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

The animal and limited human data suggest that the risk for major malformations in the embryo is low. Studies for other aspects of developmental toxicity in the embryo–fetus, however, have not been conducted.

FETAL RISK SUMMARY

Trazodone is an antidepressant. At high doses in some animal species, trazodone is fetal toxic and teratogenic. However, others have reported no teratogenicity in rats and rabbits (1).

One manufacturer has received several anecdotal descriptions concerning the use of trazodone in pregnancy (T. Donosky, personal communication, Mead Johnson Pharmaceutical Division, 1987). Included in these was a report of an infant born with an undefined birth defect after in utero exposure to the antidepressant. Another report described a normal infant exposed throughout gestation beginning with the 5th week. No confirmatory follow-up information was available for either of these cases. A third case from the manufacturer's files involved a woman who took trazodone, 50–100 mg/day, during the first 3 weeks of pregnancy and eventually delivered a normal infant. Finally, a woman was treated with trazodone for 8 days, at which time the drug was discontinued because of a positive pregnancy test. A spontaneous abortion occurred approximately 1.5 months later. No cause and effect relationship can be inferred between trazodone and any of the above adverse outcomes.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 100 newborns had been exposed to trazodone during the 1st trimester (F. Rosa, personal

communication, FDA, 1993). One (1%) major birth defect was observed (four expected), but details are not available. No anomalies were observed in six defect categories (cardiovascular defects, oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available.

A prospective multicenter study evaluated the effects of lithium exposure during the 1st trimester in 148 women (2). One of the pregnancies was terminated at 16 weeks' gestation because of a fetus with the rare congenital heart defect, Ebstein's anomaly. The fetus had been exposed to lithium, trazodone, fluoxetine, and L-thyroxine during the 1st trimester. The defect was attributed to lithium exposure.

In a 1996 descriptive case series, the European Network of the Teratology Information Services (ENTIS) prospectively examined the outcomes of 689 pregnancies exposed to antidepressants (3). Multiple drug therapy occurred in about two-thirds of the mothers. Trazodone was used in 13 pregnancies. The outcomes of these pregnancies were two elective abortions, eight normal newborns (includes one premature infant), and three normal infants who died after birth (after difficult delivery; twins delivered at 27 weeks'; multiple other drugs) (3).

A 2003 prospective controlled study described the outcomes of 147 pregnancies exposed in the 1st trimester (52 used the drugs throughout gestation) to either trazodone or nefazodone, a closely related antidepressant (4). The data were gathered from five teratology information services in Canada (two sites), the United States (two sites), and Italy. The outcomes were compared with two control groups (one exposed to other antidepressants and one exposed to nonteratogens). There were no significant differences between the three groups in terms of spontaneous abortions, elective abortions, stillbirths, major malformations, gestational age at birth, or birth weights. In the study group, there were two (1.4%) major malformations: neural tube defect and Hirschsprung disease (4).

A 2005 meta-analysis of seven prospective comparative cohort studies involving 1774 patients was conducted to quantify the relationship between 7 newer antidepressants and major malformations (5). The antidepressants were bupropion, fluoxetine, fluvoxamine, nefazodone, paroxetine, sertraline, and trazodone. There was no statistical increase in the risk of major birth defects above the baseline of 1%–3% in the general population for the individual or combined studies (5).

A prospective cohort study evaluated a large group of pregnancies exposed

to antidepressants in the 1st trimester to determine if there was an association with major malformations (6). The patient population came from the Motherisk database and involved 928 cases that met their criteria. The 928 matched (for age, smoking, and alcohol use) controls were pregnancies not exposed to antidepressants or known teratogens. In addition to the 17 trazodone cases, the other cases were 113 bupropion, 184 citalopram, 21 escitalopram, 61 fluoxetine, 52 fluvoxamine, 68 mirtazapine, 49 nefazodone, 148 paroxetine, 61 sertraline, and 154 venlafaxine. In the antidepressant group, there were 24 (2.5%) major defects compared with 25 (2.6%) in controls (odds ratio 0.9, 95% CI 0.5–1.61). There were no major defects in the pregnancies exposed to bupropion, escitalopram, or trazodone (6).

BREASTFEEDING SUMMARY

Trazodone is excreted into human milk. Six healthy lactating women, 3–8 months postpartum, were given a single 50-mg oral dose of trazodone after an overnight fast (7). Simultaneous serum and milk samples were collected at various times ≤ 30 hours after ingestion. The infants of the mothers were not allowed to breastfeed during the first 4 hours after the dose. The mean milk:plasma ratio, based on AUC for the two fluids, was 0.142. Based on 500 mL of milk consumed during a 12-hour interval, the infants would have received a trazodone dose of 0.005 mg/kg. This study was unable to include a potentially active metabolite, 1-m-chlorophenylpiperazine, in the analysis (7).

A 2006 report described six women taking quetiapine and other psychotropic agents during breastfeeding (8). One woman was treated with trazodone, quetiapine, and venlafaxine throughout gestation. Details of the pregnancy or its outcome were not provided. At 6.5 weeks postpartum, milk samples were obtained for analysis after doses of 75 mg for each drug (timing of samples and daily doses were not specified). Quetiapine was not detected (<30 nmol/L), but the milk levels of trazodone and venlafaxine were 108 and 371 nmol/L, respectively. The estimated infant daily doses for all three drugs were <0.01 mg/kg/day. In addition, the infant's behavior was assessed using the Bayley Scales of Infant Development, Second Edition, that suggested normal development (8).

Although the amount of trazodone in milk is very small, the American Academy of Pediatrics classifies trazodone as a drug for which the effect on nursing infants is unknown but may be of concern (9).

TREPROSTINIL

Hematologic Agent (Antiplatelet)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of treprostinil during human pregnancy have been located. The animal data suggest low risk, but the lack of human pregnancy experience prevents an assessment of the embryo–fetal risk. However, maternal hypotension, resulting in decreased placental perfusion and fetal hypoxia, is a potential risk.

FETAL RISK SUMMARY

Treprostinil is an inhibitor of platelet aggregation. Its action includes direct vasodilation of pulmonary and systemic arterial vascular beds. Treprostinil is administered by continuous SC infusion for the treatment of pulmonary arterial hypertension. The terminal elimination half-life is about 2–4 hours. Treprostinil is extensively metabolized in the liver but the biological activity of the metabolites is unknown (1).

Reproduction studies have been conducted in rats and rabbits. In pregnant rats during organogenesis, continuous SC infusions of doses up to about 117 times the recommended starting rate in humans based on BSA (HD) and about 16 times the average rate achieved in clinical trials (AR) revealed no evidence of fetal harm. At doses up to about 8 times the AR, continuous SC infusions administered from implantation to the end of lactation had no effect on growth or development of offspring. In pregnant rabbits during organogenesis, a continuous SC infusion at 41 times the HD and about 5 times the AR produced fetal skeletal variations. However, maternal toxicity (decreased body weight and food consumption) was evident at this dose (1).

It is not known if treprostinil crosses the human placenta. The molecular weight (about 412) is low enough that passage to the fetus should be

expected. Moreover, the drug is administered as a continuous SC infusion that should result in relatively constant plasma drug concentrations at the placental maternal–fetal interface.

BREASTFEEDING SUMMARY

No reports describing the use of treprostinil during lactation have been located. The molecular weight (about 412) and method of administration (continuous SC infusion) suggest that the drug will be excreted into breast milk. In adults, treprostinil undergoes extensive hepatic metabolism, but the biological activity of the metabolites has not been characterized. However, even if the metabolites are inactive, the neonatal immature hepatic function could allow systemic levels of the parent drug. Although the effect of this exposure on a nursing infant is unknown, treprostinil has caused clinically significant adverse effects in adults (e.g., headache, nausea/vomiting, restlessness, and anxiety). A nursing infant should be closely observed for these effects if a woman receiving treprostinil elects to breastfeed.

TRETINOIN (SYSTEMIC)

Antineoplastic/Vitamin

PREGNANCY RECOMMENDATION: Contraindicated—1st Trimester

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Tretinoin (all-trans retinoic acid; retinoic acid; vitamin A acid) is a retinoid and vitamin A (retinol) metabolite that is available both as a topical formulation (see Tretinoin [Topical]) and as an oral antineoplastic for the treatment of acute promyelocytic leukemia. As with other retinoids, all-trans retinoic acid is a potent teratogen when taken systemically during early pregnancy (see Etretinate, Isotretinoin, and Vitamin A), producing a pattern of birth defects termed retinoic acid embryopathy (CNS, craniofacial, cardiovascular, and thymic anomalies). The teratogenic effect of all-trans retinoic acid is dose-dependent because an endogenous supply of the vitamin is required for normal morphogenesis and differentiation of the embryo, including a role in physiologic developmental gene expression (1). A low serum concentrations or frank deficiency of vitamin A and all-trans retinoic acid is also teratogenic (see Tretinoin [Topical]).

FETAL RISK SUMMARY

The teratogenicity of all-trans retinoic acid in animals is summarized under the topical formulation as is the reported human pregnancy experience following topical use.

A number of reports have described the use of systemic tretinoin (45 mg/m²/day in 10 cases, 70 mg/day in 1) for the treatment of acute promyelocytic leukemia during pregnancy (2–12). In one case treatment was started during the sixth week of gestation (about 36 days from the last menstruation) (2); in six cases (one set of twins), treatment was started during the 2nd trimester (3–8); and in four cases, treatment was started during the 3rd trimester (9–12). No congenital abnormalities were observed in the 12 newborns, although 10 were premature. The growth and development in nine of

the infants (postnatal examinations not reported in two cases) were normal in the follow-up periods ranging up to 4 years.

BREASTFEEDING SUMMARY

Vitamin A and, presumably, tretinoin (all-trans retinoic acid) are natural constituents of human milk. There are no data available on the amount of all-trans retinoic acid excreted into breast milk following the doses used for the treatment of promyelocytic leukemia or the risk, if any, this may present to a nursing infant.

TRETINOIN (TOPICAL)

Dermatologic Agent

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Elevated serum concentrations of all-trans retinoic acid in early gestation are considered teratogenic in humans. Because of its relatively poor systemic absorption (if occlusive dressings are not used) after topical administration, tretinoin is not thought to present a significant fetal risk. Because some absorption does occur, however, it is not possible to exclude a teratogenic risk (1). Congenital malformations, some of which are consistent with those observed in retinoic acid embryopathy, have been reported after topical use, but a causal association has yet to be established. The reports may reflect (a) greater-than-normal fetal exposure from higher-than-usual maternal doses or enhanced systemic absorption, or (b) selective reporting of adverse outcomes that are not caused by tretinoin. Until more data are available, however, the safest course is to avoid the use of tretinoin during pregnancy, especially in the 1st trimester. But if inadvertent exposure does occur during early pregnancy, the fetal risk, if any, appears to be very low.

FETAL RISK SUMMARY

Tretinoin (all-trans retinoic acid; retinoic acid; vitamin A acid) is a retinoid and vitamin A (retinol) metabolite used topically for the treatment of acne vulgaris and other skin disorders and systemically in the treatment of acute promyelocytic leukemia (see Tretinoin [Systemic]). As with other retinoids, the drug is a potent teratogen after exposure in early pregnancy (see also Etretinate, Isotretinoin, and Vitamin A), producing a pattern of birth defects termed retinoic acid embryopathy (CNS, craniofacial, cardiovascular, and thymic anomalies). However, an endogenous supply of retinoic acid is required for normal morphogenesis and differentiation of the embryo, including a role in

physiologic developmental gene expression. The teratogenic effect of retinoic acid is manifested when the levels are excessive (2).

Low serum concentration or frank deficiency of vitamin A and all-trans retinoic acid is also teratogenic. Recent studies have shown that inhibition of the conversion of retinol to retinoic acid or depletion of retinol may be involved in the teratogenic mechanisms of such agents as ethanol (3–7) and some anticonvulsants (8).

Two manufacturers have stated that reproduction studies with topical tretinoin in animals are equivocal. In pregnant rats, daily doses >200 times the recommended human topical dose (RHTD) were associated with shortened or kinked tail. At 2000 times the RHTD, skeletal anomalies (humerus: short, bent; os parietale incompletely ossified) were observed. In rabbits, fetotoxicity was observed with doses 100 times the RHTD. Doses approximately 80 times the RHTD in pregnant rabbits were associated with domed head and hydrocephaly, anomalies that are typical of retinoid-induced malformations in this species. In addition, a dose 91 times the RHTD was also associated with an increased incidence of cleft palate (9). In contrast, other studies with topical tretinoin in rats and rabbits at doses 100–200 times the RHTD have not demonstrated a teratogenic effect (9,10).

A 1997 report described the developmental toxicity of topical and oral tretinoin in pregnant rats (11). Topical doses of ≥ 10 mg/kg/day (approximately 2000 times the RHTD) were not tolerated, causing severe local and systemic maternal toxicity. Maternal toxicity (reduced weight gain and food consumption) was also evident at doses of 2.5 mg/kg/day (approximately 500 times the RHTD) or more. A significant increase in the occurrence of supernumerary ribs was observed at this dose, a result thought to be nonspecific or maternally mediated. In contrast, oral tretinoin doses of 5 and 10 mg/kg/day were not maternally toxic, but were associated with an increased incidence of supernumerary ribs (5 mg/kg/day) and cleft palate (10 mg/kg/day). Based on these results, the investigators concluded that only the highest oral dose was teratogenic (11).

Dose-related maternal toxicity was observed in rabbits treated topically with tretinoin cream at dosages of 10 and 100 times the human clinical dose (500 mg of 0.05% cream in a 50-kg adult equals 0.005 mg/kg/day) based on body weight (12). Maternal endogenous plasma tretinoin levels were below the detection level (5 ng/mL) in all animals. After treatment, however, a few rabbits had detectable concentrations of retinoic acid, 13-cis-retinoic acid, or their metabolites. The maternal toxicity was associated with an increased incidence

of abortions, resorptions, and reduced fetal body weight. Some significant ($p \leq 0.01$) increases in malformations (open eyelids and cleft palate) and variations (nasal ossification, fused sternbrae, and irregular-shaped scapular alae) were observed. However, these were not considered to be tretinoin-related because they were not dose-related, and the litter incidences either did not differ significantly from those of controls or were within expected ranges for the species (12).

Additional literature on the teratogenicity of both systemic and topical tretinoin in various animal species has been summarized in several sources (13–17). The latter reference has particular application to the study of the teratogenic effects of tretinoin because it examined the toxicity of very small oral doses of this compound at presomite stages in mouse embryos, thought to be the most sensitive period for retinoid-induced teratogenesis (17). An increasing incidence of severe microphthalmia, anophthalmia, and iridial colobomata was produced as the dose was increased from 0 to 1.25 mg/kg. These doses were much less than those typically used for reproductive toxicity testing at later gestational periods. Slightly higher threshold doses produced exencephaly (2.5 mg/kg) and marked craniofacial defects (7.5 mg/kg) representative of the holoprosencephaly–aprosencephaly spectrum (17).

When tretinoin is used topically, its teratogenic risk had been thought to be close to 0 (18). According to one source, no cases of toxicity had been reported after nearly 20 years of use (18). In support of this, it has been estimated that even if maximal absorption (approximately 33%) occurred from a 1-g daily application of a 0.1% preparation, this would result in only about one-seventh of the vitamin A activity received from a typical prenatal vitamin supplement (19). One source stated that 80% of a 0.1% formulation in alcohol remained on the skin's surface, but when a 0.1% ointment was applied to the back with a 16-hour occlusive dressing, only 50% of the drug remained on the skin surface and 6% was excreted in the urine within 56 hours (20).

Authors of a 1992 reference reviewed the teratogenicity of vitamin A and its congeners, including tretinoin, but did not derive a conclusion on the safety of the drug after topical use (21), most likely because of the lack of studies with the drug in pregnancy.

Five reports of congenital malformations in newborns whose mother's were using tretinoin during the 1st trimester have been located (22–26). The first case involved a woman who had used tretinoin cream 0.05% during the month before her last menstruation and during the first 11 weeks of pregnancy (22). Her term, growth-restricted (weight 2620 g, <3rd percentile; length 49 cm, 25th

percentile; head circumference 32.5 cm, 3rd percentile) female infant had a crumpled right hypoplastic ear and atresia of the right external auditory meatus, a pattern of ear malformation identical with that observed with vitamin A congeners. The remainder of the examination was normal, including the eyes, cerebral computed tomography, and chromosomal analysis (22).

The second report described the female infant of a woman who had used an over-the-counter alcohol-based liquid preparation of 0.05% tretinoin for severe facial acne (23). The infant had multiple congenital defects consisting of supraumbilical exomphalos, a diaphragmatic hernia, a pericardial defect, dextroposition of the heart, and a right-sided upper limb reduction defect.

A 1998 case report described the pregnancy outcome of a woman who had used, before conception and during the first 2 months of gestation, a topical alcohol-based preparation of tretinoin 0.05% combined with benzoyl peroxide 2.5% for facial acne (24). Except for doxycycline (200 mg/ day) that had been taken for an unknown duration, she had no other exposures to medications or vitamins. An ultrasound examination at 5 months' gestation detected hand and heart malformations. The female infant (2800 g; length 48 cm; normal karyotype 46,XX) was delivered at term with coarctation of the aorta, hypoplastic left hand, and small ear canals. The authors noted the similarity of some of the anomalies to those observed in retinoic acid embryopathy and speculated that the keratolytic action of benzoyl peroxide may have enhanced the cutaneous absorption of tretinoin. However, they also noted that any association between tretinoin and the birth defects may have been fortuitous (24).

Severe malformations were reported in a term, female infant whose mother had used tretinoin (0.05%) twice daily for facial acne before and throughout gestation (25). The defects were thought to be consistent with abnormal cranial neural crest cell migration. They included craniofacial defects (cleft palate and harelip, fused palpebral fissures, hypertelorism, a depressed nasal bridge, and deficient left naris) and CNS anomalies (disorganized rudimentary optic cup derivatives with optic tract dysgenesis, arrhinencephaly, agenesis of the corpus callosum, fornices and cingulate gyri, cerebellar hypoplasia, and aqueduct stenosis with hydrocephalus) (25).

The fifth case report involved a 4090-g term male infant who was born with absence of the right ear and external auditory canal (26). The mother had used tretinoin 0.025% topically on her face and over a large area of her back before conception and during the first 2–3 months of gestation. She took prenatal vitamins during pregnancy. The father was using isotretinoin before conception.

Examinations at 16 and 20 months of age revealed a nonverbal infant with poor receptive language consistent with cognitive impairment. He had age-appropriate muscle strength, tone and bulk. There was a diminished optokinetic response and no oculovestibular response when rotating toward the right. Extensive examinations revealed cerebral calcification of the right posterior hemisphere, an overall reduction in the volume of the right cerebral hemisphere, a remote infarct in the deep basal ganglia, focal atrophy and encephalomalacia of the right parieto-occipital lobe. Marked abnormalities were noted in the posterior cerebral artery and some of its branches. Hypometabolism, sometimes severe, was observed in several regions of the brain, including the thalamus (26).

The results of a prospective survey involving 60 completed pregnancies exposed to tretinoin early in pregnancy were presented in a 1994 abstract (27). From these pregnancies there were 53 liveborns (1 set of twins), 3 lost to follow-up, 4 spontaneous abortions, and 1 elective termination. No major malformations characteristic of retinoic acid embryopathy were observed except for one case in which the mother had also taken isotretinoin (27).

Among 25 birth defect cases with 1st trimester exposure to tretinoin reported to the FDA from 1969 to 1993, 5 were cases of holoprosencephaly (28). Six other cases of holoprosencephaly involved other vitamin A derivatives: isotretinoin (N = 4), etretinate (N = 1), and megadose vitamin A (N = 1). In contrast, among 8700 nonretinoid-exposed birth defect reports to the FDA, only 19 involved suspected holoprosencephalies (28). Pregnancy outcomes from 1120 apparent 1st trimester tretinoin exposures were also examined. Among the 49 birth defects observed (the expected incidence), no cases of holoprosencephaly were seen. Although it is speculation, the contrasting findings in the above two reports (27,28) on early pregnancy tretinoin exposure may reflect (a) fetal exposure to different doses of tretinoin at the critical times from the use of higher maternal doses or from enhanced systemic absorption, or (b) selective (biased) reporting of adverse pregnancy outcomes to the FDA.

A 1993 report summarized data gathered from the Group Health Cooperative of Puget Sound, Washington, involving 1st trimester exposure to topical tretinoin and congenital malformations (29). A total of 215 women who had delivered live or stillborn infants and were presumed to have been exposed to the drug in early pregnancy were compared with 430 age-matched nonexposed controls of women whose live or stillborn infants were delivered at the same hospitals. A total of 4 (1.9%) infants in the exposed group had major anomalies compared with 11 (2.6%) among the controls, a relative risk of 0.7 (95%

confidence interval 0.2–2.3). The defects observed in the exposed infants were hypospadias, undescended or absent testicles, metatarsus adductus, and esophageal reflux. The three stillborn infants in the exposed group were all associated with umbilical cord accidents. The authors concluded that these data provided no evidence for a relationship between topical tretinoin and the congenital abnormalities normally observed with other vitamin A congeners or for an increased incidence of defects compared with data from women not using tretinoin (29). The findings of this study were summarized in a review article on retinoids and teratogenicity (30).

A brief 1997 report described a prospective, observational, controlled study that compared the pregnancy outcomes of 94 women who had used topical tretinoin during pregnancy with 133 women not exposed to topical tretinoin or other known human teratogens (31). Both groups were composed of pregnant women who had contacted a teratology information service in the years from 1988 to 1996. No differences between the groups were found for the number of live births, miscarriages, elective terminations, major malformations, duration of pregnancy, cesarean sections, birth weight (after exclusion of one baby weighing 5396 g in the control group), and low birth weight. Two liveborn infants from the tretinoin-exposed group had major birth defects: a bicuspid aortic valve in one and dysplastic kidneys in one. Neither defect is consistent with retinoic acid embryopathy. Malformations in the four infants from the control group were congenitally dislocated hip in two, aortic valvular stenosis in one, and imperforate anus in one (31).

Several comments concerning the above study were made in a 1999 letter (32). The primary concern expressed was that the number of subjects enrolled in the study was too small to derive any conclusions as to the safety of tretinoin in the 1st trimester. The authors thought that the risk of certain birth defects, specifically cardiac anomalies and microtia, could not be excluded, and that the use of tretinoin in pregnancy was contraindicated (32).

BREASTFEEDING SUMMARY

Vitamin A and, presumably, tretinoin (all-trans retinoic acid) are natural constituents of human milk. There are no data available on the amount of all-trans retinoic acid excreted into milk after topical use. Although other retinoids are excreted (see Vitamin A), the minimal absorption that occurs after topical application of tretinoin probably precludes the detection of clinically significant amounts in breast milk from this source. Thus, use of tretinoin while breastfeeding does not appear to represent a significant risk to a nursing infant.

TRIAMCINOLONE

Corticosteroid

PREGNANCY RECOMMENDATION: Compatible (Inhaled) Human and Animal Data Suggest Risk (Oral/Parenteral)

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Triamcinolone is a corticosteroid with potency slightly greater than prednisone. Use in the 1st trimester has a small absolute risk of oral clefts. Continuous use during pregnancy has also caused fetal growth restriction. However, inhaled triamcinolone does not appear to cause embryo–fetal harm. Depending on the indication, the benefit of therapy may outweigh these risks.

FETAL RISK SUMMARY

Triamcinolone is a synthetic fluorinated corticosteroid that can be administered, depending on the preparation selected, orally, parenterally, topically, or by oral inhalation. In animal models of inflammation, triamcinolone is approximately 1–2 times as potent as prednisone, whereas triamcinolone acetonide is about 8 times more potent (1). Oral inhalation of usual therapeutic doses of the latter agent does not appear to suppress the hypothalamic–pituitary–adrenal axis (2).

Triamcinolone is teratogenic in animals. Cleft palate was induced in fetal mice and rats exposed in utero to triamcinolone, triamcinolone acetonide, or triamcinolone diacetate (3–5). In one study with mice, high dietary fat intake (48% compared with a low-fat diet of 5.6%) increased the frequency and severity of cleft palate (5). IM administration of nonlethal maternal doses (0.125–0.5 mg/kg/day) of triamcinolone acetonide in pregnant rats at various gestational ages produced fetal growth restriction at all doses tested (6). Higher doses were associated with resorption, cleft palate, umbilical hernias, undescended testes, and reduced ossification (6). A second report by these latter investigators compared the teratogenic potency, as measured by the induction of cleft palate, of triamcinolone, triamcinolone acetonide, and cortisol

in rats (7). Triamcinolone acetonide was 59 times more potent than triamcinolone, which, in turn, was more potent than cortisol. Other anomalies observed with triamcinolone acetonide were umbilical hernias, resorption, and fetal death. All three agents produced fetal growth restriction.

Morphologically abnormal lungs and increased epithelial maturation were found in fetal rat whole organ lung cultures exposed to triamcinolone acetonide (8). Similarly, accelerated fetal lung maturation was observed following administration of IM triamcinolone acetonide to pregnant rhesus macaques at various stages of gestation (9). However, treatment earlier in gestation produced growth restriction of some of the lung septa, as well as decreased body weight and length (9).

A series of studies described the teratogenic effects of single and multiple doses of IM triamcinolone acetonide administered early in gestation to nonhuman primates (bonnet monkeys, rhesus monkeys, and baboons) at doses ranging from approximately equivalent to the human dose up to 300 times the human dose (10–13). Resorption; intrauterine death; orocraniofacial anomalies; and defects of the thorax, hind limbs, thymus, adrenal glands, and kidney were observed. The most common malformations involved the central nervous system and cranium in all three species (11); growth restriction was also common in all species (10).

Published human pregnancy experience with triamcinolone is limited to 16 cases. The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 56 of whom were exposed during the 1st trimester to a category of miscellaneous corticosteroids (14). Included in this group were eight triamcinolone-exposed mother–child pairs. Two (3.6%; relative risk 0.47) newborns with malformations were observed in the total group, suggesting a lack of any relationship to large categories of major or minor malformations or to individual defects.

A 1966 reference described a woman with benign adrenogenital syndrome who took 4–8 mg of triamcinolone orally throughout gestation (15). She delivered a normal 2.61-kg male infant at 38 weeks without evidence of hypoadrenalism. A 1975 report included 5 patients treated with triamcinolone acetonide, presumably by oral inhalation, among 70 women with asthma who were treated with various corticosteroids throughout gestation (16). No adverse fetal outcomes were observed in the five triamcinolone-exposed cases, although one of the mothers delivered prematurely. None of the 70 newborns had evidence of adrenal insufficiency.

Symmetric growth restriction was observed in a 700-g, small-for-gestational-

age newborn delivered via cesarean section at 31 weeks' gestation because of fetal distress, diminished amniotic fluid, and lack of growth (17). The Dubowitz evaluation was compatible with the menstrual dates. The normotensive, nonsmoking mother had applied 0.05% triamcinolone acetonide cream to her legs, abdomen, and extremities for atopic dermatitis from 12 to 29 weeks' gestation. The authors estimated her daily dose to be approximately 40 mg, but she had no signs or symptoms of adrenal insufficiency. The newborn was breathing room air within 12 hours without evidence of respiratory distress. Although not discussed, the apparent fetal lung maturity in a 31-week fetus may have been the result of chronic corticosteroid exposure. At 14 days of age, necrotizing enterocolitis occurred and, following multiple surgeries, the infant was alive at 10 months of age on total parenteral nutrition. In an addendum to their report, the authors noted that the mother had had a second pregnancy, this time without the use of triamcinolone, and delivered a 1660-g (10th percentile for gestational age) male infant at 34 weeks' gestation. The authors attributed the growth restriction in the first infant to triamcinolone because no other cause was discovered. The result of the second pregnancy, however, probably indicates that other factors were involved in addition to any effect of the corticosteroid.

Four large epidemiologic studies have associated the use of corticosteroids during the 1st trimester with orofacial clefts. The specific corticosteroid was not identified in three of these studies (see Hydrocortisone for details), but in a 1999 study described below, the corticosteroids were listed.

In a case-control study, the California Birth Defects Monitoring Program evaluated the association between selected congenital anomalies and the use of corticosteroids 1 month before to 3 months after conception (periconceptual period) (18). Case infants or fetal deaths diagnosed with orofacial clefts, conotruncal defects, neural tubal defects (NTD), and limb anomalies were identified from a total of 552,601 births that occurred from 1987 through the end of 1989. Controls, without birth defects, were selected from the same database. Following exclusion of known genetic syndromes, mothers of case and control infants were interviewed by telephone, an average of 3.7 years (cases) or 3.8 years (controls) after delivery, to determine various exposures during the periconceptual period. The number of interviews completed were orofacial cleft case mothers (N = 662, 85% of eligible), conotruncal case mothers (N = 207, 87%), NTD case mothers (N = 265, 84%), limb anomaly case mothers (N = 165, 82%), and control mothers (N = 734, 78%) (18). Orofacial clefts were classified into four phenotypic groups: isolated

cleft lip with or without cleft palate (ICLP, N = 348), isolated cleft palate (ICP, N = 141), multiple cleft lip with or without cleft palate (MCLP, N = 99), and multiple cleft palate (MCP, N = 74). A total of 13 mothers reported using corticosteroids during the periconceptional period for a wide variety of indications. Six case mothers of infants with ICLP and three of infants with ICP used corticosteroids (unspecified corticosteroid N = 1, prednisone N = 2, cortisone N = 3, triamcinolone acetonide N = 1, dexamethasone N = 1, and cortisone plus prednisone N = 1). One case mother of an infant with NTD used cortisone and an injectable unspecified corticosteroid, and three controls used corticosteroids (hydrocortisone N = 1 and prednisone N = 2). The odds ratio for corticosteroid use and ICLP was 4.3 (95% confidence interval [CI] 1.1–17.2), whereas the odds ratio for ICP and corticosteroid use was 5.3 (95% CI 1.1–26.5). No increased risks were observed for the other anomaly groups. Commenting on their results, the investigators thought that recall bias was unlikely because they did not observe increased risks for other malformations, and it was also unlikely that the mothers would have known of the suspected association between corticosteroids and orofacial clefts (18).

A 2004 study examined the effect of inhaled corticosteroids on low birth weight, preterm births, and congenital malformations in pregnant asthmatic patients (19). The inhaled steroids and the number of patients were beclomethasone (N = 277), fluticasone (N = 132), triamcinolone (N = 81), budesonide (N = 43), and flunisolide (N = 25). Compared with the general population, the study found no increased incidence of small-for-gestational-age infants (less than 10th percentile for gestational age), low birth weight (<2500 g), preterm births, and congenital malformations (19).

A 2006 meta-analysis on the use of inhaled corticosteroids during pregnancy was published in 2006 (20). The analysis included five agents: beclomethasone, budesonide, flunisolide, fluticasone, and triamcinolone. The results showed that these agents do not increase the risk of major congenital defects, preterm delivery, low birth weight, and pregnancy-induced hypertension. Thus, they could be used during pregnancy (20).

BREASTFEEDING SUMMARY

No reports describing the use of triamcinolone during lactation have been located. The molecular weight (about 394) is low enough that excretion into breast milk should be expected. Small amounts of other corticosteroids (see Hydrocortisone and Prednisone) are excreted into milk and do not appear to present a risk to a nursing infant. Similar excretion probably occurs following

inhaled triamcinolone. At least one source states that inhaled corticosteroids used for asthma are not contraindicated during breastfeeding (21).

TRIAMTERENE

Diuretic

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Many investigators consider diuretics to be contraindicated in pregnancy, except for patients with heart disease, because they do not prevent or alter the course of toxemia, and they may decrease placental perfusion (1–3). In general, diuretics are not recommended for the treatment of gestational hypertension because of the maternal hypovolemia characteristic of this disease. Folic acid, at least 0.4 mg/day, should be taken before and during gestation because triamcinolone is a weak folic acid inhibitor.

FETAL RISK SUMMARY

Triamterene is a potassium-conserving diuretic. It is a weak folic acid antagonist. Reproduction studies in rats at doses up to 6 times the maximum recommended human dose based on BSA found no evidence of fetal harm (4).

It is not known if triamterene crosses the human placenta. The molecular weight (about 253) is low enough that exposure of the embryo–fetus should be expected.

No defects were observed in five infants exposed to triamterene in the 1st trimester (5, p. 372). For use anytime during pregnancy, 271 exposures were recorded without an increase in malformations (5, p. 441).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 318 newborns had been exposed to triamterene during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 15 (4.7%) major birth defects were observed (13 expected). Three cases of cardiovascular defects (three expected) and one case of polydactyly (one expected) were observed, but specific information was not available for the other defects. No anomalies were observed in four other categories of defects (oral clefts, spina bifida, limb

reduction defects, and hypospadias) for which data were available. These data do not support an association between the drug and congenital defects.

The effects of exposure (at any time during the 2nd or 3rd month after the last menstrual period) to folic acid antagonists on embryo–fetal development were evaluated in a large, multicenter, case–control surveillance study published in 2000 (6). The report was based on data collected between 1976 and 1998 by the Slone Epidemiology Unit Birth Defects Study from 80 maternity or tertiary care hospitals in Boston, Philadelphia, Toronto, and Iowa. Mothers were interviewed within 6 months of delivery about their use of drugs during pregnancy. Folic acid antagonists were categorized into two groups: group I—dihydrofolate reductase inhibitors (aminopterin, methotrexate, sulfasalazine, pyrimethamine, triamterene, and trimethoprim); group II—agents that affect other enzymes in folate metabolism, impair the absorption of folate, or increase the metabolic breakdown of folate (carbamazepine, phenytoin, primidone, and phenobarbital) (3). The case subjects were 3870 infants with cardiovascular defects, 1962 with oral clefts, and 1100 with urinary tract malformations. Infants with defects associated with a syndrome were excluded, as were infants with coexisting neural tube defects (NTDs; known to be reduced by maternal folic acid supplementation). Too few infants with limb reduction defects were identified to be analyzed. Controls (N = 8387) were infants with malformations other than oral clefts and cardiovascular, urinary tract, and limb reduction defects, and NTDs, but included infants with chromosomal and genetic defects. The risk of malformations in control infants would not have been reduced by vitamin supplementation, and none of the controls used folic acid antagonists (3). For group I cases, the relative risks (RRs) of cardiovascular defects and oral clefts were 3.4 (95% confidence interval [CI] 1.8–6.4) and 2.6 (95% CI 1.1–6.1), respectively. For group II cases, the RRs of cardiovascular and urinary tract defects, and oral clefts were 2.2 (95% CI 1.4–3.5), 2.5 (95% CI 1.2–5.0), and 2.5 (95% CI 1.5–4.2), respectively. Maternal use of multivitamin supplements with folic acid (typically 0.4 mg) reduced the risks in group I cases, but not in group II cases (6).

BREASTFEEDING SUMMARY

No reports describing the use of triamterene during lactation have been located. The molecular weight (about 253) is low enough that excretion into breast milk should be expected. The effect of this exposure on a nursing infant is unknown.

TRIAZOLAM

Hypnotic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

A 1990 report evaluated the available published data to determine the fetal risk that occurs from exposure to various drugs (1). The risk for triazolam, based on poor data, was determined to be “none minimal.” This risk assignment was defined as “...a magnitude that patients and physicians would generally consider to be too small to influence the management of an exposed pregnancy” (1).

FETAL RISK SUMMARY

Triazolam, a short-acting benzodiazepine, is used as a hypnotic for the treatment of insomnia. Although no congenital anomalies have been attributed to the use of triazolam during human pregnancies, other benzodiazepines (e.g., see Chlordiazepoxide and Diazepam) have been suspected of producing fetal malformations after 1st trimester exposure. Because of this association, the manufacturer classifies the drug as contraindicated in pregnancy (2). In one report, the drug was not teratogenic in pregnant animals when administered in large oral doses (3).

It is not known if triazolam crosses the human placenta. However, other benzodiazepines, such as diazepam, freely cross the placenta and accumulate in the fetus (see Diazepam). A similar distribution pattern should be expected for triazolam.

By the middle of 1988, the manufacturer had received >100 reports of in utero exposure to triazolam (J.H. Markillie, personal communication, Upjohn, 1989). Approximately one-seventh of these women were either lost to follow-up or further information was not available. Of the cases in which the outcome was known, more than one-half of the completed pregnancies ended with the

delivery of a normal infant. Some of these exposures were reported in a 1987 correspondence that also included experience with alprazolam, another short-acting benzodiazepine (4). From these two sources, a total of five infants with congenital malformations have been described after in utero exposure to triazolam: extra digit on left foot and cleft uvula; incomplete closure of the foramen ovale (resolved spontaneously); small-for-gestational-age infant with left pelvic ectopic kidney; ventricular septal defect and possible coarctation of aorta (exposed to multiple drugs including triazolam); and premature, low-birth-weight infant with ventricular septal defect, pulmonary stenosis, intraventricular hemorrhage, hydrocephalus, apnea, bradycardia, anemia, jaundice, and seizure disorder (exposed to single 0.125-mg tablet at 1–2 weeks' gestation).

Single reports received by the manufacturer of defects in infants exposed in utero to either triazolam or alprazolam include pyloric stenosis, moderate tongue-tie, umbilical hernia and ankle inversion, and clubfoot (4).

Three cases of nonmalformation toxicities have been observed in infants exposed during gestation to triazolam: tachycardia, bradycardia, respiratory pauses, hypotonia and axial hypotony, impaired arachnoid reflexes, hypothermia, sleepiness and lifeless (symptoms resolved after infant received supportive care for several days; mother took multiple medications during pregnancy); fetal distress requiring emergency cesarean section and infant resuscitation, umbilical cord wrapped around neck, seizure activity, and generalized cortical atrophy (exposed to triazolam and a second [not identified] benzodiazepine early in pregnancy and during the last week of gestation; apparent recovery with no permanent disability by 6 months of age); bradycardia, malaise, cyanosis, leukopenia, and chewing movements at 4 days of age (exposed during 3rd trimester; symptoms resolved by 1 week of age) (4).

Based on the available information, a causal relationship between triazolam and the various infant outcomes does not appear to exist. Moreover, these cases cannot be used to derive rate or incidence data, because of the probable bias involved in the reporting of pregnancy exposures to the manufacturer (4).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 138 newborns were exposed to triazolam during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of seven (5.1%) major birth defects were observed (six expected). One cardiovascular defect (one expected) and one case of polydactyly (0.5 expected) were observed, but specific information on the other defects was not available. No anomalies were observed in four other

categories of defects (oral clefts, spina bifida, limb reduction defects, and hypospadias) for which specific data were available. These data do not support an association between the drug and congenital defects.

BREASTFEEDING SUMMARY

No reports describing the use of triazolam during human lactation or measuring the amount excreted into milk have been located. The molecular weight (about 343) is low enough that passage into human milk should be expected. The effect of this exposure on a nursing infant is unknown, but closely related drugs are classified by the American Academy of Pediatrics as agents that may be of concern during breastfeeding (e.g., see Diazepam).

TRIDIHEXETHYL

[Withdrawn from the market. See 9th edition.]

TRIENTINE

Chelating Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although the animal data suggest moderate risk, no developmental toxicity has been observed in the limited human pregnancy data. Copper deficiency is thought to be teratogenic, but evidence was found in one study that fetuses exposed to trientine are not copper deficient.

FETAL RISK SUMMARY

Trientine is a chelating agent used for the removal of excess copper from the systems of patients with Wilson's disease who either cannot tolerate penicillamine or who have developed penicillamine resistance. The drug is available in the United States only as an orphan drug.

In studies with pregnant rats, trientine was teratogenic in doses similar to those used in humans (1–6). The frequency of fetal resorptions and malformations, including hemorrhage and edema, was directly related to the decrease in fetal copper concentrations.

It is not known if trientine crosses the human placenta. The molecular weight (about 147 for the free base) suggests that exposure of the embryo–fetus should be expected.

A 1996 report described the use of trientine in seven human pregnancies (7). The women were treated for Wilson's disease through 11 pregnancies. At the time of conception, the average duration of trientine therapy had been 5 years (range 2–3 weeks to 9 years). Therapy was continued throughout pregnancy in seven cases, interrupted in the 2nd trimester of one because of inability to obtain the drug, and apparently was discontinued in the final few weeks of still another because of nausea not related to trientine (7). One woman underwent a therapeutic abortion at 10 weeks' gestation and one spontaneously aborted a

normal male fetus, together with a copper contraceptive coil, at 14 weeks' gestation. Of the pregnancies ending with a live infant, there were four males, four females, and one infant whose sex was not specified. The mean birth weight of the full-term infants was 3263 g. Two of the infants were delivered prematurely, one male at 36 weeks (2400 g) and one female at 31 weeks (800 g). The latter infant had an isochromosome X, but both parents had normal X chromosomes. No other abnormalities were observed in the infants at the time of birth.

Because copper deficiency is thought to be teratogenic, the results led to the conclusion that the fetuses had not become copper depleted (7). Evidence supporting this conclusion was obtained from the mean ceruloplasmin concentration of cord blood, 9.9 mg/dL, which was nearly identical to nontreated controls (10 mg/dL) (7). Additional studies, however, are needed before this conclusion can be accepted with confidence. Except for slow progress at 3 months in the infant with the isochromosome X, development in the other children was normal during follow-up evaluations ranging from 2 months to 9 years.

In a 1998 case report, a 20-year-old woman with Wilson's disease took trientine (900 mg/day) throughout pregnancy (8). At 42 weeks', she vaginally delivered a normal 3280-g female infant with Apgar scores of 10, 10, and 10 at 1, 5, and 10 minutes, respectively. No complications were observed in the mother or infant during the postpartum period (8).

BREASTFEEDING SUMMARY

No reports describing the use of trientine during lactation have been located. The molecular weight (about 147 for the free base) is low enough that excretion into breast milk should be expected. The effect of this exposure on a nursing infant is unknown. Copper deficiency, however, is a potential toxicity.

TRIFLUOPERAZINE

Antipsychotic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although some reports have attempted to link trifluoperazine with congenital defects, most evidence suggests that the drug is safe for the mother and low risk for the embryo–fetus.

FETAL RISK SUMMARY

Trifluoperazine is a piperazine phenothiazine. The drug readily crosses the placenta (1). It has been used for the treatment of nausea and vomiting of pregnancy, but it is primarily used as a psychotropic agent.

Reproduction studies with trifluoperazine have been conducted in rats, rabbits, and monkeys (2). In rats, doses >600 times the human dose revealed an increased incidence of malformations and reduced litter size and weight associated with maternal toxicity. These effects were not observed when the dose was reduced to half (2). No fetal adverse effects were observed in rabbits or monkeys at doses of 700 and 25 times the human dose, respectively.

In 1962, the Canadian Food and Drug Directorate released a warning that eight cases of congenital defects had been associated with trifluoperazine therapy (3). This correlation was refuted in a series of articles from the medical staff of the manufacturer of the drug (4–6). In 480 trifluoperazine-treated pregnant women, the incidence of liveborn infants with congenital malformations was 1.1%, as compared with 8472 nontreated controls with an incidence of 1.5% (5). Two reports of phocomelia appeared in 1962–1963 and a case of a congenital heart defect in 1969 (7–9): twins, both with phocomelia of all four limbs (7); phocomelia of upper limbs (8); and complete transposition of great vessels in the heart (9). In none of these cases is there a clear relationship

between use of the drug and the defect.

Extrapyramidal symptoms have been described in a newborn exposed to trifluoperazine in utero, but the reaction was probably caused by chlorpromazine (see Chlorpromazine) (10).

The Collaborative Perinatal Project monitored 50282 mother–child pairs, 42 of whom had 1st trimester exposure to trifluoperazine (11). No evidence was found to suggest a relationship to malformations or an effect on perinatal mortality rate, birth weight, or IQ scores at 4 years of age.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 29 newborns had been exposed to trifluoperazine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). One (3.4%) major birth defect (one expected), a cardiovascular malformation (0.5 expected), was observed.

Attempted maternal suicide at 31 weeks' gestation with trifluoperazine and misoprostol resulting in fetal death has been described (12). The adverse fetal outcome was attributed to tetanic uterine contractions caused by misoprostol (see Misoprostol).

Reviewers have concluded that phenothiazines are not teratogenic (13,14).

BREASTFEEDING SUMMARY

No reports describing the use of trifluoperazine during lactation have been located. The molecular weight (about 408 for the free base) is low enough that passage into milk should be expected. The American Academy of Pediatrics classifies trifluoperazine as a drug for which the effect on nursing infants is unknown but may be of concern (15).

TRIFLUPROMAZINE

[Withdrawn from the market. See 9th edition.]

TRIHXYPHENIDYL

Parasympatholytic (Anticholinergic)

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The absence of animal reproduction data and the very limited human pregnancy experience prevents an assessment of the embryo–fetal risk. However, in general, anticholinergics are considered low risk in pregnancy.

FETAL RISK SUMMARY

Trihexyphenidyl is an anticholinergic agent used in the treatment of parkinsonism. In a large prospective study, 2323 patients were exposed to this class of drugs during the 1st trimester, 9 of whom took trihexyphenidyl (1). A possible association was found between the total group and minor malformations.

BREASTFEEDING SUMMARY

No reports describing the use of trihexyphenidyl during human lactation have been located.

TRIMETHOBENZAMIDE

Antiemetic

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The animal reproduction data and the limited human pregnancy experience suggest that the embryo–fetal risk with this drug is low.

FETAL RISK SUMMARY

Trimethobenzamide is an antiemetic agent. Reproduction studies have been conducted in rats and rabbits and revealed no evidence of teratogenicity (1). An increased incidence of resorptions and stillborn pups was noted in rats (at 20 and 100 mg/kg) and an increased number of resorptions in rabbits (at 100 mg/kg), but these adverse effects occurred in only one or two dams in both species (1).

It is not known if trimethobenzamide crosses the human placenta. The molecular weight (about 389 for the free base) suggests that exposure of the embryo–fetus should be expected.

Trimethobenzamide has been used in pregnancy to treat nausea and vomiting (2,3). No adverse effects in the fetuses were observed. In a third study, 193 patients were treated with trimethobenzamide in the 1st trimester (4). The incidences of severe congenital defects at 1 month, 1 year, and 5 years were 2.6%, 2.6%, and 5.8%, respectively. The 5.8% incidence was increased compared with nontreated controls (3.2%) ($p < 0.05$), but other factors, including the use of other antiemetics in some patients, may have contributed to the results. The authors concluded that the risk of congenital malformations with trimethobenzamide was low.

BREASTFEEDING SUMMARY

No reports describing the use of trimethobenzamide during lactation have been located. The molecular weight (about 389 for the free base) is low enough that

excretion into breast milk should be expected. The effect of this exposure on a nursing infant is unknown.

PREGNANCY RECOMMENDATION: Human and Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Trimethoprim is a dihydrofolate reductase inhibitor that is teratogenic in animals and humans. Defects that have been associated with trimethoprim include cardiovascular defects and neural tube defects (NTDs), and possibly oral clefts. Folic acid supplementation, at least 0.4 mg/day, started before conception or concurrently with trimethoprim may reduce the risk of these congenital defects.

FETAL RISK SUMMARY

Trimethoprim is available as a single agent and in combination with various sulfonamides (see Sulfonamides). Because trimethoprim is a folate antagonist, caution has been advocated for its use in pregnancy (1–3). Published case reports and placebo-controlled trials involving several hundred patients, during all phases of gestation, have failed to demonstrate an increase in fetal abnormalities (4–13). However, other reports (14–20) and the unpublished data cited below are suggestive that trimethoprim use during the 1st trimester may result in structural defects. Maternal supplementation with multivitamins that contain folic acid may reduce this risk (16).

Trimethoprim (200 mg/kg) given to pregnant rats resulted in cleft palates (21). The no-effect dose was 192 mg/kg. When trimethoprim (88 mg/kg) was combined with sulfamethoxazole (355 mg/kg), cleft palates were observed in one of nine litters. In two other rat studies, however, no teratogenic effects were seen at a combined dose of 128 and 512 mg/kg, respectively. In some studies with pregnant rabbits, a trimethoprim dose 6 times the human therapeutic dose was associated with resorptions, fetal death, and malformations (21).

Trimethoprim (molecular weight about 290) crosses the placenta, producing similar levels in fetal and maternal serum and in amniotic fluid (22–25). Using an

in vitro perfused human cotyledon, both trimethoprim and sulfamethoxazole were shown to cross the placenta (25). After 1 hour in a closed system at maternal trimethoprim concentrations of 7.2 and 1.0 mcg/mL, concentrations on the fetal side were 1.4 (19%) and 0.08 mcg/mL (8%), respectively. Under similar conditions, maternal sulfamethoxazole levels of 29.6, 112.6, and 127.7 mcg/mL produced fetal levels of 5.1 (17%), 9.6 (9%), and 14.8 mcg/mL (12%). (Note: The mean steady state serum levels following 160 mg/800 mg trimethoprim–sulfamethoxazole orally twice daily are 1.72 and 68 mcg/mL, respectively [21].)

A 27-year-old woman consumed a low-calorie (Nutra System) diet 10 months before conception through the 4th gestational week (14). Her pregnancy was complicated by otitis, treated with a combination of trimethoprim–sulfamethoxazole for 10 days beginning in the 3rd week, and the onset of hyperemesis gravidarum at 5–6 weeks' gestation that lasted until the 8th month. Dimenhydrinate was taken intermittently as an antiemetic from the 7th week through the 8th month. She gave birth at 38 weeks' gestation to a 3225-g female infant with a lobar holoprosencephaly. The malformations included a median cleft lip and palate, a flat nose without nostrils, hypoplasia of the optic discs, and a single ventricle and midline fused thalami. The infant developed progressive hydrocephalus, myoclonic jerks, intractable seizures, and muscle tone that changed from hypotonic to hypertonic at 2 months of age. Although the critical period for development of holoprosencephaly was thought to be during the period of gastrulation (i.e., the 3rd week of pregnancy), the cause of the defects was unknown (14).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 2296 newborns had been exposed to the combination of trimethoprim–sulfamethoxazole during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 126 (5.5%) major birth defects were observed (98 expected). This incidence is suggestive of an association between the drug combination and congenital defects. Specific data were available for 6 defect categories, including (observed/expected) 37/23 cardiovascular defects, 3/4 oral clefts, 1/1 spina bifida, 7/7 polydactyly, 3/4 limb reduction defects, and 7/5 hypospadias. Only the cardiovascular defects are suggestive of an association among the six specific malformations, but other factors such as the mother's disease, concurrent drug use, and chance may be involved.

A 2000 case report described the adverse pregnancy outcomes, including NTDs, of two pregnant women with HIV infection who were treated with the

anti-infective combination, trimethoprim–sulfamethoxazole, for prophylaxis against *Pneumocystis carinii*, concurrently with antiretroviral agents (15). In the first case, a 32-year-old woman with a 3-year history of HIV and recent diagnosis of acquired immunodeficiency syndrome was treated before and throughout gestation with the anti-infective combination plus zidovudine and zalcitabine. Folic acid, 10 mg/day, was added after the diagnosis of pregnancy (gestational age not specified). At term, a female infant without HIV infection was delivered by cesarean section, but she had a bony mass in the lumbar spine (identified by ultrasound at 32 weeks' gestation). A diagnostic evaluation revealed that the second lumbar vertebra consisted of hemivertebrae and projected posteriorly into the spinal canal. A malformed and displaced first lumbar vertebra was also noted. Surgery was planned to correct the defect. The second case involved a 31-year-old woman who presented at 15 weeks' gestation. She was receiving trimethoprim–sulfamethoxazole, didanosine, stavudine, nevirapine, and vitamin B supplements (specific vitamins and dosage not given) that had been started before conception. A fetal ultrasound at 19 weeks' gestation revealed spina bifida and ventriculomegaly. The patient elected to terminate her pregnancy. The fetus did not have HIV infection. Defects observed at autopsy included ventriculomegaly, an Arnold-Chiari malformation, sacral spina bifida, and a lumbo-sacral meningocele. The authors attributed the NTDs in both cases to the antifolate activity of trimethoprim (15).

The effects of exposure (at any time during the 2nd or 3rd month after the last menstrual period) to folic acid antagonists on embryo–fetal development were evaluated in a large, multicenter, case–control surveillance study published in 2000 (16). The report was based on data collected between 1976 and 1998 by the Slone Epidemiology Unit Birth Defects Study from 80 maternity or tertiary care hospitals in Boston, Philadelphia, Toronto, and Iowa. Mothers were interviewed within 6 months of delivery about their use of drugs during pregnancy. Folic acid antagonists were categorized into two groups: group I—dihydrofolate reductase inhibitors (aminopterin, methotrexate, sulfasalazine, pyrimethamine, triamterene, and trimethoprim); group II—agents that affect other enzymes in folate metabolism, impair the absorption of folate, or increase the metabolic breakdown of folate (carbamazepine, phenytoin, primidone, and phenobarbital). The case subjects were 3870 infants with cardiovascular defects, 1962 with oral clefts, and 1100 with urinary tract malformations. Infants with defects associated with a syndrome were excluded, as were infants with coexisting NTDs (known to be reduced by maternal folic acid

supplementation). Too few infants with limb reduction defects were identified to be analyzed. Controls (N = 8387) were infants with malformations other than oral clefts and cardiovascular, urinary tract, and limb reduction defects and NTDs, but included infants with chromosomal and genetic defects. The risk of malformations in control infants would not have been reduced by vitamin supplementation, and none of the controls used folic acid antagonists (16). For group I cases, the relative risks (RRs) of cardiovascular defects and oral clefts were 3.4 (95% confidence interval [CI] 1.8–6.4) and 2.6 (95% CI 1.1–6.1), respectively. For group II cases, the RRs of cardiovascular and urinary tract defects, and oral clefts were 2.2 (95% CI 1.4–3.5), 2.5 (95% CI 1.2–5.0), and 2.5 (95% CI 1.5–4.2), respectively. Maternal use of multivitamin supplements with folic acid (typically 0.4 mg) reduced the risks in group I cases. For cardiovascular defects, the RR and 95% CI without or with folic acid were 7.7 (2.8–21.7) and 1.5 (0.6–3.8), respectively. The same comparison for oral clefts could not be completed because only three case infants were exposed to folic acid during the second and third month. However, there were six (0.3%) cases of oral clefts without folic acid and three (0.2%) with folic acid. In contrast, in group II cases, folic acid did not reduce the risks of cardiovascular defects, oral clefts, or urinary tract defects (16).

Additional data related to the above study appeared in a reply to correspondence (17). Analysis for trimethoprim exposure resulted in an RR of 4.2 (95% CI 1.5–11.5) for cardiovascular defects based on 12 cases. Additional analysis for oral clefts (three cases) and urinary tract defects (one case) was not conducted because of the small number of exposures (17).

A 2001 case–control study, using the same database as in the above study, compared data on 1242 infants with NTDs (spina bifida, anencephaly, and encephalocele) with a control group of 6660 infants with congenital defects not related to vitamin supplementation (18). Based on five exposed cases, the adjusted odds ratio (OR) for trimethoprim was 4.8, 95% CI 1.5–16.1. For all folic acid antagonists (carbamazepine, phenobarbital, phenytoin, primidone, sulfasalazine, triamterene, and trimethoprim), based on 27 cases, the adjusted OR was 2.9, 95% CI 1.7–4.6 (18).

A 2002 review, briefly citing the above two studies, stated that the results were consistent with previous studies that folic acid supplementation early in pregnancy reduces the risk of cardiac defects, oral clefts, and NTDs (19). However, additional studies are needed to determine if early folic acid supplementation would also reduce the risk of these anomalies from trimethoprim (19).

A 2001 case–control study used the population-based dataset of the Hungarian Case–Control Surveillance of Congenital Abnormalities, 1980–1996, to examine the teratogenic risk of trimethoprim in combination with either sulfamethoxazole or sulfamethazine (20). There were 22,865 case women who had delivered an infant with congenital malformations and 38,151 controls who had infants without malformations. In the cases and controls, 351 (1.5%) and 443 (1.2%) were treated with trimethoprim–sulfamethoxazole, respectively, in the 2nd/3rd months of pregnancy. For trimethoprim–sulfamethazine, 45 (0.2%) cases and 39 (0.1%) controls were treated, respectively, in the 2nd/3rd months of pregnancy. Because both combinations contained trimethoprim, the drugs were combined in the case–control pair analysis. Two congenital abnormalities had higher use of drug treatments: cardiovascular anomalies (29 vs. 10; adjusted OR 2.9, 95% CI 1.4–6.0) and multiple anomalies (mainly urinary tract and cardiovascular) (9 vs. 1; adjusted OR 9.0, 95% CI 1.1–71.0). For NTDs, analysis of trimethoprim–sulfamethoxazole in the 1st month revealed nine cases (adjusted OR 4.3, 95% CI 2.1–8.6) and seven cases in the 2nd/3rd months (adjusted OR 2.2, 95% CI 1.0–4.8) (20).

A case of Niikawa-Kuroki syndrome (i.e., Kabuki make-up syndrome) has been described in a non-Japanese girl whose mother had a viral and bacterial infection during the 2nd month of pregnancy (26). The bacterial infection was treated with trimethoprim–sulfamethoxazole. The syndrome is characterized by mental and growth restriction and craniofacial malformations (26). The cause of the defects in this patient, as in all cases of this syndrome, was unknown. Some have speculated, however, that the syndrome is caused by autosomal dominant inheritance (27).

Sulfonamide–trimethoprim combinations have been shown to cause a drop in the sperm count after 1 month of continuous treatment in males (28). Decreases varied between 7% and 88%. The authors theorized that trimethoprim deprived the spermatogenetic cells of active folate by inhibiting dihydrofolate reductase.

No interaction between trimethoprim–sulfamethoxazole and oral contraceptives was found in one study (29). Short courses of the anti-infective combination are unlikely to affect contraceptive control.

BREASTFEEDING SUMMARY

Trimethoprim is excreted into breast milk in low concentrations. Following 160 mg twice daily for 5 days, milk concentrations varied between 1.2 and 2.4 mcg/mL (average 1.8 mcg/mL) with peak levels occurring at 2–3 hours (30). No

adverse effects were reported in the infants. Nearly identical results were found in a study with 50 patients (31). Mean milk levels were 2.0 mcg/mL, representing a milk:plasma ratio of 1.25. The authors concluded that these levels represented a negligible risk to the suckling infant.

In a 1993 cohort study, diarrhea was reported in 32 (19.3%) nursing infants of 166 breastfeeding mothers who were taking antibiotics (32). For the 12 women taking trimethoprim–sulfamethoxazole, no diarrhea was observed in the infants but 2 (17%) had poor feeding, an effect that was considered minor because it did not require medical attention (32).

The American Academy of Pediatrics classifies the combination of trimethoprim–sulfamethoxazole as compatible with breastfeeding (33).

TRIMETREXATE

[Withdrawn from the market. See 9th edition.]

TRIMIPRAMINE

Antidepressant

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

The animal data suggest low risk but, if the comparison to the human dose had been based on BSA, the toxic dose would have been close to the human dose. The human data are too limited to assess the risk to the embryo–fetus. In general, though, most tricyclic antidepressants do not have a known teratogenic effect in humans (1). In addition, of the tricyclic antidepressants, nortriptyline and desipramine are preferred during pregnancy because they have the least sedative action and maternal adverse effects (1).

FETAL RISK SUMMARY

Trimipramine is a tricyclic antidepressant in the same class as amitriptyline, clomipramine, doxepin, and imipramine. It is indicated for the relief of symptoms of depression (2). Trimipramine has an elimination half-life of 9–11 hours and it is metabolized in the liver to an active metabolite (3).

Reproduction studies have been conducted in rats, rabbits, and mice. In rats and rabbits, evidence of embryotoxicity and/or increased incidence of major anomalies (type not specified) were observed at doses 20 times the human dose (2). A single SC dose given to mice on day 9 of gestation resulted in exencephaly and other defects of the central nervous system (4). In the isolated rat uterus, trimipramine had greater antihistamine H₂ activity than cimetidine, amitriptyline, or imipramine (5).

It is not known if trimipramine or its active metabolite crosses the human placenta. The molecular weight of the free base (about 294) and the long elimination half-life suggest that both compounds will cross to the embryo–fetus.

In a 1996 descriptive case series, the European Network of the Teratology

Information Services (ENTIS) prospectively examined the outcomes of 689 pregnancies exposed to antidepressants (6). Multiple drug therapy occurred in about two-thirds of the mothers. There were nine exposures to trimipramine. The outcomes of these pregnancies were eight normal newborns (including three premature infants) and one normal infant with a neonatal disorder (bilateral metatarsus varus [possibly positional]) (6).

BREASTFEEDING SUMMARY

No reports describing the use of trimipramine during human lactation have been located. The molecular weight of the free base (about 294) and the long elimination half-life (9–11 hours) suggest that both compounds will be excreted into milk. The effect of this exposure on a nursing infant is unknown. However, the American Academy of Pediatrics classifies other tricyclic antidepressants as drugs whose effect on the nursing infant is unknown but may be of concern (see Amitriptyline).

TRIPLENNAMINE

[Withdrawn from the market. See 9th edition.]

TRIPROLIDINE

Antihistamine

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

The human pregnancy experience with triprolidine suggests low risk. In general, antihistamines are considered low risk in pregnancy. However, exposure near birth of premature infants has been associated with an increased risk of retrolental fibroplasia.

FETAL RISK SUMMARY

Tripolidine is an antihistamine in the same class as brompheniramine, chlorpheniramine, and dexchlorpheniramine. The drug is used in a number of proprietary decongestant–antihistamine mixtures.

It is not known if triprolidine crosses the human placenta. The molecular weight (about 279 for the nonhydrated free base) suggests that exposure of the embryo–fetus should be expected.

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 16 of whom had 1st trimester exposure to triprolidine (1). From this small sample, no evidence was found to suggest a relationship to large categories of major or minor malformations or to individual malformations.

In a 1971 study, infants and mothers who had ingested antihistamines during the 1st trimester actually had fewer abnormalities when compared with controls (2). Tripolidine was the third most commonly used antihistamine. The manufacturer claims that in more than 20 years of marketing the drug, no reports of triprolidine teratogenicity have been received (M.F. Frosolono, personal communication, Burroughs Wellcome, 1980). Their animal studies have also been negative.

Two studies, one appearing in 1981 (3) and the second in 1985 (4), described the 1st trimester drug exposures of 6837 and 6509 mothers, respectively, treated by the Group Health Cooperative of Puget Sound and

whose pregnancies terminated in a live birth. Both studies covered 30-month periods, 1977–1979 and 1980–1982, respectively. From the total of 13,346 mothers, 628 (4.7%) consumed during the 1st trimester (based on the filling of a prescription) a proprietary product containing triprolidine and pseudoephedrine (Actifed). Nine (1.4%) of the exposed infants had a major congenital abnormality (type not specified). Spontaneous or induced abortions, stillbirths, and many minor anomalies, such as clubfoot, syndactyly, polydactyly, clinodactyly, minor ear defects, coronal or first-degree hypospadias, and hernia, were excluded from the data.

In two surveillance studies of Michigan Medicaid recipients involving 333,440 completed pregnancies conducted between 1980 and 1983, and 1985 and 1992, 910 newborns had been exposed to triprolidine during the 1st trimester (F. Rosa, personal communication, FDA, 1994). Of the 900 exposed newborns identified in the 1980–1983 group, 65 (7.2%) had major birth defects (59 expected), 10 of which were cardiovascular defects (8 expected). No cases of cleft lip and/or palate were observed. None of the 10 newborns included in the 1985–1992 data had congenital malformations.

BREASTFEEDING SUMMARY

Tripolidine is excreted into breast milk (5). Three mothers, who were nursing healthy infants, were given an antihistamine–decongestant preparation containing 2.5 mg of triprolidine and 60 mg of pseudoephedrine. The women had been nursing their infants for 14 weeks, 14 weeks, and 18 months, respectively. Tripolidine was found in the milk of all three subjects, with milk:plasma ratios in one woman at 1, 3, and 12 hours of 0.5, 1.2, and 0.7, respectively. Using AUCs in the other two women gave more reliable results of 0.56 and 0.50 (5). The authors calculated that a milk production of 1000 mL/24 hours would contain 0.001–0.004 mg of triprolidine base, or about 0.06%–0.2% of the maternal dose. The American Academy of Pediatrics classifies triprolidine as compatible with breastfeeding (6).

TROGLITAZONE

[Withdrawn from the market. See 9th edition.]

TROLEANDOMYCIN

[Withdrawn from the market. See 9th edition.]

TROSPIUM

Urinary Tract Agent (Antispasmodic)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of trospium in human pregnancy have been located. The drug caused fetal death in two animal species but maternal toxicity was also evident. There was no evidence of malformations or developmental delays in surviving offspring. Although the absence of human pregnancy experience prevents a full assessment of the embryo–fetal risk, there is no evidence that other parasympatholytics (e.g., see Atropine), in the absence of maternal toxicity, cause developmental toxicity. Until human experience is available, the safest course is to avoid trospium in pregnancy. However, if inadvertent exposure in pregnancy does occur, the embryo–fetal risk is probably low.

FETAL RISK SUMMARY

Trospium, a quaternary ammonium compound, is an antispasmodic, antimuscarinic agent indicated for the treatment of overactive bladder with symptoms or urge urinary incontinence, urgency, and urinary frequency. The drug has negligible affinity for nicotinic receptors compared with muscarinic receptors. Trospium is in the same subclass as darifenacin, flavoxate, oxybutynin, solifenacin, and tolterodine. A mean 9.6% of an oral dose is absorbed under fasting conditions, but when ingested with a high fat meal, this limited systemic bioavailability is reduced by 70%–80%. Protein binding in serum ranges from 50% to 85% at therapeutic concentrations. The plasma elimination half-life is about 20 hours (1).

Reproduction studies have been conducted in rats and rabbits. In rats, a dose producing exposure about 10 times the human exposure (HE) caused maternal toxicity and a decrease in fetal survival. However, no impaired fertility,

malformations, or developmental delays were observed. The no-effect levels for maternal and fetal toxicity were approximately equivalent to the HE. Neither malformations nor developmental delays were observed in pregnant rabbits. The no-effect levels for maternal and fetal toxicity were 5–6 times the HE. Trospium was not carcinogenic in long-term studies conducted in mice and rats and was not mutagenic in various assays (1).

It is not known if trospium crosses the human placenta. The molecular weight (about 428) and elimination half-life suggest that the drug will cross. However, trospium is a water-soluble quaternary ammonium compound that is ionized at physiologic pH. These characteristics should limit the amount of drug reaching the embryo–fetal compartment.

BREASTFEEDING SUMMARY

No reports describing the use of trospium during human lactation have been located. The molecular weight (about 428) and elimination half-life (about 20 hours) suggest that the drug will be excreted, especially into colostrum during the first 2–3 days after birth. Trospium is a water-soluble quaternary ammonium compound that is ionized at physiologic pH. This should limit the amount of drug reaching mature milk. Although neonates are particularly sensitive to anticholinergics, two other agents in this class (both tertiary amine compounds) are classified by the American Academy of Pediatrics as compatible with breastfeeding (see Atropine and Scopolamine). The effect of exposure to trospium on a nursing infant is unknown, but the risk of toxicity is probably low.

U

ULIPRISTAL

Emergency Contraceptive

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of ulipristal in human pregnancy have been located. As an emergency contraceptive, the main action is delaying or inhibiting ovulation (1–5). Animal studies suggest that pregnancy loss is a risk, but the absence of human pregnancy experience prevents a more complete assessment of this effect. The drug is contraindicated in pregnancy.

FETAL RISK SUMMARY

Ulipristal is an oral selective progesterone receptor modulator with potent antagonist/partial agonist properties that is used as an emergency contraceptive. It is indicated for prevention of pregnancy within 120 hours (5 days) after unprotected intercourse or a known or suspected contraceptive failure. The pharmacodynamic effects of ulipristal depend on the phase of the menstrual cycle when it is administered. Administration in the mid-follicular phase results in the inhibition of folliculogenesis and a reduction in estradiol concentration. When given at the time of the luteinizing hormone peak, follicular rupture is delayed by 5–9 days. Dosing in the early luteal phase does not significantly delay endometrial maturation but does decrease endometrial thickness, thereby interfering with implantation. Ulipristal is metabolized to its active metabolite, monodemethyl-ulipristal. Ulipristal is highly bound (>94%) to plasma proteins, including lipoproteins, α -1-acid glycoprotein, and albumin. The terminal half-lives of ulipristal and monodemethyl-ulipristal are about 32 and 27 hours, respectively (1).

Reproduction studies have been conducted in rats, rabbits, and monkeys. In rats and rabbits, doses during organogenesis at daily exposures that were 0.33 and 0.5 times, respectively, the human exposure based on BSA (HE-BSA) resulted in embryo–fetal loss in all of the pregnant rats and in half of the pregnant rabbits. No malformations were noted in the surviving fetuses. Adverse effects were not observed in rat offspring when the dose was about 0.04 times the HE based on AUC during organogenesis through lactation. In pregnant monkeys, daily doses for 4 days during the 1st trimester that were about 4 times the HE-BSA caused pregnancy termination in two of five animals (1).

Carcinogenicity studies have not been conducted with ulipristal. The drug was not genotoxic in multiple assays. In rats, single doses at 2 times the HE-BSA prevented ovulation in 50% of the animals. When given on postcoital days 4 or 5, single doses that were 4–12 times the HE-BSA prevented pregnancy in 80%–100% of the rats. Similar doses in rabbits on postcoital days 5 or 6 prevented pregnancy in 50% of the animals. Lower doses for 4 days in rats and rabbits were also effective in preventing ovulation and pregnancy (1).

It is not known if ulipristal or its active metabolite crosses the human placenta. The molecular weights (about 476 for ulipristal acetate; lower for the active metabolite) and the long elimination half-lives of both agents suggest that they will cross to the embryo–fetus, but the high plasma protein binding may limit the exposure.

BREASTFEEDING SUMMARY

No reports describing the use of ulipristal during human lactation have been located. The molecular weights (about 476 for ulipristal acetate; lower for the active metabolite) and the long elimination half-lives (32 and 27 hours) of the parent drug and active metabolite suggest that both will be excreted into breast milk, but the high plasma protein binding may limit the amount excreted. The effect on a nursing infant from short-term exposure to a potent progesterone antagonist/partial agonist is unknown. However, not breastfeeding is the best course.

UREA

Diuretic

PREGNANCY RECOMMENDATION: No Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Urea is an osmotic diuretic that is used primarily to treat cerebral edema. Topical formulations for skin disorders are also available. No reports of its use in pregnancy following IV, oral, or topical administration have been located. Urea, given by intra-amniotic injection, has been used for the induction of abortion (1).

BREASTFEEDING SUMMARY

No reports describing the use of urea during human lactation have been located.

UROKINASE

Thrombolytic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The use of urokinase during pregnancy does not appear to represent a major risk to the fetus. The drug is not fetotoxic or teratogenic in rodents. However, only two human cases treated with this thrombolytic agent during the 1st trimester (one at 14 weeks and the other at 3 months) have been reported. It is not known whether the drug crosses the placenta to the fetus, but placental tissue contains proteinase inhibitors that inactivate urokinase (1,2). Placental separation and hemorrhage is a potential complication and has been reported in one case.

FETAL RISK SUMMARY

Urokinase, 100,000 IU/kg intraperitoneal, was not teratogenic in rats or mice (3). The manufacturer cites studies in which doses up to 1000 times the human dose did not impair fertility or produce fetal harm in rats and mice (4). Six reports of its use in human pregnancy have been located.

A woman at 28 weeks' gestation was treated with urokinase, 4400 IU/kg for 10 minutes followed by 4400 IU/kg/hr for 12 hours, for pulmonary embolism (5). Heparin therapy was then administered, first IV and then SC, for the remainder of the pregnancy. A healthy term infant was delivered 2 months after initiation of therapy (5).

A 1995 review briefly cited two reports of patients treated with urokinase, apparently without fetal or neonatal complications, for thrombosed prosthetic heart valves (6). A 36-year-old woman was treated at 14 and 32 weeks' gestation and had an uncomplicated cesarean delivery at 34 weeks (6,7). The other patient, a 32-year-old woman, was treated twice with different thrombolytics: first at 3 months' gestation with urokinase and second at 6

months' gestation with streptokinase (6,8). Minor uterine hemorrhage because of placental separation occurred at 3 months and a cesarean section was performed at 7 months' gestation. Maternal transfusion and surgical drainage were required following the delivery.

A 27-year-old woman in premature labor developed a massive pulmonary embolism at 31 weeks' gestation (9). She was initially treated with a bolus dose of urokinase (200,000 IU) and heparin. Dobutamine was also administered to maintain a stable hemodynamic state. Because her condition continued to deteriorate, she was treated with low-dose alteplase with eventual successful resolution of the embolism. A healthy preterm 2100-g male infant was delivered about 3 days after urokinase administration (9).

A 1994 report described a woman at 26 weeks' gestation who suffered a myocardial infarction (10). Following stabilization, she underwent cardiac catheterization 9 days after the initial infarction, which revealed 90% occlusion of the proximal right coronary artery and mild narrowing of other cardiac arteries. A prolonged intracoronary infusion of urokinase, in preparation for a planned angioplasty, failed to improve the right coronary occlusion, and coronary stents were subsequently placed. A healthy female infant was eventually delivered at 39 weeks (10).

The treatment of massive pulmonary embolism, diagnosed in a 20-year-old woman at 21 weeks' gestation, with urokinase and heparin was described in a 1995 case report (11). The patient markedly improved after receiving two courses of urokinase, 4400 IU/kg for 10 minutes followed by 4400 IU/kg/hr continuous infusion for 12 hours, approximately 6 hours apart, followed by continuous heparin. No complications of therapy were observed in the fetus, and she eventually delivered a healthy 3122-g male infant at term (11).

BREASTFEEDING SUMMARY

No reports describing the use of urokinase during lactation have been located. Because of the nature of the indications for urokinase and its very short half-life (≤ 20 minutes), the opportunities for its use during lactation and the potential exposure of the nursing infant are minimal.

URSODIOL

Gastrointestinal Agent (Gallstone Solubilizing Agent)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Ursodiol is effective in the treatment of intrahepatic cholestasis of pregnancy and its use for this purpose appears to be low risk for the fetus. Studies have shown a significant decrease in maternal morbidity and fetal mortality. No explanation could be found for the case of stillbirth, but these outcomes in untreated cholestasis have been reported.

FETAL RISK SUMMARY

Ursodiol (ursodeoxycholic acid) is a naturally occurring bile acid used orally to dissolve gallstones. The drug has been used for the treatment of intrahepatic cholestasis of pregnancy.

No fetal adverse effects were observed when ursodiol (up to 200 mg/kg/day) was fed to pregnant rats (1). Embryotoxicity was observed in another rat study, but this was less than with another closely related bile acid, chenodiol, and no evidence of hepatotoxicity was observed at three dose levels (2). Reproduction studies in rats with doses up to 22 times the recommended maximum human dose based on BSA (RMHD) and in rabbits with doses up to 7 times the RMHD revealed no evidence of impaired fertility or fetal harm (3).

Ursodiol is absorbed from the small intestine and is extracted and conjugated by the liver. Although 30%–50% of a dose may enter the systemic circulation, continuous hepatic uptake keeps ursodiol blood levels low and uptake by tissues other than the liver is considered nil (4). These factors combined with tight binding to albumin probably indicate that placental passage to the fetus does not occur.

During clinical trials, inadvertent exposure during the 1st trimester to therapeutic doses of ursodiol in four women had no effect on their fetuses or newborns (3). Several reports, summarized below, described the apparent

safe use of ursodiol in the latter portion of human pregnancy for the treatment of intrahepatic cholestasis.

A brief 1991 report described the use of ursodiol in the treatment of late-onset intrahepatic cholestasis during pregnancy (5). A 30-year-old primigravida was given ursodiol 600 mg/day in two divided doses for 20 days starting at 34 weeks' gestation. No signs of fetal distress were observed during treatment. Labor was induced at 37 weeks' gestation and a healthy 2670-g female infant was delivered with Apgar scores of 9 and 10 at 1 and 5 minutes, respectively (5).

A second report, published in 1992, briefly described the successful outcome of eight pregnant women with intrahepatic cholestasis treated with ursodiol, 1 g/day for 3 weeks (6). The full report of this study was also published in 1992 (7). Treatment began after 25 weeks' gestation in the eight women, five receiving 1 g/day in divided dose for 20 consecutive days and the other three receiving the same dose for two 20-day treatment courses, separated by a 14-day drug-free interval (7). The mean dose was 14 mg/kg/day (range 12–17 mg/kg/day). All of the newborns had Apgar scores >7 at 1 and 5 minutes and all were progressing normally at a 5-month follow-up (7).

A 1994 report described the use of ursodiol, 450 mg/day, in three pregnancies (singleton, twin, and quintuplet) for intrahepatic cholestasis (8). Ursodiol was started because of unsuccessful attempts to control the disease with cholestyramine or ademetionine (S-adenosyl-L-methionine [SAME]). The singleton pregnancy was treated from 29 weeks' gestation to delivery at 37 weeks' gestation, the twin pregnancy from 27 to 33 weeks' gestation, and the woman with quintuplets from 21 weeks' gestation to delivery at 30 weeks' gestation. No adverse effects were observed in the eight newborns (8).

A significant reduction in the perinatal mortality and morbidity associated with cholestasis of pregnancy following the use of ursodiol was described in a study published in 1995 (9). Eight women with a history of 13 pregnancies affected by the disease were referred to a specialty clinic before conception. Expectant management had been used in 12 of the 13 pregnancies, with 11 experiencing adverse outcomes: 8 stillbirths, 2 premature deliveries with 1 death in the perinatal period, and 1 emergency cesarean section for fetal distress. Subsequently, three of the women became pregnant again and each suffered a recurrence of cholestasis. Therapy with ursodiol, 750 mg/day in two and 1000 mg/day in one, was initiated at 31, 33, and 37 weeks' gestation, respectively. The first patient had been pretreated with ademetionine from 16 to 31 weeks in an unsuccessful attempt to prevent cholestasis. Each of the three women

showed rapid clinical improvement and resolution of abnormal liver tests following initiation of ursodiol. Normal infants, who were doing well, were delivered at 35, 35, and 38 weeks, respectively (9).

A double-blind, placebo-controlled trial in women with intrahepatic cholestasis of pregnancy compared the effect of ursodiol treatment (N = 8) with placebo (N = 8) (10). Significant decreases in the pruritus score and all liver biochemical parameters occurred in the ursodiol group, but only the pruritus score and alanine aminotransferase were significantly improved in controls. Moreover, the gestational age at delivery in the treated group was 38 weeks compared with 34 weeks in controls ($p < 0.01$), resulting in higher mean birth weights (2935 vs. 2025 g). Apgar scores were also higher in the treated group. Fetal distress was observed in four of the control pregnancies (none in the study group) and these were delivered by cesarean section. In the treated group, six of the eight newborns were delivered vaginally. At a 5-month follow-up, all infants were developing normally (10). A number of other reports have found that ursodiol is safe and effective for the treatment of cholestasis of pregnancy (11–15).

A 2006 case report described a woman at 28 weeks' gestation who presented with intrahepatic cholestasis of pregnancy (16). She was initially treated with cholestyramine and then changed to two separate courses of ursodiol with resulting decreased transaminases and bile acids. Although the patient's course was followed closely, death of a 3400-g female fetus occurred at 39 3/7 weeks. At autopsy, meconium was noted in the bronchioles and alveoli, but no other abnormalities were found. The cause of the fetal death was unknown (16).

BREASTFEEDING SUMMARY

No reports have been located that described the use of ursodiol during lactation. Because only small amounts of ursodiol appear in the systemic circulation, which are tightly bound to albumin, it is doubtful that clinically significant amounts are excreted into breast milk.

USTEKINUMAB

Immunologic Agent (Immunomodulator)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No published reports describing the use of ustekinumab in human pregnancy have been located. Thirteen pregnancies (protocol deviations) were identified during clinical studies, but specific details of the outcomes are very limited. Although the animal data suggest low risk, the limited human pregnancy experience prevents a more complete assessment of the embryo–fetal risk.

FETAL RISK SUMMARY

Ustekinumab is a human immunoglobulin G_{1k} (IgG_{1k}) monoclonal antibody against the P40 subunit of the interleukin (IL)-12 and IL-23 cytokines. It is given as an SC injection that is repeated at 4 weeks and then every 12 weeks. There are no other agents in this subclass. Ustekinumab is indicated for the treatment of patients with moderate to severe plaque psoriasis who are candidates for phototherapy or systemic therapy. Although the metabolism has not been fully characterized, the antibody is expected to be degraded into small peptides and amino acids similar to endogenous IgG. The mean half-life is about 15–46 days, but ranges are very long (1).

Reproduction studies were conducted in pregnant monkeys with doses up to 45 times the human dose based on body weight (HD) given either SC twice weekly or IV once weekly during organogenesis. No significant adverse developmental effects were observed. In a separate study, monkeys were given SC doses twice weekly up to 45 times the HD from the beginning of organogenesis to day 33 after delivery. In dams, there were no treatment-related effects on mortality, clinical signs, body weight, food consumption, hematology, or serum biochemistry. There were two neonatal deaths: one at

22.5 times the HD and one at 45 times the HD. No drug-related abnormalities were observed in the offspring from birth through 6 months of age in clinical signs, body weight, hematology, serum biochemistry, functional development before and after weaning, morphologic and immunologic development, and gross and histopathologic examinations (1).

Studies evaluating the carcinogenic or mutagenic potential of ustekinumab have not been conducted. However, in mice, inhibition of IL-12/IL-23p40 increased the risk of malignancy, but the relevance of these findings for malignancy risk in humans is unknown. The antibody did not cause toxicity or affect fertility parameters in male monkeys. An analogous antibody did not cause toxicity or affect fertility parameters in female mice that were given SC doses of the agent twice weekly beginning 15 days before cohabitation and continuing through gestational day 7 (1).

It is not known if ustekinumab crosses the human placenta before term. The molecular weight (range 148,079–149,690) is high, but IgG crosses the placenta late in pregnancy (see Immune Globulin Intravenous). Placental transfer of IgG was a function of dose, as well as gestational age. Moreover, the long half-life will place the protein at the maternal–fetal interface for prolonged periods. In unpublished data, ustekinumab crossed the placenta at the time of cesarean section (2).

During clinical studies, 30 pregnancies occurred (protocol deviations), 13 involved exposures in pregnant women and 17 were the result of paternal exposure (2). The drug was discontinued at the time of pregnancy diagnosis in all women. The outcome of the 13 cases were 2 live births with no defect or other adverse effect, 1 spontaneous abortion (SAB), 5 elective abortions (EABs) (all within 12 weeks of pregnancy), 3 ongoing pregnancies, and 2 unknown outcomes. The SAB occurred at 12 weeks' in a 42-year-old woman. No information was available on the presence or absence of fetal abnormalities in the EABs (2).

BREASTFEEDING SUMMARY

No reports describing the use of ustekinumab during human lactation have been located. The molecular weight (range 148,079–149,690) is high, but immunoglobulins and other large proteins are excreted into colostrum during the first 48 hours after birth. Moreover, the long half-life (15–46 days) will assure that the antibody is in the maternal plasma for long periods. In addition, ustekinumab is excreted into the milk of lactating monkeys (1). These data suggest that the antibody will be excreted into breast milk. The effect of this

exposure on a nursing infant is unknown, but there may be an increased risk of infections and malignancies.

V

VACCINE, ADENOVIRUS TYPE 4 AND TYPE 7, LIVE

Vaccine

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No apparent embryo or fetal harm was observed in four pregnancies inadvertently exposed to the vaccine. However, because naturally occurring infections with adenoviruses have been associated with fetal harm, the vaccine is contraindicated in pregnancy. Animal reproduction studies have not been conducted. If a pregnant woman receives the vaccine or becomes pregnant within 6 weeks following vaccination, clinicians are encouraged to report the exposure to the Adenovirus Pregnancy Registry by calling 1-866-790-4549 (1).

FETAL RISK SUMMARY

Adenovirus Type 4 and Type 7 vaccine, live, consists of nonattenuated, selected strains of human adenovirus Type 4 and human adenovirus Type 7. The vaccine is given as a single oral dose of two enteric coated tablets, one containing adenovirus Type 4 and the other adenovirus Type 7. The tablets are designed to pass intact through the stomach and release the live virus in the intestine. The vaccine is indicated for active immunization for the prevention of febrile acute respiratory disease caused by the two types of virus and is approved for use in military populations 17 through 50 years of age. Virus shedding in the stool following vaccination occurs over 28 days (1).

Animal studies for effects on reproduction and fertility have not been

conducted, nor have studies for carcinogenicity or mutagenicity (1).

The manufacturer reported the pregnancy outcomes of four women enrolled in clinical trials who were given the vaccine. In three cases, the subjects were estimated to have conceived 2–13 days before vaccination, whereas the fourth subject conceived about 21 weeks after vaccination. In all four cases, healthy infants were born at estimated gestational ages of 36–40 weeks (1).

The effects of fetal infection with adenovirus were described in two case reports (2,3). In the first case, a 26-year-old woman presented at 29 weeks' gestation with a 1-week history of pedal and facial edema and polyhydramnios (2). Two weeks earlier, the woman had an upper respiratory tract infection characterized by low grade fever, conjunctivitis, rhinorrhea, and general malaise. At presentation, the fetal heart rate was 140–200 beats/minute. An ultrasound examination revealed fetal anasarca, massive ascites, scalp and skin edema, and pericardial and pleural effusions secondary to myocarditis presenting as nonimmune hydrops fetalis. A 2670-g female infant was born at 34 weeks' with an Apgar scores of 4 and 8 at 1 and 5 minutes, respectively. The infant had poor respiratory function and low heart rate that improved with treatment, scattered facial and truncal petechiae, periorbital edema, prominent right ventricular impulse without murmur, and hepatomegaly. An infection with adenovirus type 2 was diagnosed by polymerase chain reaction (PCR). The infant was discharged home at 2 weeks of age and was doing well 8 months later (2). The second case involved a 25-year-old woman with twins at 20 weeks' gestation (3). An ultrasound screen had noted hydrops fetalis in twin B. The mother had experienced upper airway congestion, myalgias, and malaise beginning 2 weeks before the screen. PCR analysis of the amniotic fluid revealed adenovirus (type not specified) in twin B but not in twin A. Polyhydramnios developed in twin B at 24 weeks'. Intrauterine fetal death of both twins occurred at 26 weeks'. Twin A weighed 615 g and twin B weighed 1685 g. No congenital anomalies were noted at autopsy (3).

BREASTFEEDING SUMMARY

No reports describing the exposure to the vaccine during lactation have been located. The live, nonattenuated viruses are shed in the stool over 28 days. The potential for febrile respiratory disease in a nursing infant from exposure is unknown. Nevertheless, the safest course is to avoid the vaccine during breastfeeding and for at least 28 days after vaccination.

VACCINE, ANTHRAX

Vaccine

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Although animal reproduction studies with anthrax vaccine adsorbed (AVA) have not been conducted, there appears to be no plausible biological mechanism for adverse pregnancy effects. Because of the absence of human pregnancy experience, however, the use of AVA during gestation is not recommended. The human reproduction data, limited to vaccination before conception, do not appear to suggest a risk from vaccination to either a woman's subsequent fertility or a subsequent pregnancy outcome. However, the published study cited below lacked sufficient power to detect adverse birth outcomes (1). Until more data are available, the recommendation made by the CDC in 2000 and 2008 (2,3) that "pregnant women should be vaccinated against anthrax only if the potential benefits outweigh the potential risks to the fetus" is still relevant.

FETAL RISK SUMMARY

Anthrax vaccine adsorbed is prepared from a cell-free, noninfectious filtrate of *Bacillus anthracis* that contains a mix of cellular products adsorbed to aluminum hydroxide (2). This vaccine has replaced a previously available alum-precipitated vaccine. An avirulent, nonencapsulated strain (V770-NP10R) of *B. anthracis* is used in the production of the vaccine, which contains no dead or live bacteria (1,2). The cellular products in the vaccine include, in unknown amounts, three proteins known as protective antigen (PA), lethal factor (LF), and edema factor (EF). Live *B. anthracis* forms combinations of these proteins resulting in two exotoxins known as lethal toxin (PA and LF) and edema toxin (PA and EF). The recommended vaccination schedule is 0.5 mL at 0, 2, and 4 weeks; three booster vaccinations at 6, 12, and 18 months; and then an annual booster injection (2).

Reproduction studies with anthrax vaccine have not been conducted in

animals (4). However, no plausible biological mechanism for an adverse effect on an embryo or fetus has been proposed (1).

The placental transfer of the three proteins contained in the vaccine has not been studied. Because of the very high molecular weight, simple diffusion does not appear to be possible for transfer.

Only one study has been located that examined the effects of anthrax vaccine, administered before conception, on pregnancy outcome (1). Women, aged 17–44 years, assigned to two U.S. Army installations formed the study population. During the study period from January 1999 to March 2000, 3136 women received at least one dose of the vaccine (most received two or three doses), whereas 962 women were not vaccinated. Departure from the study sites was the most common reason for not receiving the vaccine. The only acceptable medical indications to defer or refuse the vaccine were pregnancy or immunity-compromising disease. There were 385 pregnancies after at least one dose of the vaccine. The annualized pregnancy rates in those vaccinated and not vaccinated were 159.5 and 160.0 per 1000 person-years, respectively. These rates were nearly identical to the pregnancy rates before the study. Compared with unvaccinated women, vaccinated women were 1.2 times as likely to give birth (95% confidence interval [CI] 0.8–1.8). Adjustment for marital status, race, and age did not change the odds ratio (OR). A total of 327 births (vaccinated and unvaccinated) were available for outcome analysis. Low birth weight (<2500 g) occurred in 11 cases (3.4%). After adjustment, the OR for vaccination and low birth weight was 1.3, 95% CI 0.2–6.4. Congenital malformations (specific details not provided) were observed in 15 cases, but no unusual patterns or clusters were noted. Only one malformation (polydactyly of the fingers) had multiple occurrences (three cases: two vaccinated, one unvaccinated). After adjustment, the OR for vaccination and structural anomalies was 0.7, 95% CI 0.2–2.3. The adjusted OR for vaccination and any adverse birth outcome was 0.9, 95% CI 0.4–2.4 (1).

BREASTFEEDING SUMMARY

No reports describing the use of anthrax vaccine in lactating women have been located. Because of the nature of anthrax vaccine, the potential for adverse effects in a nursing infant appear to be nil. The CDC states that there is no evidence to suggest a risk to the mother or nursing infant, and the administration of the vaccine during breastfeeding is not medically contraindicated (2,3).

VACCINE, BCG

Vaccine

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably
Compatible

PREGNANCY SUMMARY

BCG vaccine is a live, attenuated bacteria vaccine used to provide immunity to tuberculosis (1). Animal reproduction studies have not been conducted with the vaccine. The risk to the fetus from maternal vaccination is unknown. Because it is a live preparation, the CDC recommends that it not be used in pregnancy (2).

BREASTFEEDING SUMMARY

No reports describing the use of BCG vaccine in human lactation have been located. However, there does not appear to be any risk to a nursing infant if the mother receives the vaccine (2).

VACCINE, CHOLERA

Vaccine

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Cholera vaccine is a killed bacteria vaccine (1). Cholera during pregnancy may result in significant morbidity and mortality to the mother and the fetus, particularly during the 3rd trimester. The risk to the fetus from maternal vaccination is unknown because there is no specific information on the safety of the vaccine during pregnancy (2).

BREASTFEEDING SUMMARY

Maternal vaccination with cholera vaccine has increased specific IgA antibody titers in breast milk (3). In a second study, cholera vaccine (whole cell plus toxoid) was administered to six lactating mothers, resulting in a significant rise in milk anticholera toxin IgA titers in five of the patients (4). Milk from three of these five mothers also had a significant increase in anti-cholera toxin IgG titers.

VACCINE, ESCHERICHIA COLI

Vaccine

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Escherichia coli (E. coli) vaccine is a nonpathogenic strain of bacteria used experimentally as a vaccine. Two reports of its use (strains O111 and 083) in pregnant women in labor or waiting for the onset of labor have been located (1,2). The vaccines were given to these patients in an attempt to produce antimicrobial activity in their colostrum. No adverse effects in the newborns were noted.

BREASTFEEDING SUMMARY

Escherichia coli (E. coli strains O111 and 083) vaccines were given to mothers in labor or waiting for the onset of labor (1,2). Antibodies against E. coli were found in the colostrum of 7 of 47 (strain 0111) and 3 of 3 (strain 083) treated mothers but in only 1 of 101 controls. No adverse effects were noted in the nursing infants.

VACCINE, GROUP B STREPTOCOCCAL

Vaccine

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Group B Streptococcus (GBS) capsular polysaccharides (CPS) vaccine has been used in pregnancy in an attempt to prevent infection in the newborn (1). The vaccine is considered safe in pregnancy.

FETAL RISK SUMMARY

Forty women at a mean gestational age of 31 weeks (range 26–36 weeks) were administered a single 50-mcg dose of type III CPS of GBS (1). No adverse effects were observed in the 40 newborns. The overall response rate to the vaccine, which is not commercially available, was 63%. Of the 25 infants born to mothers who had responded to the vaccine, at 1 and 3 months of age, 80% and 64%, respectively, continued to have protective levels of antibody (1). Although the vaccine is considered safe (2), as are other bacterial vaccines (3), the clinical effectiveness of the vaccine has not been determined and its use remains controversial (4–7).

In an attempt to improve on the immunogenic response in adults, researchers designed a GBS type III CPS–tetanus toxoid conjugate vaccine (8). Although administered to nonpregnant women, vaccination with the CPS–protein conjugate preparation resulted in enhanced immunogenicity compared with uncoupled vaccine. Although the results are encouraging, it is not known at the present time whether this vaccine will produce a similar response in pregnant women or whether it will prevent perinatal infection.

BREASTFEEDING SUMMARY

Although there are no reports describing the use of Group B streptococcal vaccine during lactation, the agent should represent no risk to a nursing infant.

VACCINE, HAEMOPHILUS B CONJUGATE

Vaccine

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Commercially available Haemophilus b conjugate vaccine is a combination of the capsular polysaccharides or oligosaccharides purified from Haemophilus influenzae type b bound with various proteins including tetanus toxoid, diphtheria toxoid, meningococcal protein, or diphtheria CRM₁₉₇ (1). The human pregnancy experience is very limited, but the vaccine is probably compatible in pregnancy.

FETAL RISK SUMMARY

Two reports (2,3) and a review (4) have described the maternal immunization with the capsular polysaccharide vaccine of H. influenzae type b during the 3rd trimester of pregnancy to achieve passive immunity in the fetus and newborn. No adverse effects were observed in the newborns.

BREASTFEEDING SUMMARY

Women who were vaccinated with Haemophilus b conjugate vaccine at 34–36 weeks' gestation had significantly higher antibody titers (>20 times) in their colostrum than either nonimmunized women or those who were vaccinated before pregnancy (5). Breast milk antibody titers were also significantly higher (>20 times) than the comparison groups at 3 and 6 months after delivery.

VACCINE, HEPATITIS A

Vaccine

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Hepatitis A virus vaccine inactivated is a noninfectious vaccine (1,2). No reports describing the use of the vaccine in pregnant humans have been located, but based on similar vaccines, the risk to the fetus from maternal vaccination appears to be minimal.

FETAL RISK SUMMARY

Animal reproduction studies have not been conducted with the vaccine.

The CDC considers the theoretical risk to the developing fetus to be low (3,4). The CDC and others state that hepatitis A vaccine can be given to pregnant women at high risk of exposure (3–5).

BREASTFEEDING SUMMARY

No data are available, but based on other inactivated viral vaccines, hepatitis A vaccine does not appear to be contraindicated during nursing.

VACCINE, HEPATITIS B

Vaccine

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Hepatitis B virus vaccine inactivated (recombinant) is a noninfectious surface antigen (HBsAg) vaccine. Animal reproduction studies have not been conducted with the vaccine. No risks to the fetus from maternal vaccination have been reported (1,2).

FETAL RISK SUMMARY

One source recommends administration after the 1st trimester, because of a theoretical risk of teratogenicity (3). However, the CDC states that there is no apparent risk of fetal adverse effects (based on unpublished CDC data) and that pregnancy is not a contraindication to vaccination in women (1,2). Preexposure and postexposure prophylaxis is indicated in pregnant women at high risk of infection (2,4) (see also Immune Globulin, Hepatitis B).

BREASTFEEDING SUMMARY

No data are available, but the vaccine can be used during lactation (1).

VACCINE, HUMAN PAPILOMAVIRUS BIVALENT (TYPES 16 AND 18), RECOMBINANT

Vaccine

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Animal studies in one species found no evidence of reproductive or developmental toxicity at doses based on body weight that were much higher than those used in humans (1). The human experience supports the lack of embryo–fetal toxicity from vaccination received around the time of conception. Moreover, the vaccine is noninfectious and preservative free. As of 2010, the CDC recommends avoiding the vaccine in pregnant women (2). If the vaccine is given in pregnancy, health care professionals are encouraged to call the toll-free number 877-311-8972 for information about patient enrollment in the Organization of Teratology Information Specialists (OTIS) study.

FETAL RISK SUMMARY

Human papillomavirus bivalent (HPV-B) is a noninfectious, recombinant, AS04-adjuvanted vaccine that contains the major antigenic protein of the capsid of HPV types 16 and 18. It contains no preservatives. HPV-B is indicated for the prevention of the following diseases caused by oncogenic HPV types 16 and 18: cervical cancer, cervical intraepithelial neoplasia (CIN) grade 2 or worse and adenocarcinoma in situ, and CIN grade 1. It is approved for use in females 10 through 25 years of age. It is administered as an IM injection (1).

Reproduction studies have been conducted in rats. Doses that were about 47 times the human dose based on body weight revealed no evidence of impaired fertility or fetal harm. When given before conception and during organogenesis, no adverse effects on mating, fertility, pregnancy, parturition, lactation, or prenatal or postnatal development were observed. The vaccine did not cause

teratogenicity. The vaccine has not been evaluated for carcinogenic or mutagenic potential (1).

In clinical studies, pregnancy was excluded before administration of each dose of the vaccine and patients were instructed to avoid pregnancy until 2 months after the last vaccination (1). Before licensure, 7276 pregnancies were reported among 3696 women who had received the vaccine and 3580 women who had received the control dose (hepatitis A vaccine or placebo). The pregnancy outcomes for the subjects and controls were similar in terms of normal infants, spontaneous abortions (SABs), elective abortions, abnormal infants other than congenital anomaly, and premature birth. There also were no differences between the groups in the rate of congenital anomaly, stillbirth, and ectopic pregnancy. In a sub-analysis, the pregnancy outcomes were examined in 761 women (396 subjects and 365 controls) who had their last menstrual period within 30 days before, or 45 days after a vaccine dose. The same outcomes noted above were again similar, but more SABs had occurred in subjects (13.6% vs. 9.6%). It was not known if the increased numbers of SABs was a vaccine-related effect (1).

A 2010 study examined the possible association of HPV-B vaccine with SABs (3). Women who received three doses of the vaccine (N = 13,075) were compared with controls given hepatitis A vaccine (N = 13,055). The estimated rate of SABs in the two groups was 11.5% and 10.2%, respectively. In secondary descriptive analyses of pregnancies that began within 3 months of the latest vaccination, the SAB rates were 14.7% and 9.1%. The authors concluded that there was no evidence for an association between HPV-B and SAB (3).

BREASTFEEDING SUMMARY

It is not known if anti-HPV-16 and anti-HPV-18 antibodies are excreted into breast milk (1). If they are, the effect on a nursing infant is unknown. However, based on the human experience with the quadrivalent vaccine, the bivalent vaccine is probably compatible with breastfeeding.

VACCINE, HUMAN PAPILOMAVIRUS QUADRIVALENT, RECOMBINANT

Vaccine

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Animal studies in one species found no evidence of reproductive or developmental toxicity at doses, based on body weight, that were much higher than those used in humans. The human pregnancy experience supports the lack of toxicity for the embryo and/or fetus. Moreover, the vaccine is noninfectious and preservative- and antibiotic-free. If the vaccine is given in pregnancy, health care professionals are encouraged to call the toll-free number 877-311-8972 for information about patient enrollment in the Organization of Teratology Information Specialists (OTIS) study.

FETAL RISK SUMMARY

Human papillomavirus (HPV) quadrivalent vaccine is prepared by recombinant technology to contain virus-like particles of the major capsid protein of HPV types 6, 11, 16, and 18. It is administered as an IM injection. The vaccine is not infectious and does not contain preservatives or antibiotics. HPV vaccine is indicated in girls and women 9–26 years of age for prevention of the following diseases caused by HPV: cervical cancer, genital warts (condyloma acuminata), cervical adenocarcinoma in situ, and intraepithelial neoplasia of the cervix (grades 1, 2 and 3), vulva (grades 2 and 3), and vagina (grades 2 and 3) (1).

Reproduction studies have been conducted in rats. In pregnant rats, doses up to 300 times the human dose revealed no effects on fertility, pregnancy, parturition, lactation, or embryo or fetal pre- or postweaning development. No vaccine-related structural malformations were observed. In addition, there were no effects on the development, behavior, reproductive performance, or fertility of the offspring (1).

In the third annual report from the Merck Pregnancy Registry covering the period June 2006–May 2009, there were 1636 prospective reported pregnancies, but 396 were lost to follow-up and 132 outcomes were pending. Of the remaining 1108 pregnancies, there were 968 live births (974 newborns includes 1 surviving twin), 64 spontaneous abortions (SABs), 65 elective abortions (EABs), 10 fetal deaths (1 of twins), and 2 ectopic pregnancies (2). The reasons for the EABs were usually unknown, but one termination involved a fetus with anencephaly and a hypoplastic heart defect. Of the 974 newborns, 926 (95%) were normal, 21 had major defects, 26 had minor defects, and there was 1 early neonatal death of an infant born at about 30 weeks with intrauterine growth restriction (mother had antiphospholipid syndrome and was homozygous for methylene-tetra-hydro-folate reductase mutation). The prevalence of major structural anomalies recognized at birth was 2.4 cases per 100 live births. Among 261 retrospective (reported after the outcome was known) cases, there were 12 major defects. The Registry stated that the limited number of reports with known outcomes prevented any definite conclusions about the potential effects of exposure to the vaccine in pregnancy. However, the rates of SABs and major defects, and the fact that the anomalies were varied, suggested that the outcomes were related to the background risk rather than to the vaccine (2).

A 2009 study reported the pregnancy and infant outcomes during phase III clinical trials with quadrivalent HPV vaccine (Note: The Registry data presented above updates the number of exposures) (3). Women aged 15–45 years received the vaccine or placebo on day 1 and months 2 and 6. If a pregnancy test immediately before a dose was positive they were excluded from further doses. During the study, the number of pregnancies with known outcomes in the vaccinated and placebo groups was 1796 and 1824, respectively. There were no significant differences in the proportion of pregnancies resulting in live births, fetal loss, or spontaneous abortion. Congenital anomalies were noted in 40 and 30 neonates, respectively (ns). The anomalies were diverse and consistent with those commonly seen in the general population (3). Two comments on this study were published in 2009 and 2010 (4,5). Because the vaccine and placebo groups did not represent comparable randomized populations, and because some pregnancies were still ongoing, the author recommended that avoiding the vaccine in pregnancy or near the time of conception was still warranted (5).

The American College of Obstetricians and Gynecologists recommends avoiding HPV vaccine in pregnancy. If a woman becomes pregnant before

completion of the three-dose schedule, completion of the series should be delayed until the pregnancy is completed (6). As of 2010, the CDC also recommends avoiding the vaccine in pregnant women (7).

BREASTFEEDING SUMMARY

It is not known if the HPV antigens or the antibodies induced by the vaccine are excreted into human breast milk. Five hundred nursing mothers were given the vaccine during clinical trials, compared with 495 women who received a placebo vaccine. The number of nursing infants experiencing a serious adverse experience was higher in the mothers receiving the vaccine than in those receiving a placebo, 4.2% (N = 21) vs. 2.0% (N = 10), respectively. However, none of the adverse experiences were judged to be related to the vaccine. In clinical studies, more nursing infants with acute respiratory illnesses were found in the group of mothers who had received the vaccine within 30 days (N = 6), than in the control group (N = 2) (1,2).

The American College of Obstetricians and Gynecologists states that the vaccine can be given to lactating women because it is safe for the mother and the nursing infant (6). Until further studies demonstrate otherwise, the use of HPV vaccine can be classified as compatible with breastfeeding.

VACCINE, INFLUENZA

Vaccine

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Influenza vaccine is an inactivated virus vaccine (1). The vaccine is considered safe during all stages of pregnancy (2–7). However, the intranasal vaccine spray contains a live, attenuated virus and should not be used in pregnancy (1). Animal reproduction studies have not been conducted with the vaccine. If influenza vaccine is used in pregnancy, health care professionals are encouraged to call the toll-free number 877-311-8972 for information about patient enrollment in the Organization of Teratology Information Specialists (OTIS) study.

FETAL RISK SUMMARY

Neonatal passive immunization of short duration has been documented in some studies (4). The American College of Obstetricians and Gynecologists recommends that the vaccine be given to women who will be pregnant during the flu season (October–mid May) and to those at high risk for pulmonary complications regardless of trimester (1).

The CDC recommends the inactivated vaccine for women who will be pregnant during the influenza season (5). In addition, pregnant women who have medical conditions that increase their risk for complications from influenza should receive the vaccine (5).

A 2005 study used an electronic database to identify 252 pregnant women who had received influenza vaccine between 1998 and 2003 (8). Vaccination occurred at a mean gestational age of 26.1 weeks (range 4–39 weeks). There were no serious adverse events within 42 days of vaccination. Compared with controls who were not vaccinated, there were no differences between the groups in terms of pregnancy outcomes and infant medical conditions from birth to 6 months of age (8).

BREASTFEEDING SUMMARY

Maternal vaccination is compatible with breastfeeding and presents no risk to the nursing infant (5).

VACCINE, INFLUENZA A (H1N1)

Vaccine

PREGNANCY RECOMMENDATION: Compatible (Inactivated Vaccine) No Human Data—Probably Compatible (Live Virus Vaccine and Adjuvanted Vaccine)

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Because the H1N1 vaccines were released late in 2009, there are no reports describing their use in pregnancy. However, pregnant women are a priority population to receive the inactivated H1N1 vaccine because they are at high risk for morbidity and mortality. There is no evidence that influenza virus types A and B vaccines caused embryo or fetal harm (see Vaccine, Influenza). There is, however, a possible increased rate of spontaneous abortions from disease caused by these viruses (1). Inactivated virus vaccines are preferred over vaccines containing live viruses. The American College of Obstetricians and Gynecologists classifies live virus vaccines as usually contraindicated (1). The potential for developmental toxicity from the adjuvants, added to one of the H1N1 vaccines to enhance the immune response to the antigen (i.e., the virus), is not known. In rats, however, developmental toxicity was observed in two studies with AS03-adjuvanted H5N1 antigen. Neither of the vaccines available in the United States contains an adjuvant. If H1N1 vaccine is used in pregnancy, health care professionals are encouraged to call the toll-free number 877-311-8972 for information about patient enrollment in the Organization of Teratology Information Specialists (OTIS) study.

FETAL RISK SUMMARY

Three vaccines, two with inactivated virus and one with live virus, are available to prevent infection with novel influenza A (H1N1) (previously known as swine flu). The vaccines are indicated for the active immunization against influenza disease caused by pandemic (H1N1) 2009 virus (2–4). Influenza A (H1N1) 2009 monovalent vaccine, given by IM injection, is an inactivated vaccine

indicated for persons 6 months of age and older (2). Influenza A (H1N1) 2009 monovalent vaccine live, given intranasally, is indicated for individuals 2–49 years of age (3). Arepanrix H1N1 inactivated virus vaccine, available in Canada, is indicated in an officially declared pandemic situation (4). The adjuvants in Arepanrix are DL- α -tocopherol, squalene, and polysorbate 80.

Animal reproduction studies with H1N1 vaccines have not been conducted (2–4). Neither have studies been conducted for carcinogenesis, mutagenesis, or impairment of fertility. Two reproductive studies in rats with AS03-adjuvanted H5N1 antigen (doses not specified) have been conducted to evaluate the embryo–fetal and postnatal toxicity up to the end of the lactation period (4). The findings in the two studies were an increased incidence of postimplantation loss, fetal malformations (markedly medially thickened/kinked ribs and bent scapula), dilated ureter, and delayed neurobehavioral maturation. However, the significance of the outcomes was uncertain because not all findings were observed in both studies (4).

BREASTFEEDING SUMMARY

Because the H1N1 vaccines were released late in 2009, there are no reports describing their use during breastfeeding. Nevertheless, maternal vaccination with any of these vaccines is compatible with breastfeeding and presents no risk to a nursing infant.

VACCINE, LYME DISEASE

Vaccine

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The occurrence of Lyme disease during pregnancy presents a serious but apparently small risk to the fetus. The greatest fetal risk may be in cases where the mother does not receive appropriate antibiotic treatment. The data to support this conclusion are limited and controversial. Because there have been no reports on the use of Lyme disease vaccine during gestation, the fetal risk from the vaccine is unknown. However, because Lyme disease itself may cause fetal harm and the vaccine is noninfectious, vaccination of women of childbearing age who are at risk for acquiring the disease may be the safest course. Although the direct risk to a fetus appears to be low, the Advisory Committee on Immunization Practices recommends that pregnant women not receive the vaccine because its safety during pregnancy has not been established (1).

FETAL RISK SUMMARY

Lyme disease vaccine (recombinant OspA) contains an outer surface protein of *Borrelia burgdorferi sensu stricto* (lipoprotein OspA) that is noninfectious (1,2). The recombinant OspA protein is expressed in *Escherichia coli* and then purified. Only the LYMErix vaccine is licensed for use in the United States (1). The vaccine (30 mcg/0.5 mL) is administered IM on a three-dose schedule of 0, 1, and 12 months.

Lyme disease is a tickborne infection caused by the spirochete *B. burgdorferi*, with an incubation period from infection to onset of rash (erythema migrans) of 7–14 days (range 3–30 days). The disease is characterized by rash, fever, malaise, fatigue, headache, myalgia, and arthralgia. Without adequate antibiotic treatment, chronic disease of the nervous system,

musculoskeletal system, or the heart may occur (1).

No cases describing the use of Lyme disease vaccine in pregnancy have been located. Moreover, animal reproductive tests have not been conducted with the vaccine.

A 1985 case report described a woman who developed Lyme disease during the 1st trimester of pregnancy (3). She received no antibiotic therapy for her disease. She delivered a 3000-g male infant at an estimated 35 weeks' gestation who developed respiratory distress shortly after birth. Studies revealed a dilated, poorly contractile left ventricle, aortic valvular stenosis, patent ductus arteriosus, and coarctation of the aorta. The infant died at age 39 hours. Cardiovascular malformations found at autopsy were tubular hypoplasia of the ascending aorta and aortic arch, marked endocardial fibroelastosis, and a persistent left superior vena cava draining into the coronary sinus. No signs of infection, such as inflammation, necrosis, or granuloma formation, were found in the heart or other organs, but a few spirochetes similar to the Lyme disease spirochete were found in the spleen, renal tubules, and bone marrow. Evaluation of the mother was consistent with Lyme disease, and she was successfully treated with tetracycline therapy (3).

A second case of fetal death associated with Lyme disease was published in 1987 (4). A 24-year-old woman with an apparent onset of infection (annular erythematous patch noted near her left knee followed by pain and swelling in the knee) near the time of conception delivered a 2500-g stillborn infant at term. Serologic studies of maternal blood were positive for *B. burgdorferi* in two of three samples. At autopsy, the only malformation found was an atrioventricular canal ventricular septal defect. Spirochetes immunologically consistent with *B. burgdorferi* were recovered from the fetal liver, myocardium, adrenal gland, and subarachnoid space of the midbrain. The authors concluded that the fetus had died near term of overwhelming spirochetosis (4).

The outcomes of 19 pregnancies of women with documented Lyme disease were described in 1986 (5). Eight of the pregnancies were followed prospectively, and 11 were identified retrospectively. Among the 17 women with erythema chronicum migrans (ECM), 8 had the onset of disease in the 1st trimester, 7 in the 2nd trimester, and 2 in the 3rd trimester. The onset of infection could not be determined in the remaining two, but one developed facial palsy in the 1st trimester and the other developed arthritis in the 3rd trimester. Normal outcomes occurred in 14 pregnancies, 7 with onset of illness in the 1st trimester, 4 in the 2nd trimester, 2 in the 3rd trimester, and 1 with unknown time of onset. Five of the women (three in 1st trimester; one in 2nd trimester;

one in 3rd trimester) did not receive antibiotic therapy, but all delivered apparently normal infants, although two had transient problems. One of these, a 2100-g infant delivered prematurely, developed hyperbilirubinemia at 4 days of age but has had otherwise normal development through 9 years of age. Another, delivered 7 days after onset of maternal ECM and meningitis, had hyperbilirubinemia and a generalized, petechial, vesicular rash at 5 days of age. Viral and bacterial blood and skin cultures were negative; tests for *B. burgdorferi* were not available at that time. The rash faded within 1 week during treatment with penicillin. The remaining three pregnancies had abnormal outcomes as described below (time of onset of maternal illness shown in parentheses):

(1st trimester) intrauterine fetal death at 16 weeks'; no congenital abnormalities; no inflammation noted in fetal tissues; culture and indirect immunofluorescence assay of placenta and fetal tissues were negative

(2nd trimester) syndactyly (type 1) of second and third toes

(2nd trimester) full-term, healthy male infant at birth, developed cortical blindness and developmental delay at 8 months of age; diagnostic studies were negative; no serum antibodies to *B. burgdorferi* found at 1 year of age; mother had a previous child with trisomy 18

None of the five adverse outcomes described above can be directly attributed to maternal Lyme disease (5). At least one is known to be a fairly common genetic defect (i.e., syndactyly), and two were minor, transient adverse effects. Moreover, no cardiovascular anomalies were observed, but because only eight cases with ECM occurred in the 1st trimester, the power of this study to detect such defects is limited (5).

Two reports from the same group of investigators, one published in 1993 and the other in 1995, examined the effects of maternal exposure to Lyme disease and pregnancy outcome (6,7). A total of 2014 women were enrolled in the first study at their first prenatal visit (6). Of these, 11 were seropositive for Lyme disease, but information on the presence of congenital malformations was available for only 10 of their infants. Among these 10 newborns, 1 infant had a major defect (multiple major anomalies with VATER association [vertebral defects, imperforate anus, tracheoesophageal fistula, and radial and renal dysplasia]). Two other infants had minor malformations: metatarsus adductus and stomach reflux. Other outcome data included no spontaneous abortions and a mean birth weight of 3650 g. None of these outcomes differed significantly from the group without Lyme disease exposure (i.e., with no

significant titer and negative clinical history) (6).

In the second study, no difference in the incidence of total congenital malformations (odds ratio [OR] 0.87; 95% confidence interval [CI] 0.70–1.06) was observed in the infants of mothers in an endemic hospital cohort (N = 2504) compared with the infants of mothers in a control hospital (N = 2507) (7). The total number represented 81% of all eligible infants. However, the rate of cardiac malformations (most commonly ventricular septal defect [VSD]) was significantly higher in the endemic cohort (OR 2.40; 95% CI 1.25–4.59). Although the incidence of total minor malformations was no different between the groups, three minor defects (hemangiomas, polydactyly, and hydrocele) were significantly higher ($p < 0.05$) in the control group. Only the difference in polydactyly could be explained by demographic variations. Comparisons of mean birth weights between the cohorts found no significant differences (7).

In the endemic cohort, 22 of the mothers had Lyme disease before pregnancy (7). Among their 23 offspring (1 set of twins), there were 2 major malformations: multiple heart defects (infant died), and hydrocele and laryngomalacia. Six mothers contracted the disease during pregnancy and one of their infants had a major defect (hypospadias). Three infants with major malformations (VSD, vesicoureteral block with reflux, and hypospadias) and five with minor defects (inguinal hernia, laryngomalacia, hemangioma, genu varum, and metatarsus adductus) were observed in the mothers (N = 67) who had reported a tick bite during pregnancy. Of the 20 infants born from mothers who had immunoglobulin G anti-B. burgdorferi antibodies in their cord blood (all infants were tested), 1 had a minor defect (cryptorchidism). Within the endemic cohort, there were no differences between those who had possible exposure to Lyme disease or who had positive cord serology compared with those who were not exposed and had negative serology in terms of mean birth weight or the rate of major or minor abnormalities (7).

A 1999 retrospective case–control study compared 796 children with a diagnosis of congenital cardiac anomaly with 704 children from the same region without cardiac defects (8). Records of all of the children were obtained from a medical center in a suburban area where Lyme disease is endemic. All had been born in the study area. No statistical differences in the frequencies of maternal conditions and exposures between the two groups were found for cigarette smoking, alcohol use, conception while using contraceptives, the use of fertility drugs, the use of electric blankets or heated waterbeds, vaginal bleeding during pregnancy, occupational exposure to video display terminals, asthma, upper respiratory tract infections, or thyroid disorders. More study

mothers had high blood pressure (6.7% vs. 3.5%, $p = 0.007$), whereas more controls had occupational exposure to x-ray films or anesthesia (6.1% vs. 9.1%, $p = 0.03$). There were no statistical differences between the groups in Lyme disease during pregnancy (or 3 months, 1 year, or at anytime before conception) or in those who had received a tick bite during pregnancy (or 3 months, 1 year, or at anytime before conception). The authors concluded that there was no increased risk of congenital heart defects when maternal Lyme disease was contacted before or during pregnancy. However, their study could not exclude a risk to a fetus from undiagnosed and untreated Lyme disease (8).

Although there is concern that maternal Lyme disease may infect the fetus as do other spirochetal infections (e.g., syphilis) (5,9), the risk for this, based on the above studies, appears to be low. In addition, a survey published in 1994 found no cases of clinically significant nervous system disease attributable to transplacentally acquired Lyme disease that had been recognized among pediatric neurologists in regions of the United States in which Lyme disease was endemic (10). The regions surveyed included all or portions of Connecticut, Massachusetts, Minnesota, New Jersey, New York, Rhode Island, and Wisconsin. Some adult neurologists were also contacted in Connecticut. One pediatric neurologist was following three children with “congenital Lyme disease,” but none of the mothers of these children met the CDC’s diagnostic criteria for Lyme disease (10). The authors concluded that either congenital neuroborreliosis was not occurring or that the incidence was extremely low in endemic areas (10).

BREASTFEEDING SUMMARY

No reports describing the use of Lyme disease vaccine during lactation have been located. DNA of the spirochete *B. burgdorferi* has been detected in the breast milk of two women by polymerase chain reaction (PCR) (11). Breast milk samples from three healthy controls were nonreactive. Both women with reactive samples had Lyme disease as characterized by the presence of erythema migrans, and both had PCR-positive urine samples. One of the nursing infants was hospitalized at 6 months of age because of fever and vomiting. The cause of the symptoms was undetermined, but they resolved spontaneously after a few days. The urine of the infant and mother were tested 1 year later, and both were nonreactive.

VACCINE, MEASLES

Vaccine

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Measles (rubeola) vaccine is a live, attenuated virus vaccine (1,2). It should not be given in pregnancy. Animal reproduction studies have not been conducted with the vaccine.

FETAL RISK SUMMARY

Measles occurring during pregnancy may result in significant maternal morbidity, an increased abortion rate, stillbirth, prematurity, and congenital malformations (1). Although a fetal risk from the vaccine has not been confirmed, the vaccine should not be used during pregnancy because fetal infection with the attenuated viruses may occur (1–3). The manufacturer lists pregnancy as a contraindication to its use and states that pregnancy should be avoided for 3 months following vaccination (1). A shorter interval is recommended by the CDC (4). They recommend that women avoid becoming pregnant for 28 days after vaccination, but no cases of congenital malformations attributable to measles vaccine virus have been reported (4).

BREASTFEEDING SUMMARY

No reports describing the use of measles vaccine during lactation have been located. However, the vaccine is probably compatible with breastfeeding.

VACCINE, MENINGOCOCCAL

Vaccine

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The risk to the fetus from vaccination during pregnancy is unknown. The CDC recommends that if it is given during pregnancy, the woman should consult her health care provider or the vaccine manufacturer, because there are no data available on the safety of the vaccine during pregnancy (1). In one study, vaccination resulted in transfer of maternal antibodies to the fetus, but the transfer was irregular and was not dependent on maternal titer or the period in pregnancy when vaccination occurred (2). If meningococcal vaccine is given in pregnancy, health care professionals are encouraged to call the toll-free number 877-311-8972 for information about patient enrollment in the Organization of Teratology Information Specialists (OTIS) study.

FETAL RISK SUMMARY

Meningococcal vaccine is available in two formulations: meningococcal polysaccharide vaccine, groups A, C, Y, and W-135 combined (Menomune—A/C/Y/W-135), a freeze-dried product requiring reconstitution; and meningococcal (groups A, C, Y, and W-135) polysaccharide diphtheria toxoid conjugate vaccine (Menactra), a fluid product ready for administration. Either formulation is a killed bacteria (cell wall) vaccine (3,4).

Animal reproduction studies have not been conducted with Menomune (3). Reproduction studies have been conducted in mice with Menactra (4). A dose 900 times the human dose (based on body weight) had no effect on fertility, maternal health, embryo–fetal survival, or postnatal development (4). One of the 234 fetal skeletons examined had a cleft palate compared with none in the control group. This was the only skeletal and organ anomaly observed and was not thought to be related to the vaccine.

A 1998 study evaluated the pregnancy outcomes of 34 women who received meningococcal vaccine during pregnancy (5). The trimesters of exposures were 4 (11.8%) in the 1st, 17 (50.0%) in the 2nd, and 13 (38.2%) in the 3rd. There were 34 singleton deliveries with a mean follow-up of the offspring of 13.2 months (range 1–24 months). Excluding one congenital malformation, there was no increase in the observed unusual birth events compared with the expected rates. In fact, there were significantly fewer cases of newborn cardiac murmurs and physiologic jaundice in offspring of vaccinated mothers. One birth defect observed in an infant of a mother vaccinated at 33 weeks' gestation was consistent with the oromandibular limb hypogenesis spectrum (Charlie M syndrome) (expected frequency <0.00002%). This pattern of defects would probably have occurred very early in gestation. The cause of Charlie M syndrome is unknown; it has not yet been identified as a genetic defect and it has not been associated with teratogens. All of the infants had normal growth and development in the follow-up period (5).

A 1994 review stated that the use of the vaccine during pregnancy is controversial (6). However, in a 1996 study, 75 mothers received meningococcal vaccine in the last trimester of pregnancy (7). No adverse effects in the newborns attributable to the vaccine were observed.

BREASTFEEDING SUMMARY

No reports describing the administration of meningococcal vaccine during human lactation have been located.

VACCINE, MUMPS

Vaccine

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Mumps vaccine is a live attenuated virus vaccine (1,2). It should not be given in pregnancy. Animal reproduction studies have not been conducted with the vaccine.

FETAL RISK SUMMARY

Mumps occurring during pregnancy may result in an increased rate of 1st trimester spontaneous abortion (2). Although a fetal risk from the vaccine has not been confirmed, the vaccine should not be used during pregnancy because fetal infection with the attenuated viruses may occur (1–3). The manufacturer (2). In addition, the manufacturer recommends avoiding pregnancy for 3 months following vaccination (2). A shorter interval is recommended by the CDC (4), which recommends that women who receive the mumps vaccine should avoid becoming pregnant for 28 days. However, no cases of congenital malformations attributable to infection with mumps vaccine virus have been reported and having been vaccinated with the vaccine should not be a reason to terminate a pregnancy (5).

BREASTFEEDING SUMMARY

No reports describing the administration of mumps vaccine during human lactation have been located.

VACCINE, PERTUSSIS (ACELLULAR)

Vaccine/Toxoid

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Although no reports describing the use of tetanus toxoid/reduced diphtheria toxoid/acellular pertussis vaccine adsorbed (Tdap) or diphtheria/tetanus toxoids/acellular pertussis vaccine adsorbed (DTaP) in human pregnancy have been located, one report did describe the inadvertent administration of acellular pertussis vaccine without toxoids in early gestation. Diphtheria/tetanus toxoids are recommended in pregnancy under certain conditions (see Diphtheria/Tetanus Toxoids [Adult]) and whole cell pertussis vaccine (no longer available) has been used in late pregnancy. Studies in which Tdap is given in the 2nd and 3rd trimesters have been proposed to determine if higher titers of pertussis antibodies can be obtained in the newborn (1–4). Currently, if tetanus or diphtheria protection is needed during pregnancy, the CDC and the American College of Obstetricians and Gynecologists (ACOG) recommend that Tdap be considered in the 2nd or 3rd trimesters, or earlier if protection is needed urgently (5–7). Tdap should only be given once during a lifetime.

Pertussis antibodies are known to cross the placenta and could potentially provide infants greater protection until they reach the age for active immunization. The American Academy of Pediatrics has recommended that pregnant adolescents should be given the same consideration for immunization as nonpregnant adolescents, and that the vaccine should be given before 36 weeks' gestation (4). However, the CDC concluded that it was not clear if the increased titers of pertussis antibodies would be adequate to protect the infant from pertussis, nor was it known if the increased titers would interfere with later active immunization of the infant (6). If Tdap is used in pregnancy, health care professionals are encouraged to call the toll-free number 877-311-8972 for information about patient enrollment in the Organization of Teratology Information Specialists

FETAL RISK SUMMARY

Acellular pertussis vaccine is available in five formulations: Tdap (for adolescents/adults) (Adacel, Boostrix); and DTaP (for infants/children) (Daptacel, Infanrix, Tripedia). Pertussis vaccine is a combination, noninfectious product containing the two toxoids and inactivated pertussis vaccine (8–12) (see also Tetanus/Diphtheria Toxoids [Adult]). Compared with DTaP, Tdap has reduced diphtheria toxoid. All five of the vaccines are given as an IM injection. The acellular vaccine replaced the whole cell vaccine in 1997 (13). In addition to the two toxoids, the vaccines contain three pertussis antigens (inactivated pertussis toxin [PT], formaldehyde-treated filamentous hemagglutinin [FHA], and pertactin) adsorbed onto aluminum hydroxide. The pertussis antigens are isolated from *Bordetella pertussis*, the cause of whooping cough. The adolescent/adult formulations are indicated for active booster immunization to prevent tetanus, diphtheria, and pertussis as a single dose in persons 10–18 years of age (Boostrix) and 11–64 years of age (Adacel) (8,9). The infant/children products are indicated for the active immunization of infants and children 6 weeks to 7 years of age (before the seventh birthday) (10–12). The information presented here applies to all of the formulations.

Reproduction studies have been conducted in rats and rabbits. DTaP (Infanrix) was given IM to rats prior to gestation and Tdap (Boostrix) was administered IM during organogenesis (days 6, 8, and 11) and later in pregnancy (day 15) (8). Each dose of Boostrix was about 45 times the human dose based on body weight (HD). No adverse effects were observed on pregnancy, lactation, or embryo–fetal or preweaning development, and there was no evidence of teratogenic effects. Studies have not been conducted for carcinogenicity, mutagenicity, or effects on fertility (8).

In rabbits, Adacel was administered IM twice before conception, during organogenesis (day 6), and later in pregnancy (day 29). Each dose was 17 times the HD. No adverse effects were observed on pregnancy, parturition, lactation, embryo–fetal or preweaning development, and there was no evidence of teratogenic effects (9).

A 1986 review on the epidemiology of pertussis cited a 1943 reference in which pertussis vaccine was given to 29 women during the sixth and seventh month of pregnancy (14). High protective antibody titers were found in mothers and their newborns. Because of the date, the product used was probably the

whole cell pertussis vaccine (14).

A 2003 article reviewed the current prevalence of pertussis in the United States including its morbidity and mortality in different age groups (13). The author also discussed a 1990 serologic study conducted in her institution in which the placental transfer of maternal antibodies to pertussis was evaluated (the mothers had not received a pertussis vaccine during pregnancy) (15). Antibodies to PT in cord sera were 2.9 times higher than those in maternal sera, suggesting active transport to the embryo–fetus. In contrast, cord sera titers of antibodies to FHA and agglutinin did not differ significantly from maternal sera. Because cord blood concentrations of anti-pertussis immunoglobulin G (IgG) were nearly comparable to maternal titers, the author concluded that maternal immunization would be effective in providing infants with protection until they reached the age for active immunization (13).

A 1999 study evaluated the safety and efficacy of an acellular pertussis vaccine, which did not contain diphtheria or tetanus toxoids, in healthy men and women 18 years of age or older (16). Although pregnant women were excluded, 2 of the 200 female subjects conceived. The first woman conceived about 8 days after immunization. A spontaneous abortion occurred on gestational day 34. The second woman became pregnant within 0–4 weeks of immunization. She underwent an elective abortion at about 1 month of gestation. The investigators concluded that neither outcome was related to the vaccine (16).

BREASTFEEDING SUMMARY

No reports describing the administration of any of the four formulations of pertussis vaccine during human lactation have been located. Tdap should present no risk to a nursing infant because antibodies to pertussis, tetanus, and diphtheria should be present in both the mother and the infant. Moreover, DTaP is indicated for infants and children 6 weeks through 6 years of age (before seventh birthday). The CDC and ACOG recommend Tdap in breastfeeding women who have not received the vaccine previously or 2 years or more have elapsed since the most recent Td administration (5,6).

VACCINE, PLAGUE

Vaccine

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Plague vaccine is a killed bacteria vaccine (1). No risk to the fetus from vaccination during pregnancy has been reported. Animal reproduction studies have not been conducted with the vaccine.

BREASTFEEDING SUMMARY

No reports describing the administration of plague vaccine during human lactation have been located.

Reference

VACCINE, PNEUMOCOCCAL POLYVALENT

Vaccine

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The risk to the fetus from pneumococcal polysaccharide vaccine during the 1st trimester of pregnancy is unknown (1–3). However, the Advisory Committee on Immunization Practices (ACIP) states that there are no reports of adverse consequences in newborns whose mothers were inadvertently vaccinated during pregnancy (3,4).

FETAL RISK SUMMARY

Pneumococcal vaccine polyvalent is a killed bacteria vaccine that contains a mixture of purified capsular polysaccharides from 23 types of *Streptococcus pneumoniae* (1,2). Animal reproduction studies have not been conducted with the vaccine (1,2). A 1991 review stated that maternal antibodies induced by pneumococcal polyvalent vaccine cross the placenta and may offer significant protection to the newborn (5).

A study conducted in Bangladesh and published in 1995 described the administration of pneumococcal polyvalent vaccine to healthy women at 30–34 weeks' gestation (6). Meningococcal vaccine was administered to a control group. The immunologic response of the infants resulting from the maternal immunization was monitored from birth to 5 months of age. The results indicated that sufficient amounts of specific immunoglobulin G serum antibody passed to the fetus to provide passive immunity to invasive pneumococcal infection in early infancy. The authors concluded that, in geographic regions where such infections are a serious public health problem, maternal immunization would be a safe and inexpensive method to reduce the incidence of the disease, if subsequent studies did not show that passive immunity of the infants interfered with active immunization later in life (6).

In a 1996 study, pneumococcal polyvalent vaccine was administered in the

3rd trimester in an attempt to protect against pneumococcal disease in the infant during the first few months of life (7). The degree and duration of protection was uncertain because the pneumococcal antibodies in the infants disappeared rapidly. A 1998 reference noted that large studies are needed to determine if maternal administration of the vaccine can decrease infant mortality and morbidity (8). Because of the high cost of vaccinations with newly developed conjugate vaccines, one author thought that vaccination of pregnant women with the polysaccharide vaccine might be the most practical method for preventing pneumococcal sepsis in young infants in developing countries (9).

BREASTFEEDING SUMMARY

In a study conducted in Bangladesh (described above), marked increases of specific immunoglobulin A (IgA) antibody titers were measured in the colostrum of mothers who had received pneumococcal polyvalent vaccine at 30–34 weeks' gestation (6). Antibody titers remained higher than controls up to 5 months after delivery.

VACCINE, POLIOVIRUS INACTIVATED

Vaccine

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Poliovirus vaccine inactivated (Salk vaccine, IPV) is an inactivated virus vaccine administered by injection (1). Animal reproductions studies have not been conducted with the vaccine. Although fetal damage may occur when the mother contracts the disease during pregnancy, the risk to the embryo–fetus from the vaccine appears to be low if at all.

FETAL RISK SUMMARY

No adverse effects attributable to the use of the inactivated vaccine have been reported (1,2). The CDC recommends use of the vaccine during pregnancy only if an increased risk of exposure exists (2). If immediate protection against poliomyelitis is needed, the Advisory Committee on Immunization Practices (ACIP) states that the IVP may be used in accordance with the recommended schedules for adults (see reference for specific details) (2).

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 6774 of whom had 1st trimester exposure to the vaccine (3, p. 315). Congenital malformations were observed in 461 (standardized relative risk [SRR] 1.03). In general, no associations (SRR >1.5) were found (3, p. 318). Specific malformations with SRR >1.5 were: craniosynostosis, 6 (SRR 2.1); atrial septal defect, 6 (SRR 4.0); cleft lip with or without cleft palate, 9 (SRR 1.6); omphalocele, 5 (SRR 2.4); and any malignant tumors, 7 (SRR 3.3) (3, pp. 473–4). For use anytime in pregnancy, 18,219 mother–child pairs were exposed (3, p. 436). A total of 374 newborns had anomalies (SRR 1.08). Specific malformations with SRR >1.5 were: hypoplasia of limb or part thereof, 24 (SRR 1.6); malformations of thoracic wall, 9 (SRR 2.4); anomalies of the teeth, 8 (SRR 2.0); corneal opacity, 5 (SRR 3.5); and CNS tumors, 7 (SRR 17.9) (3, pp. 486–7). The authors of this study cautioned that these data cannot be

interpreted without independent confirmation from other studies and that any positive or negative association may have occurred by chance (3).

BREASTFEEDING SUMMARY

No reports describing the administration of poliovirus inactivated vaccine during human lactation have been located (see also Vaccine, Poliovirus Live).

VACCINE, POLIOVIRUS LIVE

Vaccine

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Poliovirus vaccine live (Sabin vaccine; OPV; TOPV) is a live, trivalent (types 1, 2, and 3) attenuated virus strain vaccine administered orally. Animal reproductions studies have not been conducted with the vaccine. Although fetal damage may occur when the mother contracts the disease during pregnancy, the risk to the embryo–fetus from the vaccine appears to be low if at all. (Withdrawn from the United States market.)

FETAL RISK SUMMARY

A brief 1990 report found no increase in spontaneous abortions or adverse effect on the placenta or embryo following 1st trimester use of oral poliovirus vaccine (1).

The Advisory Committee on Immunization Practices (ACIP) recommends use of the vaccine during pregnancy only if an increased risk of exposure exists (2). If immediate protection against poliomyelitis is needed, the ACIP states that either the inactivated or the oral vaccine may be used in accordance with the recommended schedules for adults (see reference for specific details) (2). The inactivated vaccine, however, was preferred over the oral form because of a lower risk of vaccine-associated paralysis.

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 1628 of whom had 1st trimester exposure to oral live poliovirus vaccine (3, p. 315). Congenital malformations were observed in 114 (standardized relative risk [SRR] 1.11) of the newborns. Malformations identified with SRR >1.5 were gastrointestinal (GI) defects (SRR 1.67) and Downs' syndrome (SRR 1.60) (3, p. 319). Specific malformations with SRR >1.5 were omphalocele, 3 (SRR 5.4); malrotation of the GI tract, 5 (SRR 7.9); and any benign tumors, 7 (SRR 1.8) (3, p. 474). For use anytime in pregnancy, 3059 mother–child pairs were exposed (3, p. 436). In this group, there were 44 malformed children (SRR

0.81) with the following specific malformations having SRR >1.5: Hirschsprung's disease, 4 (SRR 8.8); any benign tumors, 12 (SRR 1.7); and pectus excavatum, 8 (SRR 2.0) (3, p. 487). The authors of this study cautioned that these data cannot be interpreted without independent confirmation from other studies and that any positive or negative association may have occurred by chance (3).

The death of a 3-month old male infant because of complications arising from bilateral renal dysplasia affecting predominantly the glomeruli was thought possibly to be caused by maternal vaccination with oral poliovirus vaccine during the 1st or 2nd month of pregnancy (4). A causal relationship, however, could not be established based on the pathologic findings.

A 19-year-old previously immune woman inadvertently received oral poliovirus vaccine at 18 weeks' gestation (5). For other reasons, she requested termination of the pregnancy at 21 weeks' gestation. Polio-like changes were noted in the small-for-dates female fetus (crown-rump and foot length compatible with 17.5–19 weeks' gestation) consisting of damage to the anterior horn cells of the cervical and thoracic spinal cord with more limited secondary skeletal muscle degenerative changes in the arm (5). Poliovirus could not be isolated from the placenta or fetal brain, lung, or liver. Specific fluorescent antibody tests for poliovirus types 2 and 3 were positive in the dorsal spinal cord but not at other sites.

In response to an outbreak of wild-type 3 poliovirus in Finland, a mass vaccination program of adults was initiated with trivalent oral poliovirus vaccine in 1985, with 94% receiving the vaccine during about a 1-month period (6). Because Finland has compulsory notification of all congenital malformations detected during the first year of life, a study was conducted to determine the effect, if any, on the incidence of birth defects from the vaccine. In addition to all defects, two indicator groups were chosen because of their high detection and reporting rates: central nervous system defects and orofacial clefts. No significant changes from the baseline prevalence were noted in the three groups, but the data could not exclude an increase in less common types of congenital defects (6).

A follow-up to the above report was published in 1993 that included all structural malformations occurring during the 1st trimester (7). The outcomes of approximately 9000 pregnancies were studied, divided nearly equally between those occurring before, during, or after (i.e., one study and two reference cohorts) the vaccination program. Women in the study group had been vaccinated during the 1st trimester (defined as from conception through 15

weeks). A total of 209 cases (2.3%) were identified from liveborns, stillborns, and known abortions. There was no difference in outcomes between the cohorts (the study had a statistical power estimate to detect an increase greater than 0.5%) (7).

The analysis of Finnish women receiving the oral poliovirus vaccine during gestation was expanded to anytime during pregnancy in a 1994 report (8). The outcomes of three study groups (about 3000 pregnant women vaccinated in each of the three trimesters of pregnancy) were compared with two reference cohorts (about 6000 pregnant women who delivered before the vaccination program and about 6000 who conceived and delivered afterward). No differences were found between the study and reference groups in terms of intrauterine growth or in the prevalence of stillbirth, neonatal death, congenital anomalies, premature birth, perinatal infection, and neurologic abnormalities (8). The authors concluded that the vaccination of pregnant women with the oral poliovirus vaccine, as conducted in Finland, appeared to be safe.

A 1993 report described the use of oral poliovirus vaccine in a nationwide (Israel) vaccination campaign, including pregnant women, after the occurrence of 15 cases of polio in the summer of 1988 (9). The investigators compared the frequency of anomalies and premature births in their area in 1988 (controls) with those in 1989 (exposed). In 1988, 15,021 live births occurred, with 204 malformed newborns (1.4%) and 999 (6.7%) premature infants. These numbers did not differ statistically from those in 1989; 15,696, 243 (1.5%), and 1083 (6.9%), respectively. The authors concluded that oral poliovirus vaccine was preferred to the inactivated vaccine if vaccination was required during pregnancy (9).

In a follow-up of the Israel vaccination campaign, investigators measured the presence of neutralizing antibodies to the three poliovirus types in the sera of infants whose mothers had been vaccinated 2–7 weeks before delivery (10). In newborns, higher levels of protecting antibodies were found for poliovirus types 1 and 2 than for type 3, indicating less placental transfer and a greater risk of infection with poliovirus type 3.

BREASTFEEDING SUMMARY

Human milk contains poliovirus antibodies in direct relation to titers found in the mother's serum. When oral poliovirus vaccine (Sabin vaccine, OPV) is administered to the breastfed infant in the immediate neonatal period, these antibodies, which are highest in colostrum, may prevent infection and development of subsequent immunity to wild poliovirus (11–22). To prevent

inhibition of the vaccine, breastfeeding should be withheld 6 hours before and after administration of the vaccine, although some authors recommend shorter times (17–21).

In the United States, the ACIP and the Committee on Infectious Diseases of the American Academy of Pediatrics do not recommend vaccination before 6 weeks of age (3,23). At this age or older, the effect of the oral vaccine is not inhibited by breastfeeding and no special instructions or planned feeding schedules are required (3,23–27).

VACCINE, RABIES (HUMAN)

Vaccine

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably
Compatible

PREGNANCY SUMMARY

Rabies vaccine (human) is an inactivated virus vaccine (1). Animal reproduction studies have not been conducted with the vaccine. Because rabies is nearly 100% fatal if contracted, the vaccine should be given for postexposure prophylaxis (1,2).

FETAL RISK SUMMARY

The CDC states that indications for prophylaxis are not altered by pregnancy (1). Three reports described the use of rabies vaccine (human) during pregnancy (3–5). Passive immunity was found in one newborn (titer >1:50) but was lost by 1 year of age (3). No adverse effects from the vaccine were noted in the newborn. The mother had not delivered at the time of the report in the second case (4).

A 1990 brief report described the use of rabies vaccine in 16 pregnant women, 15 using the human diploid cell vaccine and 1 receiving the purified chick embryo cell product (5). In 15 cases, the stage of pregnancy was known: nine 1st trimester, three 2nd trimester, and three 3rd trimester. Two women had spontaneous abortions, but the causes were probably not vaccine related. The remaining pregnancy outcomes were 12 full-term healthy newborns, 1 premature delivery at 36 weeks' gestation, and 1 newborn with grand-mal seizures on the 2nd day. In the latter case, no anti-rabies antibodies were detectable in the infant's serum, indicating that the condition was not vaccine related (5).

In two reports, duck embryo-cultured vaccine was used during pregnancy (6,7). In 1974, a report appeared describing the use of rabies vaccine (duck embryo) in a woman in her 7th month of pregnancy (6). She was given a 21-

day treatment course of the vaccine. She subsequently delivered a healthy term male infant who was developing normally at 9 months of age. The second case was described in 1975 involving a woman exposed to rabies at 35 weeks' gestation (7). She was treated with a 14-day course of vaccine (duck embryo) followed by three booster injections. She gave birth at 39 weeks' gestation to a healthy male infant. Cord blood rabies neutralizing antibody titer was 1:30, indicative of passive immunity, compared with a titer of 1:70 in maternal serum. Titers in the infant fell to 1:5 at 3 weeks of age, then to <1:5 at 6 weeks. Development was normal at 9 months of age (7).

A 1989 report from Thailand described the use of purified Vero cell rabies vaccine for postexposure vaccination in 21 pregnant women (8). Equine rabies immune globulin was also administered to 12 of the women with severe exposures. One patient aborted 3 days after her first rabies vaccination, but she had noted vaginal bleeding on the day of rabies exposure. No congenital malformations were observed and none of the mothers or their infants developed rabies after a 1-year follow-up (8).

In a subsequent prospective study, the above researchers administered the purified Vero cell rabies vaccine (five-dose regimen) after exposure to 202 pregnant women (9). Some of these women also received a single dose of rabies immune globulin (human or equine). Follow-up of 1 year or greater was conducted in 190 patients; 12 patients were lost to follow-up following postexposure treatment. No increase in maternal (spontaneous abortion, hypertension, placenta previa, or gestational diabetes) or fetal (stillbirth, minor birth defect, or low birth weight) complications was observed in comparison with a control group of nonvaccinated, nonexposed women. The one minor congenital defect observed in the treated group was a type of clubfoot (talipes equinovagum) (9).

BREASTFEEDING SUMMARY

No reports describing the administration of rabies (human) vaccine during human lactation have been located.

VACCINE, RUBELLA

Vaccine

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Although no defects attributable to rubella vaccine have been reported, the CDC calculates the theoretical risk of congenital rubella syndrome (CRS) following vaccination with the RA 27/3 vaccine to range from 0% to 1.6%, or from 0% to 1.2%, if data from all rubella vaccines are included (1). These risks are considerably lower than the $\geq 20\%$ risk associated with wild rubella virus infection during the 1st trimester (2). Because a theoretical risk does exist, the use of the vaccine in pregnancy is contraindicated (1–6). Moreover, both the manufacturer and the CDC recommend that women should avoid becoming pregnant for 3 months after receiving the vaccine (1,4). However, if vaccination does occur within 3 months (now 4 weeks [3]) of conception or during pregnancy, the actual risk, as stated above, is considered to be negligible and, in itself, should not be an indication to terminate the pregnancy (2,3,5–8).

FETAL RISK SUMMARY

Rubella (German measles) vaccine is a live, attenuated virus vaccine (4). Animal reproduction studies have not been conducted with the vaccine.

Rubella occurring during pregnancy may result in the CRS. The greatest risk period for viremia and congenital defects is 1 week before to 4 weeks after conception (5). Moreover, rubella reinfection, most often presenting as a subclinical infection that can be detected by a rise in antibody titers, may occur in previously vaccinated patients and in those who are naturally immune (9,10). The fetal risk of infection in these cases is low but has not yet been quantified.

The CDC defines CRS as any two complications from list A or one complication from list A plus one from list B (5):

List A

Cataracts or congenital glaucoma

Congenital heart disease
Loss of hearing
Pigmentary retinopathy

List B

Purpura
Splenomegaly
Jaundice (onset within 24 hours of birth)
Microcephaly
Mental retardation
Meningoencephalitis
Radiolucent bone disease

Before April 1979, the CDC collected data on 538 women vaccinated within 3 months before or after conception with either the Cendehill or HPV-77 vaccines (5). A total of 149 of these women were known to be susceptible at the time of vaccination and the outcome of pregnancy was known for 143 (96%). No evidence of CRS or other maternal or fetal complication was found in any of these cases or in an additional 196 infants exposed during pregnancy. Eight infants had serologic evidence of intrauterine infection after maternal vaccination, but follow-up for 2–7 years revealed no problems attributable to CRS (5).

Since January 1979, only RA 27/3 rubella vaccine has been available in the United States. In the United States between January 1979 and December 1988, a total of 683 women vaccinated with RA 27/3 have been reported to the CDC (2). The outcomes of these pregnancies were as follows:

| | |
|---|-----------------------|
| <i>Total vaccinated (1/79–12/88)</i> | 683 |
| <i>Susceptible at vaccination</i> | 272 |
| Live births | 212 (2 sets of twins) |
| Spontaneous abortions or stillbirths | 13 |
| Induced abortions | 31 |
| Outcome unknown | 18 |
| <i>Immune or unknown at vaccination</i> | 411 |
| Live births | 350 (1 set of twins) |
| Spontaneous abortions or stillbirths | 9 |
| Induced abortions | 24 |
| Outcome unknown | 29 |

Evidence of subclinical infection was found in 3 (2%) of the 154 liveborn infants from susceptible mothers who were serologically evaluated (2).

However, no evidence of defects compatible with CRS was found in the total sample of 212 liveborn infants. Two infants did have asymptomatic glandular hypospadias, but both mothers had negative rubella-specific immunoglobulin M (IgM) titers in the cord blood at birth (2). In a 1985 evaluation of earlier CDC data, no defects compatible with CRS were found in any of the fetuses or infants in whom the outcome was known (6). Examinations up to 29 months after birth have revealed normal growth and development (2,6).

A 2000 report described six women who received rubella vaccine (live, attenuated vaccine strain RA27/3) either in the pre- or periconceptional periods (11). No evidence of fetal infection was observed in five of the women. In one case, however, vertical transmission of the virus was documented that resulted in persistent fetal infection. The 25-year-old woman, unaware of her pregnancy, received the vaccine 3 weeks after conception. Virus isolation and polymerase chain reaction (PCR) of amniotic fluid obtained by amniocentesis at 16 weeks' gestation confirmed the vertical transmission. Multiple maternal and fetal serologic and virologic testings were done throughout the pregnancy. Rising IgG titers and persistent IgM levels were measured in the fetus. At 39 weeks' gestation, a cord blood sample was positive for virus isolation and PCR. Although a persistent rubella viral infection was documented, frequent monitoring of the pregnancy revealed no pathologic findings or complications and a healthy 3450-g male infant was delivered at 40 weeks' gestation. Apgar scores were 9, 9, and 10 at 1, 5, and 10 minutes, respectively. At 23 weeks of age, IgM, PCR, and virus isolation in his peripheral blood were negative. His growth and development have been normal up to 14 months of age (11).

BREASTFEEDING SUMMARY

The CDC recommends vaccination of susceptible women with rubella vaccine in the immediate postpartum period (1). Many of these women will breastfeed their newborns. Although two studies failed to find evidence of the attenuated virus in milk, subsequent reports have demonstrated transfer (12–16).

In one case, the mother noted rash and adenopathy 12 days after vaccination with the HPV-77 vaccine on the 1st postpartum day (14). Rubella virus was isolated from her breast milk and from the infant's throat (14). A significant level of rubella-specific cell-mediated immunity was found in the infant, but there was no detectable serologic response as measured by rubella hemagglutination inhibition antibody titers (14). No adverse effects were noted in the infant. In a second case report, a 13-day-old breastfed infant developed rubella about 11 days after maternal vaccination with HPV-77 (17). It could not

be determined whether the infant was infected by virus transmission via the milk (18,19). Nine (69%) of 13 lactating women given either HPV-77 or RA 27/3 vaccine in the immediate postpartum period shed virus in their milk (15). In another report by these same researchers, 11 (69%) of 16 vaccinated women shed rubella virus or virus antigen in their milk (16). No adverse effects or symptoms of clinical disease were observed in the infants.

VACCINE, SMALLPOX

Vaccine

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

The CDC classifies smallpox vaccine as contraindicated during pregnancy, within 28 days of conception, and in persons who might have close contact with pregnant women within 28 days of their vaccination (1,2). Other sources also consider smallpox vaccine to be contraindicated during pregnancy (3–6). However, the vaccine should be given to pregnant women who have been exposed to smallpox or monkeypox (1,2,7). Because the risk for fetal vaccinia is low, inadvertent exposure to the vaccine during or before pregnancy should not be a reason for pregnancy termination (1).

FETAL RISK SUMMARY

Smallpox vaccine is a live, attenuated virus vaccine (3,4). Although smallpox infection had a high mortality rate, the disease has been largely eradicated from the world (3,5). Vaccination during pregnancy between 3 and 24 weeks has resulted in fetal death (4,5). A 1974 reference reviewed the published reports of smallpox vaccination during pregnancy and found 20 cases of fetal vaccinia among more than 8500 maternal vaccinations (8). Of the 21 exposed fetuses (1 set of twins), only 3 of the 10 liveborns survived. There was only weak evidence, however, that vaccination during the 1st trimester increased fetal wastage compared with that occurring later in gestation (8).

In a 2004 review that documented the rarity of fetal vaccinia, only about 50 cases were found of fetal infection after smallpox vaccination during pregnancy or shortly before conception (9). Although the exact number of women given the vaccine during pregnancy was unknown, the number is probably large because, in past years, pregnant women were routinely vaccinated during outbreaks of smallpox. The 50 cases were documented in women who had received the vaccine at anytime in pregnancy, after primary vaccination and revaccination, and in nonvaccinated women who had contact with vaccines. The authors

concluded that there was insufficient evidence to recommend prophylactic treatment with vaccinia immune globulin if the woman was pregnant or shortly before conception when she received the vaccine (9).

The CDC announced the establishment of the National Smallpox Vaccine in Pregnancy Registry in 2003 (10). The Registry was established to monitor pregnancy outcomes of women who had received the vaccine during pregnancy, or who became pregnant or were in close contact with a vaccinee within 28 days after vaccination. Health care providers and public health staff were encouraged to report cases by calling 877-554-4625 or 404-639-8253 (10).

Two months after the above announcement, the CDC reported, for the period of November 2001–April 2003, that 103 women had received the vaccine either during pregnancy or within 4 weeks of conception (1). The exposures occurred in military personnel, civilian health care and public health workers, and clinical studies. In the civilian group, two women conceived within 1 week before vaccination and four conceived within 28 days after vaccination. Two (timing of vaccination not specified) of the six women had early spontaneous abortions (1). Other pregnancy outcomes, other than these two, have apparently not yet been reported.

BREASTFEEDING SUMMARY

No reports of nursing women receiving smallpox vaccine have been located. In an unusual report, however, tertiary contact vaccinia transmission from a mother to her nursing infant through direct skin-to-skin and skin-to-mucous membrane contact was documented (11). The father, a soldier in the United States Army, had received smallpox vaccination, but had reportedly taken standard precautions to avoid spread to his family. Approximately 1–2 weeks later, his wife developed vesicles on both areolas. About 2 weeks later, a papule developed on the philtrum of the breastfeeding infant. Polymerase chain reaction and culture for vaccinia of the mother and infant confirmed contact vaccinia (11).

Because of the risk of contact vaccinia in a nursing infant, the CDC recommends that breastfeeding mothers should not be routinely vaccinated (11). However, based on the recommendations during pregnancy, if a nursing woman is exposed to smallpox or monkeypox, she should receive the vaccine but should probably stop breastfeeding.

VACCINE, TC-83 VENEZUELAN EQUINE ENCEPHALITIS

Vaccine

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

One case of human pregnancy exposure to TC-83 Venezuelan equine encephalitis vaccine has been reported, but the adverse fetal outcome combined with the animal data indicate that the vaccine should not be given to pregnant women. In the United States, routine immunization is not practiced, but some laboratory workers may require the vaccine because of potential exposure to the virus in their work (1). Based on the available data, pregnancy should be excluded before administration of the vaccine, and the woman warned against conception in the immediate future (in the case above, the woman was advised not to become pregnant for 1 month after vaccination, but references confirming this as a safe interval for this vaccine have not been located).

FETAL RISK SUMMARY

A live, attenuated strain of Venezuelan equine encephalitis (VEE) virus, TC-83, is used as a vaccine (1). VEE, transmitted by mosquitoes, is primarily found in South America and Central America, but cases have occurred in Texas (1). Although many human cases of VEE are asymptomatic, some patients may have severe symptoms, including confusion, seizures, and nuchal rigidity (1).

VEE was embryo- and fetotoxic and teratogenic in rats inoculated with the virulent Guajira strain during the first 2 weeks of pregnancy (2). All embryos died within 3–4 days with evidence of necrosis and hemorrhage. Inoculation later in pregnancy resulted in similar outcomes, including infarcts of the placenta.

Fetal rhesus monkeys were administered TC-83 VEE virus vaccine via the intracerebral route at 100 days' gestation and then were allowed to proceed to

term (159–161 days' gestation) (3). All of the infected fetuses were born alive. Some of the newborns were killed and examined within 24 hours of birth, others at 1 month, and the remainder at 3 months. Malformations evident in all of the offspring were microencephaly, hydrocephaly, and cataracts, and two-thirds had porencephaly.

A 1977 brief accounting of the 1962 outbreak of VEE in Venezuela cited the frequent abortion of women who were infected during the 1st trimester (4). In addition, the infection of seven pregnant women, between the 13th and 36th weeks of gestation, and the subsequent fatal fetal and newborn outcomes were discussed (4). All of the fetuses and newborns had destruction of the fetal cerebral cortex, the degree of which was determined by the interval between infection and delivery. In one of the cases, the mother had severe encephalitis at 13 weeks and eventually gave birth at 33 weeks' gestation. Microcephaly, microphthalmia, luxation of the hips, severe medulla hypoplasia, and the near absence of neural tissue in the cranium were evident in the stillborn fetus (4).

The fatal outcome of a case in which a 21-year-old laboratory worker became pregnant (against medical advice) after receiving the TC-83 vaccine was described in a 1987 report (1). The mother's VEE virus titers were 1:20 at 17 weeks' gestation and 1:10, 3 months later. Maternal serum α -fetoprotein and an ultrasound examination were normal at 17 weeks, but a lack of fetal movement was noted at 26 weeks. One week later, a stillborn, hydropic female fetus was delivered. Generalized edema, ascites, hydrothorax, and a large multilobulated cystic hygroma were noted on examination. Mononuclear infiltrate was found in the myocardium and pulmonary arterioles and an inflammatory cell infiltrate was noted in the trachea, intestinal adventitia, brain, uterus, and fallopian tubes (1). Marked autolysis of the brain had occurred. Abnormalities in the placenta included calcifications, infarcts, petechiae, and thrombosis in the decidua (1).

BREASTFEEDING SUMMARY

No reports describing the administration of TC-83 Venezuelan equine encephalitis vaccine during human lactation have been located.

VACCINE, TULAREMIA

Vaccine

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably
Compatible

PREGNANCY SUMMARY

Tularemia vaccine is a live, attenuated bacteria vaccine (1,2). Because tularemia is a severe disease, preexposure prophylaxis of indicated persons should occur regardless of pregnancy (1).

FETAL RISK SUMMARY

Tularemia is a serious infectious disease occurring primarily in laboratory personnel, rabbit handlers, and forest workers (1). The risk to the fetus from the vaccine is unknown. One report described vaccination in a woman early in the 1st trimester with transplacental passage of antibodies (2,3). No adverse effects were observed in the term infant or at 1-year follow-up.

BREASTFEEDING SUMMARY

No reports describing the administration of tularemia vaccine during human lactation have been located.

References

VACCINE, TYPHOID

Vaccine

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably
Compatible

PREGNANCY SUMMARY

Typhoid is a serious infectious disease with high morbidity and mortality. The risk to the fetus from the vaccine is unknown (1).

FETAL RISK SUMMARY

Three typhoid vaccines are available: typhoid Vi polysaccharide vaccine that is given IM (2); typhoid vaccine live attenuated oral Ty21a (3); and typhoid vaccine of inactivated (killed) bacteria that is given SC (4). No animal reproduction studies have been conducted with any of the vaccine types.

BREASTFEEDING SUMMARY

No reports describing the administration of typhoid vaccine during human lactation have been located.

VACCINE, VARICELLA VIRUS

Vaccine

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

The risk of congenital varicella syndrome with natural (wild) varicella virus is approximately 1%–2% during the first 20 weeks of gestation. Moreover, there is significant risk for infectious morbidity and possible mortality in the neonate and young child when maternal varicella infection occurs after the 1st trimester. The risk from the vaccine is thought to be much less, because the virulence of the attenuated virus used in the vaccine is less than that of the natural virus. Although varicella virus vaccine is contraindicated immediately before and during pregnancy because of unknown fetal effects, the potential for harmful fetal effects appears to be very low as estimated below. No cases of varicella vaccine-induced fetal harm have been identified to date. Because of this, the Advisory Committee on Immunization Practices (ACIP) recommends that a decision to terminate a pregnancy should not be based on whether the vaccine was given during pregnancy (1). Health care professionals are encouraged to report patients who receive the vaccine 3 months before or at any time during pregnancy to the Varivax Pregnancy Registry by calling 800-986-8999.

FETAL RISK SUMMARY

Varicella virus vaccine is prepared from the Oka/Merck strain of live, attenuated varicella-zoster virus (1,2). The vaccine became commercially available in May 1995. Animal reproductive studies have not been conducted with the vaccine.

The manufacturer considers vaccination of a woman within 3 months of conception and during pregnancy to be contraindicated because the effects of the vaccine on the fetus are unknown (2). Both the ACIP and the American Academy of Pediatrics, however, recommend avoiding pregnancy for only 1 month following an immunization injection (1,3). Vaccination of a child is not

contraindicated if the child's nonimmune mother or other nonimmune household member is pregnant (1,3).

Many references have described the effects of natural (wild) varicella infection during pregnancy on the fetus and newborn (3,4–39). Infection with wild varicella-zoster virus during the first 20 weeks of pregnancy is associated with a risk of congenital varicella syndrome (1,4–6). The syndrome is commonly characterized by low birth weight. Other clinical features, not all of which may be apparent in each case, are shown below (1,4–6):

Cutaneous: cicatricial skin lesions, denuded skin

Neurologic: microcephaly, cortical atrophy, myoclonic seizures, hypotonia, hyporeflexia, encephalomyelitis, dorsal radiculitis, Horner's syndrome, bulbar dysphagia, deafness, mental retardation

Ophthalmic: microphthalmia, chorioretinitis, cataracts, nystagmus, anisocoria, enophthalmos, hypoplasia of the optic discs, optic atrophy, squint

Skeletal: limb hypoplasia of bone and muscle (usually on same side as scarring), hypoplasia of mandible, clavicle, scapula, ribs, fingers and toes, club foot

Gastrointestinal: gastroesophageal reflux, duodenal stenosis, jejunal dilatation, microcolon, atresia of sigmoid colon, malfunction of anal sphincter

Genitourinary: neurogenic bladder

In addition, infection in the 2nd and 3rd trimesters (13 weeks' gestation to term) is associated with a risk of clinical varicella infection during the newborn period or with clinical zoster during infancy and early childhood (1). Severe neonatal varicella may occur in 17%–30% of newborns if the onset of maternal varicella infection is 5 days before to 2 days after delivery. Although based on small numbers, possibly affected by reporting bias and not reflective of modern treatment models (data reported in 1974), the death rate in neonates whose mothers had an onset of rash 0–4 days before delivery was 31% (1).

Data from five prospective studies indicate the risk of congenital varicella syndrome during the 1st trimester was 1.0% (6 of 617 infants) (range 0%–9.1%) (4,7–10). A higher risk, 2.0% (7 of 351 infants), was found if the infection occurred during 13–20 weeks' gestation (10). Based on these five studies, the overall incidence of congenital varicella syndrome from maternal infection during the first 20 weeks' gestation was 1.3% (13 of 968).

In addition to children 12 months of age or older who have not had varicella, the ACIP recommends vaccination for nonimmune adults because of the

severity of chickenpox in this population (1,3). Vaccination is contraindicated in pregnancy because of the unknown effects of the vaccine on the fetus and because of the known fetal adverse effects of the natural (wild) varicella-zoster virus (1–3).

A 1996 report from the manufacturer's pregnancy registry for Varivax described seven pregnant women who had received the vaccine between June 1995 and late 1996 (40,41). The women, thought to be nonimmune, had been exposed to varicella and were inadvertently given the vaccine instead of the indicated varicella-zoster immune globulin (see also Immune Globulin, Varicella-Zoster [Human]). Moreover, one of the women received 5 times the recommended dose of the vaccine (40,41). None of the women had histories of varicella infection, but their immune status prior to the vaccine was not reported. Four of the seven women had a gestational age at vaccination of <20 weeks, and three had pregnancy durations in the range of >20 weeks to 31 weeks. Two women had delivered healthy children but the outcomes of the other five pregnancies were pending at the time of this report.

The annual report from the Merck/CDC Pregnancy Registry covered the period from March 17, 1995, through March 16, 2009 (42). These data, which include the first seven pregnancy exposures discussed above, involved 1255 women vaccinated 3 months prior to or at any time during pregnancy and who met the enrollment criteria, but does not include 33 women who had due dates after March 16, 2009. The number of enrolled women included 1190 prospective cases (reported before the outcome was known) and 65 retrospective exposures (reported after the outcome was known). Among the prospective cases, 399 were lost to follow-up, 52 had elective abortions (EABs), and 2 pregnancies were pending. The outcomes for the remaining 737 pregnancies were 72 spontaneous abortions (SABs), 1 late fetal death (at 23 weeks, cause unknown), and 674 live births (includes 8 twins and 1 set of triplets). There were 18 prospective reports and 8 retrospective reports of major birth defects, but none had features consistent with congenital varicella syndrome. Also, there were no birth defects consistent with congenital varicella syndrome in the reports that ended with an SAB or EAB. There were 14 birth defects reported in pregnancy outcomes ≥ 20 weeks from the last menstrual period among 674 prospectively reported live births, a rate of 2.1%. These results do not support a relationship between congenital varicella syndrome or other birth defects and vaccine exposure during pregnancy. However, the Registry does not have sufficient statistical power to rule out a very low risk (42).

A 1997 report described a well-documented case of child-to-mother transmission of varicella vaccine virus (43). A 12-month-old boy received varicella vaccine and about 3 weeks later had approximately 30 generalized lesions without fever or feeling ill. The lesions were thought to be mild varicella. The 30-year-old mother had a serologic titer negative for varicella and a negative urine pregnancy test at that time. Neither the mother nor her child had any evidence (clinical or laboratory) of immunodeficiency. Sixteen days after appearance of the lesions on her child, she developed a papulovesicular rash diagnosed as varicella. A repeat urine pregnancy test was now positive with an estimated gestational age of 5–6 weeks. Five days later, approximately 100 lesions were counted on the mother, who remained afebrile. On repeat test, seroconversion was documented with a positive varicella titer. Virus was isolated from three of the mother's lesions and identified as Oka strain varicella-zoster virus by polymerase chain reaction test, indicating that her lesions resulted from the vaccine administered to her child. She had an elective abortion during the 7th gestational week because of her concerns that the fetus could acquire the congenital varicella syndrome or other malformations. No varicella-zoster virus DNA was isolated from the fetal tissue. The authors, using a transmission rate of 17% reported for vaccinees with leukemia, estimated the risk of virus transmission from a healthy vaccinee with rash to a nonimmune household member to be about 0.85% (43).

In an editorial comment on the above case, the child's medical history before vaccination was thought to be compatible with a significant allergic diathesis (44). Moreover, at the time of the vaccination his eczema was being treated with the topical corticosteroid, desonide 0.05% (45). A combination of factors, including the number of postvaccination lesions on the child, the contribution of the child's eczema to viral expression, the immunosuppression produced by the corticosteroid, the close contact of the mother to the child resulting from the child's age and the application of the topical corticosteroid, and her pregnancy, were believed to account for the abundance of lesions on the mother. The author estimated the maximum theoretical risk for congenital varicella syndrome resulting from the transmission of varicella vaccine virus to a nonimmune pregnant woman to be <1 in 10,000 (<0.01%). The actual risk, however, was thought to be "exponentially lower," possibly 0, because of the rarity of documented viremia in children after vaccination and the absence of reported embryopathy with attenuated varicella-zoster virus (44). Neither the author of the editorial (44) nor another correspondent (45) thought that vaccination of a child should be postponed if a nonimmune mother was pregnant or attempting

to conceive.

BREASTFEEDING SUMMARY

In a 1986 study, no viruses were cultured from the breast milk of two women with varicella-zoster virus infections (46). One of the women had herpes zoster dermatitis 6 months postpartum and was nursing. Direct lesion contact was prevented, and she continued to breastfeed. In the other case, the woman developed varicella pneumonia at 40 weeks' gestation and her infant was delivered by emergency cesarean section. The infant did not become infected after prophylactic treatment with immune globulin varicella-zoster (human) and parenteral acyclovir. Despite the mother's serious postpartum condition, she maintained lactation with a breast pump. Although a varicella virus culture of the milk was negative, the milk was not given to her infant, nor was the infant allowed to breastfeed (46).

A 2003 study reported that varicella DNA was not detected in 217 postvaccination samples of breast milk from 12 women who had received 2 doses of vaccine (47). Because there was no evidence of varicella vaccine virus excretion into milk, the investigators concluded that there was no need to delay vaccination in breastfeeding women (47).

Both the CDC and the American Academy of Pediatrics consider the vaccination of a varicella-zoster virus-susceptible nursing mother to be appropriate if the risk of exposure to the natural virus is high (1,3).

VACCINE, YELLOW FEVER

Vaccine

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably
Compatible

PREGNANCY SUMMARY

Yellow fever vaccine is a live, attenuated virus vaccine (1). Yellow fever is a serious infectious disease with high morbidity and mortality. The risk to the fetus from the vaccine is unknown (1,2). The CDC states that the vaccine should not be used in pregnancy except if exposure to yellow fever was unavoidable (2).

FETAL RISK SUMMARY

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 3 of whom had 1st trimester exposure to yellow fever vaccine (3). There were no birth defects.

A 1993 report described the use of yellow fever vaccine (vaccine strain 17D) in 101 women at various stages of pregnancy during the 1986 outbreak of yellow fever in Nigeria (4). The women received the vaccine during gestation either because of an unknown pregnancy or because they feared acquiring the disease. The vaccine was administered to 4 women in the 1st trimester, 8 in the 2nd trimester, and 89 in the 3rd trimester, with the gestational ages ranging from 6 to 38 weeks. Serum samples were obtained before and after vaccination from the women as well as from 115 vaccinated, nonpregnant controls. Measurements of immunoglobulin M (IgM) antibody and neutralizing antibody in these samples revealed that the immune response of pregnant women was significantly lower than that of controls. One woman, with symptoms of acute yellow fever during the week before vaccination, suffered a spontaneous abortion 8 weeks after vaccination. Although the cause of the abortion was unknown, the investigators concluded that it was not caused by the vaccine. No evidence was found for transplacental passage of the

attenuated virus. Nine of the mothers produced IgM antibody after vaccination, but the antibody was not detected in their newborns. Neutralizing antibody either crossed the placenta or was transferred via colostrum in 14 of 16 newborns delivered from mothers with this antibody. No adverse effects on physical or mental development were observed in the offspring during a 3- to 4-year follow-up period (4).

The first reported case of congenital infection following vaccination was described in a study in which attenuated yellow fever vaccine, in response to a threat of epidemic yellow fever, was administered to 400,000 people in Trinidad (5). Pregnant women, all of whom received the vaccine during the 1st trimester of pregnancies unrecognized at the time of vaccination, were identified retrospectively. Serum samples were collected from 47 women and 41 term infants, including 35 mother-child pairs. Women who delivered prematurely and those suffering spontaneous abortions were not sampled. One of the 41 infants had IgM and elevated neutralizing antibodies to yellow fever, indicating congenital infection. Natural exposure to the virus was thought to be unlikely because virus transmission during that period was limited to forest monkeys with no human cases reported. The infected 2920-g infant, the product of a normal full-term pregnancy, appeared healthy on examination and without observable effect on morphogenesis. However, because the neurotropism of yellow fever virus for the developing nervous system has been well documented (e.g., vaccine-induced encephalitis occurs almost exclusively in infants and young children), the authors considered this case as further evidence that the vaccine should be avoided during pregnancy (5).

A 1999 report from the European Network of Teratology Information Services described the prospectively ascertained outcomes in 58 of 74 pregnancies exposed to yellow fever vaccine (6). Timing of exposure was before the last menstrual period (LMP), in the 1st trimester, or in the 2nd trimester in 3, 69, and 2, respectively. Sixteen of the cases did not have complete follow-up data and were excluded from the analysis. The pregnancy outcomes included 7 spontaneous abortions, 5 induced abortions, and 46 live births. In the newborns, there were two major malformations: ureteral stenosis and triphalangeal hallux. There were also three cases of minor anomalies: bilateral pes varus, slight deviation of the nasal wall, and mild ventricular septal defect. Vaccination in all of these five cases occurred early in gestation. The rates of abortion and congenital malformations are within expected ranges. The investigators also found 4 cases exposed in utero to yellow fever vaccine among 23,925 cases of birth defects reported between 1980 and 1995 to the

France/Central-East Registry of Malformations. The defects in these cases were (timing of exposure in parentheses) right ectromelia of upper limb (1st trimester), a VATER (vertebral defects, anal atresia, tracheoesophageal fistula with esophageal atresia, and radial and renal anomalies) association (2nd trimester), stenosis of the aortic orificium (1st trimester), and hydrocephalus in an infant stillborn near term (2nd trimester). Two other cases of spontaneous abortion (respectively at 6 and 13 weeks after the LMP) were reported by a French manufacturer to the investigators. The authors concluded that although their sample was far too small to rule out a moderately increased risk of adverse outcome, their data do not support such an association and could be used to reassure pregnant women who have inadvertently received the vaccine (6).

A 1994 review concluded that pregnant women should be vaccinated, preferably after the 1st trimester, if exposure to a yellow fever epidemic is unavoidable (7).

BREASTFEEDING SUMMARY

No reports describing the administration of yellow fever vaccine during human lactation have been located.

VALACYCLOVIR

Antiviral

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

For the management of herpes in pregnancy, either valacyclovir or acyclovir are recommended for primary or first-episode infection (for 7–10 days), symptomatic recurrent episode (for 5 days), and daily suppression (from 36 weeks' gestation until delivery), but only acyclovir is recommended for severe or disseminated disease (1). Although the experience with valacyclovir in early pregnancy is limited, many studies have reported the use of acyclovir during all stages of pregnancy (see also Acyclovir). Based on the combined data, there is no evidence of a major risk to the human fetus from valacyclovir or acyclovir. Long-term follow-up of children exposed in utero to these agents is warranted.

FETAL RISK SUMMARY

Valacyclovir is biotransformed to acyclovir and L-valine by first-pass intestinal and/or hepatic metabolism. The drug is active against herpes simplex virus (HSV) types 1 and 2 and varicella-zoster virus. It is used in the treatment of herpes zoster (shingles) and recurrent genital herpes simplex.

Reproduction studies were conducted in rats and rabbits during organogenesis with doses producing concentrations 10 and 7 times human plasma levels, respectively (2). No teratogenic effects were observed with these doses.

The active metabolite, acyclovir, readily crosses the human placenta (see Acyclovir). An abstract and study, both published in 1998, compared the pharmacokinetics of valacyclovir and acyclovir in late pregnancy (3,4). Acyclovir accumulated in the amniotic fluid but not in the fetus. The mean maternal/umbilical vein plasma ratio at delivery was 1.7.

The Valacyclovir Pregnancy Registry listed 157 prospective reports of women exposed to the oral antiviral drug during gestation covering the period

from January 1, 1995, through April 30, 1999 (5). Of the total, 47 (30%) pregnancies were lost to follow-up. Among the 111 (1 set of twins) known outcomes, 29 had earliest exposure in the 1st trimester and their outcomes were 5 spontaneous abortions, 2 induced abortions, 1 infant with a birth defect (talipes), and 21 infants (including the twins) without birth defects. When the earliest exposure was in the 2nd trimester, 31 pregnancies were enrolled and their outcomes were 2 stillbirths, 2 infants with birth defects (fingers and toes fused—extensive webbing; small cleft in front gum), and 27 without birth defects. In the remaining 51, the earliest exposure occurred in the 3rd trimester, with 1 infant with a dermal sinus tract and 50 without birth defects (5).

A total of 34 retrospective reports of valacyclovir exposure during pregnancy were submitted to the Registry (5). Two of the exposures occurred during an unspecified gestational time and both resulted in live births without defects. In 14 pregnancies, the earliest exposure occurred during the 1st trimester. The outcomes of these pregnancies were three spontaneous losses, eight induced abortions, and three infants without birth defects. For the pregnancies whose earliest exposure was in the 2nd trimester (N = 4) or 3rd trimester (N = 14), there was 1 birth defect (2nd trimester exposure) and 17 infants without defects (5).

A 1999 case report described a woman at 20 weeks' gestation who had a generalized HSV infection that was treated with IV acyclovir for about 2 weeks followed by valacyclovir for the remainder of the pregnancy (6). She delivered a full-term, healthy female infant who was treated prophylactically with oral acyclovir for 1 month. No abnormalities were detected during a neurologic examination at 8 months of age (6).

A prospective, double-blind, placebo controlled trial was conducted to estimate the efficacy of valacyclovir to reduce HSV infection at delivery (7). Valacyclovir 500 mg twice daily (N = 170) or placebo (N = 168) was given from 36 weeks' gestation until delivery. Compared with controls, valacyclovir significantly reduced HSV shedding and need for cesarean section. There were no differences between the groups in terms of delivery and neonatal outcomes (7).

A 2009 review of genital herpes concluded that the benefits from the use of acyclovir or valacyclovir for the treatment of the virus in pregnancy far outweighed the potential fetal risks (8). Because there was no evidence to suggest a risk of major defects with acyclovir, the reviewers also concluded that the pro-drug valacyclovir, even though the pregnancy experience was

limited, could be viewed similarly.

A 2010 study used a population-based historical cohort of 837,795 liveborn infants in Denmark to determine if there were associations between 1st trimester exposure to acyclovir, valacyclovir, and famciclovir and major birth defects (9). Subjects were excluded if they had chromosomal abnormalities, genetic syndromes, birth defect syndromes, or congenital viral infections. Among 1804 pregnancies exposed to one of the antivirals, there were 40 (2.2%) infants with a major birth defect compared with 19,920 (2.4%) among those unexposed (adjusted prevalence odds ratio [POR] 0.89, 95% confidence interval [CI] 0.65–1.22). In the valacyclovir group, 7 (3.1%) infants had a major defect from the 229 with 1st trimester exposure (POR 1.21, 95% CI 0.56–2.62). The prevalence of major defects with acyclovir and famciclovir were 2.0% (POR 0.82, 95% CI 0.57–1.17) and 3.8%, respectively, but only 26 pregnancies (1 infant with a defect) were exposed to famciclovir. The study limited the evaluation to 13 major birth defect types by organ system. For any antiviral drug, POR >1 were found for defects of the nervous system, eye, abdominal wall, urinary tract, and a miscellaneous group of defects; none reached statistical significance. The authors concluded that 1st trimester exposure to valacyclovir and acyclovir was not associated with an increased risk of major birth defects (9). The authors of an accompanying editorial thought that the large number of exposures during organogenesis without an overall increased risk of major defects was reassuring, especially for acyclovir. However, more data were needed to examine the associations with individual defects (10).

BREASTFEEDING SUMMARY

Valacyclovir is rapidly and nearly completely converted to acyclovir and the amino acid, L-valine. Acyclovir is concentrated in human milk with milk:plasma ratios in the range 3–4 (see Acyclovir).

In a 2002 study, five healthy postpartum women who were breastfeeding were given valacyclovir (500 mg) twice daily for 7 days (11). Maternal serum and milk samples were collected after the first dose, on day 5, and 24 hours after the last dose. Infant urine samples were collected on day 5. All samples were analyzed for acyclovir. The peak milk concentration occurred 4 hours after the first dose (milk:serum ratio 3.4), whereas the peak serum level occurred at 2 hours. At steady state, the milk:serum ratio was about 1.9. The median infant urine acyclovir concentration was 0.74 mcg/mL. Twenty-four hours after the last dose, the milk:serum ratio was 0.25. The estimated infant

dose (based on a consumption of 750 mL/day of milk by a 2.75-kg infant) would be about 0.2% of the therapeutic dose for neonates (11).

Because acyclovir has been used to treat herpesvirus infections in the neonate, and because of the lack of adverse effects in reported cases in which acyclovir was used during breastfeeding, the American Academy of Pediatrics classifies acyclovir as compatible with breastfeeding (see Acyclovir). Valacyclovir also appears to be compatible with breastfeeding.

VALDECOXIB

[Withdrawn from the market. See 9th edition.]

VALERIAN

Herb

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

The very limited animal and human data do not allow a conclusion as to the safety of valerian during pregnancy. Moreover, as a natural, unregulated product, the concentration, contents, and presence of contaminants in valerian preparations cannot be easily determined. Because of this uncertainty and the potential for cytotoxicity in the fetus and hepatotoxicity in the mother, the product should be avoided during pregnancy. Other authors have arrived at the same conclusion (1,2). The risk to a fetus from short-term or inadvertent use during any part of gestation, however, is probably low, if it exists at all.

FETAL RISK SUMMARY

Valeriana officinalis, the plant most often used for medicinal purposes, is 1 species of approximately 200 of the genus *Valeriana*, an herbaceous perennial that grows widely in the temperate regions of North America, Europe, and Asia (4). A large number of preparations containing valerian are commercially available (4). The herb is used as a sedative and hypnotic for anxiety, restlessness, and sleep disturbances (1–5). Other pharmacologic claims that have been made for valerian include antispasmodic, anticonvulsive, antidepressant, and antihypertensive properties (2–4). The extracts and root oil have also been used as flavorings for foods and beverages (3).

Although the specific agents responsible for the effects of valerian are unknown, as is the mechanism of action, three classes of compounds have been identified: a volatile oil that contains sesquiterpenes; nonglycosidic iridoid esters (known as valepotriates); and alkaloids (3,4). Of these, the valepotriates, found primarily in the roots, are most likely responsible for the

sedative action, but components from the other two classes probably contribute as well (3,4). Because these compounds produce central nervous system depression, they should not be used with other depressants, such as alcohol, benzodiazepines, barbiturates, or opiates (1,2,5). Moreover, nonpregnant adult human hepatotoxicity has been associated with short-term use (i.e., a few days to several months) of herbal preparations containing valerian (6). Long-term use in a male has also been associated with benzodiazepine-like withdrawal symptoms resulting in cardiac complications and delirium (7).

Reproductive studies in animals with valerian have not shown antiovation, antifertilization, or embryotoxic effects (8). Further, the valepotriates exhibit low toxicity in mice, producing no deaths in doses of up to 1600 mg/kg IP or 4600 mg/kg orally (3). Toxicity in mice was characterized by ataxia, hypothermia, and increased muscle relaxation.

The cytotoxic activities of three valepotriate compounds, valtrate, didrovaltrate, and baldrinal (a degradation product of valtrate), in cultured rat hepatoma cells were described in a 1981 reference (9). Both valtrate and didrovaltrate demonstrated much greater cytotoxic activity than did baldrinal, with rapid and irreversible toxicity. In addition, the antitumor activity of didrovaltrate was demonstrated in vivo on female mice KREBS II ascitic tumors (9). Five surviving mice were then bred with normal male mice 50 days after treatment with didrovaltrate. Each had a normal pregnancy and produced normal offspring.

In a 1988 report, two cases of attempted suicide with valerian dry extract plus other drugs were described (10). In one case, a woman at 10 weeks' gestation ingested 2.5 g of valerian dry extract and 0.5 g of phenobarbital. An apparently normal, 4350-g female infant was delivered at 42 weeks' gestation. Examination of the child (age not specified) indicated an IQ in the range of 111–120. In the second case, the mother ingested a combination of valerian dry extract (3.0 g), phenobarbital (0.6 g), glutethimide (5.0 g), amobarbital (5.0 g), and promethazine (0.3 g) at 20 weeks' gestation. A mentally slow, 2650-g male infant was born at 36 weeks' gestation. About 2 years later in her next pregnancy, this woman again attempted suicide at 20 weeks' gestation, by ingesting glutethimide (3.75 g), amobarbital (3.75 g), and promethazine (0.23 g). She delivered another mentally slow, 2650-g male infant at 43 weeks'. The infant also had a unilateral undescended testicle. Of interest, none of the woman's other 10 children is mentally slow.

Two additional cases of self-poisoning with valerian were described in 1987 by the same group responsible for the above report (11). In both cases

exposure occurred early in gestation, with ingestion of 5 and 2 g of valerian at 3 and 4 weeks of fetal development, respectively. No congenital abnormalities were observed in the offspring.

BREASTFEEDING SUMMARY

No reports describing the use of valerian during lactation have been located. For the reasons cited above, the use of this herbal product should be avoided during breastfeeding.

VALGANCICLOVIR

Antiviral

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of valganciclovir in human pregnancy have been located. For ganciclovir, human pregnancy experience has not shown toxicity, but the number of cases is very limited. The animal data for ganciclovir are suggestive of high embryo–fetal risk because carcinogenic, mutagenic, teratogenic, and embryotoxic effects have been observed. Primary cytomegalovirus (CMV) infections occurring in pregnancy have a high risk of transplacental passage of the virus to the fetus. Some of the embryos or fetuses exposed to the virus will be damaged and the development of later toxicity in childhood is an additional concern. However, the prevention of these in utero infections by ganciclovir has not been proven (see Ganciclovir).

FETAL RISK SUMMARY

After oral administration, the prodrug valganciclovir is rapidly converted to ganciclovir by intestinal and hepatic enzymes. The antiviral effect, therefore, is identical to ganciclovir (see Ganciclovir). Valganciclovir is indicated for the treatment of CMV retinitis in patients with AIDS. Plasma protein binding of valganciclovir is not relevant because of its rapid metabolism to ganciclovir, but binding of ganciclovir is very low (1%–2%). The elimination half-life of ganciclovir after valganciclovir administration is about 4.1 hours, compared with 3.8 hours when IV ganciclovir is administered (1). Ganciclovir crosses the human placenta (see Ganciclovir).

Reproduction studies in animals have been conducted with the active metabolite ganciclovir (1) (see Ganciclovir).

BREASTFEEDING SUMMARY

No reports describing the use of valganciclovir during human lactation have been located. Because the active metabolite, ganciclovir, has the potential to cause serious toxicity in a nursing infant, mothers taking this drug should not breastfeed. Further, breastfeeding is contraindicated if the mother is infected with HIV.

VALPROIC ACID

Anticonvulsant

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Valproic acid and the salt form, sodium valproate, are human teratogens. The absolute risk of producing a child with neural tube defects (NTDs) when these agents are used between the 17th and 30th days after fertilization is 1%–2%. A characteristic pattern of minor facial defects is apparently also associated with valproic acid. Studies have suggested that a distinct constellation of defects and fetal growth restriction may exist for infants exposed in utero to the anticonvulsant. These defects involve the head and face, digits, urogenital tract, and mental and physical growth. A correlation between maternal dose and major and minor anomalies has been reported. There also are reports of a significant association with autism. Other problems, such as hyperbilirubinemia, hepatotoxicity, and fetal or newborn distress, need additional investigation.

FETAL RISK SUMMARY

Valproic acid and its salt form, sodium valproate, are anticonvulsants used in the treatment of seizure disorders. The drugs readily cross the placenta to the fetus. At term, the range of cord blood:maternal serum ratios of total valproic acid (protein bound and unbound) has been reported to be 0.52–4.6 (1–13). Studies that are more recent have reported mean ratios of 1.4–2.4 (4,7,9–13). In contrast, the mean cord blood:maternal serum ratio of free (unbound) valproic acid was 0.82 (10). Two mechanisms have been proposed to account for the accumulation of total valproic acid in the fetus: partial displacement of the drug from maternal binding sites by increased free fatty acid concentrations in maternal blood at the time of birth (10) and increased protein binding of valproic acid in fetal serum (11). Increased unbound valproic acid in the maternal serum may also be partially a result of decreased serum albumin (14).

Although one study measured a mean serum half-life for valproic acid in the newborn of 28.3 hours (9), other studies have reported values of 43–47 hours, approximately 4 times the adult value (2,4,8,10,13). In agreement with these data, valproic acid has been shown to lack fetal hepatic enzyme induction activity when used alone and will block the enzyme induction activity of primidone when the two anticonvulsants are combined during pregnancy (15).

In published reports, doses of valproic acid in pregnancy have ranged from 300 to 3000 mg (1–3,8,12,16–28). Although a good correlation between serum levels and seizure control is not always observed, most patients will respond when levels are in the range of 50–100 mcg/mL (29). In early pregnancy, high (i.e., >1000 mg) daily doses of valproic acid may produce maternal serum concentrations that are >100 mcg/mL (8). However, as pregnancy progresses and without dosage adjustment, valproic acid levels fall steadily so that in the 3rd trimester, maternal levels are often <50 mcg/mL (8). One study concluded that the decreased serum concentrations were a result of increased hepatic clearance and an increased apparent volume of distribution (8).

Fetal or newborn consequences resulting from the use of valproic acid and sodium valproate during pregnancy have been reported to include major and minor congenital abnormalities, intrauterine growth restriction, hyperbilirubinemia, hepatotoxicity (which may be fatal), transient hyperglycinemia, afibrinogenemia (one case), and fetal or neonatal withdrawal.

Before 1981, the maternal use of valproic acid was not thought to present a risk to the fetus. A 1981 editorial recommended sodium valproate or carbamazepine as anticonvulsants of choice in appropriate types of epilepsy for women who may become pregnant (30). Although the drug was known to be a potent animal teratogen (31), more potent than phenytoin and at least as potent as trimethadione (32), only a single unconfirmed case of human teratogenicity (in a fetus exposed to at least two other anticonvulsants) had been published between 1969 and 1976 (33). (An editorial comment in that report noted that subsequent investigation had failed to confirm the defect.) In other published cases, both before and after 1980, healthy term infants resulted after in utero exposure to valproic acid (1–3,12,19,27,28,32,34–38). Moreover, a committee of the American Academy of Pediatrics stated in 1982 that the data for a teratogenic potential in humans for valproic acid were inadequate and that recommendations for or against its use in pregnancy could not be given (39).

The first confirmed report of an infant with congenital defects after valproic acid exposure during pregnancy appeared in 1980 (16). The mother, who took 1000 mg of valproic acid daily throughout gestation, delivered a growth-

restricted infant with facial dysmorphism and heart and limb defects. The infant died at 19 days of age. Since this initial report, a number of studies and case reports have described newborns with malformations after in utero exposure to either valproic acid monotherapy or combination therapy (4,17–26,36,40–60).

The most serious abnormalities observed with valproic acid (or sodium valproate) exposure are defects in neural tube closure. The absolute risk of this defect is approximately 1%–2%, about the same risk for a familial occurrence of this anomaly (37,40,61,62). No cases of anencephaly have been associated with valproic acid (21,62,63). Exposure to valproic acid between the 17th and 30th day after fertilization must occur before the drug can be considered a cause of NTDs (64). Other predominant defects involve the heart, face, and limbs. A characteristic pattern of minor facial abnormalities has been attributed to valproic acid (61). Cardiac anomalies and cleft lip and palate occur with most anticonvulsants and a causal relationship with valproic acid has not been established (37,46). In addition, almost all types of congenital malformations have been observed after treatment of epilepsy during pregnancy (see Janz 1982, Phenytoin). Consequently, the list below, although abstracting the cited references, is not meant to be inclusive and, at times, reflects multiple anticonvulsant therapy.

NEURAL TUBE DEFECTS

Defects in neural tube closure (includes entire spectrum from spina bifida occulta to meningomyelocele) (17,19,21,22,24,26,40–42,44–46,53–58)

CARDIAC DEFECTS

Multiple (not specified) (21,24,26,37,42,44,51)

Levocardia (16)

Anomalies of great vessels (51)

Patent ductus arteriosus (4,26,48,50,52)

Valvular aortic stenosis (23,48)

Ventricular septal defect (4,20,48)

Tetralogy of Fallot (18,51)

Partial right bundle branch block (16)

FACIAL DEFECTS

Facial dysmorphism (4,26,42,46,50,53,59)

Small nose (16,20,24,26,50,53,59)

Small nose (16,20,24,26,50,53,59)
Depressed nasal bridge (18,20,26,50,59)
Epicanthal folds (4,26,50,53,59)
Protruding eyes (16)
Hypertelorism (4,26)
Low-set/rotated ears (4,16,24,26,50)
Micrognathia/retrognathia (16,23,26)
Depigmentation of eyelashes and brow (16,25)
Thin upper vermilion border (24,26,48,50,53)
Down-turned angles of mouth (50,59)
High forehead (24,26)
Bulging frontal eminences (16,20)
Strabismus (50)
Nystagmus (50)
Flat orbits (26)
Coarsened facies (20)
Cleft lip/palate (18,37,42,44,51)
Microstomia (24,26,48,50)
Esotropia (50)
Long upper lip (26,50,59)
Short palpebral fissure (26,48,50)
Agenesis of lacrimal ducts (51)

HEAD/NECK DEFECTS

Brachycephaly (24,26)
Hydrocephaly (19,21,42,46)
Short neck (20)
Abnormal or premature stenosis of metopic suture (24,26,50)
Microcephaly (4,21,24,38,50,64,65)
Wide anterior fontanelle (18)
Craniostenosis (26)
Aplasia cutis (60)

UROGENITAL DEFECTS

Bilateral duplication of caliceal collecting systems (25)
Bilateral undescended testes (23)
Nonspecified (26)

Hypospadias (21,23,26,46,50)
Bilateral renal hypoplasia (23)

SKELETAL/LIMB DEFECTS

Aplasia of radius (23,26)
Dislocated hip (16,26,35)
Hypoplastic thumb (20)
Hemifusion of second and third lumbar vertebrae (25)
Arachnodactyly (24,26)
Overlapping fingers/toes (24,26)
Broad or asymmetric chest (16,26)
Multiple (not specified) (24)
Rib defects (24,26)
Foot deformity (17,23,24,50)
Abnormal digits (23,26,37,42)
Shortened fingers and toes (4,20)
Abnormal sternum (16,26)
Scoliosis (25)
Clinodactyly of fingers (26)
Tracheomalacia (53)
Talipes equinovarus (53)
Reduced head circumference (85)

SKIN/MUSCLE DEFECTS

Accessory, wide-spaced, or inverted nipples (20,26)
Diastasis recti abdominis (4,25)
Syndactyly of toes (16,23,50)
Hyperconvex fingernails (24,26)
Hemangioma (4,25,26,50)
Sacral dimple (43)
Telangiectasia (4)
Cutis aplasia of scalp (50)
Weak abdominal walls (4)
Hirsutism (26)
Abnormal palmar creases (16,18,50)
Hypoplastic nails (4,18)
Umbilical hernias (4,26)

Linea alba hernia (47)
Inguinal hernia (4,26,50)
Omphalocele (59)

OTHER DEFECTS

Multiple defects (not specified) (24,51)
Duodenal atresia (25)
Withdrawal or irritation (4,50)
Mental retardation (4,20,50,51,53)
Single umbilical artery (50)

A 2010 study combined data from 8 published cohort studies (1565 pregnancies exposed to valproic acid monotherapy in the 1st trimester) to identify 118 major malformations, 14 of which were significantly more common in the offspring (66). Using these 14 malformations, they then conducted a case–control study using data from the European Surveillance of Congenital Anomalies (EUROCAT) antiepileptic study database that is derived from population-based registries that contained data for 3.8 million births (1995–2005) in 14 European countries. A total of 37,154 cases were compared with 39,472 controls without chromosomal abnormalities (group 1), and 11,763 controls with chromosomal abnormalities (group 2). First trimester exposure to valproic acid monotherapy occurred in 122, 45, and 13, respectively, of the cases and two control groups. As compared with no use of an anticonvulsant during the 1st trimester (control group 1), significantly increased risks were found for 6 of the 14 malformations under consideration (adjusted odds ratio [OR], 95% confidence interval [CI]): spina bifida 12.7 (7.7–20.7); atrial septal defect 2.5 (1.4–4.4); cleft palate 5.2 (2.8–9.9); hypospadias 4.8 (2.9–8.1); polydactyly 2.2 (1.0–4.5); and craniosynostosis 6.8 (1.8–18.8). Except for polydactyly, significant associations also were found for these malformations when compared with the control group 2 (66).

Although a wide variety of minor anomalies, many of which are similar in nature, occurs in infants of epileptic mothers, three groups of investigators have concluded that the deformities associated with valproic acid are distinctly different from those associated with other anticonvulsants and may constitute a fetal valproate syndrome (FVS) (26,50,53). The combined features cited in the three reports were (a) NTDs; (b) craniofacial: brachycephaly, high forehead, epicanthal folds, strabismus, nystagmus, shallow orbits, flat nasal bridge, small up-turned nose, hypertelorism, long upper lip, thin upper vermilion border,

microstomia, down-turned angles of mouth, low-set/rotated ears; (c) digits: long, thin, partly overlapping fingers and toes, hyperconvex nails; (d) urogenital: hypospadias (in about 50% of males); and (e) other: slow psychomotor development, low birth weight. Normal psychomotor development has been observed, however, in follow-up studies of children up to 4 years of age after in utero exposure to either mono- or combination therapy with valproic acid (3,34,65,67).

A 1995 review listed the facial features seen in the FVS as trigonocephaly, tall forehead with bifrontal narrowing, epicanthic folds, medial deficiency of eyebrows, flat nasal bridge, broad nasal root anteverted nares, shallow philtrum, long upper lip with thin vermilion border, thick upper lip, and small, downturned mouth (68). The most common major congenital defects observed were NTDs, congenital heart disease, cleft lip and palate, genital anomalies, and limb defects. Other, less common abnormalities were tracheomalacia, abdominal wall defects, and strabismus. Dose-related withdrawal symptoms (irritability, jitteriness, hypotonia, and seizures) were considered to be very common, typically occurring 12–48 hours after birth (68).

A correlation between valproic acid dosage and the number of minor anomalies in an infant has been proposed (26). Such a correlation has not been observed with other anticonvulsants (26). The conclusion was based on the high concentrations of valproic acid that occur in the 1st trimester after large doses (i.e., 1500–2000 mg/day).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 26 newborns had been exposed to valproic acid during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Five (19.2%) major birth defects were observed (one expected), one of which was a hypospadias. No anomalies were observed in five other categories of defects (cardiovascular, oral clefts, spina bifida, polydactyly, and limb reduction defects) for which specific data were available. Hypospadias has been associated with 1st trimester valproic acid exposure (see above).

A 2000 study, using data from the MADRE (**MA**lformation and **DR**ug **E**xposure) surveillance project, assessed the human teratogenicity of anticonvulsants (69). Among 8005 malformed infants, the cases included infants with a specific malformation, whereas controls were infants with other anomalies. Of the total group, 299 were exposed in the 1st trimester to anticonvulsants. Among these, exposure to monotherapy occurred in the following: valproic acid (N = 80), phenobarbital (N = 65), mephobarbital (N =

10), carbamazepine (N = 46), phenytoin (N = 24), and other agents (N = 16). Statistically significant associations (CI not overlapping 1 and $p \leq 0.05$) were found between valproic acid monotherapy and spina bifida (N = 12); hypospadias (N = 10); porencephaly/multiple cerebral cysts and other specified anomalies of brain (N = 2); microstomia, microcheilia, and other anomalies of face (N = 2); coarctation of aorta (N = 2); and limb reduction defects (N = 5). When all 1st trimester exposures (mono- and polytherapy) were evaluated, significant associations were found between valproic acid and spina bifida (N = 14), cardiac defects (N = 26), hypospadias (N = 14), porencephaly/multiple cerebral cysts and other specific anomalies of brain (N = 2), limb reduction defects (N = 5), and hypertelorism, localized skull defects (N = 2). Although the study confirmed some previously known associations, several new associations with anticonvulsants were discovered which require independent confirmation (see also Carbamazepine, Mephobarbital, Phenobarbital, and Phenytoin) (69).

The risk of valproic acid–induced limb deficiencies was estimated in a 2000 study that used data from the Spanish Collaborative Study of Congenital Malformations (ECEMC) collected between 1976 and 1997 (70). A total of 22,294 consecutive malformed infants (excluding genetic syndromes) were compared with 21,937 control infants. A total of 57 malformed infants and 10 controls were exposed to valproic acid during the 1st trimester (OR 5.62, 95% CI 2.78–11.71, $p < 0.0000001$). Among the 57 infants, 21 (36.8%) had congenital limb defects of different types (overlapping digits, talipes, clinodactyly, arachnodactyly, hip dislocation, pre- and postaxial polydactyly, and limb deficiencies). Five of the 21 cases, however, were thought to have resulted from immobility (e.g., talipes equinovarus) caused by spina bifida. After exclusion of these cases and their respective controls, the OR for congenital limb defects was 3.95, 95% CI 1.24–13.94, $p = 0.01$. Three of the malformed infants had limb deficiencies: hypoplasia of the left hand; unilateral forearm defect and hypoplastic first metacarpal bone in the left hand; and short hands with hypoplastic first metacarpal bone absent and hypoplastic phalanges (this case also had retrognathia, facial asymmetry, hypospadias, telangiectatic angioma in the skull, and hypotonia). The case–control analysis showed a risk for limb deficiencies of OR 6.17, 95% CI 1.28–29.66, $p = 0.023$. In their population, the prevalence at birth of limb deficiencies was 6.88 per 10,000 live births. Based on this, the risk of limb deficiencies after exposure to valproic acid in the 1st trimester was estimated to be about 0.42% (70).

A prospective study published in 1999 described the outcomes of 517 pregnancies of epileptic mothers identified at one Italian center from 1977 (71).

Excluding genetic and chromosomal defects, malformations were classified as severe structural defects, mild structural defects, and deformations. Minor anomalies were not considered. Spontaneous (N = 38) and early (N = 20) voluntary abortions were excluded from the analysis, as were 7 pregnancies that delivered at other hospitals. Of the remaining 452 outcomes, 427 were exposed to anticonvulsants of which 313 involved monotherapy: valproate (N = 44), carbamazepine (N = 113), phenobarbital (N = 83), primidone (N = 35), phenytoin (N = 31), clonazepam (N = 6), and other (N = 1). There were no defects in the 25 pregnancies not exposed to anticonvulsants. Of the 42 (9.3%) outcomes with malformations, 24 (5.3%) were severe, 10 (2.2%) were mild, and 8 (1.8%) were deformities. There were eight malformations with valproic acid monotherapy: six (13.6%) were severe (spina bifida, hydrocephalus, pyloric stenosis, and cardiac defect), one (2.3%) was mild (inguinal hernia), and one was a deformation (arthrogryposis). The investigators concluded that the anticonvulsants were the primary risk factor for an increased incidence of congenital malformations (see also Carbamazepine, Clonazepam, Phenobarbital, Phenytoin, and Primidone) (71).

The Lamotrigine Pregnancy Registry, an ongoing project conducted by the manufacturer, was first published in January 1997. The final report was published in July 2010 (72). The Registry is now closed. Among 181 prospectively enrolled pregnancies exposed to valproate and lamotrigine, with or without other anticonvulsants, 169 were exposed in the 1st trimester resulting in 140 live births, 17 birth defects, 2 fetal deaths, 6 spontaneous abortions, and 4 elective abortions. There were 11 exposures in the 2nd/3rd trimesters resulting in 9 live births, 1 birth defect, and 1 fetal death. One live birth was exposed in an unspecified trimester (72).

A 1997 case report described autism diagnosed in a 5.5-year-old boy who had typical clinical features of the FVS (73). The mother had taken valproic acid (2000 mg/day) during the first 5 months of pregnancy for the treatment of dizzy spells, possible absence seizures, and an abnormal electroencephalogram (EEG). Although his gross motor milestones were normal, both his speech and language development were delayed. Based on their review of the literature, the authors concluded that a possible relationship between autism and FVS existed (73).

A population-based study of all children born alive in Denmark during 1996–2006 was published in 2013 (74). Of 655,615 children, 5437 had autism spectrum disorder, including 2067 with childhood autism. The estimated absolute risk was 1.53% (95% CI 1.47–1.58) for autism spectrum disorder and

0.48% (95% CI 0.46–0.51) for childhood autism. For the 508 children exposed in utero to valproate, the absolute risk was 4.4% (95% CI 2.59–1.46) for autism spectrum disorder (adjusted hazard ratio [AHR] 2.9) (95% CI 1.7–4.9), whereas for childhood autism the absolute risk was 2.50% (95% CI 1.30–4.81), AHR 5.2 (95% CI 2.7–10.0). When the analysis was restricted to the 6584 children born to mothers with epilepsy, the absolute risk of autism spectrum disorder among 432 exposed to valproate was 4.15% (95% CI 2.20–7.81), AHR 1.7 (95% CI 0.9–3.2) and for childhood autism 2.95% (95% CI 1.42–6.11), AHR 2.9 (95% CI 1.4–6.0) vs. the two outcomes for 6152 children not exposed to valproate 2.44% (95% CI 1.88–3.16) and 1.02% (95% CI 0.70–1.49). The data indicated that in utero exposure to valproate was associated with a significantly increased risk of autism spectrum disorder and childhood autism even after adjusting for maternal epilepsy (74). Other studies and reviews have reported the association between fetal valproate exposure and autism (75–77).

The relationship between maternal anticonvulsant therapy, neonatal behavior, and neurological function in children was reported in a 1996 study (78). Among newborns exposed to maternal monotherapy, 18 were exposed to phenobarbital (including primidone), 13 to phenytoin, and 8 to valproic acid. Compared with controls, neonates exposed to phenobarbital had significantly higher mean apathy and optimality scores. Phenytoin-exposed neonates also had a significantly higher mean apathy score. However, the neonatal optimality and apathy scores did not correlate with neurological outcome of the children at 6 years of age. In contrast, those exposed to valproic acid had optimality and apathy scores statistically similar to controls but a significantly higher hyperexcitability score. Moreover, the hyperexcitability score correlated with minor and major neurological dysfunction at age 6 years (78).

A 2013 study reported dose-dependent associations with reduced cognitive abilities across a range of domains at 6 years of age after fetal valproate exposure (79). Analysis showed that IQ was significantly lower for valproate (mean 97, 95% CI 94–101) than for carbamazepine (mean 105, 95% CI 102–108; $p = 0.0015$), lamotrigine (mean 108, 95% CI 105–110; $p = 0.0003$), or phenytoin (mean 108, 95% CI 104–112; $p = 0.0006$). Mean IQs were higher in children whose mothers had taken folic acid (mean 108, 95% CI 106–111) compared with children whose mothers had not taken the vitamin (mean 101, 95% CI 98–104; $p = 0.0009$) (79).

A valproate dose relationship with major fetal malformations has been reported (80–82). In these studies, doses >1100 mg/day were associated with

a higher incidence of major defects. However, a 2013 review stated that daily doses of ≥ 1000 mg, as well as polytherapy, were associated with a higher teratogenic risk (77).

Intrauterine growth restriction (IUGR) or small-for-gestational-age infants have been noted in several reports (4,16,19,23,24,47,48,50,65,84,85). Both monotherapy and combination therapy with valproic acid were involved in these cases. However, normal birth weights, heights, and head circumferences have been reported with valproic acid monotherapy (25,50,53,65). Growth impairment is a common problem with some anticonvulsant therapy (e.g., see Phenytoin), but the relationship between this problem and valproic acid needs further clarification.

A study published in 2009 examined the effect of AEDs on the head circumference in newborns (85). Significant reductions in mean birth-weight-adjusted mean head circumference (bw-adj-HC) was noted for monotherapy with carbamazepine and valproic acid. No effect on bw-adj-HC was observed with gabapentin, phenytoin, clonazepam, and lamotrigine. A significant increase in the occurrence of microcephaly (bw-adj-HC smaller than 2 standard deviations below the mean) was noted after any AED polytherapy but not after any monotherapy, including carbamazepine and valproic acid. The potential effects of these findings on child development warrant study (85).

A 1983 letter proposed that the mechanism for valproic acid-induced teratogenicity involved zinc deficiency (84). From in utero studies, the authors had previously shown that valproic acid readily binds zinc. Low zinc serum levels potentiated the teratogenicity of certain drugs in animals and produced adverse effects similar to valproic acid-induced human toxicity (84). Another proposed mechanism, especially when valproic acid is combined with other anticonvulsants, involves the inhibition of liver microsomal epoxide hydrolase, the enzyme responsible for the biotransformation of reactive epoxide metabolites (86). The inhibition of the detoxifying enzyme could result in enhanced fetal exposure to reactive epoxide metabolites, such as carbamazepine epoxide, by preventing its biotransformation to a trans-dihydrodiol metabolite. Based on these findings, the authors recommended that combination drug therapy with valproic acid be avoided during pregnancy (86).

Three reports have observed hyperbilirubinemia in nine newborns exposed in utero to valproic acid monotherapy and in one infant exposed to combination therapy (4,25,48). A causal relationship is uncertain because other studies have not reported this problem.

Liver toxicity has been observed in three infants after in utero exposure to

valproic acid (47,48). In the first report, a growth-restricted female infant, exposed to valproic acid and phenytoin, had a linea alba hernia noted at birth but her liver function tests were normal (47). The mother breastfed the child for the first several weeks. At 2.5 months of age, the infant presented with an enlarged liver, slight icterus, vomiting, and failure to thrive. Liver function tests indicated a cholestatic type of hyperbilirubinemia, and liver biopsy specimen demonstrated fibrosis with ongoing necrosis of liver cells. Although they were unable to determine which anticonvulsant caused the injury, the authors concluded that valproic acid was the more likely offending agent. The second report described two siblings born of a mother treated with valproic acid monotherapy during two pregnancies (48). A male infant, exposed in utero to 300 mg/day, was normal at birth but died at age 5 months of liver failure. Autopsy revealed liver atrophy, necrosis, and cholestasis. The female infant, exposed in utero to 500 mg/day, died at age 6 weeks of liver failure. At birth, the infant was noted to have defects characteristic of valproic acid exposure (defects described in the list above), IUGR, hyperbilirubinemia, hypoglycemia, hypocalcemia, and seizures. Liver atrophy and cholestasis were noted at autopsy (48).

Undetectable fibrinogen levels resulting in fatal hemorrhage in a full-term 2-day-old infant were attributed to in utero sodium valproate exposure (87). The mother had taken daily doses of sodium valproate 600 mg, phenytoin 375 mg, and lorazepam 1 mg throughout pregnancy. In a subsequent pregnancy, the measurement of slightly decreased maternal fibrinogen levels in late gestation caused the authors to discontinue the sodium valproate while continuing the other two agents. Oral vitamin K was also administered to the mother and she delivered a healthy infant without bleeding problems (87).

Transient hyperglycinemia has been observed in two newborns exposed in utero to sodium valproate combination therapy (combined with phenytoin in one and phenytoin, carbamazepine, and clonazepam in the other) (3). Similar increases of glycine have been observed in epileptic adults treated with valproic acid. No adverse effects in the newborns resulted from the amino acid alteration (3).

Fetal distress during labor (late decelerations, silent or accelerated beat-to-beat variations) was observed in 6 (43%) of 14 cases exposed to valproic acid monotherapy (26). Two of the newborns with fetal distress plus two others had low Apgar scores (0–3 after 1 minute or 0–6 after 5 minutes). Maternal doses were 1500–1800 mg/day in three cases and 600 mg/day in one case. Low Apgar scores were not observed in 12 infants whose mothers had been treated

with valproic acid combination therapy. Other studies and case reports have not mentioned this complication. The fetal and newborn depression was thought to have resulted from a threefold increase in the maternal serum of valproic acid free fraction (26). A similar increase had been measured in an earlier study (10).

No decreases in adrenocorticotrophic hormone or cortisol levels were measured in a mother or her newborn after the use of valproic acid 3000 mg/day during the last 3 months of pregnancy (28). The mother had received combination anticonvulsant therapy during the first 6 months of gestation.

Valproic acid has been measured in the semen of two healthy males (88). Following oral doses of 500 mg, semen levels ranged from 0.53 to 3.26 mcg/mL up to 39 hours after the dose. Simultaneous serum levels were 11–17 times those measured in the semen. No effect on sperm motility was suggested based on animal experiments (88).

Because of the risk for NTDs, women exposed during the critical period of gestation should consult their physician about prenatal testing (37,89,90).

BREASTFEEDING SUMMARY

Valproic acid and its salt, sodium valproate, are excreted into human milk in low concentrations (1,2,4,5,8,10,12,91,92). Milk concentrations up to 15% of the corresponding level in the mother's serum have been measured. In two infants, serum levels of valproate were 1.5% and 6.0% of maternal values (92).

Only one report of adverse effects in a nursing infant attributable to valproate in breast milk has been located. Thrombocytopenia purpura, anemia, and reticulocytosis were observed in a 3-month-old male breastfed infant whose mother was taking sodium valproate (monotherapy; 1200 mg/day) for epilepsy (93). The infant had a 2-week history of increasing petechiae and minor hematoma on the lower part of the legs. The infant's serum valproate level was 6.6 mcg/mL. Breastfeeding was discontinued for 5 days but had no effect on the infant's low platelet count. The mother continued to nurse for another 2 weeks and again stopped. Twelve days later, valproate was undetectable in the infant's serum and 7 days later (19 days after nursing was stopped), the platelet count began to rise, reaching normal values sometime after 35 days. At about this same time, the petechiae had resolved. The blood hemoglobin and the reticulocytes normalized between 12 and 19 days after breastfeeding was stopped (93).

In a 2010 study, 199 children who had been breastfed while their mothers were taking a single antiepileptic drug (carbamazepine, lamotrigine, phenytoin,

or valproate) were evaluated at 3 years of age cognitive outcome (94). Mean adjusted IQ scores for exposed children were 99 (95% CI 96–103), whereas the mean adjusted IQ scores of nonbreastfed infants were 98 (95% CI 95–101).

The American Academy of Pediatrics classifies valproic acid as compatible with breastfeeding (95).

VALRUBICIN

Antineoplastic

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible (Intact Bladder)

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible (Intact Bladder)

PREGNANCY SUMMARY

No reports describing the use of valrubicin in human pregnancy have been located. The animal data suggest risk, but the drug was given IV on a daily basis and neither systemic concentrations nor a no-observed-effect level (NOEL) was reported. However, the systemic levels in the animals must have been much higher than those seen in humans with intact urinary bladders. Thus, these results are not relevant to the human exposure unless perforation of the bladder has occurred. Although the lack of human pregnancy experience prevents a more complete assessment of the embryo–fetal risk, the drug should not be withheld, if indicated and the bladder is intact, because of pregnancy.

FETAL RISK SUMMARY

Valrubicin, an anthracycline antibiotic, is a semisynthetic analog of doxorubicin. It is in the same antineoplastic subclass of anthracyclines as daunorubicin, doxorubicin, epirubicin, and idarubicin. Valrubicin is indicated for intravesical therapy of BCG-refractory carcinoma in situ of the urinary bladder in patients for whom immediate cystectomy would be associated with unacceptable morbidity or mortality. The drug should not be given to patients with a perforated bladder or if the bladder mucosa has been compromised. Only nanogram quantities of valrubicin are absorbed into the systemic circulation, and valrubicin metabolites have been measured in blood. If urinary bladder perforation has occurred, much higher concentrations are absorbed which can cause systemic hematologic toxicity (1).

Reproduction studies have been conducted in rats. Daily IV doses that were one-sixth or one-third the recommended human intravesical dose based on BSA

caused fetal malformations. At the higher dose, numerous, severe alterations in the fetal skull and skeleton were observed, as well as an increase in fetal resorptions and a decrease in viable fetuses (1).

Studies for carcinogenicity and fertility have not been conducted. Valrubicin does cause damage to DNA in vitro and was mutagenic and clastogenic in assays (1).

It is not known if valrubicin crosses the human placenta. The molecular weight (about 724) and high lipophilic property suggest that the drug, if it reaches the systemic circulation, would cross to the embryo–fetus. However, in the presence of an intact urinary bladder, only nanogram amounts appear in the blood suggesting that such exposure would not be clinically significant.

BREASTFEEDING SUMMARY

No reports describing the use of valrubicin during human lactation have been located. The molecular weight (about 724) and high lipophilic property suggest that the drug, if it reaches the systemic circulation, will be excreted into breast milk. However, in the presence of an intact urinary bladder, only nanogram amounts appear in the blood and excretion of these amounts into milk probably is not clinically significant.

VALSARTAN

Antihypertensive

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The antihypertensive mechanisms of action of valsartan and angiotensin-converting enzyme (ACE) inhibitors are very close. That is, the former selectively blocks the binding of angiotensin II to AT₁ receptors, whereas the latter prevents the formation of angiotensin II itself. Therefore, use of this drug during the 2nd and 3rd trimesters may cause teratogenicity and severe fetal and neonatal toxicity identical to that seen with ACE inhibitors (e.g., see Captopril or Enalapril). Fetal toxic effects may include anuria, oligohydramnios, fetal hypocalvaria, intrauterine growth restriction, prematurity, and patent ductus arteriosus. Anuria-associated anhydramnios/oligohydramnios may produce fetal limb contractures, craniofacial deformation, and pulmonary hypoplasia. Severe anuria and hypotension, resistant to both pressor agents and volume expansion, may occur in the newborn following in utero exposure to valsartan. Newborn renal function and blood pressure should be closely monitored.

FETAL RISK SUMMARY

Valsartan is a selective angiotensin II receptor blocker (ARB) that is used, either alone or in combination with other antihypertensive agents, for the treatment of hypertension. Valsartan blocks the vasoconstrictor and aldosterone-secreting effects of angiotensin II by preventing angiotensin II from binding to AT₁ receptors (1).

Reproduction studies have been conducted in pregnant mice, rats, and rabbits (1). No teratogenic effects were observed in these species at oral doses up to 9, 18, and 0.5 times the maximum recommended human dose of 320 mg/day based on BSA (MRHD), respectively. The highest dose caused rat

maternal toxicity (reduction in body weight gain and food consumption). At this dose, administration during organogenesis or late gestation and lactation resulted in significant decreases in fetal weight, pup birth weight, and pup survival rate, and slight delays in developmental milestones (1). In rabbits, maternal toxic doses (0.25 and 0.5 times the MRHD) resulted in fetal resorptions, litter loss, abortions, and low fetal body weight as well as maternal mortality. The no-observed-adverse-effect doses in mice, rats, and rabbits were 9, 6, and 0.1 times the MRHD, respectively (1). No adverse effects on reproductive performance of male and female rats were noted at oral doses up to 6 times the MRHD (1).

It is not known if valsartan crosses the human placenta to the fetus. The molecular weight (about 436) is low enough that passage to the fetus should be expected.

A 2001 case report described the pregnancy outcome of a 40-year-old woman with well-controlled chronic hypertension and diet-controlled type 2 diabetes mellitus that was treated with valsartan (80 mg/day) and atenolol (75 mg/day) until presentation at 24 weeks' gestation (2). Anhydramnios (amniotic fluid index zero), most likely due to valsartan, was diagnosed by ultrasound, but fetal growth was appropriate for gestational age. Valsartan was stopped and atenolol was continued at the same dose. The amniotic fluid volume normalized within 2 weeks. The blood pressure and the diabetes remained under adequate control and there was no evidence of toxemia. Intrauterine fetal death was diagnosed at 31 weeks' gestation. At autopsy, very small, hypoplastic lungs were found (weight 18 g/expected 44 g), as were heavy kidneys (31 g/expected 18 g). The placenta was below the 10th percentile for gestational age (148 g/expected 311 g for gestational age at the 10th percentile). No other anomalies were detected. The very small placenta was thought to be primarily due to atenolol, but valsartan may have contributed to the condition. Death of the female fetus probably resulted from chronic placental insufficiency induced by the combination of valsartan and atenolol (2).

Three other case reports described the effects of valsartan on six pregnancy outcomes (3–5). In a 2001 report, three women were taking valsartan (80 mg/day) for hypertension at the time of conception (3). The drug therapy was stopped at 7, 10, and 18 weeks' gestation, respectively. No congenital defects or evidence of renal dysfunction were observed in the newborns delivered at 38, 38, and 32 weeks', respectively. However, growth restriction attributed to hypertension was observed in one infant (3). In the another 2001 case report, two women (one with type 2 diabetes) were taking valsartan (80 mg/day in

one, dose not specified in the other) in combination with hydrochlorothiazide during pregnancy (4). Anhydramnios was noted at 24 and 28 weeks', respectively. Although the anhydramnios resolved in both cases when valsartan was discontinued, the pregnancies were terminated. Both fetuses had foot and face deformities, hypoplastic skull bones with widely open sutures, and large kidneys that were microscopically abnormal. Neither fetus had pulmonary hypoplasia (4). In 2004, anhydramnios was observed in a woman at 20 weeks' gestation (5). She had been taking valsartan for chronic hypertension. The drug was stopped and complete recovery of the amniotic fluid was noted at 23.5 weeks'. A healthy 3050-g female infant was delivered at term and was developing normally at 6 months of age.

In a 2003 report, the outcomes of 42 pregnancies exposed to ARBs were described (6). The outcomes of 37 pregnancies (1 set of twins) exposed in the 1st trimester were 3 spontaneous abortions (drugs not specified), 4 elective abortions (one for exencephaly; candesartan until 4 3/7 weeks, carbimazole, hydrochlorothiazide, maternal obesity), 1 stillbirth (no anomalies; valsartan until week 4, cigarette smoking, other antihypertensives), 1 minor malformation (undescended testicles; therapy not specified), and 28 healthy newborns. There was one major malformation (cleft palate, patent ductus arteriosus, modest coarctation of the aorta, growth restriction; valsartan until week 13, hydrochlorothiazide, metoprolol, cigarette smoking). Five cases involved late exposure to ARBs and their outcomes involved one or more of the following: oligohydramnios/anhydramnios, anuria, hypoplastic skull bones, limb contractions, lung hypoplasia, and neonatal death (6).

A 2005 case report and review described a pregnancy complicated by chronic hypertension that was treated with valsartan (80 mg/day), hydrochlorothiazide (12.5 mg/day), prazosin (10 mg/day), and methyldopa (750 mg/day) (7). Anhydramnios was diagnosed at 24 weeks' gestation and ultrasound of the fetus revealed bilateral hyperechoic kidneys. Valsartan and hydrochlorothiazide were stopped 1 week later. Amniotic fluid volume normalized by 31 weeks'. A cesarean section at 38 weeks' delivered a 3060-g male infant with Apgar scores of 6 and 7 at 1 and 5 minutes, respectively. Mild skull bone hypoplasia (wide cranial suture), limb deformation (mild varus of the right foot), and abnormally large, hyperechogenic kidneys with decreased blood perfusion were observed in the infant. The infant's blood pressure was normal and he first passed urine at 6 hours. At 30 months of age, the child has had normal growth and development but mild chronic renal insufficiency (creatinine 1.1–1.4) (7).

In another 2005 case report, a 40-year-old woman took throughout pregnancy four daily medications for chronic hypertension: valsartan (8 mg), hydrochlorothiazide (0.15 mg), lecardinipine (20 mg) (a calcium channel blocker), and clonidine (0.15 mg) (8). At 36 weeks' gestation, oligohydramnios was diagnosed and a 2680-g female infant was delivered vaginally. The infant had a Potter's syndrome facies, hypocalvaria, and limb deformities consisting of bilateral talus valgus and fixed internal rotation of the right hand. Shortly after birth, the infant developed respiratory distress, acute renal failure (hyperechogenic kidneys with absent Cortico-medullary differentiation), and severe hypotension. However, the infant survived and renal function was normal at 8 months of age with substantial growth of the skull bones (8).

A 2007 review cited 64 published cases of pregnancies exposed to ARBs, 42.2% of which had unfavorable outcomes (9). The duration of ARB exposure was longer in the cases with poor outcomes compared with those with good outcomes, 26.3 ± 10.5 vs. 17.3 ± 11.6 weeks.

A 2012 review of the use of ACE inhibitors and ARBs in the 1st trimester concluded that there may be an elevated teratogenic risk, but the risk appeared to be related to other factors (10). The factors, that typically coexist with hypertension in pregnancy, included diabetes, advanced maternal age, and obesity.

BREASTFEEDING SUMMARY

No reports describing the use of valsartan during human lactation have been located. The molecular weight (about 436) is low enough that excretion into breast milk should be expected. The effect of this exposure on a nursing infant is unknown. The American Academy of Pediatrics classifies ACE inhibitors, a closely related group of antihypertensive agents, as compatible with breastfeeding (see Captopril or Enalapril).

VANCOMYCIN

Antibiotic

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Vancomycin is an antibiotic that is used for gram-positive bacteria when either the organisms are resistant to less toxic anti-infectives (e.g., penicillins and cephalosporins) or the patient is sensitive to these agents. No cases of congenital defects attributable to vancomycin have been located. The manufacturer has received reports on the use of vancomycin in pregnancy without adverse fetal effects (A.F. Crumley, personal communication, Eli Lilly, 1983).

FETAL RISK SUMMARY

Reproduction studies in rats and rabbits at doses up to 1 and 1.1 times the maximum recommended human dose based on BSA (MRHD), respectively, have revealed no teratogenic effects. No effects on fetal weight or development were seen with the same doses in rats or slightly lower doses in rabbits (0.74 times the MRHD) (1).

The pharmacokinetics of vancomycin in a woman at 26.5 weeks' gestation was described in a 1991 reference (2). Accumulation of the antibiotic, administered as 1 g IV every 12 hours (15 mg/kg/dose), was demonstrated in amniotic fluid (1.02 mcg/mL on day 1; 9.2 mcg/mL on day 13). At delivery at 28 weeks' gestation, cord blood levels were 3.65 mcg/mL (6 hours after the mother's maximum serum concentration), 76% of the mother's serum level. The newborn's serum level, 3.25 hours after birth, was 2.45 mcg/mL, indicating a half-life in the infant of 10 hours (2).

In a 2007 report, 13 nonlaboring, noninfected women at term, scheduled for cesarean section, were given a single 1-g IV dose of vancomycin (3). The full 1-g dose could be given to only six women, because four of five women given a 60-minute infusion and three of eight given a 90-minute infusion experienced a

reaction to the antibiotic (“red man syndrome”: pruritus, shortness of breath, flushing, headache, and one case of hypotension). All seven infants had normal Apgar scores and blood gasses. Scheduling complications also prevented giving the vancomycin at the planned intervals before delivery. The actual time intervals from the end of the infusion to maternal sample were 26–509 minutes, and there was a strong correlation between cord and maternal concentrations. Regardless of the interval, all 13 cord serum samples contained low amounts of vancomycin (3–9.4 mcg/mL), but these amounts were considered to be above the minimal inhibitory concentration for group B streptococcus (3).

Vancomycin was used for subacute bacterial endocarditis prophylaxis in a penicillin-allergic woman at term with mitral valve prolapse (4). One hour before vaginal delivery, a 1-g IV dose was given during 3 minutes (recommended infusion time is 60 minutes [1,5]). Immediately after the dose, maternal blood pressure fell from 130/74 to 80/40 mmHg and then recovered in 3 minutes. Fetal bradycardia, 90 beats/minute, persisted for 4 minutes. No adverse effects of the hypotension-induced fetal distress were observed in the newborn. The Apgar scores were 9 and 10 at 1 and 5 minutes, respectively (4).

A 1989 report examined the effects of multiple-dose vancomycin on newborn hearing and renal function (6). Ten pregnant, drug-dependent women were treated with IV vancomycin (1 g every 12 hours for at least 1 week) for suspected or documented infections caused by methicillin-resistant *Staphylococcus aureus*. Of the 10 women, 4 also received concomitant gentamicin. Two control groups, neither of which received antibiotics, were formed: 10 infants from nondrug-dependent mothers (group 2), and 10 infants from drug-dependent mothers (group 3). Auditory brainstem response testing was conducted on the infants at birth and at 3 months of age, and blood urea nitrogen and serum creatinine were measured at birth. The placental transfer of vancomycin was measured in two patients with cord blood levels of 16.7 and 13.2 mcg/mL, 6 and 2.5 hours after infusion, respectively. At birth, abnormal auditory brainstem responses were measured in a total of six infants: two infants from the study group (neither exposed to gentamicin), three from control group 2, and one from control group 3. The hearing defect in all six infants was an absent wave V at 40 dB (the average behavioral threshold of adult listeners) in one or both ears. Repeat testing at 3 months in five infants was normal, indicating that the initial tests were falsely positive. In the sixth infant (in the study group), the tests at 3 months again showed no response in either ear at 40 dB. This infant’s mother had received a 2-g vancomycin dose after initial dosing had produced low serum levels (<20 mcg/mL) of the antibiotic. The

peak serum level obtained following the double dose was 65.7 mcg/mL, a potentially toxic level if it was maintained. Following this, the mother was treated with the same regimen as the other women. On further examination, however, reduced compliance was discovered in both ears and the loss of hearing was diagnosed as a conduction defect, rather than sensorineural. Tests at 12 months, following improved compliance in both ears, were normal. Renal function studies in all 30 infants were also normal, although this latter conclusion has been challenged (7) and defended (8).

BREASTFEEDING SUMMARY

Vancomycin is excreted into breast milk. In one woman treated with IV vancomycin (1 g every 12 hours for at least 1 week), a milk level 4 hours after a dose was 12.7 mcg/mL (6). This value was nearly identical to the serum trough concentration measured at 12 hours in the mother during pregnancy. The effect on the nursing infant of vancomycin in milk is unknown. Vancomycin is poorly absorbed from the normal, intact gastrointestinal tract, and thus, systemic absorption would not be expected (5). However, three potential problems exist for the nursing infant: modification of bowel flora, direct effects on the infant (e.g., allergic response or sensitization), and interference with the interpretation of culture results if a fever workup is required.

VANDETANIB

Antineoplastic (Tyrosine Kinase Inhibitor)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of vandetanib in human pregnancy have been located. In the only animal species studied, the drug was embryotoxic, fetotoxic, and teratogenic at exposures close to or less than the human exposure. However, the absence of human pregnancy experience prevents a complete assessment of the embryo–fetal risk. Because of the risk of fetal harm, the manufacturer recommends that women of reproductive potential use effective contraception to prevent pregnancy during treatment and for at least 4 months following the last dose.

FETAL RISK SUMMARY

Vandetanib is an oral inhibitor of tyrosine kinase. There are several other agents in this subclass (see Appendix). It is indicated for the treatment of symptomatic or progressive medullary thyroid cancer in patients with unresectable locally advanced or metastatic disease. Vandetanib is metabolized to apparently inactive metabolites. The mean plasma protein binding to albumin and α_1 -acid-glycoprotein is 93.7% and the median plasma half-life is 19 days (1).

Reproduction studies have been conducted in rats. In rats before mating and through the 1st week of pregnancy, exposures that were equal to or less than the exposure expected from the recommended human dose of 300 mg/day (HE) resulted in increases in preimplantation and postimplantation loss, including embryo–fetal death, and a significant decrease in the number of live embryos. Total litter loss occurred when the drug was given during organogenesis until expected parturition. All doses (about 0.03–1.0 times the maximum concentration [C_{max}] in humans with cancer at the recommended dose) given during organogenesis caused both malformations of heart vessels and skeletal variations (delayed ossification of the skull, vertebrae, and

sternum) that indicated delayed fetal development. A no-effect level for malformations was not identified in this study. In a separate study, doses identical to those used above caused maternal toxicity and, when given during gestation and/or lactation, resulted in decreased pup survival and/or reduced postnatal pup growth (1).

Carcinogenicity studies have not been conducted. Various assays for mutagenic and clastogenic effects were negative. Fertility in male rats was not impaired but, in female rats, there was a slight decrease in the number of live embryos. There also was a trend toward increased estrus cycle irregularity and a decrease in the number of corpora lutea in the ovaries (1).

It is not known if vandetanib crosses the human placenta. The molecular weight (about 475) and the long plasma half-life suggest that the drug will cross to the embryo–fetus, but high plasma protein binding might lessen the exposure.

BREASTFEEDING SUMMARY

No reports describing the use of vandetanib during human lactation have been located. The molecular weight (about 475) and the long plasma half-life (19 days) suggest that the drug will be excreted into breast milk, but high plasma protein binding (93.7%) might lessen the exposure. The effect of this exposure on a nursing infant is unknown. However, the drug has caused serious toxicity in adults, such as skin reactions and Stevens-Johnson syndrome, pneumonitis, ischemic cerebrovascular events, and hemorrhage. The most common adverse reactions (>20%) in adults were diarrhea, rash, acne, nausea, hypertension, headache, fatigue, upper respiratory tract infections, decreased appetite, and abdominal pain. If a woman receiving the drug chooses to breastfeed, her infant should be closely monitored for these effects.

VARENICLINE

Central Nervous System Agent (Smoking Deterrent)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of varenicline in human pregnancy have been located. The animal data suggest low risk, but the absence of human pregnancy experience prevents a more complete assessment of embryo–fetal risk. However, smoking is known to cause significant developmental toxicity (as well as toxicity in the smoker) (see Cigarette Smoking). Thus, the benefit to the woman and her pregnancy appears to outweigh the unknown risk to the embryo and/or fetus. If nonpharmacologic methods to stop smoking have failed, and the use of varenicline is indicated, it should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Varenicline is a partial agonist selective for $\alpha_4\beta_2$ nicotinic acetylcholine receptor subtypes. This binding is thought to prevent nicotine from binding to these receptors. Varenicline is indicated as an aid in smoking cessation treatment. Oral bioavailability is nearly complete and metabolism of a dose is about 8%. Binding to plasma proteins also is low ($\leq 20\%$), but the elimination half-life is long (about 24 hours) (1).

Reproduction studies have been conducted in rats and rabbits. In these species, no teratogenicity was observed with daily oral doses ≤ 36 and 50 times the maximum recommended human daily exposure based on AUC at 1 mg twice daily (MRHDE), respectively. However, in the offspring of pregnant rats given the highest dose there was an increased incidence of auditory startle response. In pregnant rabbits, the highest dose resulted in decreased fetal weights. The no-effect dose in rabbits was 23 times the MRHDE (1).

In 2-year carcinogenicity studies, there was no evidence of carcinogenic

effects in mice given daily doses up to 47 times the MRHDE. In male rats, but not females, tumors of the brown fat (hibernoma) were observed at daily doses that were 23 and 67 times, respectively, the MRHDE. Various studies for mutagenicity were negative. No effects on fertility were observed in male and female rats given daily doses up to 67 and 36 times, respectively, the MRHDE. However, a decrease in fertility was noted in the offspring of pregnant rats given a daily dose that was 36 times, but not at 9 times, the MRHDE (1).

It is not known if varenicline crosses the human placenta. The molecular weight (about 361), high oral bioavailability, low metabolism and plasma protein binding, and the long elimination half-life suggest that the drug will pass to the embryo and fetus.

BREASTFEEDING SUMMARY

No reports describing the use of varenicline during human lactation have been located. The molecular weight (about 361), high oral bioavailability, low metabolism (about 8%) and plasma protein binding ($\leq 20\%$), and the long elimination half-life (about 24 hours) suggest that the drug will be excreted into breast milk. The effects of this exposure on a nursing infant are unknown. However, smoking during breastfeeding is known to represent a significant risk to the nursing infant, as well as to the mother. (See Cigarette Smoking.) Thus, the benefit to the woman and her infant appears to outweigh the unknown risk to the infant. If a woman uses this drug while breastfeeding, she should closely monitor her infant for the adverse effects commonly observed in adults: nausea and vomiting, sleep disturbance, constipation, and flatulence.

VASOPRESSIN

Pituitary Hormone

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No reports linking the use of vasopressin with congenital defects have been located. Vasopressin and the structurally related synthetic polypeptides desmopressin and lypressin have been used during pregnancy to treat diabetes insipidus, a rare disorder (1–11). Desmopressin has also been used at delivery in three women for the management of von Willebrand's disease (12). No adverse effects on the newborns were reported.

FETAL RISK SUMMARY

A threefold increase of circulating levels of endogenous vasopressin has been reported for women in the last trimester and in labor as compared with nonpregnant women (13). Although infrequent, the induction of uterine activity in the 3rd trimester has been reported after IM and intranasal vasopressin use (14). The IV use of desmopressin, which is normally given intranasally, has also been reported to cause uterine contractions (4).

Two investigators speculated that raised levels of vasopressin resulted from hypoxemia and acidosis and could produce signs of fetal distress (bradycardia and meconium staining) (15).

A 1995 reference described the use of desmopressin during pregnancy in 42 women with diabetes insipidus, 29 of whom received the drug throughout the whole pregnancy (16). One patient, treated with vasopressin during the first 6 months and then changed to desmopressin, delivered an infant who had a ventricular septal defect, a patent ductus arteriosus, and simian lines. The child died at age 14 years because of hypophyseal disease. Three of the infants exposed throughout gestation to desmopressin had birth weights close to or outside of the 99% confidence interval (two low and one high). The authors concluded that the use of desmopressin throughout pregnancy did not constitute a major fetal risk (16).

Diabetes insipidus developed in a 14-year-old girl at 33 weeks' gestation with resulting oligohydramnios and an amniotic fluid index of 0 (17). She was treated with intranasal desmopressin (10 mcg twice daily) with rapid resolution of the oligohydramnios and eventual, spontaneous delivery of a healthy 2700-g male infant at 38 weeks.

BREASTFEEDING SUMMARY

Patients receiving vasopressin, desmopressin, or lypressin for diabetes insipidus have been reported to breastfeed without apparent problems in the infant (1,2). Experimental work in lactating women suggests that suckling almost doubles the maternal blood concentration of vasopressin (13).

VECURONIUM

Autonomic (Skeletal Muscle Relaxant)

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Vecuronium has been used as an adjunct to general anesthesia during gamete intrafallopian transfer (GIFT) procedures and cesarean sections. It has also been used in the 2nd and 3rd trimesters by direct IV and IM fetal dosing to produce paralysis during various procedures. No adverse effects attributable to vecuronium on pregnancy rates, the fetus, or the newborn have been reported in these studies. Small amounts of vecuronium cross the placenta, even though this transfer is inhibited by the drug's low lipid solubility and ionization at physiologic pH. Animal reproduction studies have not been conducted with vecuronium, and no studies, animal or human, have reported its use during organogenesis. Based on this lack of information, the embryo risk from exposure to vecuronium during organogenesis cannot be determined. Use in later times of gestation, however, appears to carry little, if any, risk to the fetus or newborn.

FETAL RISK SUMMARY

The muscle relaxant vecuronium bromide is a nondepolarizing neuromuscular blocking agent that acts by competing for cholinergic receptors at the motor end plate (1). This quaternary ammonium compound belongs to the same general subclass (aminosteroidal) of neuromuscular blockers as pancuronium, pipecuronium, rapacuronium, and rocuronium (2). Vecuronium is indicated as an adjunct to general anesthesia, to facilitate endotracheal intubation, and to provide skeletal muscle relaxation during surgery or mechanical ventilation (1). Reproduction studies of vecuronium in experimental animals have not been located.

The pharmacokinetics of vecuronium in pregnancy was summarized in a 1998

review (3). At term, the elimination half-life of a 0.04 mg/kg dose was 36 minutes, approximately twice as long as atracurium but half the time of pancuronium (3).

The molecular weight (about 638) suggests that vecuronium will cross the placenta, but the ionization and low lipid solubility should limit the exposure of the embryo and fetus. Small amounts of vecuronium do cross the human placenta at term (4–8). In 20 women undergoing general anesthesia for cesarean section, vecuronium (60–80 mcg/kg) was administered between 5 and 21 minutes before delivery (4). The venous cord:maternal ratio averaged 0.11. No neonatal adverse effect was noted as evidenced by normal 1- and 5-minute Apgar scores (4). Others have reported an identical (0.11) umbilical vein:maternal vein ratio (5,6). In these studies, the mean vecuronium-to-delivery interval was 6–7 minutes. No adverse effects on the newborns were observed, as noted by the Apgar scores at 1 and 5 minutes, and the Neurologic and Adaptive Capacity Scores (NACS) determined at 15 minutes, 2, and 24 hours after birth (6).

A 1990 report described the use of vecuronium in 21 patients who were delivered at 36–41 weeks' gestation by elective cesarean section (7). In one group, 11 women received a 0.01 mg/kg IV priming dose, followed 4–6 minutes later by a 0.1 mg/kg IV dose. The second group of 10 women received a single IV dose of 0.2 mg/kg. The mean induction to delivery time intervals in the two groups was 9 and 11 minutes, respectively. The mean umbilical (UV) and maternal (MV) venous plasma concentrations of vecuronium in group 1 were 73 and 515 ng/mL, respectively, a UV/MV ratio of 0.14, whereas in group 2 the values were 107 and 838 ng/mL, respectively, a ratio of 0.13. The mean birth weights in the two groups were 3443 and 3405 g, respectively. The percentage of newborns having Apgar scores <7 in groups 1 and 2 at 1 minute were 70% and 50%, respectively, and at 5 minutes 100% and 90%, respectively. There were no significant differences between the two groups in the 1- and 24-hour NACS, or in individual tests of passive and active tone within the overall NACS profile. However, the data suggested that vecuronium caused residual effects in the infants (7). A number of other reports have discussed the safe use of vecuronium during cesarean section (8–12).

In a 1999 report, investigators concluded that a more accurate estimation of vecuronium placental transfer during cesarean section would be shown by the ratio of umbilical vein (UV) to maternal artery (MA) concentrations (13). Following an intubation dose of 0.11 mg/kg, the mean UV/MA ratio was 0.056 at an intubation-to-umbilical-cord clamping (I-D) interval of 280 seconds. As

expected, the ratio decreased as the I-D interval shortened.

Vecuronium (1–10 mg) has been used as an adjunct to general anesthesia in GIFT procedures (14). No effect on the pregnancy rate following GIFT was noted.

In a 1983 study, 19 newborns of mothers who had received vecuronium before delivery by cesarean section were compared with 9 newborns whose mothers had not received the agent (15). No significant difference in the Apgar scores at 1 and 5 minutes were observed between the two groups. In addition, vecuronium had no effect on maternal plasma cholinesterase activity (15).

A 1988 case study described the direct fetal administration of vecuronium under ultrasound guidance for fetal magnetic resonance imaging at 33 weeks' gestation of a brain defect (16). The dose used was 0.2 mg (0.1 mg/kg). A 3540-g male infant was delivered at 39 weeks' with Apgar scores of 10 and 10 at 1 and 5 minutes, respectively. Examination at 9 days of age confirmed the defect (16).

The successful anesthetic management of a woman at 32 weeks' gestation with dextrocardia, situs inversus, a double-outlet right ventricle, ventricular septal defect, and severe pulmonary stenosis was described in a 1994 report (17). No adverse effects attributable to vecuronium (0.1 mg/kg) were observed in the growth-restricted (0.94 kg) infant, who was doing well at 2 weeks of age. Vecuronium (10 mg) was used to assist mechanical ventilation in another case involving a woman at 36 weeks' gestation in labor who had developed severe respiratory distress secondary to myocardial infarction related to cocaine use (18). The mother also received fentanyl and midazolam. Four hours later, the woman delivered a live female infant. Specific information on the infant's condition was not given.

A 1998 case report described respiratory muscle rigidity in a newborn that was attributed to fentanyl (see Fentanyl) (19). In addition to other drugs, the mother had received vecuronium (7 mg) at 31 weeks' gestation.

Vecuronium was used to paralyze 14 fetuses during 17 intrauterine intravascular exchange transfusions (20). The mean gestational age was 29.2 weeks (range 22–35 weeks) and the mean estimated fetal weight was 1610 g (range 500–2500 g). The dose used (0.1 mg/kg) resulted in a mean onset of paralysis of 97.6 seconds (range 45–150 seconds) with a mean duration, as determined by maternal perception of fetal movements, of 122 minutes. The duration of paralysis was not correlated with gestational age. No maternal or fetal adverse effects were noted. All fetuses were delivered alive at a mean 35.8 weeks' gestation (20). In another 1992 report, vecuronium (0.15 mg/kg IV

or IM) was used in nine intrauterine procedures involving five fetuses (21). The authors noted that whereas vecuronium caused no fetal heart rate changes, pancuronium caused increased fetal heart rates and decreased beat-to-beat variability for 2.5 hours postdose.

Two pregnant women undergoing general anesthesia for cesarean section developed difficulty with breathing after receiving IV priming doses of vecuronium (10 and 13.7 mcg/kg) (22). Rapid sequence induction was initiated and healthy infants with normal Apgar scores were delivered.

BREASTFEEDING SUMMARY

No reports describing the use of vecuronium during lactation have been located. However, even if such use was reported, it is doubtful if clinically significant amounts of vecuronium would be excreted into breast milk. The molecular weight (about 638) is low enough, but the low lipid solubility and ionization at physiologic pH would inhibit its excretion into milk. These factors suggest that vecuronium represents no risk to a breastfeeding infant.

VELAGLUCERASE ALFA

Endocrine/Metabolic Agent (Gaucher Disease)

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports of human pregnancy exposure to velaglucerase alfa have been located. Animal studies have not suggested risk. Limited information is available on pregnancies complicated by type I Gaucher disease and treated with similar enzyme-replacement therapies, alglucerase or imiglucerase, and these data have not suggested fetal risk. Pregnancy may exacerbate existing disease or result in new disease manifestations, but the limited human data for alglucerase and imiglucerase suggest that treatment during pregnancy may reduce risks for spontaneous abortion and bleeding complications.

FETAL RISK SUMMARY

Velaglucerase alfa, an enzyme given by IV infusion, is used in the treatment of patients with type I Gaucher disease. Velaglucerase alfa replaces the endogenous enzyme β -glucocerebrosidase with a product produced by gene activation technology in a human cell line. The enzyme has the same amino acid sequence as the naturally occurring human enzyme. After infusion, the terminal elimination half-life ranges between 5 and 12 minutes (1).

Developmental and reproductive toxicology studies have been conducted in rats and rabbits at doses of 17 and 20 mg/kg, respectively. It is unclear how these compare with recommended human doses but they appear to be substantially higher than the maximum recommended human dose of 60 U/kg on a mg/kg basis. No maternal or developmental treatment-related effects were demonstrated in either species (1).

The carcinogenic and mutagenic potential of velaglucerase alfa has not been studied. Reproductive toxicity studies in male and female rats revealed no

evidence of impaired fertility (1).

It is not known if velaglucerase alfa crosses the human placenta. The high molecular weight (about 63,000) and the short terminal half-life suggest that placental transfer may be limited.

Outcomes of exposed pregnancies treated with other similar enzyme therapies, alglucerase or imiglucerase, have been summarized from surveys gathered from international treatment centers, from reports in the literature, and the manufacturer's pharmacovigilance database (see Alglucerase and Imiglucerase) (2,3).

BREASTFEEDING SUMMARY

No reports of velaglucerase alfa in human lactation have been located. The high molecular weight (about 63,000) and the short terminal half-life suggest that excretion into milk will be limited. Moreover, the glycoprotein probably is destroyed in the digestive tract and even if small amounts are transferred into breast milk, the enzyme is unlikely to reach the systemic circulation of a breastfed infant.

VEMURAFENIB

Antineoplastic (Kinase Inhibitor)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Only one report describing the use of vemurafenib in human pregnancy has been located. The fetus had growth restriction, but the reduced growth had begun a week before treatment was started. Although the drug crossed the placenta, the infant eventually did well. The animal data suggest low risk, but the exposures were around the clinical exposure. Higher doses may have not been possible because of maternal toxicity. Because of the drug's mechanism of action, the manufacturer states that it may cause fetal harm (1). If the drug is used in pregnancy, the patient should be informed of the potential risk to the fetus.

FETAL RISK SUMMARY

Vemurafenib is an inhibitor of some mutated forms of BRAF serine-threonine kinase and other kinases that are given orally. It is indicated for the treatment of patients with unresectable or metastatic melanoma with BRAF^{V600E} mutation as detected by an FDA-approved test. Metabolism is very limited. Following a single oral dose, mean data from plasma samples analyzed over a 48-hour period found that vemurafenib and its metabolites represented 95% and 5%, respectively, of the components in plasma. Vemurafenib is highly (>99%) bound to plasma albumin and α_1 -acid-glycoprotein. The median elimination half-life is about 57 hours (range about 30–120 hours) (1).

Animal reproduction studies have been conducted in rats and rabbits. In these species, no evidence of teratogenicity was observed at doses resulting in exposures up to about 1.3 and 0.6 times, respectively, the human clinical exposure based on AUC (HCE). Fetal levels of vemurafenib were 3%–5% of the maternal levels (1).

The carcinogenic potential of vemurafenib has not been studied. However, the drug increased the development of cutaneous squamous cell carcinomas in

patients in clinical trials. Various assays for genetic damage were negative. Although vemurafenib-induced impairment of fertility in animals has not been studied, no histopathological findings were observed in the reproductive organs of male and female rats and dogs during repeat-dose toxicological studies (1).

Vemurafenib crosses the human placenta. In the report below, infant levels were about 45% of the maternal concentration at birth. The molecular weight (about 490), minimal metabolism, and long elimination half-life are consistent with this report, but the high plasma protein binding might have limited the exposure.

A 2013 case report described the use of vemurafenib in a pregnant woman with malignant melanoma (2). After corticosteroids for fetal lung maturity, the standard dose of 960 mg twice daily was started at 25 weeks' gestation. The patient rapidly responded to the treatment with a decrease in pain and new metastasis disappeared. Fetal growth restriction (of the body, not the head) that had started a week before initiation of vemurafenib continued and a cesarean section was performed in the 30th week of gestation. Blood concentrations of vemurafenib at birth in the mother, umbilical cord, and 1028-g infant were 24.3, 10.9, and 10.9 mcg/mL, respectively. The infant had uncomplicated stay in the neonatal ward and was eventually discharged home in good condition. The mother died 3.5 months after initiation of vemurafenib therapy (2).

BREASTFEEDING SUMMARY

No reports describing the use of vemurafenib during human lactation have been located. The molecular weight (about 490), minimal metabolism, and long elimination half-life suggest that the drug will be excreted into breast milk, but the high plasma protein binding might limit the exposure. The effect of this exposure on a nursing infant is unknown. The most common adverse reactions in adults ($\geq 30\%$) treated with the drug are arthralgia, rash, alopecia, fatigue, photosensitivity reaction, nausea, pruritus, and skin papilloma (1). Moreover, there was a 24% incidence of cutaneous squamous cell carcinoma in clinical trials (1). Thus, there is potential risk to a nursing infant and, if the mother requires the drug, the best course would be to not breastfeed.

VENLAFAXINE

Antidepressant

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 3rd Trimester

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Neither the animal reproduction data nor the human pregnancy experience suggests that venlafaxine is a major risk for structural anomalies. However, venlafaxine, as well as selective serotonin reuptake inhibitors (SSRIs), have been associated with developmental toxicity, including spontaneous abortions (SABs), low birth weight, prematurity, neonatal serotonin syndrome, neonatal behavioral syndrome (withdrawal including seizures), possibly sustained abnormal neurobehavior beyond the neonatal period, and respiratory distress. Persistent pulmonary hypertension of the newborn (PPHN) is an additional potential risk, but confirmation is needed.

FETAL RISK SUMMARY

Venlafaxine is an antidepressant structurally unrelated to other available antidepressants. It is in the same serotonin-norepinephrine reuptake inhibitors (SNRIs) antidepressant subclass as desvenlafaxine, duloxetine, and milnacipran. Venlafaxine is indicated for the treatment of major depressive disorder. Venlafaxine is metabolized to an active metabolite, O-desmethylvenlafaxine (ODV). Oral venlafaxine is well absorbed (at least 92%). Plasma protein binding of venlafaxine and ODV are minimal (27% and 30%, respectively), but the elimination half-lives are 5 and 11 hours, respectively (1).

Reproduction studies in rats and rabbits at doses ≤ 2.5 and 4 times the maximum recommended human daily dose based on BSA (MRHD), respectively, did not reveal teratogenicity (1). When rats were given the same maximum dose during pregnancy through weaning, however, there was a decrease in pup weight and an increased number of stillbirths and pup deaths during the first 5 days of lactation. The no-effect dose for pup mortality was

0.25 times the MRHD (1).

Both venlafaxine and ODV cross the human placenta (2). In 11 women taking a median 225 mg/day (range 150–300 mg/day), the cord blood concentrations at birth of venlafaxine and ODV were 20 mcg/L (9–53 mcg/L) and 184 mcg/L (123–348 mcg/L), respectively. These results are consistent with the molecular weight of venlafaxine (about 314), the minimal protein binding, and the moderately long elimination half-lives. The median cord:maternal ratio for the parent drug and metabolite were 0.72 and 1.08, respectively (2).

A 1994 review of venlafaxine included citations of data from the clinical trials of this drug involving its use during gestation in 10 women for periods ranging from 10 to 60 days (3), apparently during the 1st trimester. No adverse effects of the exposure were observed in four of the infants (information not provided for the other six exposed pregnancies).

In a 2001 prospective controlled study, the pregnancy outcomes of 150 women exposed to venlafaxine were compared with those of 150 women exposed to other SSRI antidepressants and 150 women exposed to nonteratogenic agents (4). There were no significant differences in the outcomes in the three groups in terms of SABs, elective abortions, gestational age at birth, live births, birth weights, and major malformations. In the cases exposed to venlafaxine, there were two infants with birth defects (hypospadias; neural tube defect and clubfoot). In the control groups, there were three defects in the other-SSRI group (ventricular septal defect; pyloric stenosis; and absent corpus callosum) and one in the nonteratogen group (congenital heart defect). The results suggested that venlafaxine does not increase the rates of major congenital defects over that expected in a nonexposed population (4).

A 2010 review evaluated 15 prospective studies involving antidepressants that had been published in 1975–2009 to determine if there was an association between specific agents and SABs (5). Most of the studies involved tricyclic antidepressants or SSRIs. After adjustment, only paroxetine (odds ratio [OR] 1.7, 95% confidence interval [CI] 1.3–2.3) and venlafaxine (OR 2.1, 95% CI 1.3–3.3) were significantly associated with the risk of SABs (5).

The use of venlafaxine late in the 3rd trimester may result in functional and behavioral deficits in the newborn infant. The product information was changed by the manufacturer in 2004 to reflect this potential developmental toxicity (1). The observed toxicities include respiratory distress, cyanosis, apnea, seizures, temperature instability, feeding difficulty, vomiting, hypoglycemia, hypotonia, hypertonia, hyperreflexia, tremor, jitteriness, irritability, and constant crying. The clinical features are consistent with either a direct toxic effect or drug

discontinuation syndrome and, occasionally, may resemble a serotonin syndrome. The complications may require prolonged hospitalization, respiratory support, and tube feeding (1).

Evidence for the neonatal behavioral syndrome that is associated with in utero exposure to SSRIs and SNRIs (collectively called serotonin reuptake inhibitors [SRIs]) in late pregnancy was reviewed in a 2005 reference (6). The report followed a recent agreement by the FDA and manufacturers for a class labeling change about the neonatal syndrome. Analysis of case reports, case series, and cohort studies revealed that late exposure to SRIs carried an overall risk ratio of 3.0 (95% confidence interval [CI] 2.0–4.4) for the syndrome compared with early exposure. The case reports (N = 18) and case series (N = 131) involved 97 cases of paroxetine, 18 fluoxetine, 16 sertraline, 12 citalopram, 4 venlafaxine, and 2 fluvoxamine. Nine cohort studies were analyzed. The typical neonatal syndrome consisted of central nervous system, motor, respiratory, and gastrointestinal signs that were mild and usually resolved within 2 weeks. Only 1 of 313 quantifiable cases involved a severe syndrome consisting of seizures, dehydration, excessive weight loss, hyperpyrexia, and intubation. There were no neonatal deaths attributable to the syndrome (6).

A 30% incidence of SSRI-induced neonatal abstinence syndrome was found in a 2006 cohort study (7). Sixty neonates with prolonged in utero exposure to SSRIs were compared with nonexposed controls. The agents used were paroxetine (62%), fluoxetine (20%), citalopram (13%), venlafaxine (3%), and sertraline (2%). Assessment was conducted by the Finnegan score. Ten of the infants had mild and eight had severe symptoms of the syndrome. The maximum mean score in infants with severe symptoms occurred within 2 days of birth, but some occurred as long as 4 days after birth. Because of the small numbers, a dose–response analysis could only be conducted with paroxetine (7) (see Paroxetine).

A 2004 report described the pregnancy outcomes of 11 women who had taken venlafaxine (doses 75–225 mg/day) during the 1st trimester (8). One patient also took venlafaxine for 3 weeks in the 2nd trimester, but none of the women were exposed in the second half of pregnancy. The outcomes included two induced abortions and nine healthy infants that were doing well at 12 months of age (8).

In a 2006 case, a 2-day-old infant, exposed throughout pregnancy to venlafaxine (375 mg/day), exhibited signs and symptoms of lethargy, jitteriness, rapid breathing, poor suck, and dehydration. The symptoms in the breastfed

infant slowly resolved over 1 week (9).

Another 2006 report described seizures in two infants after in utero exposure to venlafaxine (10). The first newborn, exposed to 150 mg/day, was delivered at 37 weeks' with Apgar scores of 1 and 6 at 1 and 5 minutes, respectively. At 30 minutes, the otherwise normal but depressed infant exhibited lip smacking and extensor limb posturing associated with bradycardia and hypertension. The generalized hypertonia and hyperreflexia was treated with phenobarbital for 2 weeks. The infant started breastfeeding on the day after birth. At 1 year of age, her growth and neurodevelopment were normal. The second infant was born at 39 weeks' with an Apgar score of 9 at 5 minutes. The mother was taking venlafaxine 225 mg/day. Breastfeeding was started but the infant had bilious vomiting and, at 24 hours of age, developed multifocal myoclonic seizures involving all limbs. He was treated with phenobarbital for 5 days. The child was doing well at 1 year of age (10).

A 2007 retrospective cohort study examined the effects of exposure to SSRIs or venlafaxine in the 3rd trimester on 21 premature and 55 term newborns (11). The randomly selected unexposed control group consisted of 90 neonates of mothers not taking antidepressants, psychotropic agents, or benzodiazepines at the time of delivery. There were significantly more premature infants among the subjects (27.6%) than among controls (8.9%), but the groups were not matched. The antidepressants, number of subjects, and daily doses in the exposed group were paroxetine (46; 5–40 mg), fluoxetine (10; 10–40 mg), venlafaxine (9; 74–150 mg), citalopram (6; 10–30 mg), sertraline (3; 125–150 mg), and fluvoxamine (2; 50–150 mg). The behavioral signs that were significantly increased in exposed compared with nonexposed infants were: CNS—abnormal movements, shaking, spasms, agitation, hypotonia, hypertonia, irritability, and insomnia; respiratory system—indrawing, apnea/bradycardia, and tachypnea; and other—vomiting, tachycardia, and jaundice. In exposed infants, CNS (63.2%) and respiratory system (40.8%) signs were most common, appearing during the first day of life and lasting for a median duration of 3 days. All of the exposed premature infants exhibited behavioral signs compared with 69.1% of exposed term infants. The duration of hospitalization was significantly longer in exposed premature compared with nonexposed premature infants, 14.5 days vs. 3.7 days, respectively. In 75% of the term and premature infants, the signs resolved within 3 and 5 days, respectively. There were six infants in each group with congenital malformations, but the drugs involved were not specified (11).

A 2007 review conducted a literature search to determine the risk of major

congenital malformations after 1st trimester exposure to SSRIs and SNRIs (12). Fifteen controlled studies were analyzed. The data were adequate to suggest that citalopram, fluoxetine, sertraline, and venlafaxine were not associated with an increased risk of congenital defects. In contrast, the analysis did suggest an increased risk with paroxetine. The data were inadequate to determine the risk for the other SSRIs and SNRIs (12).

A case–control study, published in 2006, found that exposure to SSRIs in late pregnancy was associated with PPHN (13) (see Paroxetine or other SSRIs). Although exposure to venlafaxine (number of exposures not specified) was correctly classified as a non-SSRI antidepressant, the action of venlafaxine is similar enough to the SSRIs that it might cause the same effect (see references 1 and 6).

Using data from the Swedish Medical Birth Registry, 732 women who had used SNRIs or noradrenergic reuptake inhibitors during gestation were identified (14). Venlafaxine was the only antidepressant used in 501 pregnancies (505 infants), whereas 12 other pregnancies (12 infants) were exposed to a combination of venlafaxine plus another antidepressant (mianserin, mirtazapine, or reboxetine). Although there was no increased risk of structural anomalies, the rate of preterm births was significantly increased (OR 1.6, CI 1.19–2.15). Compared with exposure to SSRIs during gestation, a similar pattern of neonatal symptoms was observed that included respiratory problems, low Apgar scores, hypoglycemia, and neonatal convulsions. The authors concluded that the symptoms in neonates exposed to SNRIs closely resemble those observed in infants exposed to SSRIs (14).

A 2009 prospective observational study examined the neonatal effects of venlafaxine (N = 11) and SSRIs (N = 27) in pregnancy (2). The neurobehavior of the exposed neonates (N = 38) was compared with a nonexposed, matched control group (N = 18) in six areas: habituation, social-interactive, motor, range, regulation, autonomic. Exposed cases had significantly lower scores ($p < 0.05$) than controls in habituation, social-interactive, motor, and autonomic functions. However, when the cases were divided into SSRI and venlafaxine groups, only motor (maturity, pull-to-sit, and activity level) and autonomic (tremors and startles) functions were significantly lower than controls. There were no significant differences in neurobehavior between the two antidepressant groups (2).

A prospective cohort study evaluated a large group of pregnancies exposed to antidepressants in the 1st trimester to determine if there was an association with major malformations (15). The patient population came from the Motherisk

database and involved 928 cases that met their criteria. The 928 matched (for age, smoking, and alcohol use) controls were pregnancies not exposed to antidepressants or known teratogens. In addition to the 154 venlafaxine cases, the other cases were 113 bupropion, 184 citalopram, 21 escitalopram, 61 fluoxetine, 52 fluvoxamine, 68 mirtazapine, 39 nefazodone, 148 paroxetine, 61 sertraline, and 17 trazodone. In the antidepressant group, there were 24 (2.5%) major defects compared with 25 (2.6%) in controls (OR 0.9, 95% CI 0.5–1.61). There were two major anomalies in the venlafaxine group: hypospadias and a club foot. There were no major defects in the pregnancies exposed to bupropion, escitalopram, or trazodone (15).

BREASTFEEDING SUMMARY

Venlafaxine is excreted into breast milk. A 1998 study measured the excretion of venlafaxine and its active metabolite ODV in the milk of three breastfeeding women (16). The three mothers, started on the antidepressant after delivery, had been taking a stable dose (3.04–8.18 mg/kg/day) for 0.23–5 months. The ages of the infants were 0.37–6 months. The mean milk:plasma (M:P) ratio (in two cases based on AUC and in one on a single point) for the parent drug was 4.14 (range 3.26–5.18), whereas it was 3.06 (range 2.93–3.19) for ODV. The mean infant doses for venlafaxine and ODV were 3.49% and 4.08% of the mother's weight-adjusted dose, respectively. Venlafaxine was not detected in infant's plasma, but the median infant ODV plasma concentration was 100 mcg/L (range 23–225 mcg/L). The mean total infant dose was 7.57% (range 4.74%–9.23%). No adverse effects in the suckling infants were noted. Because of the relatively high infant dose in comparison with other antidepressants, it was recommended that close observation of the infant for short-term adverse effects (e.g., agitation, insomnia, poor feeding, or failure to thrive) was required (16).

A brief 2001 report described two postpartum women who were taking venlafaxine and exclusively breastfeeding their infants (17). One mother had started the drug (75 mg/day) at delivery, whereas the other had taken the antidepressant throughout pregnancy (150 mg/day). At 3–4 weeks of age, maternal and infant samples were drawn 2–3 hours after a dose. The concentrations of parent drug and ODV in the two women were 31 and 148 ng/mL and 38 and 230 ng/mL, respectively. Parent drug was not detected in the infants, but ODV levels were 16 and 21 ng/mL, respectively. No adverse effects were observed in the infants (17).

A 2004 study was conducted in 25 women (nursing 26 infants) to quantify the

concentration of the SSRI or SNRI in their breast milk (18). The antidepressants taken by the women were citalopram (nine), paroxetine (six), sertraline (six), fluoxetine (one), and venlafaxine (three). The maternal mean dose of venlafaxine was 131 mg/day (75–225 mg/day). The mean milk concentration was 2314 nmol/L (1012–3203 nmol/L), resulting in a theoretical maximum infant dose that was 5.2% of the mother's weight-adjusted dose. Venlafaxine was detected in the serum of one infant, but the metabolite was detected in the serum of three infants (mean infant serum level 91 nmol/L, range 31–128 nmol/L [sum of parent drug plus metabolite]). There was no evidence of adverse effects in the breastfeeding infants (18).

A 2002 study determined the milk:plasma ratios (M:P) based on AUC and infant doses of venlafaxine and its metabolite desvenlafaxine in six mothers (mean age 34.5 years and weight 84.3 kg) and their seven nursing infants (mean age 7.0 months and weight 7.3 kg) (19). The median venlafaxine dose was 244 mg/day. The mean M:P ratios for the drug and its metabolite were 2.5 (range 2.0–3.2) and 2.7 (range 2.3–3.2), whereas the mean maximum milk concentrations were 1161 and 796 mcg/L. Using an estimated milk production rate of 150 mL/kg/day, the mean infant exposure expressed as a percentage of the weight-adjusted maternal dose was 3.2% (95% confidence interval [CI] 1.7%–4.7%) for venlafaxine and 3.2% (95% CI 1.9%–4.9%) for desvenlafaxine. Venlafaxine was detected in the plasma of one infant (5 mcg/L), whereas desvenlafaxine was detected in four infants (range 3–38 mcg/L). All of the infants were healthy (19).

In a 2009 report, 13 women taking venlafaxine (mean dose 194.3 mg/day) and their nursing infants (mean age about 21 weeks) were studied (20). The highest venlafaxine and desvenlafaxine concentrations in milk occurred 8 hours after maternal ingestion. For combined venlafaxine plus desvenlafaxine, the mean M:P ratio was 2.75, and the theoretical infant dose was 0.208 mg/kg/day. The relative infant dose as a percentage of the mother's weight-adjusted dose was 8.1%. The theoretical and relative infant doses for desvenlafaxine were 1.97 and 2.24 times higher than those for venlafaxine. No adverse effects were observed or reported in the infants (20).

Maternal plasma concentrations of desvenlafaxine and venlafaxine determine the amount of drug excreted into milk. In this regard, a 2009 study appears to have important implications for choosing which agent to use in a lactating woman (21). The study evaluated the effect of cytochrome P450 2D6 extensive metabolizer (EM) or poor metabolizer (PM) status on the pharmacokinetics of single doses of venlafaxine extended release and desvenlafaxine in healthy

adults. The maximum plasma concentrations and AUC of desvenlafaxine were statistically similar in the two groups. In contrast, venlafaxine concentrations and AUC were significantly higher in the PM phenotype compared with the EM phenotype, whereas the desvenlafaxine concentrations and AUC were significantly lower in the PM group (21).

The long-term effects on neurobehavior and cognitive development from exposure to SNRIs and SSRIs during a period of rapid CNS development have not been adequately studied. The American Academy of Pediatrics classifies other antidepressants as drugs for which the effect on nursing infants is unknown but may be of concern (22).

VERAPAMIL

Calcium Channel Blocker

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Verapamil is a calcium channel inhibitor used as an antiarrhythmic agent. The use of this drug in any stage of pregnancy appears to be low risk.

FETAL RISK SUMMARY

Reproductive studies in rats and rabbits at oral doses up to 60 mg/kg/day (6 times the human oral dose) and 15 mg/kg/day (1.5 times the human oral dose) found no evidence of teratogenicity (1). In rats, however, this dose was embryocidal, and it restricted fetal growth and development, probably because of maternal toxicity (1).

Placental passage of verapamil has been demonstrated in two of six patients given 80 mg orally at term (2). Cord levels were 15.4 and 24.5 ng/mL (17% and 26% of maternal serum) in two newborns delivered at 49 and 109 minutes after verapamil administration, respectively. Verapamil could not be detected in the cord blood of four infants delivered 173–564 minutes after the dose. IV verapamil was administered to patients in labor at a rate of 2 mcg/kg/minute for 60–110 minutes (3). The serum concentrations of the infants averaged 8.5 ng/mL (44% of maternal serum).

A 33-week fetus with a tachycardia of 240–280 beats/minute was treated in utero for 6 weeks with β -acetyldigoxin and verapamil (80 mg 3 times daily) (2). The fetal heart rate returned to normal 5 days after initiation of therapy, but the authors could not determine whether verapamil had produced the beneficial effect. At birth, no signs of cardiac hypertrophy or disturbances in repolarization were observed. Several other reports have described successful in utero treatment of supraventricular tachycardia with verapamil in combination with other agents (4–6). In one case, indirect therapy via the mother with verapamil, digoxin, and procainamide failed to control the fetal arrhythmia and direct fetal

digitalization was required (7). In another case, verapamil (120 mg 3 times daily) and digoxin were used successfully to control a fetal supraventricular tachycardia at 32 weeks' gestation (8). At 36 weeks' gestation, after 4 weeks of therapy, ultrasound examination showed complete resolution of both the hydropic changes and polyhydramnios, but the fetus died within 2 days. No autopsy was permitted. The authors speculated that the drug combination may have caused complete heart block (8). Maternal supraventricular tachycardia occurring in the 3rd trimester has been treated with a single 5-mg IV dose of verapamil (9). Other than the single case of fetal death in which the cause is not certain, no adverse fetal or newborn effects attributable to verapamil have been noted in the above reports.

Verapamil was used to lower blood pressure in a woman in labor with severe gestational hypertension (10). A 15-mg dose was given by rapid IV injection followed by an infusion of 185 mg during 6 hours. Fetal heart rate increased from 60 to 110 beats/minute, and a normal infant was delivered without signs or symptoms of toxicity. Tocolysis with verapamil, either alone or in combination with β -mimetics, has also been described (11–13).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 76 newborns had been exposed to verapamil during the 1st trimester (F. Rosa, personal communication, FDA, 1993). One (1.3%) major birth defect was observed (three expected), a cardiovascular defect. These data do not support an association between the drug and congenital defects.

A 1995 case report described the pregnancy outcome of a woman treated with two doses of IV verapamil for supraventricular tachycardia at about 30 and 32 weeks' gestation (14). The remainder of the pregnancy was uneventful and an apparently normal infant was delivered (birth details not provided). At 5 days of age, an echocardiogram revealed obstructive biventricular hypertrophic cardiomyopathy. The cause of the defect could not be determined, but it was noted that congenital hypertrophic cardiomyopathy in rat offspring had been associated with high doses of verapamil during gestation (14).

A brief 1993 study reported three women treated for bipolar disorder with verapamil through most of their pregnancies (15). Normal pregnancy outcomes were observed in the women.

A prospective, multicenter cohort study of 78 women (81 outcomes; 3 sets of twins) who had 1st trimester exposure to calcium channel blockers, including 41% to verapamil, was reported in 1996 (16). Compared with controls, no increase in the risk of major congenital malformations was found. Moreover, the

manufacturer has reports of patients treated with verapamil during the 1st trimester without production of fetal problems (M.S. Anderson, personal communication, GD Searle & Co., 1981). However, hypotension (systolic and diastolic) has been observed in patients after rapid IV bolus (17), and reduced uterine blood flow with fetal hypoxia is a potential risk.

BREASTFEEDING SUMMARY

Verapamil is excreted into breast milk (18–20). A daily dose of 240 mg produced milk levels that were approximately 23% of maternal serum (18). Serum levels in the infant were 2.1 ng/mL but could not be detected (<1 ng/mL) 38 hours after treatment was stopped. No effects of this exposure were observed in the infant (18). In a second lactating woman, verapamil 80 mg 4 times daily was started 9 days after delivery for recurrent supraventricular tachycardia (19). The infant was not given the mother's milk. Five days later, verapamil milk levels ranged from about 100 to 300 ng/mL, much higher than expected (19).

A mother was treated with 80 mg 3 times daily for 4 weeks before serum and milk samples were obtained for analysis (20). Steady-state concentrations of verapamil and the metabolite, norverapamil, in milk were 25.8 and 8.8 ng/mL, respectively. These values were 60% and 16% of the concentrations in plasma. The investigators estimated that the breastfed child received less than 0.01% of the mother's dose. Neither verapamil nor the metabolite could be detected in the plasma of the child (20).

The American Academy of Pediatrics classifies verapamil as compatible with breastfeeding (21).

VERTEPORFIN

Ophthalmic Phototherapy

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although the animal reproduction data suggest low risk, the near absence of human pregnancy experience prevents an assessment of the embryo–fetal risk. The human pregnancy experience is limited to three cases. Nevertheless, verteporfin is indicated for severe eye disease that might cause blindness if not treated. Therefore, if a pregnant woman requires verteporfin and she consents, treatment should not be withheld because of her pregnancy. Avoiding the period of organogenesis should be considered.

FETAL RISK SUMMARY

Verteporfin is a light-activated drug used in photodynamic therapy that is given by IV infusion. The drug then is activated in the eye with light from a nonthermal diode laser. Once activated in the presence of oxygen, highly reactive, short-lived singlet oxygen and reactive oxygen radicals are generated. Verteporfin is indicated for the treatment of patients with predominantly classic subfoveal choroidal neovascularization due to age-related macular degeneration, pathologic myopia, or presumed ocular histoplasmosis. Verteporfin undergoes limited metabolism by liver and plasma esterases. Excretion is by the fecal route. The elimination half-life of verteporfin is about 5–6 hours (1).

Reproduction studies have been performed in rats and rabbits. In pregnant rats during organogenesis, a dose resulting in exposures that were about 40 times the human exposure based on AUC (HE-AUC) caused an increased incidence of anophthalmia/microphthalmia in fetuses. At 125 times the HE-AUC, rat fetuses had an increased incidence of wavy ribs and anophthalmia/microphthalmia. In pregnant rabbits, no teratogenic effects were observed with doses that were not maternally toxic (1). Light activation was not

mentioned in any of the above studies.

Carcinogenicity studies have not been conducted with verteporfin. Photodynamic therapy as a class has been reported to cause DNA damage that might result in chromosomal aberrations and mutations. It is not known how these effects translate into human risk (1). No effects on fertility were observed in male and female rats with doses that were about ≤ 60 and ≤ 40 times the HE-AUC, respectively (1).

It is not known if verteporfin crosses the human placenta. The molecular weight (about 719), limited metabolism, and the elimination half-life suggest that exposure of the embryo–fetus will occur.

A 2004 case report described the administration of verteporfin to a 35-year-old woman in the first week after conception of her first pregnancy (2). After counseling, the woman continued her pregnancy and delivered a healthy 2750-g female infant by cesarean section at 38 weeks' gestation. Apgar scores were 9 and 10 at 1 and 5 minutes, respectively. The child was developing normally at 26 months of age (2).

A brief 2009 report described the use of verteporfin and bevacizumab in a pregnant woman treated for choroidal neovascularization secondary to punctate inner choroidopathy (3). She received photodynamic therapy with IV verteporfin about 1–2 weeks postconception. At 3 months postconception, she underwent intravitreal injection of 1.25 mg bevacizumab. The patient delivered a healthy infant at term with no evidence of congenital anomalies at birth or at 3 months of age (3).

In another 2009 report, a 45-year-old woman with choroidal neovascularization and an unknown pregnancy received fluorescein angiography at 9 weeks and verteporfin at 12 weeks (4). Pregnancy was diagnosed at about 25 weeks. At about 37 weeks, she gave birth spontaneously to a healthy 2410-g female infant without congenital anomalies and with Apgar scores of 9 and 10. The normal infant was doing well at 16 months of age (4).

BREASTFEEDING SUMMARY

Verteporfin and its diacid metabolite are excreted into human breast milk (1). After a 6 mg/m² infusion, milk concentrations of the drug were 66% of the corresponding plasma concentration. Verteporfin was undetectable in milk after 12 hours, but the metabolite was measured in milk up to at least 48 hours (1). The excretion into milk is consistent with the molecular weight (about 719), limited metabolism, and elimination half-life (5–6 hours). The effect of this exposure on a nursing infant is unknown, but adverse effects affecting many

organ systems are common in adults treated with IV infusions of the drug. Withholding breastfeeding for about 48 hours should lessen the exposure and potential risk of toxicity in the infant.

VIDARABINE

Antiviral (Ophthalmic)

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Vidarabine is only available as an ophthalmic ointment. Systemic concentrations do not occur after swallowing lacrimal secretions because the drug is rapidly deaminated in the gastrointestinal tract.

FETAL RISK SUMMARY

Vidarabine is a potent teratogen in mice, rats, and rabbits after topical and IM administration (1,2). Daily instillations of a 10% solution into the vaginas of pregnant rats in late gestation had no effect on the offspring (2).

Vidarabine was used for disseminated herpes simplex in one woman at about 28 weeks' gestation (3,4). Spontaneous rupture of the membranes occurred 48 hours after initiation of therapy, and a premature infant was delivered. The infant died on the 13th day of life of complications of prematurity. In a second case, a woman at 32 weeks' gestation with herpes simplex type II encephalitis was treated with vidarabine (10 mg/kg/day) and acyclovir (5). A female infant with culture-documented herpes neonatorum was delivered by cesarean section 13 days later. The infant responded to further treatment with acyclovir and is alive and well at 2 months of age, but the mother died 2 days after delivery.

Vidarabine, 10 mg/kg/day (800 mg/day), was administered to a woman at 26 weeks' gestation with varicella pneumonitis (6). Peak and trough levels of the agent were 12.8 and 2.7 mcg/mL, respectively. She delivered a healthy female infant at 38 weeks' gestation that is developing normally at 12 months of age. In a similar case, another woman with varicella pneumonitis at 27 weeks' gestation was treated with vidarabine (6). Except for a delay in speech at age 3 years that responded to special education, the child has done well and was

considered normal at 5 years of age.

BREASTFEEDING SUMMARY

No reports involving the use of vidarabine in lactating women have been located. The drug is only available as an ophthalmic ointment. Systemic concentrations do not occur after swallowing lacrimal secretions because the drug is rapidly deaminated in the gastrointestinal tract.

VIGABATRIN

Anticonvulsant

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

The human pregnancy experience with vigabatrin is limited. Although adverse outcomes have been described, the drug was always combined with first-generation antiepileptic drugs known to cause structural anomalies and other forms of developmental toxicity. The contribution of vigabatrin to this toxicity has not been determined. Because the drug can cause vision loss that may be permanent in a high percentage of patients, it should be reserved for resistant cases. Vision abnormalities were not found in six children exposed in utero who were examined for this toxicity. If a woman becomes pregnant while receiving vigabatrin or is given the drug during pregnancy, she should be informed of the risks of developmental toxicity. Moreover, based on an animal study, women taking the drug during pregnancy should be supplemented with folic acid, as is done with other anticonvulsants.

FETAL RISK SUMMARY

Vigabatrin is an oral anticonvulsant indicated as adjunctive therapy for adult patients with refractory complex partial seizures who have inadequately responded to several alternative treatments and for whom the potential benefits outweigh the risk of vision loss. The drug is a racemate consisting of two enantiomers, one active and one inactive. The drug is hydrophilic, is not significantly metabolized, and does not bind to plasma proteins. The half-life is about 7.5 hours (1).

Reproduction studies have been conducted in rats, rabbits, and mice. In rats given the drug throughout organogenesis, the no-effect dose for embryo–fetal toxicity was about 0.2 times the maximum recommended human dose of 3

g/day based on BSA (MRHD). Higher doses resulted in decreased fetal body weights and increased incidences of fetal anatomic variations. When given from the latter part of pregnancy through weaning, doses that were about ≥ 0.2 times the MRHD produced long-term neurohistopathologic (hippocampal vacuolation) and neurobehavioral (convulsions) abnormalities in the offspring. A no-effect dose for developmental neurotoxicity was not determined. In rabbits during organogenesis, doses greater than the no-effect dose of about 0.5 times the MRHD were associated with an increased incidence of malformations (oral clefts) and embryo–fetal death (1).

In a study that administered a single intraperitoneal (IP) dose to mice during organogenesis, an increase in malformations (including cleft palate) was observed. Another study gave the drug during the early postnatal period (4–65 days) to young rats which produced neurobehavioral (convulsions, neuromotor impairment, learning deficits) and neurohistopathological (brain vacuolation, decreased myelination, retinal dysplasia) abnormalities. The early postnatal period in rats is thought to correspond to late pregnancy in humans in terms of brain development. The no-effect dose for developmental neurotoxicity in juvenile rats was associated with plasma exposures (AUC) $< 1/30$ th of those measured in pediatric patients receiving an oral dose of 50 mg/kg (1).

In a 2001 study, mice were given a single IP dose during organogenesis and amino acid concentrations were measured (2). Compared with controls, methionine concentration was most severely affected in the mother, placenta, and fetus. The authors speculated that methionine deficiency could be a possible teratogenic mechanism (2).

A 2010 study in mice examined the effect of vigabatrin on pregnancy outcomes and maternal plasma folate and vitamin B₁₂ concentrations (3). Mice were given a single dose of 450 mg/kg in late gestation. Within 12 hours, maternal levels of the two vitamins were markedly reduced. Fetuses were examined 1–3 days after the dose and found to have a significant incidence of fetal death, abortion, intrauterine growth restriction (IUGR), and skeletal hypoplasia. When mice were given folic acid before vigabatrin, no abortions occurred and the fetuses had better body weight and a lower rate of IUGR. Because the above vigabatrin dose was maternal toxic, the study was repeated with a nonmaternal toxic dose of 350 mg/kg. This dose also caused significant fetal loss and IUGR (3).

Studies for carcinogenesis and mutagenesis were negative. No effects on fertility were observed in male and female rats (1).

Four properties of vigabatrin suggest that it crosses the human placenta, but

one suggests that the transfer will be limited. The properties suggesting placental passage are the low molecular weight (about 129), low metabolism, nonbinding by plasma proteins, and moderately long half-life, but the hydrophilic property will inhibit transfer. A 1992 study with human isolated perfused placenta found that the maternal to fetal transfer was low (4). The low transfer was confirmed in a 1998 study in two patients (5). The umbilical vein:maternal plasma concentration ratio was less than 1 for the active enantiomer.

A 1994 report described the outcome of 13 pregnancies treated with anticonvulsants, 1 of which received vigabatrin (3500 mg/day) and carbamazepine (800 mg/day) (also listed as oxcarbazepine 1500 mg/day in a table) (6). The newborn male infant had coronal hypospadias, broad depressed nasal bridge, telecanthus, high-arched palate, prominent ear shelves and lobes, upward slanting but apparently small palpebral fissures, diastasis musculus recti abdominis, slightly deep palmar flexion creases, bilateral clinodactyly of fourth toes, and apparently wide inter nipple distance. The contribution of vigabatrin to any of the defects was unknown. However, in her first pregnancy, the mother had taken carbamazepine and also gave birth to an infant with hypospadias (6).

A 1996 review listed the number of pregnancies, from postmarketing experience, exposed to vigabatrin as >80 (7). The outcomes of these pregnancies, excluding five elective abortions, were spontaneous abortions (SABs) (10%), normal (72%), and abnormal (18%) (specific details not provided). All of the exposures involved polytherapy, and there was no pattern among the malformations (7).

A 1998 noninterventional observational cohort study described the outcomes of pregnancies in women who had been prescribed ≥ 1 of 34 newly marketed drugs by general practitioners in England (8). Data were obtained by questionnaires sent to the prescribing physicians 1 month after the expected or possible date of delivery. In 831 (78%) of the pregnancies, a newly marketed drug was thought to have been taken during the 1st trimester with birth defects noted in 14 (2.5%) singleton births of the 557 newborns (10 sets of twins). In addition, two birth defects were observed in aborted fetuses. However, few of the aborted fetuses were examined. Vigabatrin was taken during the 1st trimester in 76 pregnancies. The outcomes of these pregnancies included 18 SABs, 11 elective abortions (EABs), and 45 normal newborns (8 premature). Congenital anomalies were observed in two full-term infants: bowed tibiae, increased tone (also exposed to valproate, carbamazepine, and clobazam); occipital plagiocephaly, premature fusion of lambdoid suture, and clicky hips

(also exposed to phenytoin and folic acid) (8). The study lacked the sensitivity to identify minor anomalies and late-appearing major defects may have been missed due to the timing of the questionnaires.

Bilateral anophthalmia, situs viscerum inversus, levo-isomerism, single ventricle, infundibular stenosis, agenesis of corpus callosum, enlargement of the third ventricle, and bilateral clubfoot in a male infant exposed to vigabatrin was reported in a 1997 abstract (9). The nulliparous 23-year-old woman had severe mental retardation. She took (daily dose) vigabatrin (1000 mg), carbamazepine (800 mg), and dexamethasone (0.75 mg) throughout gestation. The birth weight was 2360 g, length 44 cm, and the karyotype was normal (46,XY). The cause of the defects was unknown, but a genetic defect or multifactorial inheritance could not be excluded (9).

A brief 2003 report described the pregnancy outcome of a 32-year-old woman with a history of epilepsy and a combined liver and renal transplant for primary hyperoxaluria Type 1 (10). She took (daily dose) prednisolone (5 mg), vigabatrin (1000 mg), sodium valproate (2000 mg), and folic acid (5 mg) throughout pregnancy. At 20 weeks' gestation, an ultrasound of the fetus revealed a two-vessel cord and talipes. Labetalol was added at 22 weeks' gestation for hypertension. Because of fetal growth restriction and worsening preeclampsia, a 1280-g female infant was delivered by cesarean section at 34 weeks' gestation. Apgar scores were 5, 6, and 9 at 1, 5, and 10 minutes, respectively. In addition to bilateral talipes, the infant had mild dysmorphic features suggestive of valproate embryopathy (details not provided). At 5 weeks corrected age, poor visual fixation was suspected and a cerebral ultrasound revealed mild ventricular dilatation, but her development was normal at 5.5 months corrected age. The authors speculated that the delayed visual maturation may have been due to vigabatrin (10).

Because vigabatrin-induced visual field defect is an important safety issue with the drug, a 2005 report examined two children who had been exposed during pregnancy (11). In the first case, the mother had taken vigabatrin 1 g/day and carbamazepine until 22 weeks' gestation, at which time the vigabatrin was slowly tapered (total dose during pregnancy 190 g). Examination at 7.75 years of age revealed retrognathia, irregular placement of teeth in the lower jaw, and large prominent ears. However, the boy's visual and ophthalmic examinations were normal. In the second case, the mother had received carbamazepine and valproate until 16 weeks' gestation at which time vigabatrin was added because of resistant seizures (total dose during pregnancy 370 g). The boy had a seizure at 4.67 years of age. At 5 years of age, his

psychomotor development was deemed to be slow and he was thought to have mild mental retardation. At 6.83 years of age, multiple major and minor malformations probably due to carbamazepine and valproate were apparent, but no evidence of visual or eye abnormalities was found (11). In another study, published in 2009, four children from three mothers, two of whom exhibited vigabatrin-attributed visual field loss, had been exposed to vigabatrin in utero (12). The children, ages ranging from about 7 to 16 years, had normal visual fields and retinal nerve fiber layer thickness.

The Lamotrigine Pregnancy Registry, an ongoing project conducted by the manufacturer, was first published in January 1997. The final report was published in July 2010 (13). The Registry is now closed. Among 12 prospectively enrolled pregnancies exposed to vigabatrin and lamotrigine, with or without other anticonvulsants, 11 were exposed in the 1st trimester resulting in 10 live births without defects and 1 EAB. There was one exposure in the 2nd/3rd trimesters resulting in a live birth without defects (13).

BREASTFEEDING SUMMARY

Vigabatrin is excreted into breast milk (5). In two women, 7 days postpartum and both taking vigabatrin (1000 mg twice daily), the predose M:P ratio was <1. The ratio was also <1 in the one woman tested at 3 and 6 hours postdose. The estimated daily maximum doses that a nursing infant would receive as a percentage of the mother's daily weight-adjusted dose was 1% for the active enantiomer and 3.6% for the inactive enantiomer (5). These exposures, if confirmed by other reports, appear to be clinically insignificant (14). However, milk samples may have been obtained before the greatest amount of mature milk production (about 14 days) had been reached.

VILAZODONE

Antidepressant

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 3rd Trimester

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of vilazodone, a selective serotonin reuptake inhibitor (SSRI), in human pregnancy have been located. Although the animal data suggest low risk, SSRI antidepressants have been associated with developmental toxicities, including spontaneous abortions, low birth weight, preterm delivery, neonatal serotonin syndrome, neonatal behavioral syndrome (withdrawal), possible sustained abnormal neurobehavior beyond the neonatal period, respiratory distress, and persistent pulmonary hypertension of the newborn (PPHN). The risk:benefit ratio for using any SSRI in pregnancy must be determined on a case-by-case basis.

FETAL RISK SUMMARY

In addition to its action as an SSRI antidepressant, vilazodone hydrochloride also is a partial agonist at serotonergic 5-HT_{1A} receptors. It is indicated for the treatment of major depressive disorder. Vilazodone is in the same class of SSRIs as citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline. Vilazodone is extensively metabolized to inactive metabolites. Plasma protein binding is about 96%–99% and the terminal half-life is about 25 hours (1).

Reproduction studies have been conducted in rats and rabbits. No teratogenic effects were observed in either species at oral doses that were 48 and 17 times, respectively, the maximum recommended human dose of 40 mg based on BSA (MRHD). However, at these doses, fetal body weight gain was reduced and skeletal ossification was delayed in both rats and rabbits. These effects were not observed at doses up to 10 and 4 times, respectively, the MRHD. Some maternal toxicity (not otherwise specified) was noted in rats

given a dose that was 30 times the MRHD during organogenesis and throughout pregnancy and lactation. Fetal effects observed at this dose included decreased number of live pups and increased early postnatal pup mortality. Among surviving pups there was decreased body weight, delayed maturation, and decreased fertility in adulthood. These effects were not observed at dose 6 times MRHD (1).

Two-year carcinogenicity studies have been conducted in mice and rats. In mice, dose-related hepatocellular carcinomas were observed in males and malignant mammary gland tumors in females. Elevated levels of prolactin also were observed and are known to cause mammary tumors in rodents. No carcinogenic effects were seen in male and female rats. Vilazodone was not mutagenic in various assays. It was clastogenic in some assays but not in others. Dose-related impairment of male fertility was observed in rats but there was no effect on female fertility (1).

It is not known if vilazodone crosses the human placenta. The molecular weight (about 478) and long terminal half-life suggest that the drug will cross to the embryo–fetus. However, the high plasma protein binding may limit the amount of transfer.

BREASTFEEDING SUMMARY

No reports describing the use of vilazodone during human lactation have been located. The molecular weight (about 478) and long terminal half-life (about 25 hours) suggest that the drug will be excreted into breast milk. Although the high plasma protein binding (96%–99%) may limit the amount excreted, vilazodone is a weak base and because the pH of milk is usually lower than that of plasma, milk concentrations may be higher than plasma levels due to “ion trapping.”

The effect of exposure to the drug in milk by a nursing infant is unknown. However, excessive somnolence, decreased feeding, and weight loss have been observed in infants exposed to another SSRI (see Citalopram). Thus, nursing infants should be closely monitored for evidence of toxicity. The American Academy of Pediatrics classifies other SSRI antidepressants as drugs for which the effect on nursing infants is unknown but may be of concern (e.g., see Fluoxetine).

A 2010 study using human and animal models found that drugs that disturb serotonin balance such as SSRIs and serotonin norepinephrine reuptake inhibitors (SNRIs) can impair lactation (2). The authors concluded that mothers taking these drugs may need additional support to achieve breastfeeding goals.

VINBLASTINE

Antineoplastic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest High Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Vinblastine is an antimetabolic antineoplastic agent. Although the drug is embryocidal and teratogenic in laboratory animals (no details provided) (1), the limited human data do not support a significant association with developmental toxicity.

FETAL RISK SUMMARY

Vinblastine has been used in pregnancy, including the 1st trimester, without producing malformations (2–10). However, two cases of malformed infants have been reported following 1st trimester exposure to vinblastine (10,11). In 1974, a case of a 27-year-old woman with Hodgkin's disease who was given vinblastine, mechlorethamine, and procarbazine during the 1st trimester was described (11). At 24 weeks' gestation, she spontaneously aborted a male fetus with oligodactyly of both feet with webbing of the third and fourth toes. These defects were attributed to mechlorethamine therapy. A mother with Hodgkin's disease treated with vinblastine, vincristine, and procarbazine in the 1st trimester (3 weeks after the last menstrual period) delivered a 1900-g male infant at about 37 weeks of gestation (12). The newborn developed fatal respiratory distress syndrome. At autopsy, a small secundum atrial septal defect was found.

Vinblastine in combination with other antineoplastic agents may produce gonadal dysfunction in men and women (13–16). Alkylating agents are the most frequent cause of this problem (15). Although total aspermia may result, return of fertility has apparently been documented in at least two cases (16). Ovarian function may return to normal with successful pregnancies possible, depending on the patient's age at the time of therapy and the total dose of chemotherapy received (14,17). The long-term effects of combination chemotherapy on

menstrual and reproductive function were described in a 1988 report (18). Only 5 of 40 women treated for malignant ovarian germ cell tumors received vinblastine. The results of this study are discussed in the monograph for cyclophosphamide (see Cyclophosphamide).

In 436 long-term survivors treated with chemotherapy for gestational trophoblastic tumors between 1958 and 1978, 11 (2.5%) received vinblastine as part of their treatment regimens (19). Of the 11 women, 2 (18%) had at least one live birth (mean and maximum vinblastine dose 20 mg), and 9 (82%) did not try to conceive (mean dose 37 mg, maximum dose 80 mg). Additional details, including congenital anomalies observed, are described in the monograph for vincristine (see Vincristine).

Data from one review indicated that 40% of infants exposed to anticancer drugs were of low birth weight (20). This finding was not related to the timing of exposure. Long-term studies of growth and mental development in offspring exposed to vinblastine during the 2nd trimester, the period of neuroblast multiplication, have not been conducted (21). However, two children, exposed throughout gestation, beginning with the 3rd to 4th week of gestation, were normal at 2 and 5 years of age, respectively (10).

Occupational exposure of the mother to antineoplastic agents during pregnancy may present a risk to the fetus. A position statement from the National Study Commission on Cytotoxic Exposure and a research article involving some antineoplastic agents are presented in the monograph for cyclophosphamide (see Cyclophosphamide).

BREASTFEEDING SUMMARY

No reports describing the use of vinblastine during lactation have been located. Because of the potential for severe toxicity in a nursing infant, women who require this agent should not breastfeed.

VINCRISTINE

Antineoplastic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest High Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Vincristine is an antimetabolic antineoplastic agent. The drug is embryocidal and teratogenic in mice, hamsters, and monkeys at doses that did not cause maternal toxicity (1). The use of vincristine, always in combination with other antineoplastics, has been described in at least 36 pregnancies (1 with twins), 9 during the 1st trimester (2–31). Developmental toxicity was observed in some of these pregnancies, but the relationship to vincristine is unknown. (See Rituximab for additional data.)

FETAL RISK SUMMARY

A mother with Hodgkin's disease treated with vincristine, vinblastine, and procarbazine in the 1st trimester (3 weeks after the last menstrual period) delivered a 1900-g male infant at about 37 weeks' gestation (10). Neonatal death occurred because of respiratory distress syndrome. At autopsy, a small secundum atrial septal defect was found. In a patient with Hodgkin's disease who was treated with vincristine, mechlorethamine, and procarbazine during the 1st trimester, the electively aborted fetus had malformed kidneys (markedly reduced size and malpositioned) (16). Other adverse fetal outcomes observed following vincristine use include a 1000-g male infant born with pancytopenia who was exposed to six different antineoplastic agents in the 3rd trimester (2) and transient severe bone marrow hypoplasia in another newborn that was most likely caused by mercaptopurine (19). Intrauterine fetal death occurred in a 1200-g female fetus 36 hours after maternal treatment with vincristine, doxorubicin, and prednisone for diffuse, undifferentiated lymphoma of T-cell origin at 31 weeks' gestation (22). The fetus was macerated, but no other abnormalities were observed at autopsy. In another case, a 34-year-old woman with acute lymphoblastic leukemia was treated with multiple

antineoplastic agents from 22 weeks' gestation until delivery of a healthy female infant 18 weeks later (25). Vincristine was administered 4 times between 22 and 25 weeks' gestation. Chromosomal analysis of the newborn revealed a normal karyotype (46,XX) but with gaps and a ring chromosome. The clinical significance of these findings is unknown, but because these abnormalities may persist for several years, the potential existed for an increased risk of cancer, as well as for a risk of genetic damage in the next generation (25).

A 1999 report from France described the outcomes of pregnancies in 20 women with breast cancer who were treated with antineoplastic agents (31). The first cycle of chemotherapy occurred at a mean gestational age of 26 weeks with delivery occurring at a mean 34.7 weeks. A total of 38 cycles were administered during pregnancy with a median of two cycles per woman. None of the women received radiation therapy during pregnancy. The pregnancy outcomes included two spontaneous abortions (SABs) (both exposed in the 1st trimester), one intrauterine death (exposed in the 2nd trimester), and 17 live births, one of whom died at 8 days of age without apparent cause. The 16 surviving children were developing normally at a mean follow-up of 42.3 months (31). Vincristine (V), in combination with doxorubicin (D), epirubicin (E), and/or methotrexate (M), was administered to two women at a mean dose of 2 mg/m². The outcomes were one SAB (VEM; exposed at 6 weeks' gestation) and one surviving liveborn infant (exposed to VD in the 2nd trimester) (31).

Data from one review indicated that 40% of the infants exposed to anticancer drugs were of low birth weight (32). This finding was not related to the timing of exposure. Long-term studies of growth and mental development in offspring exposed to these drugs during the 2nd trimester, the period of neuroblast multiplication, have not been conducted (33). However, individual infants have been evaluated for periods ranging from a few weeks up to 7 years and all have had normal growth and development (17–20,22–24,26,27,29).

Vincristine, in combination with other antineoplastic agents, may produce gonadal dysfunction in men and women (34–41). Alkylating agents are the most frequent cause of this problem (38). Ovarian and testicular function may return to normal with successful pregnancies possible, depending on the patient's age at time of treatment and the total dose of chemotherapy received (34). In a 1989 case report, a woman with an immature teratoma of the ovary was treated with conservative surgery and chemotherapy consisting of six courses of vincristine, dactinomycin, and cyclophosphamide (42). She conceived 20

months after her last chemotherapy and eventually delivered a normal 3340-g male infant. The long-term effects of combination chemotherapy on menstrual and reproductive function have been described in a 1988 report (43). Of 40 women treated for malignant ovarian germ cell tumors, 29 received vincristine. The results of this study are discussed in the monograph for cyclophosphamide (see Cyclophosphamide).

In 436 long-term survivors treated with chemotherapy between 1958 and 1978 for gestational trophoblastic tumors, 132 (30%) received vincristine in combination with other antineoplastic agents (44). The mean duration of chemotherapy was 4 months with a mean interval from completion of therapy to the first pregnancy of 2.7 years. Conception occurred within 1 year of therapy completion in 45 women (antineoplastic agents used in these women were not specified), resulting in 31 live births, 1 anencephalic stillbirth, 7 SABs, and 6 elective abortions. Of the 132 women treated with vincristine, 37 (28%) had at least one live birth (numbers in parentheses refer to mean/maximum vincristine dose in milligrams) (7.4/17.0), 8 (6%) had no live births (7.1/22.0), 4 (3%) failed to conceive (7.3/18.0), and 83 (63%) did not try to conceive (11.3/46.0). The average ages at the end of treatment in the four groups were 24.9, 24.4, 24.4, and 31.5 years, respectively. Congenital abnormalities noted in the total group (368 conceptions) were two cases of anencephaly, and one case each of spina bifida, tetralogy of Fallot, talipes equinovarus, collapsed lung, umbilical hernia, desquamative fibrosing alveolitis, asymptomatic heart murmur, and mental retardation. Another child had tachycardia but developed normally after treatment. One case of sudden infant death syndrome occurred in a female infant at 4 weeks of age. None of these outcomes differed statistically from that expected in a normal population (44).

Occupational exposure of the mother to antineoplastic agents during pregnancy may present a risk to the fetus. A position statement from the National Study Commission on Cytotoxic Exposure and a research article involving some antineoplastic agents are presented in the monograph for cyclophosphamide (see Cyclophosphamide).

BREASTFEEDING SUMMARY

No reports describing the use of vincristine during lactation have been located. Because of the potential for severe toxicity in a nursing infant, women who require this agent should not breastfeed.

VINOURELBINE

Antineoplastic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Although the animal reproduction data suggest risk during organogenesis, the human pregnancy experience with vinorelbine is limited to 10 cases, all in the 2nd and 3rd trimesters. Transient anemia was observed in one infant and another had mild leukopenia and thrombocytopenia, but other antineoplastic agents were used in each case. The limited human data prevent a more complete assessment of the embryo–fetal risk. Avoiding the use of this agent in gestation, especially in the 1st trimester and/or close to delivery, is reasonable. However, if the mother’s condition requires this therapy and consent is given, vinorelbine should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Vinorelbine is a semisynthetic vinca alkaloid that is used in the treatment of cancer. It is related to two other vinca alkaloids, vinblastine and vincristine.

Reproduction studies in mice at one-third the human dose (HD) and in rabbits at one-fourth the HD have shown embryo and/or fetal toxicity (1). At maternal nontoxic doses, intrauterine growth restriction and delayed ossification were observed. Vinorelbine did not affect fertility when administered to rats at weekly doses that were one-third the HD or alternate-day doses that were one-seventh the HD before and during mating (1). The agent did reduce spermatogenesis and prostate/seminal vesicle secretion in male rats given biweekly doses about 1/15th and 1/4th the HD, respectively, for 13 or 26 weeks (1).

It is not known if vinorelbine crosses the placenta to the fetus. The molecular weight (about 1079) suggests that placental transfer of the drug to the embryo or fetus would be inhibited, but probably not prevented.

In a brief 1997 report, three pregnant women with breast cancer were successfully treated with two or three courses of vinorelbine (20–30 mg/m²) and fluorouracil (500–750 mg/m²) at 24, 28, and 29 weeks' gestation, respectively (2). Delivery occurred at 34, 41, and 37 weeks' gestation, respectively. One patient also required six courses of epidoxorubicin and cyclophosphamide. Her infant developed transient anemia at 21 days of age that resolved spontaneously. No adverse effects were observed in the other two newborns. All three infants were developing normally at about 2–3 years of age (2).

A 1999 report from France described the outcomes of pregnancies in 20 women with breast cancer who were treated with antineoplastic agents (3). The first cycle of chemotherapy occurred at a mean gestational age of 26 weeks with delivery occurring at a mean 34.7 weeks. A total of 38 cycles were administered during pregnancy with a median of two cycles per woman. None of the women received radiation therapy during pregnancy. The pregnancy outcomes included two spontaneous abortions (both exposed in the 1st trimester), one intrauterine death (exposed in the 2nd trimester), and 17 live births, 1 of whom died at 8 days of age without apparent cause. The 16 surviving children were developing normally at a mean follow-up of 42.3 months. Vinorelbine, in combination with fluorouracil, was administered to four women at a mean dose of 37 mg/m² (range 20–50 mg/m²) during the 2nd or 3rd trimesters. The outcomes were four surviving liveborn infants (3).

A 34-year-old woman with a history of breast cancer presented at 15 weeks' gestation with metastases to the spine, pelvis, and hips (4). She refused all antineoplastic therapy until about 19 weeks'. At that time, she was started on vinorelbine (25 mg/m²) but her condition continued to deteriorate. Therapy was changed to docetaxel (100 mg/m²) and methylprednisolone every 3 weeks. After three cycles, a planned cesarean section at 32 weeks' delivered a normal, 1620-g female infant with Apgar scores of 8 and 9. The child was developing normally at 20 months of age (4).

Rapidly progressing nonsmall-cell lung cancer was diagnosed in a 31-year-old woman at 25 weeks' gestation (5). One week later, she received vinorelbine (25 mg/m²) and cisplatin (100 mg/m²), but because her condition continued to worsen, a cesarean section was performed 4 days later to deliver a healthy male infant with Apgar scores of 7 and 8 at 1 and 5 minutes, respectively. Ten days after chemotherapy, a transient decrease in the infant's white blood cell and platelet counts was observed but both resolved 3 weeks after birth (5).

A 26-year-old woman with breast cancer was treated with trastuzumab, paclitaxel, fluorouracil, epirubicin, and cyclophosphamide, followed by a left mastectomy and radiation therapy (6). Fourteen months later, in the 27th week of pregnancy, multiple hepatic metastases were detected. She was treated with trastuzumab (one dose of 4mg/kg, then 2 mg/kg every week) and vinorelbine (25 mg/m² weekly for 3 weeks followed by a week of rest) until 34 weeks' gestation. Oligohydramnios occurred during therapy that was most likely secondary to trastuzumab (see Trastuzumab). Because of decreased fetal movement, labor was induced at 34 weeks' gestation and a healthy 2.6-kg male infant was delivered vaginally with Apgar scores of 9, 9, and 10. At 6 months of age, the infant was healthy and developing normally (6).

BREASTFEEDING SUMMARY

No reports describing the use of vinorelbine during lactation have been located. Because of the potential for severe toxicity (e.g., bone marrow depression as seen in adults) in a nursing infant, women who require this agent should not breastfeed.

VISMODEGIB

Antineoplastic (Miscellaneous)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of vismodegib in human pregnancy have been located. In the one animal species studied, the drug caused embryo and fetal death, as well as structural anomalies at systemic exposures that were close to or below the predicted human exposure. The absence of human pregnancy experience prevents a more complete assessment of the embryo–fetal risk. In clinical trials in women of reproductive potential, amenorrhea has been observed (1). The manufacturer recommends a negative pregnancy test within 7 days before starting therapy and a highly effective form of contraception before the first dose and for 7 months after the last dose.

FETAL RISK SUMMARY

Vismodegib is an inhibitor of the Hedgehog pathway that is given orally. It is indicated for the treatment of adults with metastatic basal cell carcinoma, or with locally advanced basal cell carcinoma that has recurred following surgery or who are not candidates for surgery, and who are not candidates for radiation. The drug undergoes limited metabolism with >98% of the total circulating drug-related components being the parent drug. Plasma protein binding to albumin and α_1 -acid-glycoprotein is high (>99%) and the elimination half-life is 4 days (1).

Reproduction studies have been conducted in rats. In this species, oral doses that resulted in exposures that were about ≥ 2 times the systemic exposure at the recommended dose based on AUC (SERD) caused preimplantation and postimplantation losses, which included early resorption of 100% of the fetuses. Exposures that were about 0.2 times the RD resulted in malformations (including missing and/or fused digits, open perineum and

craniofacial anomalies) and retardations or variations (including dilated renal pelvis, dilated ureter, and incompletely or unossified sternal elements, centra of vertebrae, or proximal phalanges and claws).

Carcinogenicity studies have not been conducted. Vismodegib was not mutagenic or clastogenic in multiple assays. Fertility impairment studies have not been done. However, data from repeat-dose toxicology studies in rats and dogs indicated that the drug may impair male and female reproductive function and fertility (1).

It is not known if vismodegib crosses the human placenta. The molecular weight (about 421) and long elimination half-life suggest that the drug will cross to the embryo–fetus, but the high plasma protein binding might limit the exposure.

BREASTFEEDING SUMMARY

No reports describing the use of vismodegib during human lactation have been located. The molecular weight (about 421) and long elimination half-life (4 days) suggest that the drug will be excreted into breast milk, but the high plasma protein binding (>99%) might limit the exposure. The effect of the exposure on a nursing infant is unknown. Some of the most common adverse reactions ($\geq 10\%$) in adults were muscle spasms, alopecia, diarrhea or constipation, nausea, vomiting, weight loss, decreased appetite, and fatigue. If a woman receiving the drug chooses to breastfeed, her infant should be closely monitored for these effects.

VITAMIN A

Vitamin

PREGNANCY RECOMMENDATION: Compatible Contraindicated (Doses above U.S. RDA)

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Excessive doses of preformed vitamin A are teratogenic, as may be marked maternal deficiency. In addition, recent evidence has demonstrated that severe maternal vitamin A deficiency may increase the risk of mother-to-child HIV transmission and reduced infant growth during the first year. β -Carotene, a vitamin A precursor, has not been associated with either human or animal toxicity (see β -Carotene). Doses exceeding the recommended daily allowance (RDA) (8000 IU/day) should be avoided by women who are pregnant or who may become pregnant. Moreover, the RDA established by the FDA should be considered the maximum dose (1).

FETAL RISK SUMMARY

Vitamin A (retinol; vitamin A₁) is a fat-soluble essential nutrient that occurs naturally in various foods. Vitamin A is required for the maintenance of normal epithelial tissue and for growth and bone development, vision, and reproduction (2). Two different daily intake recommendations for pregnant women in the United States have been made for vitamin A. The National Academy of Sciences' RDA for normal pregnant women, published in 1989, is 800 retinol equivalents/day (about 2700 IU per day of vitamin A) (2,3). The FDA's RDA (i.e., U.S. RDA) for pregnant women, a recommendation made in 1976, is 8000 IU/day (1,4). The U.S. RDA of 8000 IU/day should be considered the maximum dose (1), although the difference between the two recommendations is probably not clinically significant.

The teratogenicity of vitamin A in animals is well known. Both high levels and deficiency of the vitamin have resulted in defects (5–13). In the past, various authors have speculated on the teratogenic effect of the vitamin in humans (5,14–16). A 1983 case report suggested that the vitamin A contained in a

multivitamin product may have caused a cleft palate in one infant; however, the mother had a family history of cleft palate and had produced a previous infant with a malformation (16). Another case report, this one published in 1987, described an infant with multiple defects whose mother had consumed a vitamin preparation containing 2000 IU/day of vitamin A (17). The authors thought the phenotype of their patient was similar to the one observed with isotretinoin, but they could not exclude other causes of the defect, including a phenocopy of the isotretinoin syndrome (17). Therefore, in both cases, no definite association between the defects and vitamin A can be established, and the possibility that other causes were involved is high.

In response to the 1983 case report cited above, one investigator wrote in 1983 that there was no acceptable evidence of human vitamin A teratogenicity and none at all with doses <10,000 IU/day (18). Since that time, however, two synthetic isomers of vitamin A, isotretinoin and etretinate, have been shown to be potent human teratogens (see Isotretinoin and Etretinate). In addition, recent studies have revealed that high doses of preformed vitamin A are human teratogens. These and the other reports are summarized below. Because of the combined animal and human data for vitamin A, and because of the human experience with isotretinoin and etretinate, large doses or severe deficiency of vitamin A must be viewed as harmful to the human fetus.

Severe human vitamin A deficiency has been cited as the cause of three malformed infants (19–21). In the first case, a mother with multiple vitamin deficiencies produced a baby with congenital xerophthalmia and bilateral cleft lip (19). The defects may have been caused by vitamin A deficiency because of their similarity to anomalies seen in animals deprived of this nutrient. The second report involved a malnourished pregnant woman with recent onset of blindness whose symptoms were the result of vitamin A deficiency (20). The mother gave birth to a premature male child with microcephaly and what appeared to be anophthalmia. The final case described a blind, mentally slow girl with bilateral microphthalmia, coloboma of the iris and choroid, and retinal aplasia (21). During pregnancy, the mother was suspected of having vitamin A deficiency manifested by night blindness.

In 1986, investigators from the FDA reviewed 18 cases of suspected vitamin A-induced teratogenicity (22). Some of these cases had been reviewed in previous communications by an FDA epidemiologist (23,24). Six of the cases (25–30) had been published previously and 12 represented unpublished reports. All of the cases, except one, involved long-term, high-dose (>25,000 IU/day) consumption continuing past conception. The exception involved a

woman who accidentally consumed 500,000 IU, as a single dose, during the 2nd month of pregnancy (29). Twelve of the infants had malformations similar to those seen in animal and human retinoid syndromes (i.e., central nervous system and cardiovascular anomalies, microtia, and clefts) (22). The defects observed in the 18 infants were microtia (N = 4), craniofacial (N = 4), brain (N = 4), facial palsy (N = 1), micro/anophthalmia (N = 2), facial clefts (N = 4), cardio-aortic (N = 2), limb reduction (N = 4), gastrointestinal atresia (N = 1), and urinary (N = 4) (22).

The CDC reported in 1987 the results of an epidemiologic study conducted by the New York State Department of Health from April 1983 through February 1984 (4). The mothers of 492 liveborn infants without congenital defects were interviewed to obtain their drug histories. Vitamin A supplements were taken by 81.1% (399 of 492) of the women. Of this group, 0.6% (3 of 492) took $\geq 25,000$ IU/day and 2.6% (13 of 492) consumed 15,000–24,999 IU/day. In an editorial comment, the CDC noted that the excessive vitamin A consumption by some of the women was a public health concern (4).

Results of an epidemiologic case–control study conducted in Spain between 1976 and 1987 were reported in preliminary form in 1988 (31) and as a full report in 1990 (32). A total of 11,293 cases of malformed infants were compared with 11,193 normal controls. Sixteen of the case mothers (1.4/1000) used high doses of vitamin A either alone or in combination with other vitamins during their pregnancies, compared with 14 (1.3/1000) of the controls, an odds ratio (OR) of 1.1 (ns). Five of the case infants and 10 of the controls were exposed to doses $< 40,000$ IU/day (OR 0.5, $p = 0.15$). In contrast, 11 of the case infants and 4 controls were exposed to $\geq 40,000$ IU (OR 2.7, $p = 0.06$). The risk of congenital anomalies, although not significant, appeared to be related to gestational age because the highest risk in those pregnancies exposed to $\geq 40,000$ IU/day occurred during the first 2 months (32). The data suggested a dose–effect relationship and provided support for earlier statements that doses lower than 10,000 IU were not teratogenic (31,32).

Data from a case–control study were used to assess the effects of vitamin A supplements (daily use for at least 7 days of vitamin A either alone or with vitamin D, or of fish oils) and vitamin A-containing multivitamin supplements (33). Cases were 2658 infants with malformations derived, at least in part, from cranial neural crest cells (primarily craniofacial and cardiac anomalies). Controls were 2609 infants with other malformations. Case mothers used vitamin A supplements in 15, 14, and 10 pregnancies during lunar months 1, 2, and 3, respectively, compared with 6 control mothers in each period (33).

Although not significant, the OR in each period was 2.5 (95% confidence interval [CI] 1.0–6.2), 2.3 (95% CI 0.9–5.8), and 1.6 (95% CI 0.6–4.5), respectively. The authors cautioned that their data should be considered tentative because of the small numbers and lack of dosage and nutrition information (33). Even a small increased risk was excluded for vitamin A-containing multivitamins (33).

A congenital malformation of the left eye was attributed to excessive vitamin A exposure during the 1st trimester in a 1991 report (34). The mother had ingested a combination of liver and vitamin supplements that provided an estimated 25,000 IU/day of vitamin A. The unusual eye defect consisted of an “hourglass” cornea and iris with a reduplicated lens (34).

A brief 1992 correspondence cited the experience in the Hungarian Family Planning Program with a prenatal vitamin preparation containing 6000 IU of vitamin A (35). Evaluating their 1989 database, the authors found no relationship, in comparison with a nonexposed control group, between the daily intake of the multivitamin at least 1 month before conception through the 12th week of gestation and any congenital malformation.

A study published in 1995 examined the effect of preformed vitamin A, consumed from vitamin supplements and food, on pregnancy outcomes (36). Vitamin A ingestion, from 3 months before through 12 weeks from the last menstrual period, was determined for 22,748 women. Most of the women were enrolled in the study between week 15 and week 20 of pregnancy. From the total group, 339 babies met the criteria for congenital anomalies established by the investigators. These criteria included malformations in four categories (number of defects of each type shown): cranial-neural-crest defects (craniofacial, central nervous system, and thymic N = 69; heart defects N = 52); neural tube defects (NTDs) (spina bifida, anencephaly, and encephalocele N = 48); musculoskeletal (N = 58) and urogenital (N = 42) defects; and other defects (gastrointestinal defects N = 24; agenesis or hypoplasia of the lungs, single umbilical artery, anomalies of the spleen, and cystic hygroma N = 46) (36). The 22,748 women were divided into four groups based on their total (supplement plus food) daily intake of vitamin A: 0–5000 IU (N = 6410), 5001–10,000 IU (N = 12,688), 10,001–15,000 IU (N = 3150), and $\geq 15,001$ IU (N = 500). Analysis of this grouping revealed that the women who took $\geq 15,001$ IU/day had a higher prevalence ratio for defects associated with cranial-neural-crest tissue compared with those in the lowest group, 3.5 (95% CI 1.7–7.3). A slightly higher ratio was found for musculoskeletal and urogenital defects, no increase for neural tube defects or other defects, and for all birth defects

combined, a ratio of 2.2 (95% CI 1.3–3.8). Analysis of three groups (0–5000, 5001–10,000, and $\geq 10,001$ IU) of vitamin A ingestion levels from food alone was hampered by the small number of women and, although some increased prevalence ratios were found in the highest groups, the small numbers made the estimates imprecise. A third analysis was then conducted based on four groups (0–5000, 5001–8000, 8001–10,000, and $\geq 10,001$ IU) of vitamin A ingestion levels from supplements. Compared with the lowest group, the prevalence ratio for all birth defects in the highest group was 2.4 (95% CI 1.3–4.4) and for defects involving the cranial-neural-crest tissue, the ratio was 4.8 (95% CI 2.2–10.5). Of interest, the mean vitamin A intake in the highest group was 21,675 IU. Based on these data, the investigators concluded that following in utero exposure to more than 10,000 IU of vitamin A from supplements, about 1 infant in 57 (1.75%) had a vitamin A-induced malformation (36).

In response to the above study, a note of caution was sounded by two authors from the CDC (37). Citing results from previous studies, these authors concluded that without more data, they could not recommend use of the dose–response curve developed in the above study for advising pregnant women of the specific risk of anomalies that might arise from the ingestion of excessive vitamin A. Although they agreed that very large doses of vitamin A might be teratogenic, the question of how large a dose remained (37). A number of correspondences followed publication of the above study, all describing perceived methodologic discrepancies that may have affected the conclusions (38–42) with a reply by the authors supporting their findings (43).

Using case–control study data from California, a paper published in 1997 examined the relationship between maternal vitamin A ingestion and the risk of NTDs in singleton liveborn infants and aborted fetuses (44). Although the number of cases was small, only 16 exposed to $\geq 10,000$ IU/day and 6 to $\geq 15,000$ IU/day, the investigators did not find a relationship between these levels of exposure and NTDs.

Referring to the question on the teratogenic level of vitamin A, a 1997 abstract reported the effects of increasing doses of the vitamin in the cynomolgus monkey, a species that is a well-documented model for isotretinoin-induced teratogenicity (45). Four groups of monkeys were administered increasing doses of vitamin A (7500–80,000 IU/kg) in early gestation (day 16–27). A dose-related increase in abortions and typical congenital malformations was observed in the offspring. The NOAEL (no-observed-adverse-effect level) was 7500 IU/kg, or 30,000 IU/day based on an average 4-kg animal. A human NOAEL extrapolated from the monkey NOAEL

would correspond to >300,000 IU/day (45).

A brief 1995 report described the outcomes of 7 of 22 women who had taken very large doses of vitamin A during pregnancy, 20 of whom had taken the vitamin during the 1st trimester (46). The mean daily dose was 70,000 IU (range 25,000–90,000 IU) for a mean of 44 days (range 7–180 days). None of the offspring of the seven patients available at follow-up had congenital malformations. Data on the other 15 women were not available (46).

Two abstracts published in 1996 examined the issue of vitamin A supplementation in women enrolled in studies in Atlanta, Georgia, and in California, both during the 1980s (47,48). In the first abstract, no increase in the incidence of all congenital defects or those classified as involving cranial-neural-crest-derived was found for doses <8000 IU/day, or for those who took both a multivitamin and a vitamin A supplement (47). In the other abstract, subjects took amounts thought likely to exceed 10,000 IU/day and, again, no association with the major anomalies derived from cranial-neural-crest cells (cleft lip, cleft palate, and conotruncal heart defects) was discovered (48).

Using data collected between 1985 and 1987 in California and Illinois by the National Institute of Child Health and Human Development Neural Tube Defects Study, a case–control study published in 1997 examined whether periconceptional vitamin A exposure was related to NTDs or other major congenital malformations (49). Three study groups of offspring were formed shortly after the pregnancy outcome was known (prenatally and postnatally): those with NTDs (N = 548), those with other major malformations (N = 387), and normal controls (N = 573). The latter two groups were matched to the NTDs group. A subgroup, formed from those with other major malformations, involved those with cranial-neural-crest malformations (N = 89), consisting mainly of conotruncal defects of the heart and great vessels, including ventricular septal defects, and defects of the ear and face (49). The vitamin A (supplements and fortified cereals) exposure rates by group for those ingesting a mean >8000 IU/day or >10,000 IU/day were: NTDs (3.3% and 2.0%), other major malformations (3.6% and 1.6%), cranial-neural-crest malformations (3.4% and 2.2%), and controls (4.5% and 2.1%), respectively. None of the values were statistically significant, thus, no association between moderate consumption of vitamin A and the defect groups was found (49).

Several investigators have studied maternal and fetal vitamin A levels during various stages of gestation (5,50–61). Transport to the fetus is by passive diffusion (61). Maternal vitamin A concentrations are slightly greater than those found in either premature or term infants (50–52). In women with normal levels

of vitamin A, maternal and newborn levels were 270 and 220 ng/mL, respectively (51). In 41 women not given supplements of vitamin A, a third of whom had laboratory evidence of hypovitaminemia A, mean maternal levels exceeded those in the newborn by almost a 2:1 ratio (51). In two reports, maternal serum levels were dependent on the length of gestation with concentrations decreasing during the 1st trimester, then increasing during the remainder of pregnancy until about the 38th week when they began to decrease again (5,53). A more recent study found no difference in serum levels between 10 and 33 weeks' gestation, even though amniotic fluid vitamin A levels at 20 weeks onward were significantly greater than at 16–18 weeks (54). Premature infants (36 weeks or less) have significantly lower serum retinol and retinol-binding protein concentrations than do term neonates (50,55–57).

Mild to moderate deficiency is common during pregnancy (51,58). A 1984 report concluded that vitamin A deficiency in poorly nourished mothers was one of the features associated with an increased incidence of prematurity and intrauterine growth restriction (50). An earlier study, however, found no difference in vitamin A levels between low-birth-weight (<2500 g) and normal-birth-weight (>2500 g) infants (52). Maternal vitamin A concentrations of the low-birth-weight group were lower than those of normals, 211 vs. 273 ng/mL, but not significantly. An investigation in premature infants revealed that infants developing bronchopulmonary dysplasia had significantly lower serum retinol levels as compared with infants who did not develop this disease (57).

Relatively high liver vitamin A stores were found in the fetuses of women younger than 18 and older than 40 years of age, two groups that produce a high incidence of fetal anomalies (5). Low fetal liver concentrations were measured in 2 infants with hydrocephalus and high levels in 14 infants with NTDs (5). In another report relating to NTDs, a high liver concentration occurred in an anencephalic infant (59). Significantly, higher vitamin A amniotic fluid concentrations were discovered in 12 pregnancies from which infants with NTDs were delivered as compared with 94 normal pregnancies (60). However, attempts to use this measurement as an indicator of anencephaly or other fetal anomalies failed because the values for abnormal and normal fetuses overlapped (54,60).

The effect of stopping oral contraceptives shortly before conception on vitamin A levels has been studied (62). Because oral contraceptives had been shown to increase serum levels of vitamin A, it was postulated that early conception might involve a risk of teratogenicity. However, no difference was

found in early pregnancy vitamin A levels between users and nonusers. The results of this study have been challenged based on the methods used to measure vitamin A (63).

Vitamin A is known to affect the immune system (64). Three recent studies (65–67) and an editorial (68) have described or commented on the effect that maternal vitamin A deficiency has on the maternal–fetal transmission of HIV. In each of the studies, a low maternal level of vitamin A was associated with HIV transmission to the infant. In the one study conducted in the United States, severe maternal vitamin A deficiency ($<0.70 \mu\text{mol/L}$) was associated with HIV transmission with an adjusted OR of 5.05 (95% CI 1.20–21.24) (67). In a related study, maternal vitamin A deficiency during pregnancy in women infected with HIV was significantly related to growth failure (height and weight) during the 1st year of life in their children, after adjustment for the effects of body mass index, child gender, and child HIV status (69).

Although the minimum teratogenic dose has not yet been defined, doses of 25,000 IU/day or more, in the form of retinol or retinyl esters, should be considered potentially teratogenic (1,3,22), but based on one study, smaller doses than this may be teratogenic (36). One of the recommendations of the Teratology Society, published in a 1987 position paper, states: “Women in their reproductive years should be informed that the excessive use of vitamin A shortly before and during pregnancy could be harmful to their babies” (1). The Teratology Society also noted that the average balanced diet contains approximately 7000–8000 IU of vitamin A from various sources, and this should be considered prior to additional supplementation (1).

BREASTFEEDING SUMMARY

Vitamin A is a natural constituent of breast milk. Deficiency of this vitamin in breastfed infants is rare (70). The RDA of vitamin A during lactation is approximately 4000 IU (2). It is not known whether high maternal doses of vitamin A represent a danger to the nursing infant or whether they reduce HIV transmission via the milk.

VITAMIN B₁₂

Vitamin

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Severe maternal vitamin B₁₂ deficiency may result in megaloblastic anemia with subsequent infertility and poor pregnancy outcome. Less severe maternal deficiency apparently is common and does not pose a significant risk to the mother or fetus. Ingestion of vitamin B₁₂ during pregnancy up to the recommended daily allowance (RDA) either via the diet or by supplementation is recommended.

FETAL RISK SUMMARY

Vitamin B₁₂ (cyanocobalamin), a water-soluble B-complex vitamin, is an essential nutrient required for nucleoprotein and myelin synthesis, cell reproduction, normal growth, and the maintenance of normal erythropoiesis (1). The National Academy of Sciences' RDA for vitamin B₁₂ in pregnancy is 2.2 mcg (1).

Vitamin B₁₂ is actively transported to the fetus (2–6). This process is responsible for the progressive decline of maternal levels that occurs during pregnancy (6–14). Fetal demands for the vitamin have been estimated to be approximately 0.3 mcg/day (0.2 nmol/day) (15). Similar to other B-complex vitamins, higher concentrations of B₁₂ are found in the fetus and newborn than in the mother (5–9,16–24). At term, mean vitamin B₁₂ levels in 174 mothers were 115 pg/mL and in their newborns 500 pg/mL, a newborn:maternal ratio of 4.3 (16). Comparable values have been observed by others (5,7,21–23). Mean levels in 51 Brazilian women, in their newborns, and in the intervillous space of their placentas were approximately 340, 797, and 1074 pg/mL, respectively (24). The newborn:maternal ratio in this report was 2.3. The high levels in the placenta may indicate a mechanism by which the fetus can accumulate the vitamin against a concentration gradient. This study also found a highly

significant correlation between vitamin B₁₂ and folate concentrations. This is in contrast to an earlier report that did not find such a correlation in women with megaloblastic anemia (25).

Maternal deficiency of vitamin B₁₂ is common during pregnancy (16,17,26,27). Tobacco smoking reduces maternal levels of the vitamin even further (28). Megaloblastic anemia may result when the deficiency is severe, but it responds readily to therapy (29–32). On the other hand, tropical macrocytic anemia during pregnancy responds erratically to vitamin B₁₂ therapy and is better treated with folic acid (32,33).

Megaloblastic (pernicious) anemia may be a cause of infertility (30,31,34). One report described a mother with undiagnosed pernicious anemia who had lost her 3rd, 9th, and 10th pregnancies (30). A healthy child resulted from her 11th pregnancy following treatment with vitamin B₁₂. In another study, eight infertile women with pernicious anemia were treated with vitamin B₁₂ and seven became pregnant within 1 year of therapy (31). One of three patients in still another report may have had infertility associated with very low vitamin B₁₂ levels (34).

Vitamin B₁₂ deficiency was associated with prematurity (as defined by a birth weight ≤2500 g) in a 1968 paper (9). However, many of the patients who delivered prematurely had normal or elevated vitamin B₁₂ levels. No correlation between vitamin B₁₂ deficiency and abruptio placentae was found in two studies published in the 1960s (35,36). Two reports found a positive association between low birth weight and low vitamin B₁₂ levels (21,37). In both instances, however, folate levels were also low and iron was deficient in one. Others could not correlate low vitamin B₁₂ concentrations with the weight at delivery (11,26). Based on these reports, it is doubtful whether vitamin B₁₂ deficiency is associated with any of the conditions.

In experimental animals, vitamin B₁₂ deficiency is teratogenic (7,38). Investigators studying the cause of neural tube defects measured very low vitamin B₁₂ levels in three of four mothers of anencephalic fetuses (39). Additional evidence led them to conclude that the low vitamin B₁₂ resulted in depletion of maternal folic acid and involvement in the origin of the defects. In contrast, two other reports have shown no relationship between low levels of vitamin B₁₂ and congenital malformations (9,19).

No reports linking high doses of vitamin B₁₂ with maternal or fetal complications have been located. Vitamin B₁₂ administration at term has

produced maternal levels approaching 50,000 pg/mL with corresponding cord blood levels of approximately 15,000 pg/mL (4,5). In fetal methylmalonic acidemia, large doses of vitamin B₁₂, 10 mg orally initially then changed to 5 mg IM, were administered daily to a mother to treat the affected fetus (40). On this dosage regimen, maternal levels rose as high as 18,000 pg/mL shortly after a dose. This metabolic disorder is not always treatable with vitamin B₁₂: one study reported a newborn with the vitamin B₁₂-unresponsive form of methylmalonic acidemia (41).

BREASTFEEDING SUMMARY

Vitamin B₁₂ is excreted into breast milk. In the first 48 hours after delivery, mean colostrum levels were 2431 pg/mL and then fell rapidly to concentrations comparable with those of normal serum (42). One group of investigators also observed very high colostrum levels ranging from 6 to 17.5 times that of milk (2). Milk:plasma ratios are approximately 1.0 during lactation (19). Reported milk concentrations of vitamin B₁₂ vary widely (43–46). Mothers supplemented with daily doses of 1–200 mcg had milk levels increase from a level of 79 to a level of 100 pg/mL (43). Milk concentrations were directly proportional to dietary intake. In a study using 8-mcg/day supplements, mean milk levels of 1650 pg/mL at 1 week and 1100 pg/mL at 6 weeks were measured (44). Corresponding levels in nonsupplemented mothers were significantly different at 1220 and 610 pg/mL, respectively. Other investigators also used 8-mcg/day supplements and found significantly different levels compared with women not receiving supplements: 910 vs. 700 pg/mL at 1 week and 790 vs. 550 pg/mL at 6 weeks (45). In contrast, others found no difference between supplemented and nonsupplemented well-nourished women with 5–100 mcg/day (46). The mean vitamin B₁₂ concentration in these latter patients was 970 pg/mL. A 1983 English study measured vitamin B₁₂ levels in pooled human milk obtained from preterm (26 mothers: 29–34 weeks) and term (35 mothers: 39 weeks or longer) patients (47). Milk from preterm mothers decreased from a level of 920 pg/mL (colostrum) to a level of 220 pg/mL (16–196 days), whereas milk from term mothers decreased over the same period from a level of 490 to a level of 230 pg/mL.

Vitamin B₁₂ deficiency in the lactating mother may cause severe consequences in the nursing infant. Several reports have described megaloblastic anemia in infants exclusively breastfed by vitamin B₁₂-deficient mothers (48–52). Many of these mothers were vegetarians whose diets

provided low amounts of the vitamin (49–52). The adequacy of vegetarian diets in providing sufficient vitamin B₁₂ has been debated (53–55). However, a recent report measured only 1.4 mcg of vitamin B₁₂ intake/day in lactovegetarians (56). This amount is approximately 54% of the RDA for lactating women in the United States (1). Moreover, a 1986 case of vitamin B₁₂-induced anemia supports the argument that the low vitamin B₁₂ intake of some vegetarian diets is inadequate to meet the total needs of a nursing infant for this vitamin (57). The case involved a 7-month-old male infant, exclusively breastfed by a strict vegetarian mother, who was diagnosed as suffering from macrocytic anemia. The infant was lethargic, irritable, and failing to thrive. His vitamin B₁₂ level was less than 100 pg/mL (normal 180–960 pg/mL), but iron and folate levels were both within normal limits. The anemia responded rapidly to administration of the vitamin, and he was developing normally at 11 months of age (57).

The National Academy of Sciences' RDA for vitamin B₁₂ during lactation is 2.6 mcg (1). If the diet of the lactating woman adequately supplies this amount, maternal supplementation with vitamin B₁₂ is not needed. Supplementation with the RDA for vitamin B₁₂ is recommended for those women with inadequate nutritional intake. The American Academy of Pediatrics classifies vitamin B₁₂ as compatible with breastfeeding (58).

VITAMIN C

Vitamin

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Mild to moderate vitamin C deficiency or excessive doses do not seem to pose a major risk to the mother or fetus. Because vitamin C is required for good maternal and fetal health and an increased demand for the vitamin occurs during pregnancy, intake up to the recommended daily allowance (RDA) is recommended.

FETAL RISK SUMMARY

Vitamin C (ascorbic acid) is a water-soluble essential nutrient required for collagen formation, tissue repair, and numerous metabolic processes including the conversion of folic acid to folinic acid and iron metabolism (1). The National Academy of Sciences' RDA for vitamin C in pregnancy is 70 mg (1).

Vitamin C is actively transported to the fetus (2–5). When maternal serum levels are high, placental transfer changes to simple diffusion (5). During gestation, maternal serum vitamin C progressively declines (6,7). As a consequence of this process, newborn serum vitamin C (9–22 mcg/mL) is approximately 2–4 times that of the mother (4–10 mcg/mL) (4–19).

Maternal deficiency of vitamin C without clinical symptoms is common during pregnancy (18–20). Most studies have found no association between this deficiency and maternal or fetal complications, including congenital malformations (11,12,21–24). When low vitamin C levels were found in women or fetuses with complications, it was a consequence of the condition and not a cause. However, a 1971 retrospective study of 1369 mothers found that deficiency of vitamin C may have a teratogenic effect, although the authors advised caution in the interpretation of their results (25). In a later investigation, low 1st trimester white blood cell vitamin C levels were discovered in six mothers giving birth to infants with neural tube defects (26). Folic acid, vitamin B₁₂, and riboflavin were also low in serum or red blood cells. The low folic acid

and vitamin B₁₂ levels were thought to be involved in the etiology of the defects (see also Folic Acid, Vitamin B₁₂, and Riboflavin).

A 1965 report suggested that high daily doses of vitamin C during pregnancy might have produced a “conditioned” scurvy in two infants (27). The mothers had apparent daily intakes of vitamin C in the 400-mg range throughout pregnancy, but both of their offspring had infantile scurvy. To study this condition, laboratory animals were given various doses of vitamin C throughout gestation. Of the 10 offspring exposed to the highest doses, 2 developed symptoms and histologic changes compatible with scurvy (27). The investigators concluded that the high in utero exposure may have induced ascorbic acid dependency. More recent reports of this condition have not been located; thus, the clinical significance is unknown.

Only one report has been found that potentially relates high doses of vitamin C with fetal anomalies. This was in a brief 1976 case report describing an anencephalic fetus delivered from a woman treated with high doses of vitamin C and other water-soluble vitamins and nutrients for psychiatric reasons (28). The relationship between the defect and the vitamins is unknown. In another study, no evidence of adverse effects was found with doses up to 2000 mg/day (29).

BREASTFEEDING SUMMARY

Vitamin C (ascorbic acid) is excreted into breast milk. Reported concentrations in milk vary from 24 to 158 mcg/mL (30–38). In lactating women with low nutritional status, milk vitamin C is directly proportional to intake (31,32). Supplementation with 4–200 mg/day of vitamin C produced milk levels of 24–61 mcg/mL (31). Similarly, in another group of women with poor vitamin C intake, supplementation with 34–103 mg/day resulted in levels of 34–55 mcg/mL (32). In contrast, studies in well-nourished women consuming the RDA or more of vitamin C in their diets indicate that ingestion of greater amounts does not significantly increase levels of the vitamin in their milk (33–34). Even consumption of total vitamin C exceeding 1000 mg/day, 10 times the RDA, did not significantly increase milk concentrations or vitamin C intake of the infants (36). However, maternal urinary excretion of the vitamin did increase significantly. These studies indicate that vitamin C excretion into milk is regulated to prevent exceeding a saturation level (36).

Storage of human milk in the freezer for up to 3 months did not affect vitamin C concentrations of milk obtained from preterm mothers but resulted in a significant decrease in vitamin C concentrations in milk from term mothers (39).

Both types of milk, however, maintained sufficient vitamin C to meet the RDA for infants.

The RDA for vitamin C during lactation is 95 mg (1). Well-nourished lactating women consuming the RDA of vitamin C in their diets normally excrete sufficient vitamin C in their milk to reach a saturation level and additional supplementation is not required. Maternal supplementation up to the RDA is needed only in those women with poor nutritional status.

VITAMIN D

Vitamin

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Vitamin D analogs are a group of fat-soluble nutrients essential for human life with antirachitic and hypercalcemic activity (1). The National Academy of Sciences' recommended dietary allowance (RDA) for normal pregnant women in the United States is 400 IU (1). However, based on evidence that vitamin D deficiency is very common in pregnancy, a much higher dose is required to prevent and treat the deficiency. Although the required pregnancy dose is still under investigation, it may be in the range of 1000–2000 IU of vitamin D₃/day or 50,000 IU of vitamin D₂ every 2 weeks (see reference 37).

FETAL RISK SUMMARY

The two natural biologically active forms of vitamin D are 1,25-dihydroxyergocalciferol and calcitriol (1,25-dihydroxyvitamin D₃) (1). A third active compound, 25-hydroxydihydrotachysterol, is produced in the liver from the synthetic vitamin D analog, dihydrotachysterol.

Ergosterol (provitamin D₂) and 7-dehydrocholesterol (provitamin D₃) are activated by ultraviolet light to form ergocalciferol (vitamin D₂) and cholecalciferol (vitamin D₃), respectively. These, in turn, are converted in the liver to 25-hydroxyergocalciferol and calcifediol (25-hydroxyvitamin D₃), the major transport forms of vitamin D in the body. Activation of the transport compounds by enzymes in the kidneys results in the two natural active forms of vitamin D.

The commercially available forms of vitamin D are ergocalciferol, cholecalciferol, calcifediol, calcitriol, and dihydrotachysterol. Although differing in potency, all of these products have the same result in the mother and fetus. Thus, only the term vitamin D, unless otherwise noted, will be used in this

monograph.

High doses of vitamin D are known to be teratogenic in experimental animals, but direct evidence for this is lacking in humans. Because of its action to raise calcium levels, vitamin D has been suspected in the pathogenesis of the supravalvular aortic stenosis syndrome, which is often associated with idiopathic hypercalcemia of infancy (2–4). The full features of this rare condition are characteristic elfin facies, mental and growth restriction, strabismus, enamel defects, craniosynostosis, supravalvular aortic and pulmonary stenosis, inguinal hernia, cryptorchidism in males, and early development of secondary sexual characteristics in females (2). Excessive intake or retention of vitamin D during pregnancy by mothers of infants who develop supravalvular aortic stenosis (SAS) syndrome has not been consistently found (2,3,5). However, it is now known that SAS syndrome is a feature of a severe genetic affliction, Williams syndrome, and is not caused by vitamin D (see reference 36).

Very high levels of vitamin D have been used to treat maternal hypoparathyroidism during pregnancy (6–9). In two studies, 15 mothers were treated with doses averaging 107,000 IU/day throughout their pregnancies to maintain maternal calcium levels within the normal range (6,7). All of the 27 children were normal at birth and during follow-up examinations ranging up to 16 years. Calcitriol, in doses ≤ 3 mcg/day, was used to treat another mother with hypoparathyroidism (8). The high dose was required in the latter half of pregnancy to prevent hypocalcemia. The infant had no apparent adverse effects from this exposure. In a similar case, a mother received 100,000 IU/day throughout gestation, resulting in a healthy, term infant (9). In contrast, a 1965 case report described a woman who received 600,000 IU of vitamin D and 40,000 IU of vitamin A daily for 1 month early in pregnancy (10). The resulting infant had a defect of the urogenital system, but this was probably caused by ingestion of excessive vitamin A (see Vitamin A).

Vitamin D deficiency can be induced by decreased dietary intake or lack of exposure to sunlight. The conversion of provitamin D₃ to vitamin D₃ is catalyzed by ultraviolet light striking the skin (1). Severe deficiency during pregnancy, resulting in maternal osteomalacia, leads to significant morbidity in the mother and fetus (11–21). Pitkin (22), in a 1985 article, reviewed the relationship between vitamin D and calcium metabolism in pregnancy.

The peak incidence of vitamin D deficiency occurs in the winter and early spring when exposure to sunlight is at a minimum. Certain ethnic groups, such as Asians, seem to be at greater risk for developing this deficiency because of their dietary and sun exposure habits (11–21). In the pregnant woman,

osteomalacia may cause, among other effects, decreased weight gain and pelvic deformities that prevent normal vaginal delivery (11,12). For the fetus, vitamin D deficiency has been associated with the following:

- Reduced fetal growth (11,12)
- Neonatal hypocalcemia without convulsions (12–14,20)
- Neonatal hypocalcemia with convulsions (tetany) (15–17)
- Neonatal rickets (18,19)
- Defective tooth enamel (21,23)

Long-term use of heparin may induce osteopenia by inhibiting renal activation of calcifediol to the active form of vitamin D₃ (calcitriol or 1,25-dihydroxyvitamin D₃) (22). The decreased levels of calcitriol prevent calcium uptake by bone and result in osteopenia (see reference 23 for detailed review of calcium metabolism in pregnancy). One investigator suggests that these patients may benefit from treatment with supplemental calcitriol (22).

Numerous investigators have measured vitamin D levels in the mother during pregnancy and in the newborn (24–34). Although not universal, most studies have found a significant correlation between maternal serum and cord blood levels (24–28). In one study, a close association between both of the transport vitamin D forms in maternal and cord serum was discovered (29). No significant correlation could be demonstrated, however, between the two biologically active forms in maternal and cord blood.

Using a perfused human placenta, a 1984 report confirmed that calcifediol and calcitriol were transferred from the mother to the fetus, although at a very slow rate (35). Binding to vitamin D₃-binding protein was a major rate-limiting factor, especially for calcifediol, the transport form of vitamin D₃. The researchers concluded that placental metabolism of calcifediol was not a major source of fetal calcitriol (35).

Maternal levels of vitamin D at term are usually higher than those in the newborn because the fetus has no need for intestinal calcium absorption (24–30). Maternal levels are elevated in early pregnancy and continue to increase throughout pregnancy (32). During the winter months a weak correlation may exist between maternal vitamin D intake and serum levels, with exposure to ultraviolet light the main determinant of maternal concentrations (33,34). A Norwegian study, however, was able to increase maternal concentrations of active vitamin D significantly during all seasons with daily supplementation of 400 IU (29).

A 2004 review discussed vitamin D requirements during pregnancy and

lactation (36). The daily recommended dose of 200–400 IU was based on erroneous data and was thought to be too low, especially for persons with darkly pigmented skin. Although the appropriate dose in pregnancy and lactation as a function of latitude and race is unknown, the authors thought that daily doses exceeding 1000 IU vitamin D, such as 2000–10,000 IU, were required to overcome vitamin D deficiency and/or to maintain normal blood concentrations of vitamin D. They also cited published evidence showing that the cause of supravalvular aortic stenosis syndrome was actually a severe genetic disorder, Williams syndrome, and was not associated with high concentrations of vitamin D (36).

In a 2007 review of vitamin D deficiency, the recommended doses of vitamin D to prevent and maintain vitamin D concentrations to avoid deficiency in pregnancy or lactation caused by fetal utilization, inadequate sun exposure, or supplementation were vitamin D₃: 1000–2000 IU/day, up to 4000 IU/day is safe for 5 months; vitamin D₂: 50,000 IU every 2 or 4 weeks (37). To treat deficiency caused by the above three conditions, the recommended dose of vitamin D₂ was 50,000 IU every week for 8 weeks and, if the 25-hydroxyvitamin D concentration was <30 ng/mL, repeated for another 8 weeks (37).

In a study reported in 2010, vitamin D levels were measured in 928 pregnant women and 5173 nonpregnant women (38). The mean concentrations in the two groups were 65 and 59 nmol/L (26 and 24 ng/mL), respectively, with a prevalence of <75 nmol/L (<30 ng/mL) in 69% and 78%, respectively. Based on recent evidence, the investigators considered 75 or 100 nmol/L (30 or 40 ng/mL) to be required for optimal health. The clinical implications from this research were: (a) current recommendations for vitamin D supplementation of 200–400 IU/day are inadequate for many women and their infants; (b) vitamin D supplementation should begin a few months before pregnancy; and (c) further studies are required to determine the dose for vitamin D supplementation (38).

A 2010 report noted that vitamin D deficiency was estimated to occur in up to 50% of pregnant women and, compared with other groups African American women had a much higher risk (39). The authors described the effects of vitamin D deficiency on the mother and newborn based on serum concentrations of vitamin D. The maternal effects of severe deficiency (defined as <10 ng/mL) were an increased risk of preeclampsia, calcium malabsorption, bone loss, poor weight gain, myopathy, and higher parathyroid hormone levels, whereas those in the newborn included small for gestational age, hypocalcemia with possible seizures, heart failure, enamel defects, large fontanelle,

congenital rickets, and rickets of infancy if breastfed. For serum concentrations (11–32 ng/mL) considered insufficient, the maternal effects were bone loss and subclinical myopathy, whereas those in the newborn were hypocalcemia, decreased bone mineral activity, and rickets if breastfed. There were no maternal or newborn adverse effects if the vitamin D concentration was 32–100 ng/mL, but levels >100 ng/mL could cause maternal hypercalcemia and increased urine calcium loss, and hypercalcemia in the newborn (39).

BREASTFEEDING SUMMARY

Vitamin D is excreted into breast milk in limited amounts (40). A direct relationship exists between maternal serum levels of vitamin D and the concentration in breast milk (41). Chronic maternal ingestion of large doses may lead to greater than normal vitamin D activity in the milk and resulting hypercalcemia in the infant (42). In the lactating woman who was not receiving supplements, controversy exists about whether her milk contained sufficient vitamin D to protect the infant from vitamin deficiency. Several studies had supported the need for infant supplementation during breastfeeding (12,40,43–45). Other investigators had concluded that supplementation is not necessary if maternal vitamin D stores are adequate (28,46–48).

The National Academy of Sciences' RDA for vitamin D in the lactating woman is 400 IU (1). However, recent evidence suggests that vitamin D supplementation of lactating women with much higher doses is necessary to increase the nutritional vitamin D status of the mother and her breastfeeding infant (36,37). This is especially true for darkly pigmented individuals and those having limited exposure to ultraviolet light. Although the required dose has not been adequately studied, doses identical to those described for pregnancy (see Fetal Risk Summary section) have been suggested (37).

A study published in 1977 measured high levels of a vitamin D metabolite in the aqueous phase of milk (49). Although two other studies supported these findings, the conclusions were in direct opposition to previous measurements and have been vigorously disputed (50,51). The argument that human milk is low in vitamin D is supported by clinical reports of vitamin D deficiency-induced rickets and decreased bone mineralization in breastfed infants (44,45,52–54). Moreover, one investigation measured the vitamin D activity of human milk and failed to find any evidence for significant activity of water-soluble vitamin D metabolites (55). Vitamin D activity in the milk was 40–50 IU/L, with 90% of this accounted for by the usual fat-soluble components.

The Committee on Nutrition, American Academy of Pediatrics, recommends

vitamin D supplements for breastfed infants if maternal vitamin D nutrition is inadequate or if the infant lacks sufficient exposure to UV light (56). A second committee of the American Academy of Pediatrics classifies vitamin D as compatible with breastfeeding, but recommends monitoring the serum calcium levels of the infant if the mother is receiving pharmacologic doses (57).

VITAMIN E

Vitamin

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Neither deficiency nor excess of vitamin E has been associated with maternal or fetal complications during pregnancy. One study did find a lower birth weight in infants of women taking high doses of vitamin E during pregnancy, but the reduced weight was not thought to be clinically significant and may have been due to other factors. However, in well-nourished women, adequate vitamin E is consumed in the diet and supplementation is not required. If dietary intake is poor, supplementation up to the recommended daily allowance (RDA) for pregnancy is recommended.

FETAL RISK SUMMARY

Vitamin E (tocopherols) is comprised of a group of fat-soluble vitamins that are essential for human health, although their exact biologic function is unknown (1). The National Academy of Sciences' RDA for vitamin E in pregnancy is 10 mg (1).

Vitamin E concentrations in mothers at term are approximately 4–5 times that of the newborn (2–8). Levels in the mother rise throughout pregnancy (3). Maternal blood vitamin E level usually ranges between 9 and 19 mcg/mL with corresponding newborn levels varying from 2 to 6 mcg/mL (2–9). Supplementation of the mother with 15–30 mg/day had no effect on either maternal or newborn vitamin E concentrations at term (4). Use of 600 mg/day in the last 2 months of pregnancy produced about a 50% rise in maternal serum vitamin E (+8 mcg/mL) but a much smaller increase in the cord blood (+1 mcg/mL) (7). Although placental transfer is by passive diffusion, passage of vitamin E to the fetus is dependent on plasma lipid concentrations (8–10). At term, cord blood is low in β -lipoproteins, the major carriers of vitamin E, in comparison with maternal blood; as a consequence, it is able to transport less

of the vitamin (8). Because vitamin E is transported in the plasma by these lipids, recent investigations have focused on the ratio of vitamin E (in milligrams) to total lipids (in grams) rather than on blood vitamin E concentrations alone (9). Ratios above about 0.6–0.8 are considered normal depending on the author cited and the age of the patients (9,11,12).

A 2005 prospective, observational study reported the pregnancy outcomes of 82 women who had taken high-dose vitamin E (≥ 400 IU/day) in the 1st trimester and compared them with 130 matched controls exposed to agents not known to cause embryo–fetal harm (13). The reason given by the women for taking high doses was that large amounts of vitamins were part of a healthy lifestyle, but none took large doses of vitamins A and D. The two groups were enrolled in the study at a mean gestational age of 13.1 and 6.2 weeks', respectively. In the subject group, doses of 400, 800, or 1200 IU/day were taken by 74, 7, and 1 women, respectively. The mean duration was 6 months and 44 (54%) took a high dose throughout gestation. There were no differences in the outcomes between the groups in terms of live births, spontaneous abortions, elective abortions, stillbirths, gestational age at delivery, prematurity, and malformations. The mean birth weight, however, was lower in subjects than in controls, 3173 vs. 3417 g, respectively ($p = 0.0015$). Because only two infants had a birth weight < 2500 g, the difference was thought to have a questionable clinical significance. Moreover, vigorous exercise was thought to be part of a "healthy lifestyle" and it might also reduce birth weight (13).

Vitamin E deficiency is relatively uncommon in pregnancy, occurring in less than 10% of all patients (3,4,14). No maternal or fetal complications from deficiency or excess of the vitamin have been identified. Doses far exceeding the RDA have not proved to be harmful (7,15,16). Early studies used vitamin E in conjunction with other therapy in attempts to prevent abortion and premature labor, but no effect of the vitamin therapy was demonstrated (17,18). Premature infants born with low vitamin E stores may develop hemolytic anemia, edema, reticulocytosis, and thrombocytosis if not given adequate vitamin E in the first months following birth (16,19,20). In two studies, supplementation of mothers with 500–600 mg of vitamin E during the last 1–2 months of pregnancy did not produce values significantly different from controls in the erythrocyte hemolysis test with hydrogen peroxide, a test used to determine adequate levels of vitamin E (7,16).

BREASTFEEDING SUMMARY

Vitamin E is excreted into breast milk (11,12,21,22). Human milk is more than 5 times richer in vitamin E than cow's milk and is more effective in maintaining adequate serum vitamin E and vitamin E:total lipid ratio in infants up to 1 year of age (11,22). A 1985 study measured 2.3 mcg/mL of the vitamin in mature milk (21). Milk obtained from preterm mothers (gestational age 27–33 weeks) was significantly higher (8.5 mcg/mL) during the first week and then decreased progressively over the next 6 weeks to 3.7 mcg/mL (21). The authors concluded that milk from preterm mothers plus multivitamin supplements would provide adequate levels of vitamin E for very low-birth-weight infants (<1500 g and appropriate for gestational age).

Japanese researchers examined the pattern of vitamin E analogs (α -, γ -, δ -, and β -tocopherols) in plasma and red blood cells from breastfed and bottle-fed infants (23). Several differences were noted, but the significance of these findings to human health is unknown.

Vitamin E applied for 6 days to the nipples of breastfeeding women resulted in a significant rise in infant serum levels of the vitamin (24). The study group, composed of 10 women, applied the contents of one 400-IU vitamin E capsule to both areolae and nipples after each nursing. Serum concentrations of the vitamin rose from 4 to 17.5 mcg/mL and those in a similar group of untreated controls rose from 3.4 to 12.2 mcg/mL. The difference between the two groups was statistically significant ($p < 0.025$). Although no adverse effects were observed, the authors cautioned that the long-term effects were unknown.

The National Academy of Sciences' RDA of vitamin E during lactation is 12 mg (1). Maternal supplementation is recommended only if the diet does not provide sufficient vitamin E to meet the RDA.

VITAMINS, MULTIPLE

Vitamins

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

The use of multivitamins up to the recommended daily allowance (RDA) for pregnancy is recommended for the general good health of the mother and the fetus. There is no strong evidence to suggest that vitamin supplementation can prevent cleft lip and/or palate (CLP). However, a body of evidence has accumulated that supplementation during the first few weeks of gestation, especially with folic acid, may reduce the risk of neural tube defects (NTDs) (see Folic Acid). The evidence appears particularly strong for the prevention of NTD recurrences in England. Additional studies will be needed to establish whether the protective effect includes only certain types of patients. Until that time, it seems prudent to recommend that folate-containing multivitamin preparations should be used immediately before and during at least the first few months of pregnancy. Women who have had gastric bypass surgery for obesity may be at increased risk for delivering offspring with NTDs, and pregnancy counseling to ensure adequate nutritional intake may be of benefit.

FETAL RISK SUMMARY

Vitamins are essential for human life. Preparations containing multiple vitamins (multivitamins) are routinely given to pregnant women. A typical product will contain the vitamins A, D, E, and C, plus the B-complex vitamins thiamine (B₁), riboflavin (B₂), niacin (B₃), pantothenic acid (B₅), pyridoxine (B₆), B₁₂, and folic acid. Miscellaneous substances that may be included are iron, calcium, and other minerals. The practice of supplementation during pregnancy with multivitamins varies from country to country but is common in the United States. The National Academy of Sciences' RDA for pregnant women, as of 1989, is as follows (1):

| | | | |
|------------------------------|--------|------------------------------|---------|
| Vitamin A | 800 RE | Niacin (B ₃) | 17 mg |
| Vitamin D | 400 IU | Pyridoxine (B ₆) | 2.2 mg |
| Vitamin C | 70 mg | Folic acid | 0.4 mg |
| Thiamine (B ₁) | 1.5 mg | Vitamin B ₁₂ | 2.2 mcg |
| Riboflavin (B ₂) | 1.6 mg | Vitamin E | 10 mg |

Although essential for health, vitamin K is normally not included in multivitamin preparations because it is adequately supplied from natural sources. The fat-soluble vitamins, A, D, and E, may be toxic or teratogenic in high doses. The water-soluble vitamins, C and the B-complex group, are generally considered safe in amounts above the RDA, but there are exceptions. Deficiencies of vitamins may also be teratogenic (see individual vitamin monographs for further details).

The role of vitamins in the prevention of certain congenital defects continues to be a major area of controversy. Two classes of anomalies, CLP and NTDs, have been the focus of numerous investigations with multivitamins. An investigation into a third class of anomalies, limb reduction defects, has also appeared. The following sections will summarize the published work on these topics.

Animal research in the 1930s and 1940s had shown that both deficiencies and excesses of selected vitamins could result in fetal anomalies, but it was not until two papers in 1958 (2,3) that attention was turned to humans. These investigations examined the role of environmental factors, in particular the B-complex vitamins, as agents for preventing the recurrence of CLP. In that same year, a study was published that involved 87 women who had previously given birth to infants with CLP (4). Although the series was too small to draw statistical conclusions, 48 women given no vitamin supplements had 78 pregnancies, resulting in 4 infants with CLP. The treated group, composed of 39 women, received multivitamins plus injectable B-complex vitamins during the 1st trimester. This group had 59 pregnancies with none of the infants having CLP. A similar study found a CLP incidence of 1.9% (3 of 156) in treated pregnancies compared with 5.7% (22 of 383) in controls (5). The difference was not statistically significant. However, other researchers, in a 1964 survey, found no evidence that vitamins offered protection against CLP (6). Also in 1964, research was published involving 594 pregnant women who had previously given birth to an infant with CLP (7). This work was further expanded, and the total group involving 645 pregnancies was presented in a 1976 paper (8). Of the total group, 417 women were not given supplements during pregnancy, and they gave birth to 20 infants (4.8%) with CLP. In the

treated group, 228 women were given B-complex vitamins plus vitamin C before or during the 1st trimester. From this latter group, seven infants (3.1%) with CLP resulted. Although suggestive of a positive effect, the difference between the two groups was not significant. Another investigator found only one instance of CLP in his group of 85 supplemented pregnancies (9). These patients were given daily multivitamins plus 10 mg of folic acid. In 206 pregnancies in women not given supplements in which the infants or fetuses were examined, 15 instances of CLP resulted. The difference between the two groups was significant ($p = 0.023$). In contrast, one author suggested that the vitamin A in the supplements caused a cleft palate in his patient (10). However, the conclusion of this report has been disputed (11). Thus, the published studies involving the role of multivitamins in the prevention of cleft lip and/or palate are inconclusive. No decisive benefit (or risk) of multivitamin supplementation has emerged from any of the studies.

The second part of the controversy surrounding multivitamins and the prevention of congenital defects involves their role in preventing NTDs. (Three excellent reviews on the pathophysiology and various other aspects of NTDs, including discussions on the role that multivitamins might play in the cause and prevention of these defects, have been recently published [12–14].) In a series of articles from 1976 to 1983, British investigators examined the effect of multivitamin supplements on a group of women who had previously given birth to one or more children with NTDs (15–19). For the purpose of their study, they defined NTDs to include anencephaly, encephalocele, cranial meningocele, iniencephaly, myelocele, myelomeningocele, and meningocele but excluded isolated hydrocephalus and spina bifida occulta (17). In their initial publication, they found that, in six mothers who had given birth to infants with NTDs, there were lower 1st trimester levels of serum folate, red blood cell folate, white blood cell vitamin C, and riboflavin saturation index (15). The differences between the case mothers and the controls were significant for red blood cell folate ($p < 0.001$) and white blood cell vitamin C ($p < 0.05$). Serum vitamin A levels were comparable with those of controls. Based on this experience, a multicenter study was launched to compare mothers receiving full supplements with control patients not receiving supplements (16–19). The supplemented group received a multivitamin–iron–calcium preparation from 28 days before conception to the date of the second missed menstrual period, which is after the time of neural tube closure. The daily vitamin supplement provided:

| | | | |
|------------|---------|-------------------|-----------------|
| Vitamin A | 4000 IU | Nicotinamide | 15 mg |
| Vitamin D | 400 IU | Pyridoxine | 1 mg |
| Vitamin C | 40 mg | Folic acid | 0.36 mg |
| Thiamine | 1.5 mg | Ferrous sulfate | 75.6 mg (as Fe) |
| Riboflavin | 1.5 mg | Calcium phosphate | 480 mg |

Their findings, summarized in 1983, are shown below for the infants and fetuses who were examined (19):

| | |
|----------------------------------|------------------------|
| <i>One Previous NTD</i> | |
| Supplemented | 385 |
| Recurrences | 2* (0.5%) |
| Not supplemented | 458 |
| Recurrences | 19* (4.1%) *p = 0.0004 |
| <i>Two or More Previous NTDs</i> | |
| Supplemented | 44 |
| Recurrences | 1* (2.3%) |
| Not supplemented | 52 |
| Recurrences | 5* (9.6%) *p = 0.145 |
| <i>Total</i> | |
| Supplemented | 429 |
| Recurrences | 3 (0.7%) |
| Not supplemented | 510 |
| Recurrences | 24 (4.7%) |

Although the numbers were suggestive of a protective effect offered by multivitamins, at least three other explanations were offered by the investigators (16):

1. A low-risk group had selected itself for supplementation.
2. The study group aborted more NTD fetuses than did controls.
3. Other factors were responsible for the reduction in NTDs.

A 1980 report found that women receiving well-balanced diets had a lower incidence and recurrence rate of infants with NTDs than did women receiving poor diets (20). Although multivitamin supplements were not studied, it was assumed that those patients who consumed adequate diets also consumed more vitamins from their food compared with those with poor diets. This study, then, added credibility to the thesis that good nutrition can prevent some NTDs. Other researchers, using Smithells' protocol, observed that fully supplemented

mothers (N = 83) had no recurrences, whereas a nonsupplemented group (N = 141) had four recurrences of NTDs (21,22). Interestingly, a short report that appeared 6 years before Smithells' work found that both vitamins and iron were consumed more by mothers who gave birth to infants with anencephalus and spina bifida (23).

The above investigations have generated many discussions, criticisms, and defenses (24–57). The primary criticism centered on the fact that the groups were not randomly assigned but were self-selected for supplementation or no supplementation. A follow-up study, in response to some of these objections, was published in 1986 (58). This study examined six factors that may have influenced the earlier results by increasing the risk of recurrence of NTDs: (a) two or more previous NTDs, (b) residence in Northern Ireland, (c) spontaneous abortions immediately before the studied pregnancy, (d) <12 months between studied pregnancy and abortion, (e) social class, and (f) therapeutic abortion immediately before the studied pregnancy. The relative risk was increased only for the first four factors, and only in those cases with two or more previous NTDs was the increase significant. In addition, none of the four factors would have predicted more than a 4% increase in the recurrence rate in nonsupplemented mothers compared with those supplemented. The results indicated that none of these factors contributed significantly to the differential risk between supplemented and nonsupplemented mothers, thus leading to the conclusion that the difference in recurrence rates was caused by the multivitamin (58).

Several recent studies examining the effect of multivitamins on NTDs have been published. A case–control, population-based study evaluated the association between periconceptual (3 months before and after conception) multivitamin use and the occurrence of NTDs (59). The case group involved either liveborn or stillborn infants with anencephaly or spina bifida born during the years 1968–1980 in the Atlanta area. A total of 347 infants with NTDs were eligible for enrollment and became the case group, whereas 2829 infants without birth defects served as controls. Multivitamin usage and other factors were ascertained by interview 2–16 years after the pregnancies. This long time interval might have induced a recall problem into the study, even though the authors did take steps to minimize any potential bias (59). A protective effect of periconceptual multivitamin usage against having an infant with an NTD was found in comparison with controls with an estimated relative risk for all NTDs of 0.41 (95% confidence interval [CI] 0.26–0.66); anencephaly 0.47 (95% CI 0.25–0.91); and spina bifida 0.37 (95% CI 0.19–0.70). The odds ratios for

whites, but not for other races, were statistically significant. Except for anencephaly among whites (odds ratio [OR] 0.68, 95% CI 0.35–1.34), similar results were obtained when infants with congenital defects other than NTDs were used as controls. Although the results indicated that periconceptional use of multivitamins did protect against NTDs, the authors could not determine whether the effect was related to vitamins or to some unknown characteristic of vitamin users (59). In commenting on this study, one investigator speculated that if the lack of a statistical effect observed in black women was confirmed, it may be related to a different genetic makeup of the population (60). In other words, the gene(s) that cause NTDs are responsive to periconceptional multivitamins only in whites (60).

Three brief letter communications examined the effects of gastric or intestinal bypass surgery, performed for obesity, on the incidence of NTDs (61–63). The first report appeared in 1986 and described three births with NTDs occurring in Maine (61). During the interval 1980–1984, 261 gastric bypass procedures were performed in Maine, but only 133 were in women under the age of 35. One woman delivered an anencephalic fetus 2 years after her surgery. A second suffered a spontaneous abortion at 16 weeks' gestation, 6 years after a gastrojejunostomy. Her serum α -fetoprotein level 10 days before the abortion was 4.8 times the median. She became pregnant again 2 years later and eventually delivered a stillborn infant in the 3rd trimester. The infant had a midthoracic meningomyelocele, iniencephaly, absence of diaphragms, and hypoplastic lungs. During this latter pregnancy, she had intermittent heavy alcohol intake. In the third case, a woman, whose surgery had been done 7 years earlier, had an anencephalic fetus associated with a lumbar rachischisis diagnosed at 6 months' gestation. In response to this report, investigators in Denmark and Sweden could find no cases of NTDs in 77 infants born after their mothers had bypass operations for obesity (62). However, the procedures in these cases involved intestinal bypass, not gastric. Low birth weight and growth restriction were increased in 64 liveborn infants. Gastric bypass surgery is known to place recipients at risk for nutritional deficiencies, especially for iron, calcium, vitamin B₁₂, and folate (61,63). In the third report, of a total of 908 women who underwent the procedure, 511 (56%) responded to a questionnaire (63). Of these, 87 (17%) had been pregnant at least once after the surgery. The 87 women had 73 pregnancies (more than 20 weeks' gestation) before the operation with no cases of NTDs. After the surgery, these women had 110 pregnancies with two cases of NTDs. This represented a 12 times increase in the risk for NTDs compared with the general population (incidence 0.15%) (63).

A third case of an infant with an NTD born from a mother who had undergone the operation was identified later, but the mother was not part of the original group. In each of the three cases, the birth of the infant with an NTD had occurred >4 years after the bypass surgery. Moreover, the three mothers had not consumed vitamin supplements as prescribed by their physicians. Because of these findings, the authors recommended pregnancy counseling for any woman who has undergone this procedure and who then desires to become pregnant (63).

In another brief reference, the final results of a British clinical trial were presented in 1989 (64). Women who resided in the Yorkshire region were enrolled in the study if (a) they had one or more previous NTD infants, (b) they were not pregnant at the time of enrollment, and (c) they were considering another pregnancy. Mothers were requested to take the vitamin formulation described above for at least 4 weeks before conception and until they had missed two menstrual periods (i.e., same as previously). The results of the study included three reporting intervals: 1977–1980, 1981–1984, and 1985–1987. The 148 fully supplemented mothers (those who took vitamins as prescribed or missed taking vitamins on only 1 day) had 150 infants or fetuses, only 1 (0.7%) of whom had an NTD. In contrast, 315 nonsupplemented mothers had 320 infants or fetuses among which there were 18 (5.6%) cases of NTDs. The difference between the groups was significant ($p = 0.006$). In addition, 37 partially supplemented (defined as mothers who took the prescribed vitamin for a shorter period of time than the fully supplemented group) women had 37 pregnancies with no cases of NTDs. The investigators concluded that the difference between the groups could not be attributed to declining NTD recurrence rates or to selection bias. Summarizing these and previously published results, only 1 NTD recurrence had been observed in 315 infants or fetuses born to 274 fully supplemented mothers, and no recurrences had been observed among 57 examined infants or fetuses born to 58 partially supplemented women (64).

A 1989 study conducted in California and Illinois examined three groups of patients to determine whether multivitamins had a protective effect against NTDs (65). The groups were composed of women who had a conceptus with an NTD ($N = 571$) and two control groups: those who had a stillbirth or other defect ($N = 546$), and women who had delivered a normal child ($N = 573$). In this study, NTDs included anencephaly, meningocele, myelomeningocele, encephalocele, rachischisis, iniencephaly, and lipomeningocele. The periconceptual use of multivitamins, both in terms of vitamin supplements only

and when combined with fortified cereals, was then evaluated for each of the groups. The outcome of this study, after appropriate adjustment for potential confounding factors, revealed an OR of 0.95 (95% CI 0.78–1.14) for NTD-supplemented mothers (i.e., those who received the RDA of vitamins or more) compared with nonsupplemented mothers of abnormal infants, and an OR of 1.00 (95% CI 0.83–1.20) when the NTD group was compared with unsupplemented mothers of normal infants. Only slight differences from these values occurred when the data were evaluated by considering vitamin supplements only (no fortified cereals) or vitamin supplements of any amount (i.e., less than the RDA). Similarly, examination of the data for an effect of folate supplementation on the occurrence of NTDs did not change the results. Thus, this study could not show that the use of either multivitamin or folate supplements reduced the frequency of NTDs. However, the investigators cautioned that their results could not exclude the possibility that vitamins might be of benefit in a high-risk population. Several reasons were proposed by the authors to explain why their results differed from those obtained in the Atlanta study cited above: (a) recall bias, (b) a declining incidence of NTDs, (c) geographic differences such that a subset of vitamin-preventable NTDs was in the Atlanta region but not in the areas of the current study, and (d) the Atlanta study did not consider the vitamins contained in fortified cereals (65). However, others concluded that this study led to a null result because: (a) the vitamin consumption history was obtained after delivery, (b) the history was obtained after the defect was identified, or (c) the study excluded those women taking vitamins after they knew they were pregnant (66).

In contrast to the above report, a Boston study published in 1989 found a significant effect of folic acid–containing multivitamins on the occurrence of NTDs (66). The study population was comprised of 22,715 women for whom complete information on vitamin consumption and pregnancy outcomes was available. Women were interviewed at the time of a maternal serum α -fetoprotein screen or an amniocentesis. Thus, in most cases, the interview was conducted before the results of the tests were known to either the patient or the interviewer. A total of 49 women had an NTD outcome (2.2/1000). Among these, 3 cases occurred in 107 women with a history of previous NTDs (28.0/1000), and 2 in 489 women with a family history of NTDs in someone other than an offspring (4.1/1000). After excluding the 87 women whose family history of NTDs was unknown, the incidence of NTDs in the remaining women was 44 cases in 22,093 (2.0/1000). Among the 3157 women who did not use a folic acid–containing multivitamin, 11 cases of NTD occurred, a prevalence of

3.5/1000. For those using the preparation during the first 6 weeks of pregnancy, 10 cases occurred from a total of 10,713 women (prevalence 0.9/1000). The prevalence ratio estimate for these two groups was 0.27 (95% CI 0.12–0.59). For mothers who used vitamins during the first 6 weeks that did not contain folic acid, the prevalence was 3 cases in 926, a ratio of 3.2. The ratio, when compared with that of nonusers, was 0.93 (95% CI 0.26–3.3). When vitamin use was started in the 7th week of gestation, there were 25 cases of NTD from 7795 mothers using the folic acid–multivitamin supplements (prevalence 3.2/1000; prevalence ratio 0.92) and no cases in the 66 women who started consuming multivitamins without folate. This study, then, observed a markedly reduced risk of NTDs when folic acid–containing multivitamin preparations were consumed in the first 6 weeks of gestation.

An investigation into a third class of anomalies, limb reduction defects, was opened by a report that multivitamins may have caused this malformation in an otherwise healthy boy (52). The mother was taking the preparation because of a previous birth of a child with an NTD. A retrospective analysis of Finnish records, however, failed to show any association between 1st trimester use of multivitamins and limb reduction defects (67).

BREASTFEEDING SUMMARY

Vitamins are naturally present in breast milk (see individual vitamins). The recommended dietary allowance of vitamins and minerals during lactation (first 6 months) are as follows (1):

| | | | |
|------------------------------|---------|-------------------------|---------|
| Vitamin A | 1300 RE | Vitamin B ₁₂ | 2.6 mcg |
| Vitamin D | 400 IU | Calcium | 1200 mg |
| Vitamin E | 12 mg | Phosphorus | 1200 mg |
| Vitamin C | 95 mg | Iodine | 200 mcg |
| Folic acid | 280 mcg | Iron | 15 mg |
| Thiamine (B ₁) | 1.6 mg | Magnesium | 355 mg |
| Riboflavin (B ₂) | 1.8 mg | Zinc | 19 mg |
| Niacin (B ₃) | 20 mg | Selenium | 75 mcg |
| Pyridoxine (B ₆) | 2.1 mg | | |

VORICONAZOLE

Antifungal

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of voriconazole in human pregnancy have been located. The animal data are suggestive for a risk of toxicity and teratogenicity. However, inhibition of estrogen synthesis was observed in rats. This effect also has been noted in rats treated with another triazole agent, fluconazole. In those studies, the anti-estrogen action was thought to be responsible for the observed cleft palate and bone abnormalities (see Fluconazole). Whether this mechanism also applies to voriconazole is unknown. Nevertheless, based only on the animal data, one review concluded that voriconazole should be avoided in pregnancy (1). Although there are currently no human data, the close relationship with fluconazole, a suspected teratogen in high doses, is reason enough to avoid voriconazole in the 1st trimester. If advertent exposure has occurred, the patient should be advised of the potential but unknown risk to the embryo.

FETAL RISK SUMMARY

The antifungal drug voriconazole is indicated for the treatment of various systemic fungal infections (2). It is a triazole antifungal in the same class as fluconazole, itraconazole, posaconazole, and terconazole.

Reproduction studies have been conducted in rats and rabbits. In pregnant rats, a dose 0.3 times the recommended human maintenance dose or higher based on BSA (RHMD) was teratogenic (cleft palates, hydronephrosis, and hydroureter). Toxic effects observed at this dose were reduced ossification of sacral and caudal vertebrae, skull, and pubic and hyoid bones, super numerary ribs, anomalies of the sternbrae, and dilatation of the ureter/renal pelvis. Treatment later in gestation resulted in increased gestational length and

dystocia with a subsequent increase in perinatal pup mortality. Plasma estradiol in pregnant rats was reduced at all dose levels. In pregnant rabbits, toxic effects, noted at 6 times the RHMD, consisted of increased embryo mortality, reduced fetal weight, and increased incidences of skeletal variations, cervical ribs, and extra sternbrae ossification sites (2).

In 2-year studies, hepatocellular adenomas were observed in female rats at an oral dose 1.6 times the RHMD, and hepatocellular carcinomas were seen in male rats at oral doses 0.2 and 1.6 times the RHMD. In mice, hepatocellular adenomas were observed in male and female mice and hepatocellular carcinomas in male mice at oral doses that were 1.4 times the RHMD. Voriconazole was clastogenic in an in vitro assay with human lymphocytes, but was not genotoxic in four other assays (2).

It is not known if voriconazole crosses the placenta to the fetus. The molecular weight (about 349) is low enough that exposure of the embryo and/or fetus should be expected.

BREASTFEEDING SUMMARY

No reports describing the use of voriconazole during lactation have been located. The molecular weight (about 349) suggests that the agent will be excreted into breast milk. There is potential for toxicity in nursing infants, especially during the neonatal period when hepatic function is immature. Therefore, women taking this drug should not breastfeed.

VORINOSTAT

Antineoplastic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of vorinostat in human pregnancy have been located. The animal reproductive data suggest risk, but the absence of human pregnancy experience prevents a more complete assessment of embryo–fetal risk. However, the drug probably crosses the placenta and exposure of the embryo and/or fetus should be expected. In addition, although there are no other agents in this antineoplastic subclass, there are other histone deacetylase inhibitors (e.g., valproic acid [1]). If a pregnant woman requires vorinostat, avoiding the 1st trimester and obtaining informed consent are recommended. In case of an inadvertent pregnancy, the woman should be advised of the potential risk for severe adverse effects in the embryo and fetus.

FETAL RISK SUMMARY

Vorinostat is an oral histone deacetylase inhibitor that is indicated for the treatment of cutaneous manifestations in patients with cutaneous T-cell lymphoma who have progressive, persistent, or recurrent disease on or following two systemic therapies. It is given as a daily oral dose. Vorinostat is in the same antineoplastic subclass as romidepsin. The drug is extensively metabolized to two inactive metabolites. Plasma protein binding (71%) is moderate. The mean terminal elimination half-life of vorinostat and one metabolite is about 2 hours, but the half-life of the other inactive metabolite is about 11 hours (1).

Reproductive studies have been conducted in rats and rabbits. The highest dose tested in rats, exposures about half the human exposure based on AUC (HE), caused developmental toxicity consisting of decreased mean live fetal weights; incomplete ossifications of the fetal skull, thoracic vertebra, and

sternebrae; and skeletal variations (cervical ribs, supernumerary ribs, vertebral count, and sacral arch variations). The highest dose tested in rabbits, also about half the HE, was associated with reductions in mean live fetal weight and an increased incidence of incomplete ossification of the metacarpals. The no-observed-effect level in rats and rabbits was <0.1 times the HE. However, a dose-related increase in the incidence of gall bladder malformations was observed in rabbits (1,2).

Studies for carcinogenicity have not been conducted with vorinostat, but the drug was mutagenic and clastogenic in tests. No effects on reproductive performance were noted in male rats given doses resulting in exposures up to about 0.70 times the HE for 70 days before mating. Female rats were given doses resulting in exposures up to about 0.70 times the HE for 14 days before mating and through day 7 of gestation. Dose-related increases in corpora lutea, peri-implantation losses, and incidences of dead fetuses and in resorptions were observed at exposures that were ≥ 0.15 , ≥ 0.36 , and 0.70 times the HE, respectively (1).

It is not known if vorinostat crosses the human placenta. The molecular weight (about 264) and moderate plasma protein binding suggest that the drug will cross the human placenta, but the short elimination half-life should decrease the exposure.

BREASTFEEDING SUMMARY

No reports describing the use of vorinostat during human lactation have been located. The molecular weight (about 264) and moderate plasma protein binding (about 71%) suggest that the drug will be excreted into breast milk. However, the short elimination half-life (about 2 hours) should decrease the amount excreted. The potential effects on a nursing infant are unknown, but toxicity is possible. In adults, the most common adverse effects were gastrointestinal (diarrhea, nausea/vomiting, anorexia, weight decrease, constipation), fatigue, chills, hematologic (thrombocytopenia, anemia), and taste disorders (dysgeusia, dry mouth) (1).

Y

YOHIMBINE

Herb/Sympatholytic/Impotence Agent

PREGNANCY RECOMMENDATION: No Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of yohimbine or yohimbe in human pregnancy have been located. The one animal reproduction study located was not relevant for the reasons cited. Yohimbe is available over the counter as a herbal supplement and has been used as an aphrodisiac and for weight loss and sexual dysfunction. Although it has no FDA-sanctioned indications, yohimbine is available by prescription for male erectile dysfunction. It has also been used for treatment of orthostatic hypotension.

FETAL RISK SUMMARY

Yohimbine is an extract of the bark of the *Pausinystalia yohimbe* tree and chemically related to reserpine. The term “yohimbe” refers to the bark extract, which is available in many health stores as a supplement, while “yohimbine” refers to the pharmaceutical pure extract. Both yohimbine and yohimbe are administered orally. Yohimbine is available only by prescription. Yohimbine and yohimbe have been used as aphrodisiacs, for weight loss, and for sexual dysfunction. The primary off-label indication for yohimbine is sexual dysfunction, particularly for the treatment of male erectile dysfunction. This action may be secondary to its blockage of α_2 -adrenergic receptors. A second off-label indication is for orthostatic hypotension. Yohimbine is metabolized to apparently inactive metabolites. Plasma protein binding is 82% and the elimination half-life

is about 36 minutes (1,2).

In a reproduction study with rats, a single IM injection (20 mg/kg) of yohimbine on day 5 of gestation did not alter the course of pregnancy or affect litter size (3). However, the dose was given before the period of organogenesis (days 9–17 in rats) and thus missed the period of greatest vulnerability for structural anomalies. Moreover, the dose was not compared with the human dose based on BSA or AUC, so the results are not interpretable for estimating human risk.

No studies on the carcinogenicity, mutagenicity, or effects on fertility of yohimbine have been located. In male Swiss albino mice, oral doses of yohimbe for 90 days resulted in significant increases in sperm abnormalities and the weight of seminal vesicles, and a decrease in sperm motility and count. A nonsignificant decrease in pre- and postimplants also was observed (4).

It is not known if yohimbine crosses the human placenta. The molecular weight (about 355) suggests that exposure of the embryo–fetus will occur. However, the very short elimination half-life should limit the amount crossing the placenta.

BREASTFEEDING SUMMARY

No reports describing the use of yohimbine or yohimbe during human lactation have been located. In rats, the sympatholytic (blockage of presynaptic α_2 -adrenergic receptors) action of the herb was shown to increase prolactin levels (5). This effect has not been studied in humans. Nevertheless, the relatively low molecular weight (about 355) suggests that the herb will be excreted into breast milk. Moreover, both formulations of the herb are basic and accumulation in breast milk may occur. The effect of this exposure on a nursing infant is unknown.

Z

ZAFIRLUKAST

Respiratory Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Zafirlukast is not teratogenic in animals, and the few adverse outcomes in humans do not demonstrate a pattern that suggests a common cause. However, the human data are limited. One source stated that zafirlukast may be safe to use during pregnancy, but this conclusion was based solely on animal studies (1). A 2000 position statement of the American College of Obstetricians and Gynecologists (ACOG) and the American College of Allergy, Asthma and Immunology (ACAAI) recommended that zafirlukast could be considered in patients with recalcitrant asthma who had shown a uniquely favorable response to the drug prior to becoming pregnant (2).

FETAL RISK SUMMARY

Zafirlukast is an oral selective peptide leukotriene receptor antagonist that is indicated for the prophylaxis and chronic treatment of asthma. It is extensively metabolized to inactive compounds that are primarily eliminated in the feces. Plasma protein binding is >99%. The mean terminal half-life is about 10 hours, but other studies have reported the plasma half-lives in the 8- to 16-hour range (3).

Reproduction studies conducted in mice and rats with oral doses ≤ 160 and 410 times the maximum recommended human dose based on BSA (MRHD-BSA), respectively, and in monkeys with doses resulting in exposures up to about 20 times the MRHD based on AUC of the drug plus metabolites (MRHD-

AUC), did not observe any evidence of teratogenicity. The maximum doses in rats and monkeys were maternally toxic, resulting in maternal deaths in some cases (rats), fetal resorptions (rats), and spontaneous abortions (SABs) (monkeys) (3).

Zafirlukast was carcinogenic (hepatocellular adenomas) in male mice at a dose about 30 times the MRHD-BSA. Female mice at this dose had a greater incidence of whole-body histocytic sarcomas. Male and female rats at an exposure about 160 times the MRHD-AUC had an increased incidence of urinary bladder transitional cell papillomas. The no-effect doses in mice and rats were 10 times the MRHD-BSA and 140 times the MRHD-AUC, respectively. Assays for mutagenic and clastogenic effects were negative. In addition, no evidence of impaired fertility or reproduction was observed in male and female rats with doses up to about 410 times the MRHD-BSA (3).

It is not known if zafirlukast crosses the human placenta. The molecular weight (about 576) and long elimination half-life suggest that passage to the embryo and fetus should be expected. However, the extensive metabolism and protein binding should limit the exposure.

A 2007 report described the pregnancy outcomes of 96 women exposed to leukotriene receptor antagonists (montelukast and zafirlukast) (4). The women were enrolled in the Organization of Teratology Information Specialists (OTIS) Asthma Medications in Pregnancy study. Two comparison groups were formed consisting of 122 pregnant women who exclusively took short-acting β_2 -sympathomimetics or 346 pregnant women without asthma (control group). Among the 96 subjects, 72 took montelukast, 22 took zafirlukast, and 2 took both drugs. Most subjects (89.6%) were exposed in the 1st trimester and 50% were exposed throughout gestation. There were no differences among the three groups in terms of preterm delivery, Apgar scores at 1 and 5 minutes, birth weight and height ≤ 10 th percentile, or ponderal index < 2.2 . The adjusted mean birth weight in subject infants was significantly lower than that in infants from controls without asthma (3384 vs. 3529 g) ($p < 0.05$). There were no significant differences in pregnancy loss (SABs, ectopic pregnancies, and stillbirths), gestational diabetes, preeclampsia, and maternal weight gain. There were significantly ($p < 0.05$) more birth defects in subjects (5.95%) compared with the control group (0.3%), but the prevalence in the control group was abnormally low. There was no significant difference in the prevalence of defects between subjects and those treated with β_2 -agonists (3.9%). No birth defects were reported in stillbirths, SABs, or elective abortions. Birth defects in liveborn infants of subjects (specific exposure not given) were Sturge–Weber sequence,

congenital hip dislocation, bilateral club foot, neurofibromatosis type 1 (an autosomal-dominant inheritance pattern); and imperforate anus. The causes of the other four defects are either unknown or multifactorial, but no specific pattern of defects is evident (4).

BREASTFEEDING SUMMARY

The manufacturer reports that zafirlukast is excreted into breast milk (3). In healthy women taking 40 mg orally twice daily, the average steady-state concentration of zafirlukast in milk was 50 ng/mL compared with 255 ng/mL in the plasma (milk:plasma ratio 0.2). The effects in a nursing infant from exposure to the drug in milk are unknown. The manufacturer recommends against breastfeeding because of the potential for tumorigenicity noted in mice and rats, as well as the enhanced sensitivity to the adverse effects of the drug in neonatal rats and dogs (3).

ZALCITABINE

[Withdrawn from the market. See 9th edition.]

ZALEPLON

Hypnotic

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of zaleplon in human pregnancy have been located. The agent does compare favorably to other hypnotic benzodiazepine receptor agonists due to its rapid onset (15 minutes), short elimination half-life, and the absence of active metabolites (1). The drug is not an animal teratogen and the risk of human teratogenicity is probably low. However, information from studies in one of the animal species suggests that long-term use could potentially result in human embryo–fetal toxicity. Therefore, the use of zaleplon in pregnancy should be restricted to occasional, short-term treatment (e.g., 7–10 days).

FETAL RISK SUMMARY

The oral hypnotic, zaleplon, is chemically unrelated to benzodiazepines, barbiturates, and other known hypnotic agents, but it is a benzodiazepine receptor agonist. It is indicated for the short-term (e.g., 7–10 days) treatment of insomnia. Zaleplon undergoes substantial presystemic metabolism that significantly reduces its absolute bioavailability. Nearly all of zaleplon is metabolized to inactive metabolites. Plasma protein binding is moderate (about 60%) and the terminal-phase elimination half-life is short (about 1 hour). Zaleplon has an abuse potential similar to benzodiazepines and benzodiazepine-like hypnotics (2).

Reproduction studies have been conducted in rats and rabbits. No evidence of teratogenicity was observed in rats treated throughout organogenesis with doses up to about 49 times the maximum recommended human dose of 20 mg based on BSA (MRHD). At the maximum dose, pre- and postnatal growth was decreased in rat offspring, but this dose was also maternally toxic (clinical signs and reduced body weight). Fertility and reproductive performance in female

rats was also impaired at the maximum dose. The no-effect dose during organogenesis for reduced growth in offspring was 5 times the MRHD. However, treatment of pregnant rats in late gestation and during lactation, with a dose that did not cause maternal toxicity (about 3.4 times the MRHD or greater), did result in an increased incidence of stillbirth and postnatal death, as well as decreased growth and physical development. The toxicity was thought to have resulted from both in utero and lactational exposure to the drug. For exposure in late gestation and during lactation, the no-effect dose was about half the MRHD. In rabbits, no evidence of teratogenicity or embryo/fetal toxicity was observed at doses up to 48 times the MRHD given throughout organogenesis (2).

It is not known if zaleplon crosses the human placenta. The molecular weight (about 305) is low enough, but the short elimination half-life will limit the amount of drug available at the maternal:fetal interface.

In a study published in 2011, data from the Swedish Medical Birth Registry, covering the period 1995–2007, identified 1318 women who gave birth to 1341 infants and who reported the use of a hypnotic benzodiazepine receptor agonist at the first prenatal visit (3). The three most commonly reported agents and the number of exposed infants were zopiclone (N = 692) (not available in USA), zolpidem (N = 603), and zaleplon (N = 32). The reference group during the study period was 1,106,001 women who gave birth to 1,125,734 infants. The rate of congenital malformations was similar in the exposed and nonexposed groups, 4.3% (N = 58) and 4.7% (N = 52,773), adjusted odds ratio (aOR) 0.89, 95% confidence interval (CI) 0.68–1.16. One mother who had two infants with probably unrelated malformations (cleft lip and hypospadias) had used zopiclone in both pregnancies. For relatively severe defects, there were 42 exposed infants (3.1%) compared with 36,321 nonexposed infants (3.2%), aOR 0.95, 95% CI 0.0.69–1.30. The authors concluded that use of these agents did not appear to increase the risk of malformations (3).

BREASTFEEDING SUMMARY

Small amounts of zaleplon are excreted into breast milk (2,4). In a study by the manufacturer, the peak drug concentrations in milk occurred about 1 hour after a 10-mg dose. The mean plasma elimination half-life in five lactating women (mean weight 65.1 kg) was about 1 hour, similar to nonlactating women (2,4). The average milk:plasma ratio was 0.5 (4). The investigators estimated the maximum infant exposure during a feeding at peak milk concentrations to be in the range of 1.28–1.66 mcg (4). As the women did not breastfeed during the

study, the effects of this exposure on a nursing infant are unknown. For a 65.1-kg woman nursing a 4-kg infant, the maximum estimated infant dose, as a percentage of the mother's dose, is 0.27%. It is doubtful if this amount from a 10-mg dose would have a clinically significant effect on a nursing infant. In addition, within 5 hours of a dose, about 97% of the drug will be eliminated from the maternal plasma and milk.

ZANAMIVIR

Antiviral

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit
>>Embryo/Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Reports describing the use of zanamivir during five human pregnancies have been located. Although the animal data suggest low risk, the near absence of human pregnancy experience prevents an assessment of the risk to the embryo–fetus. Nevertheless, if the drug is indicated in a pregnant woman, the maternal benefit outweighs the unknown embryo–fetal risk.

FETAL RISK SUMMARY

Zanamivir is formulated as a powder to be administered by oral inhalation. The agent is thought to act by inhibiting influenza virus neuraminidase with the possibility of alteration of virus particle aggregation and release. Zanamivir is indicated for the treatment of uncomplicated acute illness due to influenza A and B virus in patients who have been symptomatic for no more than 2 days. It is also indicated for prophylaxis of influenza in patients aged 5 years and older. The systemic bioavailability of the drug is approximately 4%–17%, plasma protein binding is <10%, and it is excreted unchanged (no metabolites have been detected) in the urine with a serum elimination half-life of 2.5–5.1 hours (1). In April, 2009, the FDA issued an Emergency Use Authorization to allow zanamivir to be used to treat and prevent influenza in children under 1 year of age, and to provide alternate dosing recommendations for children older than 1 year (2).

Reproduction studies with IV or SC zanamivir have been conducted in rats and rabbits. In pregnant rats, the highest IV daily doses administered produced exposures that were >300 times the human exposure from the clinical dose based on AUC (HE). Drug administration, during gestational days 6–15 or

during gestational day 16 until litter day 21–23, revealed no evidence of malformations, embryotoxicity, or maternal toxicity. In a different strain of rats administered SC zanamivir 3 times daily during gestational days 7–17, the highest SC dose produced exposures that were >1000 times the HE. In this study, minor skeletal alterations and variations were observed in the exposed offspring, but the incidence of these effects was within the background rates for the strain studied. In pregnant rabbits, IV doses (identical to the rat doses, but relationship to human dose not specified) administered during gestational days 7–19 revealed no evidence of malformations, embryotoxicity, or maternal toxicity (1).

Zanamivir was not carcinogenic in 2-year studies in mice and rats, was not mutagenic in multiple assays, and did not impair fertility or mating in male and female rats (1).

It is not known if zanamivir crosses the human placenta. The molecular weight (about 332), combined with the lack of metabolism and plasma protein binding, and the moderately long elimination half-life, suggest that the drug will cross to the embryo–fetus. However, the low systemic bioavailability after oral inhalation should limit the amount of drug available for crossing at the maternal:fetal interface.

A 1999 review on the safety of zanamivir briefly described three pregnancies inadvertently exposed during clinical trials (3). The pregnancy outcomes were one spontaneous abortion, one elective abortion, and one healthy baby born 2 weeks early. These results were similar to four pregnancies exposed to placebo in the same clinical trials. A 2009 review concluded that unvaccinated women who come in contact with the H1N1 virus should receive prophylactic antiviral therapy and, although the pregnancy data are limited, it was reassuring (4). Another 2009 review mentioned a woman in Japan who had taken zanamivir at 4 weeks' gestation and gave birth to a healthy baby at term (no other details provided) (5).

A 2010 case report from Thailand described the fatal outcome of a pregnancy treated with nebulized zanamivir (6). The 25-year-old woman at 26 weeks' gestation presented with influenza A (H1N1) pneumonia. Treatment with oral oseltamivir, nebulized zanamivir, and IV dexamethasone was started. The patient was ventilated but the ventilator constantly malfunctioned, eventually leading to the patient's death. The problem was traced to filter blockade caused by the lactose in the double doses of zanamivir (20 mg) commonly used in Thailand at the time (6).

BREASTFEEDING SUMMARY

No reports describing the use of zanamivir during human lactation have been located, but two 2009 reviews consider the drug to be compatible with breastfeeding (4,5). The molecular weight (about 332), moderately long elimination half-life, and the lack of metabolism and plasma protein binding suggest that the drug will be excreted into breast milk. However, the low systemic bioavailability after oral inhalation should limit the amount of drug excreted into breast milk. The effect, if any, of this exposure on a nursing infant is unknown, but the risk of harm appears to be low.

ZICONOTIDE

Analgesic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of ziconotide in human pregnancy have been located. Ziconotide is indicated for long-term intrathecal (IT) therapy and, as such, any exposure would occur throughout gestation. However, clinically significant amounts do not appear to reach the plasma during continuous IT infusions. The small amounts that are in the systemic circulation are metabolized in organ tissues to peptide fragments and free amino acids. Moreover, animal reproduction studies in two species suggest that the risk to the human embryo or fetus is low. Although the absence of human pregnancy experience prevents a more complete assessment, the risk to the embryo–fetus appears to be low. If a woman requires IT therapy with ziconotide, the benefit to her appears to far outweigh the unknown risk to her developing baby.

FETAL RISK SUMMARY

Ziconotide, a 25-amino-acid polypeptide, is a synthetic equivalent of a naturally occurring conopeptide found in the piscivorous marine snail, *Conus magus*. The hydrophilic peptide is given as an IT infusion for the management of severe chronic pain in patients for whom IT therapy is warranted, and who are intolerant of or refractory to other treatment, such as systemic analgesics, adjunctive therapy, or IT morphine (1). The terminal half-life in the cerebrospinal fluid (CSF) is about 4.5 hours (range 2.9–6.5 hours). About 50% of ziconotide is bound to plasma proteins, but metabolism to peptide fragments and individual free amino acids occurs in organs, such as the kidney, liver, lung, and muscle, not in the CSF or blood. The biologic activity of the metabolic products has not been determined. Although ziconotide should not be given IV, minimal amounts

of the drug (<1%) were recovered from the urine after an IV infusion (1).

During constant IT infusions at rates ranging from 0.1 to 7 mcg/hr, plasma concentrations were below the level of detection (0.04 ng/mL) in slightly more than half of the patients. More patients had detectable plasma concentrations when higher doses were used (1).

Reproduction studies have been conducted in rats and rabbits. Ziconotide caused embryo death in pregnant rats given continuous IV infusions about 700 times higher than the expected plasma exposure resulting from the maximum recommended human daily IT dose of 0.8 mcg/hr (19.2 mcg/day) (MRHD). No structural defects were observed in rats and rabbits given continuous IV infusions during organogenesis that were up to about 26,000 and 940 times higher, respectively, than the expected plasma exposure resulting from the MRHD. Maternal toxicity (decreased body weight gain and food consumption) was observed at all dose levels. In rats, maternal toxicity, at doses about ≥ 8900 times higher than the expected plasma exposure resulting from the MRHD, resulted in reduced fetal weight and delayed ossification of the pubic bones. The no-observed-adverse-effect level (NOAEL) for embryo–fetal development in rats and rabbits was about 400 and 940 times higher, respectively, than the expected plasma exposure from the MRHD.

In prenatal and postnatal studies in rats, continuous IV infusions up to about 3800 times higher than the expected plasma exposure resulting from the MRHD had no effect on pup development or reproductive performance. Maternal toxicity, as noted above, was observed at all dose levels.

It is not known if ziconotide crosses the human placenta. The molecular weight (2639) and the very low plasma concentrations suggest that little, if any, drug will reach the embryo or fetus.

BREASTFEEDING SUMMARY

No reports describing the use of ziconotide during human lactation have been located. Ziconotide is a 25-amino-acid polypeptide with a molecular weight of 2639. Although excretion into milk is possible, only small, probably clinically insignificant amounts of ziconotide appear in the plasma during IT infusions. It is not known if the drug would be detectable in breast milk. The risk to a nursing infant appears to be negligible.

ZIDOVUDINE

Antiviral

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo/Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Zidovudine (AZT) is effective for the reduction of maternal–fetal transmission of HIV type 1 (HIV-1) infection with few, if any, adverse effects in the newborns. However, neonatal anemia, a known toxic effect of AZT, may occur and requires monitoring. Although yet unproven, AZT may be effective in reducing the transmission of HIV-1 from semen, thereby lessening the chance of infection in a woman who, when pregnant, could transmit the virus to her offspring. The drug is not teratogenic in animals, except at very high doses, and the experience in humans shows no pattern of birth defects. Experimental evidence, however, indicates that AZT is toxic to rodent embryos, preventing blastocyst development when administered before implantation. In addition, evidence has also been published that AZT may affect human trophoblast cell growth and function in a dose-related manner. This cytotoxicity may have resulted in the reduced fertility observed in nonhuman primates. Thus, impaired human fertility is a concern if AZT is administered in high therapeutic doses during early pregnancy. Additionally, there are unanswered questions relating to the potential for long-term toxicity, such as mutagenesis, carcinogenesis, liver disease, heart disease, and reproductive system effects. One study cited, however, found no cancer in AZT-exposed children, some of whom were followed up to 6 years of age. Mitochondrial dysfunction in offspring exposed in utero to AZT and other nucleoside reverse transcriptase inhibitors (NRTIs) has been reported. Moreover, evidence of dose-dependent mitochondrial dysfunction was demonstrated in monkey fetuses whose mothers were given a human-equivalent AZT dose. However, a recent study did not find cardiac toxicity in a small sample of children exposed to AZT during the perinatal period. The incidence and clinical significance of mitochondrial dysfunction after in utero exposure to AZT is

therefore still unknown and requires further study. If indicated, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

The thymidine analog zidovudine is an NRTI that is used for the treatment of HIV infection. Other drugs in this class are abacavir, didanosine, lamivudine, stavudine, and zalcitabine.

AZT was not teratogenic in pregnant rats or rabbits at oral doses up to 500 mg/kg/day (1). These doses resulted in peak plasma concentrations in rats 66–226 times, and in rabbits 12–87 times, the mean steady-state peak human plasma levels obtained with the recommended human dose (100 mg every 4 hours). At 150 or 450 mg/kg/day (rats) and 500 mg/kg/day (rabbits), embryo/fetal toxicity was observed as evidenced by an increased incidence of fetal resorptions (1). At a dose of 3000 mg/kg/day in rats (near the median lethal dose), marked maternal toxicity and an increased incidence of fetal malformations were observed (1). This dose produced peak plasma concentrations 350 times the peak human plasma levels (1). In an in vitro study, a dose-related reduction in blastocyst formation was noted in fertilized mouse oocytes (1).

A 1991 study in rats compared the in vitro and in vivo toxicity of five antiviral nucleoside analogs in whole-embryo cultures and on the 10th day of gestation (2). Among the agents tested (vidarabine, ganciclovir, zalcitabine, 2'3'-dideoxyadenosine [ddA], and AZT), AZT had the lowest teratogenic potential.

In an investigation conducted by the manufacturer, a split-dose regimen of 300 mg/kg on gestational day 10 in rats had no adverse effect on the mothers or offspring (3). The AZT concentration in the embryos was approximately one-third of that in the mother, 21.1 vs. 62.6 mcg/g, respectively. However, another study administered AZT to pregnant mice from days 1 to 13 of gestation and observed dose-related fetal toxicity (decrease in the number of fetuses and fetal growth) (4). Concomitant treatment with erythropoietin, vitamin E, or interleukin-3 lessened the fetal toxicity. The adverse effects were thought most likely to be caused by a direct toxic effect on fetal cells, although a partial effect of maternal bone marrow depression could not be excluded.

Four studies have confirmed a direct dose-related toxic effect of AZT on preimplantation mouse embryos (5–8). The doses tested ranged from 1 to 20 times the concentrations obtainable with therapeutic human doses. Using an in vitro model, investigators demonstrated that exposure to AZT was highly

correlated with failure to develop to the blastocyst stage (5). Similar developmental arrest, possibly caused by inhibition of DNA synthesis in blastomeres, was observed in a second study of preimplantation mouse embryos exposed in vitro to AZT (6). During the postimplantation portion of this investigation, no adverse fetal effects were observed with doses up to 300 mg/kg/day through all or part of gestation. A third study demonstrated that, when preimplantation mouse embryos were exposed to AZT either in vivo or in vitro, development was unable to proceed beyond the blastocyst stage (7). Exposure at the blastocyst and postblastocyst stages resulted in a lower degree of retarded cell division, indicating that the critical period of toxicity in mouse embryos is between ovulation and implantation. The comparative mouse embryo cytotoxicity of four antiretroviral nucleosides (AZT, didanosine, stavudine, and zalcitabine) was reported in a 1994 study (8). All of the agents showed dose-related inhibition of blastocyst formation, but AZT was the most toxic of the drugs. Cytotoxicity of the other agents was only evident at concentrations equal to the highest obtainable after therapeutic human doses (stavudine) or much higher (didanosine and zalcitabine).

AZT (1.5 mg/kg/dose every 4 hours) was administered via gastric catheter at least 10 days before and throughout gestation to pigtailed macaques (9,10). Mean plasma concentrations (AUC) of the drug were comparable to those obtained in human studies. Twelve pregnancies were brought to term (six AZT, six controls), but significantly more matings (17 vs. 9, $p = 0.007$) were required to achieve pregnancy in the AZT-treated primates. A significant decrease in maternal hemoglobin was observed in the AZT-treated animals, but no differences in the mean hematocrit of the drug-exposed newborns or in fetal growth were found in comparison with controls. Moreover, no adverse effects were discovered in neurologic, perceptual, or motor development during a 9- to 10-month follow-up.

The authors of the above investigation speculated that the retarded macaque fertility might have been related to AZT blockage of progesterone synthesis. However, the following two studies on human trophoblast growth and function indicate that inhibition of cell division before blastocyst formation, as demonstrated in the previously described murine studies (5–8), must also be considered (11,12). Human trophoblasts were isolated from 1st trimester and term pregnancies and maintained in culture (11). Using relatively high drug concentrations (20 $\mu\text{mol/L}$ vs. recommended therapeutic concentrations of 3–5 $\mu\text{mol/L}$) for prolonged periods (2–11 days), no significant effects on trophoblast function, as measured by human chorionic gonadotropin (hCG) secretion,

protein synthesis, and glucose consumption, were observed. In one of the five term placentas, AZT exposure resulted in a significant decrease (20% of the control value) in progesterone secretion, but the secretion rate (17.2 ng/hr/10⁶ cells) was still much higher than the control values of the other placentas (3.26–15.63 ng/hr/10⁶ cells).

A 1999 study investigated the effects of a single 24-hour exposure of AZT or didanosine (ddl) on human trophoblast cells using a human choriocarcinoma cell line that exhibited many characteristics of the early placenta (12). Two drug concentrations (7.6 mM or 0.076 mM) were studied for their effects on trophoblast cell proliferation and hormone production (hCG, estradiol [E₂], and progesterone [P₄]). The higher concentrations of AZT or ddl resulted in significant decreases in cell numbers and growth rate (38% and 51% of control values, respectively), but increased production of hCG, E₂, and P₄. The decrease in trophoblast cell proliferation may have been the mechanism for the increased incidence of rodent embryo loss observed with AZT (12). In contrast, the lower concentrations of AZT and ddl did not cause changes in cell numbers, producing only significant increases in E₂ production. Because of these findings, the researchers concluded that high therapeutic doses of either AZT or ddl during early human gestation were potentially embryotoxic (12).

Adverse effects on neurobehavior development in mice offspring resulting from a combination of AZT and lamivudine were described in a 2001 study (13). Pregnant mice received both drugs from day 10 of gestation to delivery. The effects on somatic and sensorimotor development were minor but more marked in exposed offspring than when either drug was given alone (13). Both development endpoints were delayed with respect to control animals. Further, alterations of social behavior were observed in both sexes of exposed offspring (13).

AZT crosses the placenta to the fetus, both in animals (14–16) and in humans (1,17–27). Placental transfer of the drug is rapid and is by simple diffusion (17–19). Seven pregnant HIV-seropositive women with gestational lengths between 14 and 26 weeks were scheduled for therapeutic abortions (20). The women were given AZT, 200 mg orally every 4 hours for five doses, 1–2.75 hours before pregnancy termination. Fetal blood concentrations of the parent compound and its inactive glucuronide metabolite ranged from 100 to 287 ng/mL and from 346 to 963.5 ng/mL, respectively. In six patients (one woman had blood levels below the level of detection), mean AZT concentrations in the maternal blood, amniotic fluid, and fetal blood were 143, 168, and 205 ng/mL, respectively.

In a 1990 study, the pregnancy of an HIV-seropositive woman was terminated at 13 weeks' gestation (21). She had been taking AZT, 100 mg four times daily, for 6 weeks, with her last dose consumed approximately 4 hours before the abortion. Both AZT and the glucuronide metabolite were found in the amniotic fluid and various fetal tissues. The lower limit of detection for the assay was 0.01 $\mu\text{mol/L}$ (0.01 nmol/g). The concentrations of the parent compound and the metabolite in maternal plasma were 0.35 and 0.90 $\mu\text{mol/L}$, respectively. In comparison, the fetal concentrations of AZT (corresponding levels of the metabolite are shown in parentheses) were amniotic fluid, 0.31 $\mu\text{mol/L}$ (1.16 $\mu\text{mol/L}$); liver, 0.14 nmol/g (0.16 nmol/g); muscle, 0.26 nmol/g (0.50 nmol/g); and CNS, 0.01 nmol/g (0.05 nmol/g). The low levels of AZT in the latter system probably indicate that transplacental passage of the drug, at this dose, may be insufficient to treat HIV infection of the fetal CNS (21). The significance of this result is increased by the finding that neurologic and neuropsychologic morbidity in infants exposed to HIV in utero is high (21,28).

A 1989 report described the treatment of a 30-year-old HIV-seropositive woman who was treated before and throughout gestation with AZT, 1200 mg/day (22). IV AZT, 0.12 mg/kg/hr, was infused 24 hours before labor induction at 39 weeks' gestation. An uncomplicated vaginal delivery occurred, resulting in the birth of a normal male infant weighing 3110 g, with a height and head circumference of 48.5 and 35 cm, respectively. The newborn's renal and hepatic functions were normal, and no other toxicity, such as anemia or macrocytosis, was noted. At birth, concentrations of AZT in the maternal blood, amniotic fluid, and cord blood were 0.28, 3.82, and 0.47 mcg/mL, respectively. AZT concentrations in the infant's blood at 6, 24, 36, and 48 hours were 0.46, 0.51, 0.44, and 0.27 mcg/mL, respectively, indicating that in the first 24 hours elimination of the drug from the newborn was negligible (22). Levels of the inactive metabolite were also determined concurrently; in each sample, the metabolite concentration was higher than that of the parent compound. The infant was doing well and growing normally at 6 months of age.

Two HIV-positive women at 18 and 21 weeks' gestation were treated with AZT (1000 mg/day) for 3 days before elective abortion (23). The final 200-mg dose was consumed 2–3 hours before abortion. Both AZT and its metabolite were found in the two women and in amniotic fluid and fetal blood, with fetal:maternal ratios for AZT of 1.10 and 6.00, respectively, and for the metabolite of 0.84 and 3.75, respectively.

Three experimental in vitro models using perfused human placentas to predict the placental transfer of NRTIs (didanosine, stavudine, zalcitabine, and AZT)

were described in a 1999 publication (29). For each drug, the predicted fetal:maternal plasma drug concentration ratios at steady state with each of the three models were close to those actually observed in pregnant macaques. Based on these results, the authors concluded that their models would accurately predict the mechanism, relative rate, and extent of in vivo human placental transfer of NRTIs (29).

The pharmacokinetics of AZT during human and nonhuman primate pregnancies have been determined in a number of studies (24,26,27,30–33). AZT was administered to seven HIV-positive women beginning at 28–35 weeks' gestation with a 200-mg IV dose on day 1, followed by 200 mg orally 5 times a day from day 2 until labor (24). The mean maternal plasma concentrations of AZT and its inactive glucuronide metabolite at delivery were 0.29 and 0.87 mcg/mL, respectively. Similar amounts were measured in umbilical cord venous blood, with mean concentrations of 0.28 and 1.01 mcg/mL, respectively, suggesting that the fetuses and newborns were unable to metabolize AZT (24). No significant drug-induced adverse effects were observed in the women or their newborns and no congenital malformations were noted. Fetal growth was normal in six and accelerated in one, and the slightly lower than normal hemoglobin values were not considered clinically significant (24).

In pregnant macaques or humans, the pharmacokinetics of AZT were not affected by pregnancy (macaques) (30), nor did AZT affect the transplacental pharmacokinetics of didanosine (macaques) (31), lamivudine (humans) (32), or stavudine (macaques) (33). Two other studies involving four women infected with HIV measured peak AZT maternal serum levels and elimination half-lives that were statistically similar to those of nonpregnant adults (26,27). However, in three women, the AUC during pregnancy was significantly less than after pregnancy (4.5 $\mu\text{mol/L}$ vs. 6.8 $\mu\text{mol/L}$, $p = 0.02$), and the apparent total body clearance was significantly greater (2.5 L/hr/kg vs. 1.7 L/hr/kg, $p = 0.05$) (26). Moreover, the difference in the apparent volume of distribution during and after pregnancy reached near significance (3.9 L/kg vs. 2.6 L/kg, $p = 0.07$) (26).

The effect of AZT on the transplacental passage of HIV is unknown. A 1990 review of AZT in pregnancy focused on the issue of whether the drug prevented HIV passage to the fetus and concluded that available data were insufficient to provide an answer to this question (22). However, a 1993 study observed that, although AZT is transferred to the fetus relatively intact, the approximately 50% retained by the placenta is extensively metabolized, with one of the metabolites being zidovudine triphosphate, the product responsible for the antiviral activity of the parent drug (34). The effect of this may be a reduction in the risk of HIV

transmission to the fetus (34).

Brief descriptions of the treatment and pregnancy outcome of 12 HIV-seropositive women were provided in a 1991 abstract (35). AZT therapy was started before conception in 4 women and between 21 and 34 weeks' (mean 25 weeks) gestation in 8. The mean duration of therapy was 8 weeks (range 1–24 weeks). Three of the women who had conceived while taking AZT underwent therapeutic abortions of grossly normal fetuses between 10 and 12 weeks' gestation. Five women had delivered grossly normal infants with a mean birth weight of 2900 g, and the infants of the remaining four women were undelivered between 24 and 36 weeks. Three other abstracts that appeared in 1992 and 1993 described 46 pregnant women treated with AZT without producing toxic effects or anomalies in their fetuses (36–38).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, two newborns had been exposed to AZT during the 1st trimester (F. Rosa, personal communication, FDA, 1993). No major birth defects were observed.

Data on 45 newborns (2 sets of twins) of 43 pregnant women, enrolled in studies conducted by 17 institutions participating in AIDS Clinical Trial Units and who had been treated with AZT, were described in 1992 (39). AZT dosage ranged from 300 to 1200 mg/day, with 24 of the women taking the drug during at least two trimesters. All the infants were born alive. No congenital abnormalities were observed in 12 infants who had been exposed in utero to AZT during the 1st trimester, although 1 newborn with elevated 17α -hydroxyprogesterone levels had clitoral enlargement. Normal levels of the hormone were measured in this infant at 4 months of age. Two term infants were growth restricted, but 38 other singleton term infants had a mean birth weight of 3287 g. Seven infants had hemoglobin values less than 13.5 g/dL; three of these were delivered prematurely. The authors concluded that the few cases of anemia and growth restriction might have been, at least partially, caused by maternal AZT therapy (39). Another report involving 29 pregnant patients treated with AZT at government-sponsored AIDS clinical trial centers appeared in 1992, but no data on the outcome of these pregnancies were given (40).

The outcomes of 104 pregnancies in which AZT was used were described in a 1994 report (41). Sixteen of the pregnancies terminated during the 1st trimester—eight spontaneous and eight elective abortions. Among the remaining 88 cases, 8 infants had birth defects, 4 after 1st trimester exposure, and 4 after exposure during the 2nd or 3rd trimesters. None of the defects

could be attributed to AZT exposure (41): multiple minor anomalies (low-set ears, retrognathia, hirsutism, triangular face, blue sclera, prominent sacral dimple)*; multiple minor anomalies (type not specified)*; extra digits on both hands, hare lip (central), cleft palate; fetal alcohol syndrome; atrial septal defect (asymptomatic) with pectus excavatum*; microcephaly, chorioretinitis (*Toxoplasma gondii* infection); pectus excavatum*; and albinism with congenital ptosis, growth restriction, and oligohydramnios (* indicates chromosomal analysis normal) (41).

The Antiretroviral Pregnancy Registry reported, for the period January 1989 through July 2009, prospective data (reported before the outcomes were known) involving 4702 live births that had been exposed during the 1st trimester to one or more antiretroviral agents (42). Congenital defects were noted in 134, a prevalence of 2.8% (95% confidence interval [CI] 2.4–3.4). In the 6100 live births with earliest exposure in the 2nd/3rd trimesters, there were 153 infants with defects (2.5%, 95% CI 2.1–2.9). The prevalence rates for the two periods did not differ significantly. There were 288 infants with birth defects among 10,803 live births with exposure anytime during pregnancy (2.7%, 95% CI 2.4–3.0). The prevalence rate did not differ significantly from the rate expected in a nonexposed population. There were 9735 outcomes exposed to AZT (3167 in the 1st trimester and 6568 in the 2nd/3rd trimesters) in combination with other antiretroviral agents. There were 264 birth defects (97 in the 1st trimester and 167 in the 2nd/3rd trimesters). In reviewing the birth defects of prospective and retrospective (pregnancies reported after the outcomes were known) registered cases, the Registry concluded that, except for isolated cases of NTDs with efavirenz exposure in retrospective reports, there was no other pattern of anomalies (isolated or syndromic) (42). (See Lamivudine for required statement.)

The failure of maternal AZT therapy to prevent the transmission of HIV-1 infection to one of the mother's female twins was described in a 1990 report (43). The woman was treated with AZT, 400 mg/day, from 18 weeks' gestation until delivery. A cesarean section was performed at 27 weeks' gestation because of premature labor that was not responsive to tocolytic therapy. Twin A was diagnosed with culture-proven HIV-1 and cytomegalovirus infection. At the time of the report, the child was 9 months old with limited sight, severe failure to thrive, and encephalopathy. An HIV-1 culture in twin B was negative, but analysis for HIV-1 antigens continued to be positive through 20 weeks of age. A number of possible explanations were proposed by the authors concerning the failure of AZT to protect twin A from infection. Included among

these were passage of the virus before the onset of treatment at 18 weeks' gestation, intrauterine transfer of the virus via an amniocentesis performed at 14 weeks' gestation, viral resistance to the drug, low fetal tissue drug levels, maternal noncompliance (doubtful), and acquisition of the virus during birth (43).

A 1992 review on the treatment of HIV-infected pregnant women stated that most obstetric experts offered AZT therapy in cases of AIDS, AIDS-related complex, or when the CD4+ cell counts were below 200 cells/micro-L (44). Although no fetal toxicity secondary to AZT had been reported, the author recommended caution with 1st trimester use of the agent and noted the potential for fetal bone marrow depression and resulting anemia.

A clinical trial, the subject of several reviews and editorials (45–51), conducted from 1991 to 1993 and published in 1994, found that the risk of maternal–infant transmission of HIV disease could be decreased by 67.5% by treatment of pregnant women (who had mildly symptomatic HIV disease) with AZT (52). The randomized, double-blind, placebo-controlled trial enrolled untreated HIV-infected pregnant women, at 14–34 weeks' gestation, which had CD4+ T-lymphocyte counts above 200 cells/mm³ and no clinical indications for antenatal antiretroviral therapy. The maternal AZT treatment regimen consisted of antepartum oral therapy (100 mg orally five times daily) and intrapartum IV dosing (2 mg/kg for 1 hour, then 1 mg/kg/hr until delivery). The newborns were treated with oral AZT (2 mg/kg every 6 hours) for 6 weeks. A total of 477 women were enrolled, 409 of whom delivered 415 liveborn infants during the study period. Among those with known HIV-infection status were 180 infants from the AZT-treated group and 183 placebo-treated controls. The authors of this study used statistical methods to predict the number of infants who would be HIV-infected at 18 months of age, thus allowing a faster analysis of their data. They estimated that the number of HIV-infected children would be 8.3% (95% CI 3.9%–12.8%) in the AZT group and 25.5% (95% CI 18.4%–32.5%) in the placebo group (52). This was a 67.5% (95% CI 40.7%–82.1%) reduction in the risk of HIV transmission ($p = 0.00006$). No differences in growth, prematurity, or the number and patterns of major or minor congenital abnormalities were observed between the two groups. Thirty-three liveborn infants had congenital defects, 17 of 206 (8.3%) in the treatment group and 16 of 209 (7.7%) in the nontreated controls. Cardiac malformations were observed in 10 infants (5 in each group), CNS defects in 5 (3 in the AZT group, 2 in controls), and 9 unspecified defects in each group. The total incidence of congenital malformations is higher than expected in the general population, but this probably reflects the population studied. The only drug-related adverse

effect observed in the newborns was a decrease in hemoglobin concentration in those exposed to AZT in utero. The maximum difference in hemoglobin concentration between the groups, 1 g/dL, occurred at 3 weeks of age, but by 12 weeks of age, the hemoglobin values were similar (52).

Although AZT appeared to be effective in reducing transmission of HIV-1 to the fetus, some infants became infected despite treatment. Possible reasons proposed for these failures included (a) virus transmission before treatment began, (b) ineffective suppression of maternal viral replication, (c) poor maternal compliance with the drug regimen, and (d) virus resistance to AZT (52).

A series of studies and editorials appeared in 1998–2000 that evaluated or discussed the effect of short courses of AZT on the perinatal transmission of HIV in various populations (53–59). The most effective therapy, however, involved starting treatment of the mother at 28 weeks' gestation, with 6 weeks of treatment in the infant (58,59).

A 2000 review described seven clinical trials that have been effective in reducing perinatal transmission, five with AZT alone, one with AZT plus lamivudine, and one with nevirapine (60). Six of the trials were in less-developed countries. Prolonged use of AZT in the mother and infant was the most effective for preventing vertical transmission of HIV, but also was the most expensive. The combination of AZT and lamivudine, consisting of antepartum, intrapartum, and postpartum maternal therapy with continued therapy in the infant for 1 week, may have been as effective as prolonged AZT (60).

A study published in 1999 evaluated the safety, efficacy, and perinatal transmission rates of HIV in 30 pregnant women receiving various combinations of antiretroviral agents (61). Many of the women were substance abusers. AZT was used by 26 women in various combinations that included didanosine, lamivudine, indinavir, nelfinavir, nevirapine, saquinavir, and delavirdine. Antiretroviral therapy was initiated at a median of 14 weeks' gestation (range preconception to 32 weeks). Despite previous histories of extensive antiretroviral experience and of vertical transmission of HIV, combination therapy was effective in treating maternal disease and in preventing transmission to the current newborns. The outcomes of the pregnancies included one stillbirth, one case of microcephaly, and five infants with birth weights <2500 g, two of which were premature (61).

In another 1999 study, the safety and efficacy of a short course of nevirapine was compared with AZT for the prevention of perinatal transmission of HIV-1

(62). At the onset of labor, women were randomly assigned to receive either a single dose of nevirapine (200 mg) plus a single dose (2 mg/kg) to their infants within 72 hours of birth (N = 310) or AZT (600 mg then 300 mg every 3 hours until delivery) plus 4 mg/kg twice daily for 7 days to their infants (N = 308). Nearly all (98.8%) of the women breastfed their infants immediately after birth. Up to age 14–16 weeks, significantly fewer infants in the nevirapine group were HIV-1 infected, lowering the risk of infection or death, compared with AZT, by 48% (95% CI 24%–65%) (62). The prevalence of maternal and infant adverse effects were similar in the two groups. In an accompanying study, the nevirapine regimen was shown to be cost-effective in various seroprevalence settings (63).

In an unusual case, a woman was exposed to HIV through self-insemination with fresh semen obtained from a man with a high HIV ribonucleic acid viral load (>750,000 copies/mL plasma) (64). Ten days later, she was started on a prophylactic regimen of AZT (600 mg/day), lamivudine (300 mg/day), and indinavir (2400 mg/day). Pregnancy was confirmed 14 days after insemination. The indinavir dose was reduced to 1800 mg/day 4 weeks after the start of therapy because of the development of renal calculi. All antiretroviral therapy was stopped after 9 weeks because of negative tests for HIV. She gave birth at 40 weeks' gestation to a healthy 3490-g male infant, without evidence of HIV disease, who was developing normally at 2 years of age (64).

A case of life-threatening anemia following in utero exposure to antiretroviral agents was described in 1998 (65). A 30-year-old woman with HIV infection was treated with AZT, didanosine, and trimethoprim/sulfamethoxazole (three times weekly) during the 1st trimester. Vitamin supplementation was also given. Because of an inadequate response, didanosine was discontinued and lamivudine and zalcitabine were started in the 3rd trimester. Two weeks before delivery, the HIV viral load was undetectable. At term, a pale, male infant was delivered who developed respiratory distress shortly after birth. Examination revealed a hyperactive precordium and hepatomegaly without evidence of hydrops. The hematocrit was 11% with a reticulocyte count of zero. An extensive work-up of the mother and infant failed to determine the cause of the anemia. Bacterial and viral infections, including HIV, parvovirus B19, cytomegalovirus, and others, were excluded. The infant received a transfusion and was apparently doing well at 10 weeks of age. Because no other cause of the anemia could be found, the authors attributed the condition to bone marrow suppression, most likely to AZT. A contribution of the other agents to the condition, however, could not be excluded (65).

A study of the inhibitory effects of AZT on hematopoiesis was published in 1996 (66). The researchers compared the effect of increasing concentrations of AZT on hematopoietic progenitors from women of childbearing age (from bone marrow aspirates), mid-trimester aborted fetuses (from bone marrow and liver), and term newborns (from cord blood). The inhibitory effect of AZT was more pronounced on fetal and neonatal erythroid progenitors than those from the bone marrow of the women. AZT had no effect on granulocyte colony-stimulating factor or erythropoietin. The authors concluded that neonatal anemia after in utero exposure to AZT was due to reduced clonal maturation of erythroid progenitors (66).

A 1999 report from France described the possible association of AZT and lamivudine (NRTIs) use in pregnancy with mitochondrial dysfunction in the offspring (67). Mitochondrial disease is relatively rare in France (estimated prevalence is 1 in 5000–20,000 children). From an ongoing epidemiological survey of 1754 mother–child pairs exposed to AZT and other agents during pregnancy, however, eight children with possible mitochondrial dysfunction were identified. None of the eight infants were infected with HIV, but all received prophylaxis for up to 6 weeks after birth with the same antiretroviral regimen as given during pregnancy. Four of the cases were exposed to AZT alone and four to a combination of AZT and lamivudine. Two from the combination group died at about 1 year of age. All eight cases had abnormally low respiratory-chain enzyme activities. The authors concluded that their results supported the hypothesis of a causative association between mitochondrial respiratory-chain dysfunction and NRTIs. Moreover, the toxicity may have been potentiated by a combination of these agents (67).

In a paper following the above study, investigators noted that NRTIs inhibit DNA polymerase γ , the enzyme responsible for mitochondrial DNA replication (68). They then hypothesized that this inhibition would induce depletion of mitochondrial DNA and mitochondrial DNA-encoded mitochondrial enzymes, thus resulting in mitochondrial dysfunction (69). Moreover, they stated that support for their hypothesis was suggested by the closeness of the clinical manifestations of inherited mitochondrial diseases with the adverse effects attributed to NRTIs. These adverse effects included polyneuropathy, myopathy, cardiomyopathy, pancreatitis, bone marrow suppression, and lactic acidosis. They also postulated that this mechanism was involved in the development of a lipodystrophy syndrome of peripheral fat wasting and central adiposity, a condition that has been thought to be related to protease inhibitors (68).

A commentary on the above two studies concluded that the evidence for

NRTI-induced mitochondrial dysfunction was equivocal (69). First, the clinical presentations in the infants were varied and not suggestive of a single cause; indeed, three of the infants were symptom-free and one had Leigh's syndrome, a classic mitochondrial disease (69). Second, the clinical features, in some cases, were not suggestive of mitochondrial dysfunction. Although three had neurologic symptoms, none had raised levels of lactate in the cerebrospinal fluid. Moreover, histologic or histochemical features of mitochondrial disease were only found in two cases. Finally, low mitochondrial DNA, which would have been a direct evidence of NRTI toxicity, was not found in the three cases in which it was measured (69).

A case of combined transient mitochondrial and peroxisomal β -oxidation dysfunction after exposure to NRTIs (AZT and lamivudine) combined with protease inhibitors (ritonavir and saquinavir) throughout gestation was reported in 2000 (70). A male infant was delivered at 38 weeks' gestation. He received postnatal prophylaxis with AZT and lamivudine for 4 weeks until the drugs were discontinued because of anemia. Other adverse effects that were observed in the infant (age at onset) were hypocalcemia (shortly after birth); group B streptococcal sepsis, ventricular extrasystoles, prolonged metabolic acidosis, and lactic acidemia (8 weeks); a mild elevation of long-chain fatty acids (9 weeks); and neutropenia (3 months). The metabolic acidosis required treatment until 7 months of age, whereas the elevated plasma lactate resolved over 4 weeks. Cerebrospinal fluid lactate was not determined nor was a muscle biopsy conducted. Both the neutropenia and the cardiac dysfunction had resolved by 1 year of age. The elevated plasma fatty acid level was confirmed in cultured fibroblasts, but other peroxisomal functions (plasmalogen biosynthesis and catalase staining) were normal. Although mitochondrial dysfunction has been linked to NRTI agents, the authors were unable to identify the cause of the combined abnormalities in this case. The child was reported to be healthy and developing normally at 26 months of age (70).

A study involving *Erythrocebus patas* monkeys exposed in utero to AZT was thought to be relevant to the reports of mitochondrial dysfunction in humans (71). Ten pregnant monkeys in the last half of gestation were given daily oral doses of AZT (1.5 mg/kg/day [N = 3] or 6 mg/kg/day [N = 3]) or no AZT (controls [N = 4]). The doses of AZT were 21% and 86% of the human dose, respectively, based on body weight for a 70-kg pregnant woman. All fetuses were delivered by cesarean section 24 hours after the last AZT dose and 3–5 days before term. No gross defects were evident in the heart left ventricle tissue or skeletal muscle tissue from AZT-exposed or control fetuses.

Mitochondria observed by electron microscopy in the two tissue sites were similar in the AZT low-dose and control groups. In contrast, numerous abnormalities were observed in both heart and muscle tissue mitochondria from fetuses exposed to the AZT high-dose group. Moreover, there were dose-dependent alterations in oxidative phosphorylation enzyme assays, in the specific activities of NADH dehydrogenase (complex I), succinate dehydrogenase (complex II), and cytochrome-c oxidase (complex IV), and a dose-dependent depletion of mitochondrial DNA levels. The data were consistent with AZT-induced cardiac and skeletal muscle mitochondrial myopathy (71).

Based on the findings of the above research, a prospective study of the left ventricular structure and function of 382 noninfected (36 exposed to AZT) and 58 HIV-infected (12 exposed to AZT) infants born to HIV-infected women was published in 2000 (72). The median length of in utero exposure to AZT was 103 days (105 days for those not infected and 68 days for those infected at birth). Echocardiographic studies (mean left ventricular fractional shortening, contractility, end-diastolic dimension, and left ventricular mass) were conducted every 4–6 months during the first 14 months of life. All echocardiograms were examined without knowledge of the child's clinical status or medications. No statistical differences were found among the four echocardiographic measures in the four groups of children. The investigators identified at least four limitations of their study, including a small sample size that was unable to estimate the frequency of an uncommon toxic effect, the lack of an assessment of a possible dose effect, the possibility that the sickest children were missed because they were unable to attend follow-up visits, and the effects of other drug therapy in the HIV-infected subgroup that could obscure the effects of AZT. Nonetheless, they concluded that perinatal exposure to AZT was not associated with acute or chronic abnormalities in left ventricular structure or function (72).

A 2000 case report described the adverse pregnancy outcomes, including NTDs, of two pregnant women with HIV infection who were treated with the anti-infective combination trimethoprim/sulfamethoxazole for prophylaxis against *Pneumocystis carinii*, concurrently with antiretroviral agents (73). Exposure to AZT occurred in one of these cases. A 32-year-old woman with a 3-year history of HIV and recent diagnosis of AIDS was treated before and throughout gestation with the anti-infective combination plus AZT and zalcitabine. Folic acid 10 mg/day was added after the diagnosis of pregnancy (gestational age not specified). At term, a female infant was delivered by cesarean section without

HIV infection, but with a bony mass in the lumbar spine (identified by ultrasound at 32 weeks' gestation). A diagnostic evaluation revealed that the second lumbar vertebra consisted of hemivertebrae and projected posteriorly into the spinal canal. A malformed and displaced first lumbar vertebra was also noted. Surgery was planned to correct the defect. The authors attributed the NTDs in both cases to the antifolate activity of trimethoprim (73).

The case of a 6-month-old male infant who was diagnosed with acute lymphoblastic leukemia (ALL) was described in a 2000 case report (74). His mother had been diagnosed with HIV infection during the 5th month of gestation. She had been treated with oral AZT for the last 3 months of pregnancy. The 3.5-kg infant had been delivered by cesarean section and treated with AZT prophylaxis (2 mg/kg 4 times a day) for 6 weeks. All tests for HIV in the infant were negative. He achieved complete remission after chemotherapy for the ALL and was currently receiving the maintenance phase of chemotherapy at age 16 months. The relationship between AZT exposure and the ALL was unknown (74).

Because of the AZT-induced carcinogenicity observed in animal studies, a 1999 study evaluated the short-term risk for tumors in a total of 727 children who had been exposed in utero (antepartum) and/or during the neonatal period to HIV and AZT (75). The children were participants in one of two multicenter clinical studies: Pediatric AIDS Clinical Trials Group (PACTG) 076/219 (N = 115) or the Women and Infants Transmission Study (WITS) (N = 612). The mean infant follow-up in the PACTG 076/219 group was 38.3 months (366.9 person-years follow-up), whereas it was 14.5 months (743.7 person-years follow-up) for WITS participants. The range for all children was 1 month to 6 years. No tumors of any nature were reported in the children (relative risk 0, 95% CI 0–17.6) (75).

The long-term effects of in utero exposure to AZT were the subject of a study published in 1999 (76). HIV-uninfected children (N = 234) born to 231 HIV-infected women enrolled in the PACTG 076 were evaluated under the PACTG 219 protocol (122 exposed to AZT, 112 in the placebo group). The main outcome measures included physical growth, immunologic parameters, cognitive/developmental function, tumors, and mortality data. Children were evaluated every 6 months up to 24 months, then yearly thereafter or as clinically indicated. The median age at the time of last follow-up was 4.2 years (range 3.2–5.6 years). There were no significant differences between those exposed to AZT and those not exposed in terms of the sequential outcome measurements. In addition, there were no deaths or malignancies. In the 137

(59%) children who had at least one ophthalmologic examination, 72 were in the AZT group and 65 were in the placebo group. Although there was no significant difference ($p = 0.99$) between the groups in abnormal ophthalmic findings, astigmatism was noted in two (AZT group), ptosis in one (AZT group), and epicanthal folds in one (placebo group). Two other AZT-exposed children had ophthalmic abnormalities: (a) bilateral “thinned vessels; discs look slightly pale” in one with normal vision; and (b) one with a fundus reported as “copper beaten look” that was not thought to be related to metabolic disease. One other asymptomatic, healthy 4-year-old child in the AZT group had a mild cardiomyopathy on echocardiogram (76).

New York Medicaid data were used in a study published in 2000 to determine if there was an association between prenatal AZT use and congenital anomalies (77). The study cohort included 1932 liveborn infants delivered from 1993 to 1996 to HIV-infected women in the state of New York, 29.5% of whom were exposed in utero to AZT. The prevalence of any anomaly in the study cohort was 2.76 (95% CI 2.36–3.17) compared with the general New York State population. When AZT-exposed outcomes were compared with those not exposed, the adjusted odds ratios (aORs) for major congenital malformations by trimester of first prescription were as follows: 1.20 (95% CI 0.58–2.51) (1st trimester), 1.47 (95% CI 0.85–2.55) (2nd trimester), and 1.84 (95% CI 1.04–3.25) (3rd trimester). There was an increased unadjusted OR for CNS defects when compared with those not exposed to AZT (7.98 [95% CI 1.56–37.46]). However, this finding was based on only four such defects and must be interpreted cautiously (77).

High semen levels of AZT have been reported (78). Six males with HIV disease were treated with 200 mg of the antiviral agent orally every 4–6 hours. AZT concentrations in semen 3.0–4.5 hours after a dose ranged from 1.68 to 6.43 $\mu\text{mol/L}$, representing semen:serum ratios of 1.3–20.4. The semen levels were above the in vitro minimum inhibitory concentration for HIV-1. A 1994 study reported that AZT reversed the effects of HIV-1 disease progression on semen quality, including ejaculate volume, sperm concentration and total count, and the number of abnormal sperm forms (79). Moreover, AZT therapy significantly reduced the semen white blood cell count, the principal HIV-1 host cells in ejaculates of HIV-1-infected males. The researchers concluded that this might explain why infected males treated with AZT have a reduced viral load in their semen and a lower rate of sexual transmission (79).

Two reviews, one in 1996 and the other in 1997, concluded that all women currently receiving antiretroviral therapy should continue to receive therapy

during pregnancy and that treatment of the mother with monotherapy should be considered inadequate therapy (80,81). The same conclusion was reached in a 2003 review with the added admonishment that therapy must be continuous to prevent emergence of resistant viral strains (82). In 2009, the updated U.S. Department of Health and Human Services guidelines for the use of antiretroviral agents in HIV-1-infected patients continued the recommendation that therapy, with the exception of efavirenz, should be continued during pregnancy (83). If indicated, AZT should not be withheld in pregnancy because the expected benefit to the HIV-positive mother outweighs the unknown risk to the fetus. Updated guidelines for the use of antiretroviral drugs to reduce perinatal HIV-1 transmission also were released in 2010 (84). Women receiving antiretroviral therapy during pregnancy should continue the therapy but, regardless of the regimen, AZT administration is recommended during the intrapartum period to prevent vertical transmission of HIV to the newborn (84).

BREASTFEEDING SUMMARY

Only one report describing the excretion of AZT in breast milk has been located (85). Six HIV-seropositive women were given a single 200-mg dose of AZT, and serum and breast milk samples were collected 1, 2, 4, and 6 hours later. Peak serum and milk concentrations, ranging between 422.1 and 1019.3 ng/mL and 472.1 and 1043.0 ng/mL, respectively, were measured at approximately 1–2 hours after the dose. The milk:serum ratio (based on AUC) ranged between 1.11 and 1.78. The authors speculated that the milk concentrations were sufficiently high to decrease the viral load in milk, thereby reducing the potential for maternal–infant HIV transmission (85).

Breastfeeding is not recommended in women with HIV infection because HIV-1 is transmitted in milk (80,81,83,86–88). Until 1999, no studies had been published that examined the effect of any antiretroviral therapy on HIV-1 transmission in milk. In that year, a double-blind, placebo-controlled trial investigated the effect of oral AZT in the postpartum period on the transmission of HIV-1 to the breastfeeding infant (56). Infants (at 6 months of age) of women who had received an oral AZT regimen of 300 mg twice daily until labor, 600 mg at beginning of labor, then 300 mg twice daily for 7 days postpartum, had a 38% reduction (relative efficacy 0.38, 95% CI 0.05–0.60; $p = 0.027$) in vertical transmission of HIV-1 infection despite breastfeeding when compared with controls. Furthermore, no excess of major adverse biological or clinical events were observed in the AZT group compared with controls (56).

ZILEUTON

Respiratory Agent

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports on the use of zileuton in human pregnancy have been found. One source, based solely on animal data, recommends that the drug be avoided during gestation (1).

FETAL RISK SUMMARY

Zileuton, a specific inhibitor of the enzyme (5-lipoxygenase) that catalyzes the formation of leukotrienes (LTB₄, LTC₄, LTD₄, and LTE₄) from arachidonic acid, is given orally for the prophylaxis and chronic treatment of asthma (2).

Reproduction studies have been conducted in rats and rabbits. No effects on fertility were observed in male and female rats given oral doses approximately 8 and 18 times the systemic exposure (AUC) achieved at the maximum recommended human daily oral dose (MRHD), respectively. However, at doses ≥ 9 times the MRHD-AUC, a reduction in fetal implants was observed. At ≥ 4 times the MRHD-AUC, increases in gestation length and the number of stillbirths were noted. In addition, offspring of pregnant rats given 18 times the MRHD-AUC had reduced body weight and increased skeletal variations. A decrease in rat pup survival and growth occurred at this same dose in perinatal and postnatal studies. In pregnant rabbits given oral doses equivalent to the MRHD (based on BSA), 3 (2.5%) of 118 fetuses had cleft palates (2).

It is not known if zileuton crosses the human placenta to the fetus, but the molecular weight (about 236) is low enough that transfer should be expected. The drug and/or its metabolites cross the rat placenta (2).

BREASTFEEDING SUMMARY

No reports describing the use of zileuton during human lactation have been located. The molecular weight (about 236) is low enough that passage into human breast milk should be expected. The effects on a nursing infant from this exposure are unknown.

ZIPRASIDONE

Antipsychotic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Two reports describing the use of ziprasidone in human pregnancy have been located, one of which described an infant with a cleft palate. The animal reproduction data suggests risk as all aspects of developmental toxicity were observed. However, the limited human pregnancy experience prevents a more complete assessment of embryo–fetal risk. Although none of the antipsychotic class of agents has been proven to cause structural anomalies, there is a concern for long-term neurobehavioral deficits. Therefore, until human pregnancy data are available, the safest course is to avoid ziprasidone in pregnancy. However, if a woman requires treatment and informed consent is obtained, ziprasidone should not be withheld because of pregnancy. If an inadvertent pregnancy does occur during treatment, the woman should be advised of the unknown risks to her embryo–fetus. If ziprasidone is used in pregnancy, healthcare professionals are encouraged to call the toll-free number 800-670-6126 for information about patient enrollment in the Motherisk study.

FETAL RISK SUMMARY

The atypical antipsychotic ziprasidone is a benzisoxazole derivative in the same subclass of antipsychotic agents as iloperidone, paliperidone, and risperidone. Ziprasidone is indicated for the treatment of schizophrenia, including acute agitation in schizophrenic patients. It also is indicated for the treatment of acute manic or mixed episodes associated with bipolar disorder. Elimination is mostly by hepatic metabolism to inactive metabolites. After oral administration, the mean terminal elimination half-life is about 7 hours, but a mean 2–5 hours after a single IM dose. Plasma protein binding to albumin and α_1 -acid glycoprotein is

>99% (1).

Reproduction studies have been conducted in rats and rabbits. In rats, oral doses that were 0.5–8 times the maximum recommended human dose of 200 mg/day based on BSA (MRHD) given during organogenesis or throughout gestation caused embryo–fetal toxicity consisting of decreased fetal weights and delayed skeletal ossification. There was no evidence of structural anomalies. Doses that were 2 and 8 times the MRHD were maternally toxic. The developmental no-effect dose for embryo–fetal toxicity was 0.2 times the MRHD. When rats were treated throughout gestation and lactation with a dose that was half the MRHD, there was an increase in the number of pups born dead and decreased postnatal survival during the first 4 days of lactation. Developmental delays and impaired neurobehavioral function were observed in offspring with doses ≥ 0.2 times the MRHD. A no-effect dose for these effects was not established (1).

In pregnant rabbits during organogenesis, a dose 3 times the MRHD was associated with an increased incidence of ventricular septal defects, other cardiovascular malformations, and kidney alterations. There was no maternal toxicity at this dose. The developmental no-effect dose was equivalent to the MRHD (1).

Two-year studies for carcinogenicity were conducted in rats and mice with doses that were 0.1–0.6 and 1–5 times, respectively, the MRHD. In rats and male mice, there was no evidence of an increased incidence of tumors. However, in female mice, there were dose-related increases in the incidences of pituitary gland adenoma and carcinoma, and mammary gland adenocarcinoma at all doses tested. These effects have been observed in rodents with other antipsychotic agents and were thought to be prolactin-mediated. Ziprasidone was mutagenic in some tests (1).

In fertility tests with rats, doses that were 0.5–8 times the MRHD increased the time to copulation. Fertility was decreased at 8 times the MRHD, but there was no effect on fertility at 2 times the MRHD. The effect appeared to be confined to female rats as fertility was not impaired in male rats given a dose that was 8 times the MRHD and mated with untreated females. In addition, there were no treatment-related effects in the testes in a study with male rats at 10 times the MRHD for 6 months (1).

It is not known if ziprasidone crosses the human placenta. The molecular weight of the free base (about 413) and the elimination half-life suggest that the drug will cross to the embryo and/or fetus. However, the very high plasma protein binding should limit the amount crossing to the embryo/fetus.

A 2009 case report described the pregnancy of a 26-year-old woman with severe psychotic depression (2). She was treated with ziprasidone 40 mg/day and citalopram 60 mg/day throughout pregnancy. At 39 weeks' gestation, she gave birth to a healthy, 2.64-kg male infant with Apgar scores of 8 and 9 at 1 and 5 minutes, respectively. No anomalies, drug-related adverse effects, or withdrawal were observed in the infant who was doing well at 6 months of age (2).

In a 2010 case report, a 33-year-old woman with paranoid schizophrenia was treated throughout pregnancy with ziprasidone (daily doses of 120 mg during first 3 months, then 80 mg for 2 months, then 40 mg until birth), fluvoxamine and diazepam (doses not specified) (3). She gave birth at term to a 3.070-kg female infant with a cleft palate. The infant's karyotype was normal, and the mother denied smoking, drinking coffee or alcohol, taking other drugs during pregnancy (3).

BREASTFEEDING SUMMARY

A woman with schizophrenia who was breastfeeding her infant was started on ziprasidone on postpartum day 9 (4). Breastfeeding was stopped because of concerns of toxicity in the infant. Ziprasidone was not detected (limit of quantification was 10 ng/mL) until day 10 of treatment. At that time, the milk and maternal plasma concentrations were 11 and 170 ng/mL (milk:plasma ratio 0.06). The theoretical relative dose received by the infant per kg body weight based on the weight-adjusted maternal dose was 1.2% (4).

In a 2009 case (see Fetal Risk Summary), a mother taking ziprasidone and citalopram breastfed her full-term infant for 6 months. No adverse effects were noted and the infant was deemed healthy by his pediatrician (2).

Consistent with the molecular weight of the free base (about 413) and the elimination half-life (up to 7 hours), ziprasidone is excreted into breast milk but, as suggested by the very high plasma protein binding (>99%), only low levels were excreted. However, the absorption of ziprasidone in adults is increased twofold in the presence of food (1).

Although no adverse effects were observed in one case, additional data are needed before a better assessment of risk can be made. Moreover, because treatment with ziprasidone will usually be long term, there is concern for potential adverse effects involving the neurobehavior of an infant.

ZIV-AFLIBERCEPT

Antineoplastic (Tyrosine Kinase Inhibitor)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of ziv-aflibercept in human pregnancy have been located. Animal reproduction data suggest risk, but the absence of human pregnancy experience prevents a more complete assessment of embryo–fetal risk. However, ziv-aflibercept is given in combination with two other antineoplastics and the three agents potentially could cause embryo–fetal harm. In addition, ziv-aflibercept has caused reversible impaired fertility in male and female cynomolgus monkeys at systemic exposures that were less than those obtained in humans. Taken in sum, the drug should be considered contraindicated in pregnancy. Moreover, the manufacturer recommends that females and males of reproductive potential should use highly effective contraception during treatment and up to a minimum of 3 months after the last dose (1).

FETAL RISK SUMMARY

Ziv-aflibercept, a dimeric glycoprotein, is a recombinant fusion protein that binds to vascular endothelial growth factor-A (VEGF-A). It is indicated, in combination with 5-fluorouracil, leuvovorin, and irinotecan, for patients with metastatic colorectal cancer that is resistant to or has progressed following an oxaliplatin-containing regimen (see also Fluorouracil, Irinotecan, and Leuvovorin). The metabolism and plasma protein binding were not specified, but the elimination half-life of free ziv-aflibercept was about 6 days (range 4–7 days) (1).

Reproduction studies have been conducted in rabbits. In this species, IV doses that resulted in systemic exposures that were about $\geq 30\%$ of the AUC in patients at the recommended dose, given every 3 days during organogenesis resulted in adverse embryo–fetal effects. These effects included increased incidences of postimplantation losses and external (anasarca, umbilical hernia,

diaphragmatic hernia and gastroschisis, cleft palate, ectrodactyly, and atresia), visceral (great vessels and arteries in the heart), and skeletal fetal anomalies (fused vertebrae, sternebrae, and ribs; supernumerary arches and ribs, and incomplete ossification). The incidence and severity of fetal anomalies increased with increasing dose (1).

Studies for carcinogenicity and mutagenicity have not been conducted. In sexually mature young cynomolgus monkeys given IV doses that were about $\geq 60\%$ of the AUC in patients at the recommended dose every 2 weeks for 6 months, impaired reproductive function was noted at all doses tested. In females, the drug inhibited ovarian function and follicular development as shown by decreased ovary weight, amount of luteal tissue, and number of maturing follicles; atrophy of uterine endometrium and myometrium, vaginal atrophy, abrogation of progesterone peaks and menstrual bleeding. In males, alterations in sperm morphology and decreased sperm motility were noted. All of these effects were reversible within 18 weeks after cessation of therapy (1).

It is not known if free ziv-aflibercept crosses the human placenta. The molecular weight (about 115,000) suggests that it will not cross, at least early in gestation, but the elimination half-life is very long. Moreover, the drug did cause embryo–fetal toxicity in rabbits during organogenesis.

BREASTFEEDING SUMMARY

No reports describing the use of ziv-aflibercept during human lactation have been reported. The molecular weight (about 115,000) suggests that it will not be excreted into mature milk, but it probably will be excreted during the colostrum period. However, the drug is given in combination with 5-fluorouracil, leucovorin, and irinotecan (see also these three agents) and the two antineoplastic agents are probably excreted into breast milk. Consequently, breastfeeding should be considered contraindicated if a woman is receiving this combined therapy.

ZOLEDRONIC ACID

Bisphosphonate

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

One report has described the use of zoledronic acid use in human pregnancy. The animal data suggest risk, but the limited human pregnancy experience prevents a complete assessment of the embryo–fetal risk. The amount of zoledronic acid incorporated into bone and eventually released back into the systemic circulation is directly related to the total dose and duration of treatment. Because zoledronic acid probably crosses the placenta, the use of the drug shortly before or during gestation could expose the embryo and/or fetus to a potentially toxic agent. Thus, administration before pregnancy may result in low-level, continuous exposure throughout gestation. The use of zoledronic acid in women who may become pregnant or during pregnancy is not recommended. However, based on the animal and limited human data, inadvertent exposure during early pregnancy does not appear to represent a major risk to the embryo–fetus.

FETAL RISK SUMMARY

Zoledronic acid is given by IV infusion. It is indicated for the treatment of hypercalcemia of malignancy. Other agents in this pharmacologic class are alendronate, etidronate, ibandronate, pamidronate, risedronate, and tiludronate. Only about 3% of an oral dose is absorbed into the systemic circulation. Zoledronic acid is not metabolized, and plasma protein binding is only 22%. The postinfusion half-life in the plasma is 1.87 hours, whereas the terminal elimination half-life is 146 hours, correlating with the low concentrations in the plasma observed up to 28 days postdose (1).

Reproduction studies have been conducted in rats and rabbits. In pregnant

rats, daily SC doses producing exposures 1.2, 2.4, and 4.8 times the human systemic exposure after an IV dose of 4 mg based on AUC (HSE) were associated with adverse fetal effects. At 1.2 times the HSE, fetal skeletal variations were noted. Doses producing exposures 2.4 and 4.8 times the HSE caused pre- and postimplantation losses; decreases in viable fetuses; and fetal skeletal, visceral, and external malformations. The fetal skeletal effects observed at 4.8 times the HSE were unossified or incompletely ossified bones; thickened, curved, or shortened bones; wavy ribs, and shortened jaw. Other adverse fetal effects observed in the high-dose group were reduced lens, rudimentary cerebellum, reduction or absence of liver lobes, reduction or absence of lung lobes, vessel dilation, cleft palate, and edema, but maternal toxicity (reduced body weight and food consumption) also was observed (1).

In female rats given SC doses producing exposures ≥ 0.2 times the HSE for 15 days before mating and continuing through gestation, the number of stillbirths was increased and survival of neonates was decreased. Higher exposure (1.2 times the HSE) inhibited ovulation, resulting in a decrease in the number of pregnant rats. Maternal toxicity (dystocia and periparturient mortality) was observed at all exposures ≥ 0.7 times the HSE. This toxicity was thought to be secondary to drug-induced inhibition of skeletal calcium mobilization, resulting in hypocalcemia, a bisphosphonate class effect (1).

In pregnant rabbits, SC doses resulting in exposures ≤ 0.5 times the HSE did not cause fetal harm. However, exposures >0.05 times the HSE were associated with maternal mortality and abortion in all treatment groups. The maternal toxicity may have been caused by drug-induced hypocalcemia (1).

Long-term carcinogenicity studies with oral zoledronic acid were positive in male and female mice but not in rats. Various assays for mutagenicity were negative (1).

It is not known if zoledronic acid crosses the human placenta. The molecular weight (about 290 for the hydrated form), lack of metabolism, low plasma protein binding, plasma half-life, and the prolonged terminal elimination half-life all suggest that exposure of the embryo and/or fetus will occur. Moreover, detectable amounts of the drug can be measured in plasma for up to 28 days postdose (1).

A 33-year-old woman with metastatic breast cancer was treated with zoledronic acid (two IV courses 28 days apart; dose not specified) and tamoxifen in the 2nd and 3rd trimesters (2). She also received five cycles of 5-fluorouracil, epirubicin, and cyclophosphamide before conception and during the 1st trimester, as well as radiotherapy at 17 weeks' gestation. Her pregnancy

was diagnosed at 28 weeks. A cesarean section at 35 weeks' delivered a 2070-g female infant with Apgar scores of 10 at 1 and 5 minutes, respectively. All hematologic and biochemistry parameters were normal for age. The healthy infant apparently was developing normally at 12 months of age (2).

A 2008 review described 51 cases of exposure to bisphosphonates before or during pregnancy: alendronate (N = 32) pamidronate (N = 11), etidronate (N = 5), risedronate (N = 2), and zoledronic acid (N = 1) (3). They concluded that although these drugs may affect bone modeling and development in the fetus, no such toxicity has yet been reported.

BREASTFEEDING SUMMARY

No reports describing the use of zoledronic acid during human lactation have been located. The molecular weight (about 290 for the hydrated form), lack of metabolism, low plasma protein binding, plasma half-life, and the prolonged terminal elimination half-life suggest that the drug will be excreted into breast milk. Detectable amounts of the drug are measured in adult plasma for up to 28 days postdose (1). Although the low lipid solubility of zoledronic acid may limit the amount present in milk, and maternal treatment may be compatible with nursing, the best course is to not breastfeed until data are available.

ZOLMITRIPTAN

Antimigraine

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of zolmitriptan in human pregnancy have been located. The animal data suggest low risk, but an assessment of the actual risk cannot be determined until human pregnancy experience is available. Although a 2008 review of triptans in pregnancy found no evidence for teratogenicity, the data did suggest a possible increase in the rate of preterm birth (1).

FETAL RISK SUMMARY

Zolmitriptan is an oral selective serotonin (5-hydroxytryptamine; 5HT) receptor agonist that has high affinity for 5HT_{1B} and 5HT_{1D} receptors. The drug is closely related to almotriptan, eletriptan, frovatriptan, naratriptan, rizatriptan, and sumatriptan. It is indicated for the acute treatment of migraine with or without aura in adults. Protein binding is low (about 25%). Zolmitriptan has a several metabolites, one of which is 2–6 times more potent for the 5HT_{1B/1D} receptors than is the parent compound. The active metabolite contributes a substantial portion of the pharmacologic effect because its concentrations are about two-thirds that of zolmitriptan (2). The elimination half-life of zolmitriptan is apparently unknown.

Reproduction studies have been conducted in rats and rabbits. In rats, zolmitriptan was given during organogenesis at oral doses resulting in maternal exposures ranging from 280 to 5000 times the exposure in humans receiving the maximum recommended total daily dose of 10 mg (MRHD). A dose-related increase in embryoletality was observed, which became statistically significant at the high dose, but maternal toxicity (decreased weight gain during gestation) was also noted. When pregnant rats were treated throughout gestation and

lactation, an increased incidence of hydronephrosis was seen in the offspring at a dose 1100 times the MRHD. This dose was also maternally toxic. In pregnant rabbits treated during organogenesis, an increased incidence of embryoletality was observed at maternally toxic doses ≥ 11 times the MRHD. At 42 times the MRHD, increased incidences of fetal malformations (fused sternbrae, rib anomalies) and variations (blood vessels, rib ossification) were observed. The no-effect dose was equivalent to the MRHD (2).

It is not known if zolmitriptan or its active metabolite crosses the human placenta to the fetus. The molecular weight of the parent compound (about 287) and the minimal plasma protein binding suggest that the drug will cross to the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use of zolmitriptan during human lactation have been located. The molecular weight (about 287) and low plasma protein binding (25%) suggest that the drug, and possibly its active metabolite, will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown.

ZOLPIDEM

Hypnotic

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Although no increased risk of congenital malformations has been observed, two studies did find increased risks for preterm birth, low birth weights, small for gestational age (SGA) infants, and cesarean birth. Although the drug has addiction potential, withdrawal symptoms have not been reported in exposed newborns.

FETAL RISK SUMMARY

Zolpidem is a nonbenzodiazepine hypnotic of the imidazopyridine class. In subjects with normal liver function, a single 5-mg dose of zolpidem had a relatively short elimination half-life (2.6 hours; range 1.4–4.5 hours) (1).

In reproductive studies in rats, no teratogenic effects were observed, but dose-related toxicity was observed in the fetuses (delayed maturation as characterized by incomplete ossification of the skull) at doses about 25 and 125 times the maximum human dose based on BSA (MHD) (1). The no-effect dose was 5 times the MHD. In rabbits, increased postimplantation fetal loss and incomplete ossification of the sternum in surviving fetuses were observed at about 28 times the MHD, both possibly related to maternal toxicity (decreased weight gain) (1). The no-effect dose in rabbits was 7 times the MHD. No teratogenic effects of the drug were observed. Shepard (2) reviewed a reproductive toxicity study in rats during organogenesis that found no teratogenicity, but did observe a decrease in fetal weight at doses ranging from 5 to 125 mg/kg and an increase in wavy ribs at the highest dose.

The FDA had not received any reports of adverse fetal or newborn outcomes from pregnancy exposures to zolpidem between its approval in December 1992 and 1996 (F. Rosa, personal communication, FDA, 1996).

Consistent with the molecular weight (about 765 for the tartrate salt),

zolpidem crosses the placenta, at least at term. A 2007 report described the pregnancy outcome of a woman apparently addicted to zolpidem (3). The woman experienced vaginal bleeding and abdominal pain, diagnosed as placental abruption, at about 27 weeks' gestation. She had been taking 10–15 zolpidem tablets/night (strength not specified). Within 24 hours of hospitalization, the patient had withdrawal-like symptoms (nervousness and anxiety) that were thought to be due to zolpidem withdrawal. She was prescribed zolpidem 15 mg/night and was discharged home on hospital day 7. Polyhydramnios was diagnosed at 35 weeks but had resolved by 37 weeks. At 38 weeks, she delivered vaginally a healthy 3.9-kg female infant with Apgar scores of 8 and 9. No withdrawal signs were observed in the neonate or the mother over a 48-hour interval until discharge. The cord blood concentration of zolpidem was 41 ng/mL. In adults, the mean peak plasma levels after 5- and 10-mg doses are 29–113 ng/mL (mean 59 ng/mL) and 58–272 ng/mL (mean 121 ng/mL), respectively. Although the interval between the mother's last dose and delivery was not known, the interval from admission and the cord blood sample was about 14.33 hours (3). No follow-up on the infant was reported.

A 2009 study evaluated the placental passage of zolpidem at term and infant outcomes in 45 women with psychiatric illness who had taken the drug during pregnancy compared with 45 matched pregnant women who had not (4). Exposures to zolpidem occurred in 17 (38%) women in the 1st trimester, 25 (56%) in the 2nd trimester, and 35 (78%) in the 3rd trimester. The drug was taken throughout pregnancy in 11 (24%). The mean dose was 8.8 ± 3.9 mg/day and the mean duration of exposure was 13.8 ± 12.9 weeks. In comparisons between those exposed and those not exposed, there were higher rates of preterm birth (26.7% vs. 13.3%) and low birth weight (15.6% vs. 4.4%) in those exposed, but the differences were not statistically significant. In six subjects, the mean zolpidem concentrations in cord and maternal blood were 8.2 and 17.3. The mean cord:maternal ratio was 1.34. No major malformations were noted in any of the infants of the 90 women (4).

A 1998 noninterventional, observational cohort study described the outcomes of pregnancies in women who had been prescribed ≥ 1 of 34 newly marketed drugs by general practitioners in England (5). Data were obtained by questionnaires sent to the prescribing physicians 1 month after the expected or possible date of delivery. In 831 (78%) of the pregnancies, a newly marketed drug was thought to have been taken during the 1st trimester with birth defects noted in 14 (2.5%) singleton births of the 557 newborns (10 sets of twins). In addition, two birth defects were observed in aborted fetuses. However, few of

the aborted fetuses were examined. Zolpidem was taken during the 1st trimester in 18 pregnancies. The outcomes of these pregnancies included 2 spontaneous abortions, 6 elective abortions, and 11 normal, term infants (1 set of twins) (5).

A 2010 study from Taiwan compared the outcomes of 2497 women who had used zolpidem during pregnancy with 12,485 randomly selected mothers who had not received the drug (6). In four outcomes, the adjusted odds ratios (aORs) were higher in exposed pregnancies: preterm birth (1.49, 95% confidence interval [CI] 1.28–1.74; $p < 0.001$), low birth weight (1.39, 95% CI 1.17–1.64; $p < 0.001$), small for gestational age (1.34, 95% CI 1.20–1.49; $p < 0.001$), and cesarean section (1.74, 95% CI 1.59–1.90; $p < 0.001$). Congenital anomalies were observed in 12 (0.48%) infants exposed in utero compared with 81 (0.65%) infants not exposed (0.70, 95% CI 0.38–1.28) (6).

In a study published in 2011, data from the Swedish Medical Birth Registry, covering the period 1995–2007, identified 1318 women who gave birth to 1341 infants and who reported the use of a hypnotic benzodiazepine receptor agonist at the first prenatal visit (7). The three most commonly reported agents and the number of exposed infants were zopiclone (N = 692) (not available in USA), zolpidem (N = 603), and zaleplon (N = 32). The reference group during the study period was 1,106,001 women who gave birth to 1,125,734 infants. The rate of congenital malformations was similar in the exposed and nonexposed groups, 4.3% (N = 58) and 4.7% (N = 52,773), aOR 0.89, 95% CI 0.68–1.16. One mother who had two infants with probably unrelated malformations (cleft lip and hypospadias) had used zopiclone in both pregnancies. For relatively severe defects, there were 42 exposed infants (3.1%) compared with 36,321 nonexposed infants (3.2%), aOR 0.95, 95% CI 0.0.69–1.30. The authors concluded that use of these agents did not appear to increase the risk of malformations (7).

BREASTFEEDING SUMMARY

Zolpidem is excreted into breast milk, but the effects, if any, on a nursing infant have not been studied. In a 1989 report, five lactating women were administered a single 20-mg dose 3–4 days after delivery of a full-term infant (8). Breastfeeding was halted for 24 hours after drug administration. Milk and serum samples were collected before and 1.5 (serum only), 3, 13, and 16 hours after the dose. The total amount of zolpidem in milk at 3 hours (both breasts emptied with an electric breast pump and the milk pooled for each woman) ranged from 0.76 to 3.88 mcg, representing 0.004%–0.019% of the

dose. The drug was not detected in milk (detection level 0.5 ng/mL) at the other sampling times (8). The dose used in this study was twice the current maximum recommended human hypnotic dose.

In healthy adult patients, zolpidem has a relatively short serum half-life (about 2.6 hours) and accumulation is not expected to occur. The small amount of drug measured in milk after a dose that was twice the recommended human dose probably indicates that few, if any, adverse effects would occur in a nursing infant whose mother was consuming this hypnotic. In those instances in which the mother is taking zolpidem, however, she should observe her nursing infant for increased sedation, lethargy, and changes in feeding habits. Based on the one study above, the American Academy of Pediatrics classifies zolpidem as compatible with breastfeeding (9).

ZONISAMIDE

Anticonvulsant

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest High Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Zonisamide is teratogenic in three animal species and embryolethal in a fourth at doses or exposures very near or less than doses and systemic concentrations used or obtained clinically. Human pregnancy experience is limited. Two infants with congenital anomalies have been observed, but in both cases, other anticonvulsants known to be human teratogens also were used. If treatment with zonisamide in pregnancy is required, monotherapy using the lowest effective dose is preferred, but because of its status as adjunctive therapy, this may not be possible.

FETAL RISK SUMMARY

Zonisamide, a sulfonamide derivative, is indicated as adjunctive therapy in the treatment of partial seizures. Its anticonvulsant mechanism of action is unknown. The drug is bound extensively to erythrocytes with concentrations in red blood cells eight times higher than in plasma. Approximately 40%–60% is bound to plasma proteins, mainly albumin (1,2). After single oral doses, the elimination half-lives from erythrocytes and from plasma are 105 and 50–68 hours, respectively (1,2). The plasma elimination half-life is decreased to about 25–35 hours if the patient is receiving concurrent treatment with hepatic enzyme-inducing anticonvulsants (carbamazepine, phenytoin, phenobarbital, or primidone) (2).

Reproduction studies with zonisamide have been conducted during organogenesis in mice, rats, dogs, and cynomolgus monkeys. In pregnant mice, doses approximately 1.5–6.0 times the maximum recommended human dose of 400 mg/day based on BSA (MRHD-BSA) were associated with increased rates of fetal malformations (skeletal and/or craniofacial defects). In

rats, increased frequencies of malformations (cardiovascular defects) and variations (persistent cords of thymic tissue and decreased skeletal ossification) were observed at all doses tested (0.5–5.0 times the MRHD-BSA). Perinatal deaths resulted when a dose 1.4 times the MRHD-BSA was given in the latter part of gestation up to weaning. The no-effect level for this toxicity was 0.7 times the MRHD-BSA (1).

In pregnant dogs, doses that produced peak maternal plasma levels (25 mcg/mL) about 0.5 times the highest plasma levels measured in humans receiving the maximum recommended human dose of 400 mg/day (MRHD-PL) resulted in an increased incidence of fetal cardiovascular defects (ventricular septal defects, cardiomegaly, and valvular and arterial anomalies). At doses that produced plasma levels (44 mcg/mL) approximately equal to the MRHD-PL, about 50% of the fetuses had cardiovascular malformations as well as increased incidences of skeletal malformations. Fetal growth restriction and increased rates of skeletal variations were observed with peak maternal dog plasma levels produced by all doses tested (0.25–1.0 times the MRHD-PL). When zonisamide was given to pregnant monkeys at doses approximately 0.1 times the MRHD-PL or higher, embryo–fetal deaths were observed. The cause of the deaths was unknown, but the possibility that they were due to malformations could not be excluded (1).

Zonisamide was not carcinogenic in mice and rats after 2 years of dietary administration. The agent was mutagenic in one test but not mutagenic or clastogenic in other tests (1).

No reports describing the placental crossing of zonisamide early in gestation have been located. At term delivery of one newborn, the cord blood and maternal blood concentrations were 14.4 and 15.7 mcg/mL (ratio 0.92), respectively (3). A comparable amount of drug was found in a second full-term newborn, but specific data were not given. Zonisamide probably also crosses the placenta early in gestation because of its low molecular weight (about 212). In addition, the long elimination half-life from red blood cells and plasma will result in prolonged concentrations of the drug at the maternal blood:placenta interface, thus increasing the opportunity for embryo/fetal exposure.

A 1996 report described the outcomes of 26 offspring whose mothers had been treated with zonisamide during pregnancy (22 women; 25 pregnancies; 1 set of twins). The offspring were exposed to zonisamide either alone (4 cases) or combined with other anticonvulsants (22 cases) (4). Doses ranged from 100 to 600 mg/day. There were 2 elective abortions and 24 liveborn infants (1 set of twins). Two offspring (7.7%), both exposed to combination anticonvulsants,

had major malformations. Neither of the mothers experienced seizures during pregnancy. The first case, electively terminated at 16 weeks' gestation, involved an anencephalic fetus (sex unknown) exposed to zonisamide (100 mg/day) and phenytoin (275 mg/day) throughout gestation. The second infant, a 2022-g female, was delivered by cesarean section at 37 weeks' gestation. She had an atrial septal defect. Combination therapy throughout gestation included zonisamide (200 mg/day), phenytoin (200 mg/day), and valproic acid (400 mg/day) (4).

In a 2002 case report, two women took multiple anticonvulsants throughout gestation and delivered apparently normal infants at about 40 weeks' gestation (3). One of the women took zonisamide (400 mg/day), carbamazepine (1000 mg/day) and clonazepam (1 mg/day), whereas the other took zonisamide (400 mg/day) and carbamazepine (800 mg/day). Both newborns had Apgar scores at 1 and 5 minutes of 8 and 9, respectively. Birth weights were 3094 g and 3164 g, respectively (3).

The Lamotrigine Pregnancy Registry, an ongoing project conducted by the manufacturer, was first published in January 1997. The final report was published in July 2010 (5). The Registry is now closed. There were 12 prospectively enrolled pregnancies exposed to zonisamide and lamotrigine, with or without other anticonvulsants in the 1st trimester, resulting in 12 live births without birth defects (5).

The effect of zonisamide on folic acid levels and metabolism is unknown. A 2003 review recommended that to reduce the risk of birth defects from anticonvulsants, women should start multivitamins with folic acid before conception (6). Although the recommendation did not specify the amount of folic acid, a recent study found that multivitamin supplements with folic acid (typically 0.4 mg) did not reduce the risk of congenital malformations from four first-generation anticonvulsants (see Carbamazepine, Phenytoin, Phenobarbital, or Primidone). Therefore, until further information is available, the best course is to start folic acid supplementation before conception. Although a specific dosage has not been recommended for patients receiving anticonvulsants, 4 mg/day appears to be reasonable.

BREASTFEEDING SUMMARY

Zonisamide is excreted into breast milk. A woman took 300 mg/day (100 mg three times daily) during pregnancy and continued the anticonvulsant while breastfeeding (7). The cord plasma drug concentration at delivery was 6.72 mcg/mL, 2.5 hours after a dose. Milk and maternal plasma levels were

determined on postpartum days 3, 6, 14, and 30 (1.5–2.5 hours after a dose). Milk concentrations ranged from 8.25 (day 3) to 10.5 mcg/mL (day 30), whereas maternal plasma levels ranged from 9.52 (day 14) to 10.6 mcg/mL (day 3). The milk:plasma (M:P) ratio consistently increased at each sampling. The average milk:plasma ratio was 0.93 (range 0.81–1.03). No neonatal behavior problems were observed (7).

In another report, two mothers receiving zonisamide (400 mg/day) and other anticonvulsants (mother no. 1: carbamazepine and clonazepam; mother no. 2: carbamazepine) throughout gestation as well as postpartum breastfed their apparently normal infants (see above) (3). Zonisamide concentrations were determined in the breast milk of mother no. 1. From delivery to postpartum day 9, the unbound maternal plasma zonisamide concentration ranged from 10.7 to 13.3 mcg/mL, whereas the total zonisamide level ranged from 17.5 to 25.2 mcg/mL. During the same interval, the drug concentrations in the watery portion of the milk (i.e., whey) ranged from 8.9 to 10.9 mcg/mL. The breast milk transfer rate was 41%–57%. The plasma zonisamide level in the infant on day 24 was 3.9 mcg/mL (15% of the mother's level on postpartum day 9). No adverse effects in either nursing infant were mentioned (3).

No adverse effects were noted in four nursing infants, but the milk concentrations were high enough that clinically significant doses appear to have been ingested. The relatively high plasma level found in one infant supports this assessment. Therefore, if a woman under treatment with zonisamide chooses to breastfeed, close clinical monitoring of her infant is recommended as well as the measurement of infant plasma drug levels. The long-term effects on nursing infants from this exposure are unknown but warrant investigation.

ZUCLOPENTHIXOL

[Withdrawn from the market. See 9th edition.]

APPENDIX

Classification of Drugs by Pharmacologic Category

[See drug's generic name in Index for location of drug in this Appendix.]

1. ANESTHETICS

A. Local

Benzocaine
Camphor
Lidocaine
Pramoxine
Ropivacaine
Tetracaine

B. General

Desflurane
Enflurane
Halothane
Isoflurane
Ketamine
Methohexital Sodium
Nitrous Oxide
Sevoflurane

2. ANTIDOTES

Acetylcysteine
Black Widow Spider Antivenin
Centruroides Immune (Scorpion) F(ab')₂ (Equine)
Deferasirox
Deferoxamine
Digoxin Immune FAB (Ovine)
Dimercaprol

Edetate Calcium Disodium
Flumazenil
Fomepizole
Glucagon
Glucarpidase
Lanthanum Carbonate
Pralidoxime
Sapropterin
Sevelamer
Succimer

3. ANTIHISTAMINES

Azelastine
Brompheniramine
Carbinoxamine
Cetirizine
Chlorcyclizine
Chlorpheniramine
Clemastine
Cyclizine
Cyproheptadine
Desloratadine
Dexbrompheniramine
Dexchlorpheniramine
Dimenhydrinate
Diphenhydramine
Doxylamine
Epinastine
Fexofenadine
Hydroxyzine
Levocetirizine
Loratadine
Meclizine
Olopatadine
Pheniramine
Phenyltoloxamine
Promethazine
Pyrilamine

Tripolidine

4. ANTI-INFECTIVES

A. Amebicide

Iodoquinol
Metronidazole
Paromomycin

B. Aminoglycosides

Amikacin
Gentamicin
Kanamycin
Neomycin
Paromomycin
Streptomycin
Tobramycin

Enfuvirtide
Maraviroc

J. Other Antivirals

Acyclovir
Adefovir
Amantadine
Boceprevir
Cidofovir
Entecavir
Famciclovir
Foscarnet
Ganciclovir
Idoxuridine
Oseltamivir
Penciclovir
Ribavirin
Rimantadine
Telaprevir
Valacyclovir
Valganciclovir
Vidarabine
Zanamivir

K. Cephalosporins

Cefaclor

Cefadroxil
Cefazolin
Cefdinir
Cefditoren
Cefepime
Cefixime
Cefotaxime
Cefotetan
Cefoxitin
Cefpodoxime
Cefprozil
Ceftaroline
Ceftazidime
Ceftibuten
Ceftizoxime
Ceftriaxone
Cefuroxime
Cephalexin

L. Iodine

Iodine
Povidone-Iodine

M. Leprostatics

Clofazimine
Dapsone

N. Macrolides

Azithromycin
Clarithromycin
Erythromycin

O. Penicillins

Amoxicillin
Ampicillin
Carbenicillin
Dicloxacillin
Nafcillin

Oxacillin
Penicillin G
Penicillin G, Benzathine
Penicillin G, Procaine
Penicillin V
Piperacillin
Ticarcillin

P. Quinolones

Cinoxacin
Ciprofloxacin
Gemifloxacin
Levofloxacin
Lomefloxacin
Moxifloxacin
Nalidixic Acid
Norfloxacin
Ofloxacin

Q. Scabicide/Pediculicide

Benzyl Alcohol
Lindane
Permethrin
Pyrethrins with Piperonyl Butoxide

R. Sulfonamides

Sulfonamides

S. Tetracyclines

Chlortetracycline
Clomocycline
Demeclocycline
Doxycycline
Minocycline
Oxytetracycline
Tetracycline
Tigecycline

T. Trichomonacides

Metronidazole

U. Urinary Germicides

Cinoxacin

Methenamine

Methylene Blue

Nalidixic Acid

Nitrofurantoin

5. ANTILIPEMIC AGENTS

A. Bile Acid Sequestrants

Cholestyramine

Colesevelam

Colestipol

B. Fibric Acid Derivatives

Gemfibrozil

Fenofibrate

C. HMG-CoA Inhibitors (statins)

Atorvastatin

Fluvastatin

Lovastatin

Pitavastatin

Pravastatin

Rosuvastatin

Simvastatin

D. Thyroid

Dextrothyroxine

E. Vitamin

Niacin

F. Miscellaneous

Ezetimibe
Lomitapide

6. ANTINEOPLASTICS

Cytoprotectants

Amifostine

Dexrazoxane

Mesna

A. Alkylating Agents

Bendamustine

Busulfan

Carmustine

Chlorambucil

Cyclophosphamide

Dacarbazine

Ifosfamide

Mechlorethamine

Melphalan

Streptozocin

B. Anthracenedione

Mitoxantrone

C. Anthracycline Antibiotics

Daunorubicin

Doxorubicin

Epirubicin

Idarubicin

Valrubicin

D. Antiandrogen

Enzalutamide

E. Antibody-Drug Conjugate

Brentuximab Vedotin

F. Antibiotics

Bleomycin
Dactinomycin
Mitomycin

G. Antimetabolites

i. Folic Acid Antagonists

Methotrexate
Pemetrexed
Pralatrexate

ii. Purine Analogs

Cladribine
Clofarabine
Fludarabine phosphate
Mercaptopurine
Pentostatin
Thioguanine

iii. Pyrimidine Analogs

Capecitabine
Cytarabine
Floxuridine
Fluorouracil
Gemcitabine

iv. Agents That Reduce Uric Acid Levels

Allopurinol
Rasburicase

H. Antimitotics

i. Epothilones

Ixabepilone

ii. Taxoids

Cabazitaxel
Docetaxel
Paclitaxel

iii. Vinca Alkaloids

Vinblastine
Vincristine
Vinorelbine

I. Aromatase inhibitors

Letrozole

J. Biological Response Modifiers

Aldesleukin

Denileukin Diftitox

K. DNA Demethylation Agents

Azacitidine

Decitabine

Nelarabine

L. DNA Topoisomerase Inhibitors

Irinotecan

Topotecan

M. Enzymes

Asparaginase

N. Epipodophyllotoxins

Etoposide

Teniposide

O. Histone Deacetylase Inhibitors

Romidepsin

Vorinostat

P. Hormones

Abiraterone Acetate

Exemestane

Leuprolide

Tamoxifen

Q. Imidazotetrazine Derivatives

Temozolomide

R. Kinase Inhibitors

i. BRAF Inhibitor

Vemurafenib

ii. Janus Associated Kinase Inhibitor

Ruxolitinib

iii. mTOR Inhibitors

Everolimus

Temsirolimus

iv. Multikinase Inhibitors

Sorafenib

Regorafenib

v. Tyrosine Kinase Inhibitors

Axitinib

Bosutinib

Cabozantinib

Crizotinib

Dasatinib

Erlotinib

Gefitinib

Imatinib

Lapatinib

Nilotinib

Pazopanib

Ponatinib

Sunitinib

Vandetanib

Ziv-Aflibercept

S. Methylhydrazine Derivatives

Procarbazine

T. Monoclonal Antibodies

Alemtuzumab

Bevacizumab

Cetuximab

Ipilimumab

Ibritumomab Tiuxetan

Ofatumumab

Panitumumab

Pertuzumab

Rituximab
Trastuzumab

U. Nontaxane Microtubule Dynamic Inhibitor

Eribulin

V. Platinum Coordination Complex

Carboplatin

Cisplatin

Oxaliplatin

W. Protein Synthesis Inhibitor

Omacetaxine

X. Proteasome Inhibitor

Bortezomib

Carfilzomib

Y. Retinoids

Bexarotene

Tretinoin (Systemic)

Z. Substituted Ureas

Hydroxyurea

ZZ. Miscellaneous

Interferon Alfa

(includes Interferon Alfa -n3, -NL, -2a, and -2b)

Porfimer

Thiotepa

Trimetrexate

Vismodegib

7. ARTIFICIAL SWEETENERS

Aspartame

Cyclamate

Saccharin

8. AUTONOMICS

A. Parasympathomimetics (Cholinergics)

Bethanechol
Carbachol
Cevimeline
Echothiophate
Edrophonium
Neostigmine
Physostigmine
Pilocarpine
Pyridostigmine

B. Parasympatholytics (Anticholinergics)

Atropine
Belladonna
Benztropine
Clidinium
Dicyclomine
Glycopyrrolate
Homatropine
l-Hyoscyamine
Mepenzolate
Methscopolamine
Propantheline
Scopolamine
Trihexyphenidyl

C. Sympatholytics

Acebutolol
Atenolol
Betaxolol
Bisoprolol
Carteolol
Carvedilol
Dihydroergotamine
Doxazosin
Ergotamine

Esmolol
Guanethidine
Guanfacine
Labetalol
Metoprolol
Nadolol
Nebivolol
Penbutolol
Pindolol
Prazosin
Propranolol
Sotalol
Tamsulosin
Terazosin
Timolol

D. Sympathomimetics (Adrenergics)

Albuterol
Cocaine
Dobutamine
Dopamine
Ephedrine
Epinephrine
Isometheptene
Isoproterenol
Isoxsuprine
Midodrine
Norepinephrine
Oxymetazoline
Phenylephrine
Pseudoephedrine
Terbutaline

9. BISPHOSPHONATES

Alendronate
Etidronate
Ibandronate
Pamidronate

Risedronate
Tiludronate
Zoledronic Acid

10. CALCIUM RECEPTOR AGONIST

Cinacalcet

11. CARDIOVASCULAR DRUGS

A. Antihypertensives

i. Angiotensin Converting Enzyme Inhibitors

Benazepril
Captopril
Enalapril
Fosinopril
Lisinopril
Moexipril
Perindopril
Quinapril
Ramipril
Trandolapril

ii. Angiotensin II Receptor Antagonists

Azilsartan
Candesartan Cilexetil
Eprosartan
Irbesartan
Losartan
Olmesartan
Telmisartan
Valsartan

iii. Renin Inhibitor

Aliskiren

iv. Other Antihypertensives

Acebutolol
Atenolol
Betaxolol
Bisoprolol

Carteolol
Carvedilol
Clonidine
Diazoxide
Doxazosin
Epoprostenol
Esmolol
Fenoldopam
Guanabenz
Guanadrel
Guanethidine
Guanfacine
Hydralazine
Labetalol
Mepindolol
Methyldopa
Metoprolol
Metyrosine
Minoxidil
Nadolol
Nebivolol
Nitroprusside
Oxprenolol
Penbutolol
Phenoxybenzamine
Phentolamine
Pindolol
Prazosin
Propranolol
Reserpine
Terazosin
Sotalol
Timolol

B. Calcium Channel Blockers

Amlodipine
Clevidipine
Diltiazem

Felodipine
Isradipine
Nicardipine
Nifedipine
Nimodipine
Nisoldipine
Verapamil

C. Cardiac Drugs

Acetyldigitoxin
Adenosine
Amiodarone
Deslanoside
Digitalis
Digitoxin
Digoxin
Disopyramide
Dofetilide
Dronedarone
Flecainide
Ibutilide
Lanatoside C
Lidocaine
Mexiletine
Milrinone
Morcizine
Procainamide
Propafenone
Quinidine
Sotalol

D. Vasodilators

Ambrisentan
Amyl Nitrite
Bosentan
Epoprostenol
Erythryl Tetranitrate
Hydralazine

Iloprost
Isosorbide Dinitrate
Isosorbide Mononitrate
Isoxsuprine
Minoxidil
Nesiritide
Nitroglycerin
Sildenafil

E. Sclerosing Agents

Polidocanol

F. Miscellaneous Antianginal Agents

Ranolazine

12. CENTRAL NERVOUS SYSTEM DRUGS

A. Analgesics and Antipyretics

Acetaminophen
Antipyrine
Ziconotide

B. Antialcoholic Agents

Acamprosate
Disulfiram

C. Antichorea

Tetrabenazine

D. Anticonvulsants

Bromides
Carbamazepine
Clobazam
Clonazepam
Clorazepate
Ethosuximide
Ethotoin
Ezogabine

Felbamate
Gabapentin
Gabapentin Enacarbil
Lacosamide
Lamotrigine
Levetiracetam
Magnesium Sulfate
Methsuximide
Oxcarbazepine
Perampanel
Phenobarbital
Phenytoin
Pregabalin
Primidone
Rufinamide
Tiagabine
Topiramate
Valproic Acid
Zonisamide

E. Antidepressants

i. Aminoketone

Bupropion

ii. Monoamine Oxidase Inhibitors

Isocarboxazid

Phenelzine

Tranylcypromine

iii. Phenylpiperazine

Nefazodone

iv. Selective Serotonin Reuptake Inhibitors

Citalopram

Escitalopram

Fluoxetine

Fluvoxamine

Paroxetine

Sertraline

Vilazodone

v. Serotonin and Norepinephrine Reuptake Inhibitors

Duloxetine
Desvenlafaxine
Milnacipran
Venlafaxine

vi. Tetracyclics

Maprotiline
Mirtazapine

vii. Tricyclics

Amitriptyline
Amoxapine
Clomipramine
Desipramine
Doxepin
Imipramine
Nortriptyline
Protriptyline
Trimipramine

viii. Triazolopyridine

Trazodone

F. Antimigraine Agents

Almotriptan
Dihydroergotamine
Eletriptan
Ergotamine
Frovatriptan
Naratriptan
Rizatriptan
Sumatriptan
Zolmitriptan

G. Antiparkinson Agents

Amantadine
Carbidopa
Entacapone
Levodopa
Pramipexole
Rasagiline

Ropinirole
Selegiline
Tolcapone

H. Antipsychotics

Typical Antipsychotics

i. Phenylbutylpiperadines

Butyrophenones
Droperidol
Haloperidol
Diphenylbutylpiperadines
Pimozide

ii. Phenthiazines

Chlorpromazine
Fluphenazine
Perphenazine
Prochlorperazine
Thioridazine
Trifluoperazine

iii. Thioxanthenes

Thiothixene

Atypical Antipsychotics

i. Benzoisothiazol

Lurasidone

ii. Benzisoxazoles

Iloperidone
Paliperidone
Risperidone
Ziprasidone

iii. Dibenzapines

Asenapine
Clozapine
Loxapine
Olanzapine
Quetiapine

iv. Quinolinones

Aripiprazole

Miscellaneous Antipsychotics

Lithium

I. Central Analgesics

Clonidine

J. Cholinesterase Inhibitors

Donepezil

Galantamine

Rivastigmine

K. Hallucinogens

Lysergic Acid Diethylamide

Marijuana

Mescaline

Peyote

Phencyclidine

Salvia Divinorum

L. Narcotic Agonist Analgesics

Alfentanil

Codeine

Dihydrocodeine

Fentanyl

Heroin

Hydrocodone

Hydromorphone

Levorphanol

Meperidine

Methadone

Morphine

Oxycodone

Oxymorphone

Remifentanil

Sufentanil

Tapentadol

Tramadol

M. Narcotic Agonist–Antagonist Analgesics

Buprenorphine
Butorphanol
Nalbuphine
Pentazocine

N. Narcotic Antagonists

Methylnaltrexone
Naloxone
Naltrexone

O. Nonsteroidal Anti-inflammatory Drugs

Aspirin
Celecoxib
Diclofenac
Diflunisal
Etodolac
Fenoprofen
Flurbiprofen
Ibuprofen
Indomethacin
Ketoprofen
Ketorolac
Meclofenamate
Mefenamic Acid
Meloxicam
Nabumetone
Naproxen
Oxaprozin
Oxyphenbutazone
Piroxicam
Sulindac
Tolmetin

P. Physical Adjunct

Botulinum Toxin Type A

Q. Potassium Channel Blocker

Dalfampridine

R. Psychotherapeutics (Miscellaneous)

Atomoxetine

Sodium Oxybate

S. Sedatives and Hypnotics

Alprazolam

Amobarbital

Bromides

Buspirone

Butalbital

Chloral Hydrate

Chlordiazepoxide

Clorazepate

Dexmedetomidine

Diazepam

Dichloralphenazone

Estazolam

Eszopiclone

Ethanol

Ethchlorvynol

Etomidate

Flurazepam

Fospropofol

Lorazepam

Mephobarbital

Meprobamate

Methotrimeprazine

Midazolam

Oxazepam

Pentobarbital

Phenobarbital

Propofol

Quazepam

Ramelteon

Secobarbital

Temazepam

Triazolam
Zaleplon
Zolpidem

T. Skeletal Muscle Relaxants

Atracurium
Baclofen
Carisoprodol
Chlorzoxazone
Cyclobenzaprine
Dantrolene
Metaxalone
Methocarbamol
Orphenadrine
Pancuronium
Rocuronium
Succinylcholine
Tizanidine
Vecuronium

U. Smoking Deterrents

Bupropion
Clonidine
Nicotine Replacement Therapy
Nortriptyline
Varenicline

V. Stimulants and/or Anorexiant

Amphetamine
Armodafinil
Benzphetamine
Caffeine
Cigarette Smoking
Dexmethylphenidate
Dextroamphetamine
Diethylpropion
Doxapram
Ecstasy

Lisdexamfetamine
Lorcaserin
Methamphetamine
Methylphenidate
Modafinil
Phendimetrazine
Phentermine

W. Miscellaneous

Riluzole

13. CHELATING AGENTS

Deferoxamine
Deferasirox
Penicillamine
Succimer
Trientine

14. DERMATOLOGIC AGENTS

Acitretin
Adapalene
Anthralin
Azficel-T
Butenafine
Calcipotriene
Calcitriol
Collagenase Clostridium Histolyticum
Etretinate
Fluocinolone
Fluocinonide
Hydroquinone
Ingenol Mebutate
Isotretinoin
Kunecatechins
Methoxsalen
Spinosad
Tazarotene

Tretinoin (Topical)

15. DIAGNOSTIC AGENTS

Diatrizoate
Ethiodized Oil
Evans Blue
Fluorescein Sodium
Gadobenate Dimeglumine
Gadobutrol
Gadodiamide
Gadofosveset
Gadopentetate Dimeglumine
Gadoteridol
Gadoversetamide
Indigo Carmine
Iocetamic Acid
Iodipamide
Iodoxamate
Ioflupane I¹²³
Iohexol
Iopamidol
Iopanoic Acid
Iothalamate
Iodate
Methylene Blue
Technetium Tc-99m

16. DIETARY SUPPLEMENTS

Chondroitin
Glucosamine
Omega-3 Fatty Acid Supplements
Stevia

17. DIURETICS

Acetazolamide
Amiloride
Bendroflumethiazide

Benzthiazide
Bumetanide
Chlorothiazide
Chlorthalidone
Dehydroepiandrosterone
Dichlorphenamide
Ethacrynic Acid
Furosemide
Hydrochlorothiazide
Hydroflumethiazide
Indapamide
Isosorbide
Mannitol
Methazolamide
Methyclothiazide
Metolazone
Polythiazide
Spironolactone
Torsemide
Triamterene
Trichlormethiazide
Urea

18. ELECTROLYTES

Potassium Chloride
Potassium Citrate
Potassium Gluconate

19. ENDOCRINE/METABOLIC AGENTS

A. Adrenal

Beclomethasone
Betamethasone
Budesonide
Cortisone
Dexamethasone
Hydrocortisone

Prednisolone
Prednisone
Triamcinolone

B. Androgens

Danazol
Fluoxymesterone
Methyltestosterone
Testosterone

C. Antiadrenal

Aminoglutethimide

D. Antidiabetic Agents

i. Alpha-Glucosidase Inhibitors

Acarbose
Miglitol

ii. Amylin Analog

Pramlintide

iii. Biguanides

Metformin

iv. Dipeptidyl Peptidase-4 Inhibitors

Linagliptin
Saxagliptin
Sitagliptin

v. Glucagon-like Peptide 1 Receptor Agonists

Exenatide
Liraglutide

vi. Insulins

Insulin
Insulin Aspart
Insulin Detemir
Insulin Glargine
Insulin Glulisine
Insulin Lispro

vii. Meglitinides

Nateglinide
Repaglinide

viii. Sulfonylureas

Chlorpropamide

Glimepiride

Glipizide

Glyburide

Tolazamide

Tolbutamide

ix. Thiazolidinediones

Pioglitazone

Rosiglitazone

E. Antiestrogens

Tamoxifen

F. Antigout

i. Uricosurics

Allopurinol

Febuxostat

Pegloticase

Probenecid

ii. Miscellaneous

Colchicine

G. Antiprogestogen

Mifepristone

H. Antithyroid

Carbimazole

Methimazole

Propylthiouracil

Sodium Iodide ¹³¹I

I. Calcium Regulation Hormone

Calcitonin-Salmon

J. Emergency Contraceptive

Ulipristal

K. Enzymes

Agalsidase Alfa
Agalsidase Beta
Alglucosidase Alfa
Alpha-Galactosidase A
Galsulfase
Laronidase

L. Estrogens

Clomiphene
Diethylstilbestrol
Estradiol
Estrogens, Conjugated
Estrone
Ethinyl Estradiol
Mestranol
Oral Contraceptives

M. Gaucher Disease

Alglucerase
Imiglucerase
Miglustat
Taliglucerase Alfa
Velaglucerase Alfa

N. Growth Hormone Receptor Antagonist

Pegvisomant

O. Growth Hormone Releasing Factor

Tesamorelin

P. Hyperammonemia

Carglumic Acid

Q. Pineal Gland

Melatonin

R. Pituitary

Corticotropin/Cosyntropin
Desmopressin
Leuprolide
Somatostatin
Vasopressin

S. Progestogens

Ethinodiol
17 Alpha-Hydroxyprogesterone
Medroxyprogesterone
Norethindrone
Norgestrel
Oral Contraceptives

T. Prostaglandins

Carboprost
Dinoprostone

U. Selective Estrogen Receptor Modulator

Raloxifene

V. Somatostatin Analogs

Octreotide
Pasireotide

W. Thyroid Agents

Levothyroxine
Liothyronine
Liotrix
Thyroglobulin
Thyroid
Thyrotropin

X. Vasopressin Receptor Antagonists

Conivaptan
Tolvaptan

Y. Miscellaneous Agents

Bromocriptine
Cabergoline
Ivacaftor

20. GASTROINTESTINAL AGENTS

A. Antacids

Calcium Carbonate
Sodium Bicarbonate

B. Antidiarrheals

Alosetron
Bismuth Subsalicylate
Crofelemer
Diphenoxylate
Kaolin/Pectin
Loperamide
Opium

C. Antiemetics

Alosetron
Aprepitant
Cyclizine
Dimenhydrinate
Dolasetron
Doxylamine
Dronabinol
Droperidol
Granisetron
Meclizine
Metoclopramide
Nabilone
Ondansetron
Palonosetron
Prochlorperazine
Promethazine
Trimethobenzamide

D. Antiflatulents

Simethicone

E. Anti-inflammatory Bowel Disease Agents

Balsalazide

Infliximab

Mesalamine

Olsalazine

Sulfasalazine

F. Antisecretory Agents

i. H₂-Receptor Antagonists

Cimetidine

Famotidine

Nizatidine

Ranitidine

ii. Proton Pump Inhibitors

Dexlansoprazole

Esomeprazole

Lansoprazole

Omeprazole

Pantoprazole

Rabeprazole

iii. Miscellaneous

Misoprostol

Sucralfate

G. Gallstone Solubilizing Agents

Chenodiol

Ursodiol

H. Glucagon-Like Peptide-2 Analog

Teduglutide

I. Laxatives/Purgatives

Bisacodyl

Casanthranol

Cascara Sagrada

Castor Oil
Docusate Calcium
Docusate Potassium
Docusate Sodium
Glycerin
Lactulose
Linaclotide
Lubiprostone
Magnesium Sulfate
Mineral Oil
Polyethylene Glycol (3350 & 4000)
Senna

J. Lipase Inhibitors

Orlistat

K. Peripheral Opioid Antagonist

Alvimopan

L. Stimulants

Dexpanthenol
Metoclopramide

21. HEMATOLOGIC AGENTS

A. Anticoagulants

Apixaban
Coumarin Derivatives
Dalteparin
Dabigatran Etexilate
Enoxaparin
Ethyl Biscoumacetate
Fondaparinux
Heparin
Nicoumalone
Phenindione
Phenprocoumon
Reviparin

Rivaroxaban
Warfarin

B. Antiheparin

Protamine

C. Antihemophilic

Factor XIII Concentrate (Human)

D. Antiplatelet

i. Aggregation Inhibitors

Cilostazol

Clopidogrel

Prasugrel

Ticagrelor

Ticlopidine

Treprostinil

ii. Glycoprotein IIb/IIIa Inhibitors

Abciximab

Eptifibatide

Tirofiban

iii. Miscellaneous

Anagrelide

Dipyridamole

E. Bradykinin Inhibitor

Icatibant

F. Hematopoietic

Darbepoetin Alfa

Eltrombopag

Epoetin Alfa

Filgrastim

Hemin

Oprelvekin

Pegfilgrastim

Peginesatide

Plerixafor

Romiplostim
Sargramostim

G. Hemorrhologic

Pentoxifylline

H. Hemostatics

Aminocaproic Acid

Aprotinin

Tranexamic Acid

I. Kallikrein Inhibitor

Ecallantide

J. Thrombin Inhibitor

Antithrombin III (Human)

Argatroban

Bivalirudin

Desirudin

Lepirudin

K. Thrombolytics

Alteplase

Drotrecogin Alfa (Activated)

Retepase

Tenecteplase

Urokinase

22. HERBS

Arnica

Black Seed/Kalanji

Blue Cohosh

Chamomile

Echinacea

Evening Primrose Oil

Feverfew

Garlic

Ginger

Ginkgo Biloba
Ginseng
Kudzu
Nutmeg
Passion Flower
Peppermint
Pumpkin Seed
Raspberry Leaf
Safflower
Salvia Divinorum
St. John's Wort
Valerian
Yohimbine

23. IMMUNOLOGIC AGENTS

A. Antihemolysis

Eculizumab

B. Antiosteoporosis

Denosumab

C. Antirheumatic Agents

Abatacept

Auranofin

Gold Sodium Thiomalate

Hydroxychloroquine

Infliximab

Leflunomide

Methotrexate

Sulfasalazine

Tofacitinib

D. Immunomodulators

Adalimumab

Anakinra

Belimumab

Canakinumab

Certolizumab Pegol
Etanercept
Fingolimod
Golimumab
Imiquimod
Infliximab
Interferon Alfa (includes Interferon Alfa-n3, -NL, -2a, and -2b)
Interferon Beta-1b
Interferon Gamma-1b
Lenalidomide
Natalizumab
Pimecrolimus
Rilonacept
Teriflunomide
Thalidomide
Tocilizumab
Ustekinumab

E. Immunosuppressants

Alefacept
Azathioprine
Basiliximab
Belatacept
Cyclosporine
Daclizumab
Efalizumab
Glatiramer
Muromonab-CD3
Mycophenolate
Rituximab
Sirolimus
Tacrolimus

24. IMPOTENCE AGENTS

Avanafil
Sildenafil
Yohimbine

25. KERATOLYTIC AGENTS

Podofilox
Podophyllum

26. KERATINOCYTE GROWTH FACTOR

Palifermin

27. NUTRIENTS/NUTRITIONAL SUPPLEMENTS

Calcium Carbonate
Hyperalimentation, Parenteral
Lipids
L-Lysine
Melatonin

28. OPHTHALMICS

A. Antihistamine

Alcaftadine
Bepotastine

B. Anti-infective

Besifloxacin
Gatifloxacin

C. Corticosteroid

Fluocinolone

D. Mast Cell Stabilizer

Lodoxamide

D. Nonsteroidal Anti-inflammatory

Bromfenac
Nepafenac

E. Phototherapy

Verteporfin

F. Prostaglandin Agonist

Bimatoprost

Latanoprost

Tafluprost

Travoprost

G. Selective Vascular Endothelial Growth Factor Antagonist

Pegaptanib

Ranibizumab

H. Sympathomimetic (Adrenergic)

Naphazoline

I. Miscellaneous

Ocriplasmin

29. OXYTOCICS

Castor Oil

Methylergonovine Maleate

Misoprostol

30. RADIOPHARMACEUTICALS

Sodium Iodide ¹²⁵I

Sodium Iodide ¹³¹I

31. RESPIRATORY DRUGS

A. Anti-inflammatory (Inhaled)

Cromolyn Sodium

Nedocromil Sodium

B. Antitussives

Codeine

Dextromethorphan

Hydrocodone

C. Bronchodilators

i. β_2 -Adrenergic Agents

Albuterol

Arformoterol

Formoterol

Indacaterol

Levalbuterol

Metaproterenol

Pirbuterol

Salmeterol

Terbutaline

ii. Other Sympathomimetics

Ephedrine

Epinephrine

Isoproterenol

iii. Xanthine Derivatives

Aminophylline

Dyphylline

Theophylline

iv. Anticholinergics

Aclidinium

Ipratropium

Tiotropium

D. Corticosteroids (Inhaled)

Beclomethasone

Budesonide

Ciclesonide

Flunisolide

Fluticasone

Mometasone

Triamcinolone

E. Expectorants

Ammonium Chloride

Guaifenesin

Iodinated Glycerol

Potassium Iodide

Sodium Iodide
Terpin Hydrate

F. Leukotriene Receptor Antagonists

Montelukast
Zafirlukast

G. Leukotriene Formation Inhibitor

Zileuton

H. Monoclonal Antibody

Omalizumab
Palivizumab

I. Mucolytic

Acetylcysteine
Dornase Alfa

J. Phosphodiesterase Inhibitor

Roflumilast

32. SERUMS AND TOXOIDS

A. Serums

Immune Globulin, Hepatitis B
Immune Globulin Intramuscular
Immune Globulin Intravenous
Immune Globulin, Rabies
Immune Globulin, Tetanus
Immune Globulin, Varicella Zoster (Human)

B. Toxoids

Tetanus/Diphtheria Toxoids (Adult)

33. TOXINS

Ciguatoxin

34. URINARY TRACT AGENTS

A. Analgesic

Pentosan

Phenazopyridine

B. Antispasmodics

Darifenacin

Fesoterodine

Flavoxate

Mirabegron

Oxybutynin

Solifenacin

Tolterodine

Trospium

C. Urinary Acidifier

Ammonium Chloride

D. Urinary Alkalinizers

Potassium Citrate

E. Urinary Germicides

(see Anti-infectives, Section T)

35. VACCINES

Adenovirus Type 4 and Type 7, Live

Anthrax

BCG

Cholera

Escherichia coli

Group B Streptococcal

Haemophilus b Conjugate

Hepatitis A

Hepatitis B

Human Papillomavirus Bivalent

Human Papillomavirus Quadrivalent

Influenza
Influenza A (H1N1)
Lyme Disease
Measles
Meningococcal
Mumps
Plague
Pneumococcal Polyvalent
Poliovirus Inactivated
Poliovirus Live
Rabies (Human)
Rubella
Smallpox
TC-83 Venezuelan Equine Encephalitis
Tetanus/Diphtheria Toxoids & Acellular Pertussis
Tularemia
Typhoid
Varicella Virus
Yellow Fever

36. VAGINAL SPERMICIDES

Nonoxynol-9/Octoxynol-9

37. VITAMINS

Acitretin
 β -Carotene
Calcifediol
Calcitriol
Cholecalciferol
Dexpanthenol
Dihydrotachysterol
Ergocalciferol
Etretinate
Folic Acid
Isotretinoin
Leucovorin
Niacin

Niacinamide
Pantothenic Acid
Paricalcitol
Phytonadione
Pyridoxine
Riboflavin
Thiamine
Tretinoin (Systemic)
Vitamin A
Vitamin B₁₂
Vitamin C
Vitamin D
Vitamin E
Vitamins, Multiple

38. MISCELLANEOUS

Electricity
Silicone Breast Implants

Index

Generic names are shown in **bold** with two sets of page numbers. The first set, also shown in **bold**, refers to the page number in the text where the monograph is located. The second set, shown in parentheses, refers to the page number in the Appendix where the drug is located by pharmacologic class. The trade names and synonyms are shown with one set of page numbers. These refer to their location in the text.

A

A-200, see Pyrethrins with Piperonyl Butoxide, 1172

A-Acido, see Tretinoin, 1395

Abacavir, 1, (1524)

Abatacept, 2, (1531)

Abbecillin, see Penicillin G, 1080

Abbecillin-VK, see Penicillin V, 1082

Abboject, see Erythromycin, 491

Abbokinase, see Urokinase, 1414

Abboticin, see Erythromycin, 491

Abboticine, see Erythromycin, 491

Abciximab, 3, (1530)

AB Elixir, see Theophylline, 1350

Aberel, see Tretinoin, 1395

Aberela, see Tretinoin, 1395

Aberil, see Thiamine, 1352

Abicol, see Reserpine, 1207

Abilify, see Aripiprazole, 83

Abine, see Gemcitabine, 617

Abiraterone Acetate, 4, (1525)

Ablavar, see Gadofosveset, 607

Abopur, see Allopurinol, 40

Abstensyl, see Disulfiram, 420

Abstinyll, see Disulfiram, 420

Acalix, see Diltiazem, 410

Acamprosate, 5, (1527)

Acarbose, 6, (1529)

ACC, see Acetylcysteine, 13

ACC 200, see Acetylcysteine, 13

Accolate, see Zafirlukast, 1502

Accupaque, see Iohexol, 730

Accupril, see Quinapril, 1184

Accurbron, see Theophylline, 1350

Accutane, see Isotretinoin, 745

Acebutolol, 7, (1526)

Acecoline, see Acetylcholine, 13

Acemuc, see Acetylcysteine, 13

Acemucol, see Acetylcysteine, 13

Acenocoumarin, see Nicoumalone, 978

Acenocoumarol, see Nicoumalone, 978

Aceon, see Perindopril, 1091

Aceta, see Acetaminophen, 8

Acetaminophen, 8, (1527)
Acetazid, see Acetazolamide, 12
Acetazolamide, 12, (1529)
Acetexa, see Nortriptyline, 1006
Acetohexamide, 12
Acetophenazine, see 8th edition
Acetophenetidin, see Phenacetin, 1097
Acetopt, see Sulfonamides, 1297
Acetylcholine, see 9th edition
Acetylcysteine, 13, (1523), (1532)
Acetyldigitoxin, 15, (1526)
Acetylphenetid, see Phenacetin, 1097
Acetylsalicylic Acid, see Aspirin, 92
Acetyst, see Acetylcysteine, 13
Achromycin, see Tetracycline, 1339
Acid A Vit, see Tretinoin, 1395
Acidocort, see Dexamethasone, 377
A-Cillin, see Ampicillin, 69
Aciphex, see Rabeprazole, 1190
Acitretin, 15, (1528), (1532)
Acidinium bromide, 17
Acnavit, see Tretinoin, 1395
Acocillin, see Penicillin V, 1082
Acortan, see Corticotropin/Cosyntropin, 326
Acova, see Argatroban, 82
Acovil, see Pheniramine, 1100
Acoviletas, see Pheniramine, 1100
Acretin, see Tretinoin, 1395
Acriflex, see Chlorhexidine, 247
Actamin, see Acetaminophen, 8
Actemra, see Tocilizumab, 1372
ACTH, see Corticotropin/Cosyntropin, 326
Acthar, see Corticotropin/Cosyntropin, 326
Acticin, see Permethrin, 1093
Actidil, see Triprolidine, 1410
Actidilon, see Triprolidine, 1410
Actifral D3, see Cholecalciferol, 257
Actigall, see Ursodiol, 1415
Actilyse, see Alteplase, 45
Actimmune, see Interferon Gamma-1b, 726
Actinomycin D, see Dactinomycin, 348
Actinospectacin, see Spectinomycin, 1277
Actiplas, see Alteplase, 45
Activase, see Alteplase, 45
Actomol, see Dexamethasone, 377
Acton, see Corticotropin/Cosyntropin, 326
Actonel, see Risedronate, 1219
ActoPlus Met, see Pioglitazone & Metformin, 873
Actos, see Pioglitazone, 1124
Actyron, see Thyrotropin, 1357
Acyclovir, 18, (1524)
Acyfanid, see Acetyldigitoxin, 15
Acyfanide, see Acetyldigitoxin, 15
Adacel, see Vaccine, Pertussis (Acellular), 1431

Adalat, see Nifedipine, 978
Adalimumab, 22, (1531)
Adalate, see Nifedipine, 978
Adam, see Ecstasy, 449
Adapalene, 24, (1528)
Adapin, see Doxepin, 430
Adcetris, see Brentuximab Vedotin, 157
Adcortyl, see Triamcinolone, 1398
Adefovir, 25, (1524)
Adenine Arabinoside, see Vidarabine, 1472
Adenocard, see Adenosine, 26
Adenock, see Allopurinol, 40
Adenosine, 26, (1526)
Adermina, see Fluocinolone, 559
ADH, see Vasopressin, 1461
Adhaegon, see Dihydroergotamine, 409
Adiab, see Glyburide, 634
Adifax, see Dexfenfluramine, 380
Adipalit, see Piperazine, 1126
Adipex-P, see Phentermine, 1107
Adomal, see Diflunisal, 405
Adophen, see Phendimetrazine, 1099
Adrazine, see Sulfonamides, 1297
Adrenalin, see Epinephrine, 477
Adrenor, see Norepinephrine, 1001
Adria, see Doxorubicin, 431
Adriamycin, see Doxorubicin, 431
Adronat, see Alendronate, 35
Adsorbocarpine, see Pilocarpine, 1120
Adumbran, see Oxazepam, 1036
Advair, see Fluticasone & Salmeterol, 1242
Advanced Eye Relief, see Naphazoline, 955
Advicor, see Niacin & Lovastatin, 823
Aerflu, see Flunisolide, 557
Aerius, see Desloratadine, 374
Aerobid, see Flunisolide, 557
Aerolate, see Theophylline, 1350
Aerolid, see Flunisolide, 557
Aerolone, see Isoproterenol, 742
Aeromax, see Salmeterol, 1242
Aeromuc, see Acetylcysteine, 13
Aeroseb-Dex, see Dexamethasone, 377
Aerosporin, see Polymyxin B, 1133
AErrane, see Isoflurane, 737
Aethazolum, see Sulfonamides, 1297
Afatin, see Dextroamphetamine, 385
Afinitor, see Everolimus, 526
Afko-Lube, see Docusate Sodium, 423
Aflexa, see Glucosamine, 633
Afluon, see Azelastine, 115
Afos, see Fosfomycin, 595
Afrazine, see Oxymetazoline, 1041
African, see Hydroquinone, 668
Afrin, see Oxymetazoline, 1041

Afrinol, see Pseudoephedrine, 1168
Agalsidase Alfa, 28, (1529)
Agalsidase Beta, 28, (1529)
Agarolleten, see Bisacodyl, 145
Agenerase, see Amprenavir, 71
Aggrastat, see Tirofiban, 1369
Aggrenox, see Dipyridamole & Aspirin, 92
Agit, see Dihydroergotamine, 409
Agrastat, see Tirofiban, 1369
Agylin, see Anagrelide, 73
A-Hydrocort, see Hydrocortisone, 661
Airol, see Tretinoin, 1395
Ajenuz, see Black Seed/Kalanji, 148
AK-Con, see Naphazoline, 955
AK-Fluor, see Fluorescein Sodium, 560
Akindex, see Dextromethorphan, 385
Akineton, see Biperiden, 145
Akotin, see Niacin, 973
Alagyl, see Clemastine, 290
Albacort, see Triamcinolone, 1398
Albamycin, see Novobiocin, 1007
Alatrofloxacin, see Trovafloxacin, 1412
Albenza, see Albendazole, 29
Albendazole, 29, (1523)
Albicort, see Triamcinolone, 1398
Albiotic, see Lincomycin, 801
Albucid, see Sulfonamides, 1297
Albulair, see Levalbuterol, 788
Albuterol, 30, (1526), (1531)
Alcaftadine, 33, (1531)
Alcohol, see Ethanol, 506
Alconefrin, see Phenylephrine, 1110
Alcover, see Sodium Oxybate, 1272
Aldactazide, see Spironolactone & Hydrochlorothiazide, 659
Aldactone, see Spironolactone, 1278
Aldactone-R, see Spironolactone, 1278
Aldara, see Imiquimod, 698
Aldecin, see Beclomethasone, 125
Aldesleukin, 33, (1525)
Aldomet, see Methyldopa, 894
Aldometil, see Methyldopa, 894
Aldurazyme, see Laronidase, 780
Alefacept, 34, (1531)
Alemtuzumab, 35, (1525)
Alendronate, 35, (1526)
Alendros, see Alendronate, 35
Alercrom, see Cromolyn Sodium, 332
Alergicap, see Diphenhydramine, 414
Alerlisin, see Cetirizine, 238
Alermine, see Chlorpheniramine, 252
Alermizol, see Astemizole, 97
Alesion, see Epinastine, 476
Aleudrin, see Isoproterenol, 742
Alexan, see Cytarabine, 343

Alfaferone, see Interferon Alfa, 723
Alfatrofin, see Corticotropin/Cosyntropin, 326
Alfenta, see Alfentanil, 37
Alfentanil, 37, (1528)
Alferon N (Interferon alfa-n3), see Interferon Alfa, 723
Alferos, see Azelastine, 115
Alfin, see Sildenafil, 1261
Algaphan, see Propoxyphene, 1162
Alglucosidase Alfa, 39, (1529)
Alglucerase, 38, (1529)
Algobid, see Diflunisal, 405
Algovatine, see Phenylbutazone, 1109
Aliskiren, 39, (1526)
Alimix, see Cisapride, 279
Alimta, see Pemetrexed, 1077
Alinia, see Nitazoxanide, 983
Alinol, see Allopurinol, 40
Alius, see Dimethothiazine, 413
Alivioderm, see Nitrofurazone, 986
Alkarau, see Reserpine, 1207
Alka-Seltzer, see Sodium Bicarbonate, 1270
Alka-Seltzer (Aspirin Buffered), see Aspirin, 92
Alkeran, see Melphalan, 860
Allegra, see Fexofenadine, 543
Allegro, see Fluticasone, 576
Allerbid, see Chlorpheniramine, 252
Allerest nasal, see Phenylephrine, 1110
Allerest 12 Hour Nasal, see Oxymetazoline, 1041
Allergefon, see Carbinoxamine, 205
Allergex, see Chlorpheniramine, 252
Allergisan, see Chlorpheniramine, 252
Allergodil, see Azelastine, 115
Allergon, see Pyrilamine, 1178
Allergron, see Nortriptyline, 1006
Allerhist, see Chlorpheniramine, 252
Allermine, see Chlorpheniramine, 252
Allertab, see Chlorpheniramine, 252
Allertoc, see Pyrilamine, 1178
All-Heal, see Valerian, 1447
Allium sartivum L., see Garlic, 614
Alloprin, see Allopurinol, 40
Allopur, see Allopurinol, 40
Allopurin, see Allopurinol, 40
Allopurinol, 40, (1525), (1529)
Alloremed, see Allopurinol, 40
Allozym, see Allopurinol, 40
Allural, see Allopurinol, 40
Allurit, see Allopurinol, 40
Allvoran, see Diclofenac, 395
Almarytm, see Flecainide, 548
Almocarpine, see Pilocarpine, 1120
Almopen, see Penicillin G Procaine, 1082
Almotriptan, 42, (1527)
Aloginan, see Clemastine, 290

Alomide, see Lodoxamide, [813](#)
Alophen, see Phenolphthalein or Bisacodyl, [145](#)
Aloral, see Allopurinol, [40](#)
Alosetron, [43](#), (1530)
Aloxi, see Palonosetron, [1049](#)
Alphaderm, see Urea, [1414](#)
Alphalin, see Vitamin A, [1481](#)
