Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of the information in a particular situation remains the professional responsibility of the practitioner.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is

particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in the publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.

In Memory

Sumner J. Yaffe, M.D.

May 9, 1923–August 10, 2011

On August 10, 2011, Dr. Sumner J. Yaffe, often regarded as the father of pediatric clinical pharmacology, passed away. He had a long and distinguished career as a renowned researcher and expert in pediatric pharmacology.

Dr. Yaffe was our friend, colleague, and co-author for 31 years. In 1980, he enthusiastically accepted our offer to co-author this book. At that time, he was the Director of the Center for Research for Mothers and Children at the National Institute of Child Health and Human Development. Over the years, he authored and/or contributed to nearly 300 scientific articles and books, including ours. His comments on our reviews were always on target. Our readers and ourselves have reaped the benefits of his vast experience. We were indeed fortunate to have received his wise advice and counsel over three decades.

Foreword

This book is now in its 10th edition and continues to enjoy great success with physicians and other professionals involved in the care of pregnant and lactating patients. Many of the reviews are exhaustive but pertinent to the management of pregnant and lactating patients who have already ingested a drug or who are in need of drug therapy where a cost–benefit analysis may be necessary for appropriate counseling. There are seldom absolute answers to questions a woman may have when she ingests a drug when pregnant or nursing because human experience is usually, of necessity, somewhat anecdotal. Even with all the information in this publication, there are risks that are yet unknown that may apply to a small number of people making the dictum of not using drugs in pregnancy without good cause still important. The effect of drugs in animals, the importance of timing and dose, and the effect of environmental factors are all involved in the risks and benefits of drugs in pregnant and/or lactating women and their fetuses/neonates. These factors are considered when data are available, but we must admit that in no individual case is the understanding of risks and benefits absolute.

Because many pregnant and lactating women take substances, both legal and illegal, without the knowledge of their caregivers, the challenge to understand the risks/benefits of any drug and its interactions with these substances is daunting. Today, we are just beginning to understand the specific genetic influences on the action, toxicity, and teratogenicity of drugs in an individual. I expect in the future there will be many identified genetic factors that will influence therapeutic decisions.

The contributions of Dr. Sumner J. Yaffe, who died after the last edition, will be greatly missed. His vast experience and expertise regarding the use of drugs in pregnancy and lactation were significant contributions to all editions of this book.

It is our hope that the 10th edition will continue to provide the practitioner appropriate assistance with questions regarding drugs in pregnancy and lactation.

Preface

In 2011, our co-author, Dr. Sumner J. Yaffe, MD, passed away. Our tribute to this great man is shown on the In Memory page.

We have been writing this book for 34 years. The first edition was released in 1983, 31 years ago. With each new edition, we have tried to make improvements that would benefit our readers. The same is true for this edition.

Not only is the 10th edition in a print version, it is now completely online for those who prefer that method to acquire information. We have attempted to reduce the size of the book by removing 161 reviews of drugs no longer marketed. If information is needed for these agents, it can be obtained by referring to the 9th edition. There are 124 new drugs in this edition. Unfortunately, the majority have no reported human pregnancy experience. Consequently, to estimate the embryo–fetal risk, we had to rely on information from other drugs that had the same mechanism of action (if they had human data) and/or on animal data. Finally, 201 drug reviews have been revised with new information, but no new relevant data were found for an additional 300 drugs. However, the search for new data on all drugs in this edition is an ongoing process. Although new or revised drug reviews published in future quarterly Updates will not be in the print version of this edition, they will be available online. We believe this will be a significant benefit for our readers.

The revision focus has been on drugs with no human pregnancy data and those where new information would change our pregnancy or breastfeeding recommendation. Nevertheless, there are still a large number of drugs that have little or no published human pregnancy experience, thus making the counseling function difficult.

As in previous editions, some drug reviews have toll-free telephone numbers for the use of health care professionals or patients to enroll in observational studies. These studies are an important method for gathering prospective data on pregnancy exposures for high-risk drugs. In fact, such studies are often the only human pregnancy experience available for new drugs and pharmacologic drug classes. The data generated by these studies and registries can be valuable for the raising of hypotheses of major teratogenicity or providing some assurance that the agent is not a significant teratogen. Because their importance is so high, health care professionals and patients are encouraged to

call for information about patient enrollment.

We take great pleasure for the opportunity to thank the many individuals who have helped us. To those who have sent us references, know that your efforts are sincerely appreciated. We also appreciate those who have commented on our work because it identifies areas that may need modification or topics that we need to cover. In addition, the questions we received served to keep us informed of your information needs and often lead to the preparation of new reviews. On the following page, we have listed the names of those who have been particularly helpful in the preparation of this edition.

It also is a pleasure to announce that we have two new co-authors who will assist us in the next edition. Dr. Craig Towers, M.D., is a Maternal-Fetal Specialist and a professor at the University of Tennessee Medical Center, Knoxville. We have had the pleasure of working with Dr. Towers in the past and look forward to renewing that relationship. Dr. Alicia Forinash, Pharm.D, FCCP, BCPS, BCACP, is an Associate Professor, Saint Louis College of Pharmacy, and a Clinical Pharmacy Specialist in the Maternal-Fetal Care Clinic at Saint Mary's Health Center in Saint Louis. We believe both will have a significant and beneficial impact on future editions of this book.

Acknowledgment

It is a pleasure to acknowledge the assistance of Dr. Christine Chambers, PhD, MPH, for her help in the preparation of several drug reviews. In addition, we want to thank Elizabeth Mason-Renteria, Parks Medical Library, Long Beach Memorial Medical Center, who retrieved numerous references for us during the preparation of this edition. Without her assistance, this edition would have been much harder to prepare.

We also are pleased to acknowledge the assistance of our former students in the preparation of some of the reviews contained in this edition. The students came from five schools of pharmacy. During their clerkship training in obstetrics/gynecology, each researched and wrote two drug reviews. It was their first experience in how to assess the reproductive toxicity of drugs, and they did very well.

Introduction, 9th Edition

Sumner J. Yaffe, MD

It is now generally accepted that the developing fetus may be adversely affected by exposure to drugs and environmental chemicals. The stage of development of the intrauterine host is a major determinant of the resultant effect as well as the nature and the concentration of the drug or chemical agent. On a more positive side, fetal therapy (i.e., treatment of fetal disease in utero by administering the drug to the mother or directly to the fetus) has been recognized recently as a rational approach to treat fetal disease.

Forty years ago, the thalidomide catastrophe (limb defects) occurred when this drug was administered to pregnant women as an antianxiety and hypnotic agent during the 1st trimester. Thalidomide had been evaluated for safety in several animal species, had been given a clean bill of health, and had come to be regarded as a good pharmacologic agent (hypnotic/sedative). It is of interest that this drug is being re-evaluated today for use in leprosy and approval for this use has been given by the FDA.

It is important to note that, even though thalidomide produces a distinct cluster of anatomic defects that are virtually pathognomonic for this agent, it required several years of thalidomide use and the birth of many thousands of grossly malformed infants before the cause-and-effect relationship between thalidomide administration in early pregnancy and its harmful effects was recognized. This serves to emphasize the difficulties that exist in incriminating drugs and chemicals that are harmful when administered during pregnancy. Hopefully, we will never have another drug prescribed for use during pregnancy whose teratogenicity is as potent as thalidomide (about one-third of women taking this agent during the 1st trimester gave birth to infants with birth defects).

Concern about the safety of foreign compounds administered to pregnant women has been increasingly evident since thalidomide. The direct response to this misadventure led to the promulgation of the drug regulations of 1962 in the United States. According to these regulations, a drug must be demonstrated to be safe and effective for the conditions of use prescribed in its labeling. The regulations concerning this requirement state that a drug should be investigated for the conditions of use specified in the labeling, including dosage levels and patient populations for whom the drug is intended. In addition, appropriate

information must be provided in the labeling and be available when the drug is prescribed. The intent of the regulations is not only to ensure adequate labeling information for the safe and effective administration of the drug by the physician but also to ensure that marketed drugs have an acceptable benefit:risk ratio for their intended uses.

It is clear that any drug or chemical substance administered to the mother is able to cross the placenta to some extent unless it is destroyed or altered during passage, or its molecular size and low lipid solubility limit transplacental transfer. Placental transport of maternal substrates to the fetus and of substances from the fetus to the mother is established at about the 5th week of embryo life. Substances of low molecular weight diffuse freely across the placenta, driven primarily by the concentration gradient. It is important to note, therefore, that almost every substance used for therapeutic purposes can and does pass from the mother to the fetus. Of greater importance is whether the rate and extent of transfer are sufficient to result in significant concentrations within the fetus. Today, the concept of a placental barrier must be discarded.

Experiments with animals have provided considerable information concerning the teratogenic effects of drugs. Unfortunately, these experimental findings cannot be extrapolated with certainty from species to species, or even from strain to strain within the same species, much less from animals to humans. Research in this area and the prediction of toxicity in the human are further hampered by a lack of specificity between cause and effect.

Traditionally, teratogenic effects of drugs have been noted as anatomic malformations. It is clear that these are dose and time related and that the fetus is at greater risk during the first 3 months of gestation. However, it is possible for drugs and chemicals to exert their effects upon the fetus at other times during pregnancy. Functional and behavioral changes are much more difficult to identify as to cause and effect. Consequently, they are rarely recognized. A heightened awareness on the part of health care providers and recipients will make this task easier.

The use of dietary supplements as well as complementary or alternative medicine products has been increasing markedly in the Western industrialized world. This use continues unabated during pregnancy and lactation. The efficacy of these compounds is generally unknown, with rare exception, and their safety poorly studied. In particular, little is known about the interaction between the use of a broad range of dietary supplements, alternative medicine products, and health outcomes in women, developing fetuses and nursing neonates. Such knowledge is essential to the evaluation of both the justification

and safety of the use of these products during these critical periods of development. Until this occurs, women should be advised about current lack of knowledge and cautioned as to their use. A notable exception is folic acid supplementation during pregnancy to prevent neural tube defects.

It is crucial that concern also be given to events beyond the narrow limits of congenital anatomic malformations; evidence exist that intellectual, social, and functional development can also be adversely affected by drug administration during pregnancy. There are examples that toxic manifestations of intrauterine exposure to environmental agents may be subtle, unexpected, and delayed. Concern for the delayed effects of drugs, following intrauterine exposure, was first raised following the tragic discovery that female fetuses exposed to diethylstilbestrol (DES) are at an increased risk for adenocarcinoma of the vagina. This type of malignancy is not discovered until after puberty. Many of the drugs prescribed to pregnant women have been evaluated in the following pages as to their propensity to produce congenital anatomic malformations. During the past several decades, awareness that many of these compounds may act after the period of organogenesis, through birth and into lactation, has increased. We now realize that drugs considered safe (i.e., not producing anatomic malformations) can still produce more subtle yet permanent alterations in the physiology and biochemistry of the developing perinate. Furthermore, many of these subtle hitherto unrecognized defects are not present at birth and may be dormant and latent until years later after the time of administration. The teratogen appears to produce a programming or imprinting defect in the developing tissue or organ. This defect need not be expressed until adulthood, because the program may not be required until that time. Consequently, in the absence of anatomical defects readily recognized, there is the danger that these late-onset dysfunctions will either be unrecognized or will be attributed to some other cause.

The purpose of the above paragraph is to raise the concept of a little known but potentially serious health hazard in children and adults. This refers to the ability of perinatally consumed drugs and food additives and nonprescription alternative agents to produce the subtle biochemical defects undetectable or unrecognized in the neonate but expressed years or even decades after birth. How serious a problem is the in utero exposure to drugs and chemicals to the delayed latent defect? The answer may in lie in the use of animals for these fetal origins of adult disease.

The physician is confronted with two imperatives in treating the pregnant woman: alleviate maternal suffering and do no harm to the fetus. Until now, the

emphasis has been on the amelioration of suffering, but the time has come to concentrate on not harming the fetus. The simple equation to be applied here is to weigh the therapeutic benefits of the drug to the mother against its risk potential to the developing fetus. Since fetal ova may also be exposed to drugs given to the mother, effects may be evident in future generations.

When one considers that more than a billion drug prescriptions are written each year, that there is unlimited self-administration of over-the-counter drugs, and that approximately 500 new pharmaceutical products are introduced annually, the need for prudence and caution in the administration of pharmaceuticals has reached a critical point. Pregnancy is a symptom-producing event. Pregnancy has the potential of causing women to increase their intake of drugs and chemicals, with the potential being that the fetus will be nurtured in a sea of drugs.

In today's society, the physician cannot stand alone in the therapeutic decision-making process. It has now become the responsibility of each woman of childbearing age to consider her use of drugs carefully. In a pregnant woman, the decision to administer a drug should be made only after a collaborative appraisal between the woman and her physician of the risk:benefit ratio.

BREASTFEEDING AND DRUGS

Between 1930 and the late 1960s, there was a dramatic decline in the percentage of American mothers who breastfed their babies. This was also accompanied by a reduction in the length of breastfeeding for those who did nurse. The incidence of breastfeeding declined from approximately 80% of the children born between 1926 and 1930 to 49% of children born some 25 years later. For children born between 1966 and 1970, 28% were breastfed. Indeed, in 1972 only 20% of newborns were breastfed. As data have become available for the following years, it is clear the decline has been reversed. By 1975, the percentage of first-born babies who were breastfed rose to 37%. At the present time in the United States, a number of surveys indicate that more than 50% of babies discharged from the hospital are breastfed, and the number is increasing. Breastfeeding is difficult to contemplate, as more than 50% of mothers work and return to work soon after delivery. New solutions must be found by employers to encourage breastfeeding and develop the logistics to enable employees to breastfeed on the job.

Breast milk is known to possess nutritional and immunologic properties superior to those found in infant formulas. An American Academy of Pediatrics

position paper emphasizes breastfeeding as the best nutritional mode for infants for the first 6 months of life. In addition to those qualities, studies also suggest significant psychologic benefits of breastfeeding for both the mother and the infant.

The upswing in breastfeeding, together with a markedly increased concern about health needs on the part of parents, has led to increased questioning of the physician, pharmacist, and other health professionals about the safety and potential toxicity of drugs and chemicals that may be excreted in breast milk. Answers to these questions are not very apparent. Our knowledge concerning the long- and short-term effects and safety of maternally ingested drugs on the suckling infant is meager. We know more now than Soranus did in 150 AD, when he admonished wet nurses to refrain from the use of drugs and alcohol, lest it have an adverse effect on the nursing infant. We must know more! The knowledge to be acquired should be specific with respect to dose administered to the mother, amount excreted in breast milk, and amount absorbed by the suckling infant. In addition, effects on the infant should be determined (both acute and chronic).

It would be easy to recommend that the medicated mother not nurse, but it is likely that this recommendation would be ignored by the mother and may offend many health providers, as well as their patients, on both psychosocial and physiologic grounds.

It must be emphasized that many of the investigations concerned with milk secretion and synthesis have been carried out in animals. The difficulty in studying human lactation using histologic techniques and the administration of radioactive isotopes is obvious. There are considerable differences in the composition of milk in different species. Some of these differences in composition would obviously bring about changes in drug elimination. Of great importance in this regard are the differences in the pH of human milk (pH usually >7.0) compared with the pH of cow's milk (pH usually <6.8) where drug excretion has been extensively studied.

A number of reviews give tables of the concentration of drugs in breast milk. Often, these tables also give the milk:plasma ratio. Most of the values from which the tables are derived consist of a single measurement of the drug concentration. Important information, such as the maternal dose, the frequency of dose, the time from drug administration to sampling, the frequency of nursing, and the length of lactation, is not given.

The significance of these concentration tables only means that the drug is present in the milk, and they offer no advice to the physician. Because the drug

in the nursing infant's blood or urine is not measured, we have little information about the amount that is actually absorbed by the infant from the milk and, therefore, have no way of determining the possible pharmacologic effects on the infant. In fact, a critical examination of the tables that have been published reveals that much of the information was gathered decades ago when analytic methodology was not as sensitive as it is today. Because the discipline of pharmacokinetics was not developed until recently, many of the studies quoted in the tables of the review articles do not precisely look at the time relationship between drug administration and disposition.

Certain things are evident with regard to drugs administered during lactation. It is necessary that physicians become aware of the results of animal studies in this area and of the potential risk of maternal drug ingestion to the suckling infant. Many drugs prescribed to the lactating woman need to be studied more so that their safety during lactation can be assessed. It is clear that if the mother needs a drug that has a moderate-to-high potential to cause infant harm, then she should consider not nursing. The ultimate decision must be individualized according to the specific illness and the therapeutic modality. Nursing should be avoided following the administration of radioactive pharmaceuticals that are usually given to the mother for diagnostic purposes.

CONCLUSIONS

Two basic situations are dealt with throughout this book: (a) risk potential to the fetus of maternal drugs ingested during the course of pregnancy, and (b) risk potential to the infant of drugs taken by the mother while nursing.

The obvious solution to fetal and nursing infant risk avoidance is maternal abstinence. However, from a pragmatic standpoint, that would be impossible to implement. Another solution is to disseminate knowledge, in an authoritative manner, to all those involved in the pregnancy and breastfeeding processes: physician, mother, midwife, nurse, father, and pharmacist.

This book helps to fill a communication and information gap. We have carefully evaluated the research literature, animal and human, applied and clinical. Each of the more than 1180 drugs has a risk factor assigned by the manufacturer or ourselves in keeping with the FDA guidelines. We have also assigned our own recommendations for use of these drugs in pregnancy and lactation. We believe that this book will be helpful to all concerned parties in developing the risk:benefit decision.

This is but a beginning. It is our fervent hope that the information gained from the use of this book will cause the concerned parties to be more trenchant in

their future decision-making, either before prescribing or before ingesting drugs during pregnancy and lactation.

Instructions for Use of the Reference Guide

The Reference Guide is arranged so that the user can quickly locate a monograph. If the American generic name is known, go directly to the monographs, which are listed in alphabetical order. If only the trade or foreign name is known, refer to the Index for the appropriate American generic name. Foreign trade names have been included in the Index. To the best of our knowledge, all trade and foreign generic names are correct as shown, but because these may change, the reader should check other reference sources if there is any question as to the identity of an individual drug. Some prescription combination products are listed in the Index. If not listed, the user should refer to the manufacturer's product information for the specific ingredients, and then use the Reference Guide as for single entities.

Each monograph contains eight parts:

- Generic Name (United States)
- Pharmacologic Class
- Pregnancy Recommendation
- Breastfeeding Recommendation
- Pregnancy Summary
- Fetal Risk Summary
- Breastfeeding Summary
- References

PREGNANCY SUMMARY

The Pregnancy Summary is intended as a brief overview of the reported data in pregnancy, both animal and human, whereas the Fetal Risk Summary provides the specific details of the data. Both the Pregnancy Summary and the Fetal Risk Summary support the Pregnancy Recommendation.

FETAL RISK SUMMARY

The Fetal Risk Summary is an analysis of the literature concerning use of the drug in pregnancy. The intent is to provide clinicians and others with sufficient data to counsel patients and to arrive at conclusions as to the risk:benefit ratio a particular drug poses for the embryo, fetus, and newborn. The molecular

weight of most drugs has been included in the reviews because they help determine if a drug can reach the embryo or fetus, but this value, by itself, may not predict the amount crossing the placenta. The major determinant of the drug concentration in the embryo or fetus is the blood concentration of the drug in the mother. Other important factors include the elimination half-life, metabolism, placental blood flow, the placental surface area available for crossing (i.e., correlated to the gestational age), and the lipid solubility, protein binding, and the amount of ionization of the drug at physiologic pH.

Because few absolutes are possible in the area of human teratology, the reader must carefully weigh the evidence, or lack thereof, before utilizing any drug in a pregnant woman. Readers who require more details than are presented should refer to the specific references listed at the end of the monograph. See Definitions for recommendations.

BREASTFEEDING SUMMARY

The Breastfeeding Summary is a brief review of the literature concerning excretion of the drug into human breast milk and the effects, if any, on a nursing infant. Unfortunately, in many cases, there is no published information about use of the drug during lactation. Moreover, when studies do exist, infants often were not allowed to breastfeed. Readers should pay close attention to this distinction (i.e., excretion into milk vs. effects on the nursing infant) when using a Summary. Those who require more details than are presented should refer to the specific references listed at the end of the monograph. See Definitions for recommendations.

PREGNANCY AND BREASTFEEDING RECOMMENDATIONS

The pregnancy recommendations are intended to assist the reader in determining the level of risk of a specific drug. They only apply to the usual therapeutic dose of the drug in a typical patient. Because the genetic makeup of a specific patient may significantly alter the risk, the recommendations may not apply to the entire population. In addition to the animal reproduction data and known human pregnancy outcomes, the assessment of risk includes, when relevant, other major factors such as route of administration, metabolism to active metabolites, species differences, type of defects, pharmacokinetics, effects of other agents in the drug class, and the embryo–fetal effects of untreated or undertreated maternal disease. Moreover, drug exposures represent different levels of risk depending on the stage of pregnancy and,

thus, timing of the exposure is critical in determining risk. Because short statements of risk may not always adequately assess the risk throughout the pregnancy, readers are encouraged to review the entire monograph before estimating the risk for a specific patient.

The risks also change during breastfeeding because nearly all reported adverse effects in nursing infants have occurred in infants <6 months of age. The neonate and very young infant are most at risk for toxic effects from drugs present in breast milk. The recommendations for breastfeeding are based on the known toxicity of the drug or similar drugs in adults or children (when known) and the amount of drug excreted into breast milk (if known). Although most drugs taken by the mother are probably present in milk, the milk concentrations are usually unknown. Fortunately, the amounts are usually too low to cause toxicity. However, the therapeutic dose for infants of most drugs is rarely known. Therefore, we used a proposal from the literature (Ito S. N Engl J Med 2000;343:118–28) to classify exposures as clinically insignificant if, in the absence of data suggesting otherwise, the estimated dose ingested by a nursing infant was no more than 10% of the mother's weight-adjusted dose. In some cases, this classification may not be relevant. For example, the potential for neurotoxicity in a nursing infant from long-term maternal use of psychotropic medications continues to be a concern.

DEFINITIONS OF PREGNANCY RECOMMENDATIONS

COMPATIBLE

The human pregnancy experience, either for the drug itself or drugs in the same class or with similar mechanisms of action, is adequate to demonstrate that the embryo–fetal risk is very low or nonexistent. Animal reproduction data are not relevant.

NO (LIMITED) HUMAN DATA—PROBABLY COMPATIBLE

There may or may not be human pregnancy experience, but the characteristics of the drug suggest that it does not represent a significant risk to the embryo–fetus. For example, other drugs in the same class or with similar mechanisms are compatible or the drug does not obtain significant systemic concentrations. Any animal reproduction data are not relevant.

COMPATIBLE—MATERNAL BENEFIT >> EMBRYO– FETAL RISK

There may or may not be human pregnancy experience, but the potential maternal benefit far outweighs the known or unknown embryo–fetal risk. Animal reproduction data are not relevant.

HUMAN DATA SUGGEST LOW RISK

There is limited human pregnancy experience, either for the drug itself or drugs in the same class or with similar mechanisms of action, including the 1st trimester, suggesting that the drug does not represent a significant risk of developmental toxicity (growth restriction, structural anomalies, functional/behavioral deficits, or death) at any time in pregnancy. The limited human pregnancy data outweigh any animal reproduction data.

NO (LIMITED) HUMAN DATA—ANIMAL DATA SUGGEST LOW RISK

Either there is no human pregnancy experience or the few pregnancy exposures have not been associated with developmental toxicity (growth restriction, structural anomalies, functional/behavioral deficits, or death). The drug does not cause developmental toxicity (at doses that did not cause maternal toxicity) in all animal species studied at doses ≤ 10 times the human dose based on body surface area (BSA) or AUC*.

NO (LIMITED) HUMAN DATA—ANIMAL DATA SUGGEST MODERATE RISK

Either there is no human pregnancy experience or the few pregnancy exposures have not been associated with developmental toxicity (growth restriction, structural anomalies, functional/behavioral deficits, or death). The drug causes developmental toxicity (at doses that did not cause maternal toxicity) in one animal species at doses ≤ 10 times the human dose based on body surface area (BSA) or AUC*.

NO (LIMITED) HUMAN DATA—ANIMAL DATA SUGGEST RISK

Either there is no human pregnancy experience or the few pregnancy exposures have not been associated with developmental toxicity (growth restriction, structural anomalies, functional/behavioral deficits, or death). The drug causes developmental toxicity (at doses that did not cause maternal toxicity) in two animal species at doses ≤ 10 times the human dose based on body surface area (BSA) or AUC*.

NO (LIMITED) HUMAN DATA—ANIMAL DATA SUGGEST HIGH RISK

Either there is no human pregnancy experience or the few pregnancy exposures have not been associated with developmental toxicity (growth restriction, structural anomalies, functional/behavioral deficits, or death). The drug causes developmental toxicity (at doses that did not cause maternal toxicity) in three or more animal species at doses ≤ 10 times the human dose based on body surface area (BSA) or AUC*.

CONTRAINDICATED—1ST TRIMESTER

Human exposures in the 1st trimester, either to the drug itself or to drugs in the same class or with similar mechanisms of action, have been associated with developmental toxicity (growth restriction, structural anomalies, functional/behavioral deficits, or death). The drug should not be used in the 1st trimester.

CONTRAINDICATED—2ND AND 3RD TRIMESTERS

Human exposures in the 2nd and 3rd trimesters, either to the drug itself or to drugs in the same class or with similar mechanisms of action, have been associated with developmental toxicity (growth restriction, structural anomalies, functional/behavior deficits, or death). The drug should not be used in the 2nd and 3rd trimesters.

CONTRAINDICATED

Human exposures at any time in pregnancy, either to the drug itself or to drugs in the same class or with similar mechanisms of action, have been associated with developmental toxicity (growth restriction, structural anomalies, functional/behavioral deficits, or death). Animal reproduction data, if available, confirm the risk. The drug should not be used in pregnancy.

NO (LIMITED) HUMAN DATA—NO RELEVANT ANIMAL DATA

There is no human pregnancy data or relevant data in animals, or the human pregnancy experience, that may or may not include the 1st trimester, is limited. The risk in pregnancy cannot be assessed.

HUMAN DATA SUGGEST RISK IN 1ST TRIMESTER

Evidence (for the drug or similar drugs) suggests that there may be an embryo–fetal risk for developmental toxicity (growth restriction, structural anomalies, functional/behavioral deficits, or death) in the 1st trimester but not in the 2nd and 3rd trimesters. The human pregnancy data outweigh any animal reproduction data.

HUMAN DATA SUGGEST RISK IN 1ST AND 3RD TRIMESTERS

Evidence (for the drug or similar drugs) suggests that there may be an embryo–fetal risk for developmental toxicity (growth restriction, structural anomalies, functional/behavioral deficits, or death) in the 1st and 3rd trimesters but not in the 2nd trimester. The human pregnancy data outweigh any animal reproduction data.

HUMAN DATA SUGGEST RISK IN 2ND AND 3RD TRIMESTERS

Evidence (for the drug or similar drugs) suggests that there may be a fetal risk

for developmental toxicity (growth restriction, structural anomalies, functional/behavioral deficits, or death) in the 2nd and 3rd trimesters but not in the 1st trimester. The human pregnancy data outweigh any animal reproduction data.

HUMAN DATA SUGGEST RISK IN 3RD TRIMESTER

Evidence (for the drug or similar drugs) suggests that there may be a fetal risk for developmental toxicity (growth restriction, structural anomalies, functional/behavioral deficits, or death) in the 3rd trimester, or close to delivery but not in the 1st or 2nd trimesters. The human pregnancy data outweigh any animal reproduction data.

HUMAN (AND ANIMAL) DATA SUGGEST RISK

The human data for the drug or drugs in the same class or with the same mechanism of action, and animal reproduction data if available, suggest there may be a risk for developmental toxicity (growth restriction, structural anomalies, functional/behavioral deficits, or death) throughout pregnancy. Usually, pregnancy exposure should be avoided, but the risk may be acceptable if the maternal condition requires the drug.

DEFINITIONS OF BREASTFEEDING RECOMMENDATIONS

COMPATIBLE

Either the drug is not excreted in clinically significant amounts into human breast milk or its use during lactation does not, or is not expected to, cause toxicity in a nursing infant.

HOLD BREASTFEEDING

The drug may or may not be excreted into human breast milk, but the maternal benefit of therapy far outweighs the benefits of breast milk to an infant. Breastfeeding should be held until maternal therapy is completed and the drug has been eliminated (or reaches a low concentration) from her system.

NO (LIMITED) HUMAN DATA—PROBABLY COMPATIBLE

Either there is no human data or the human data are limited. The available data suggest that the drug does not represent a significant risk to a nursing infant.

NO (LIMITED) HUMAN DATA—POTENTIAL TOXICITY

Either there is no human data or the human data are limited. The characteristics of the drug suggest that it could represent a clinically significant risk to a nursing infant. Breastfeeding is not recommended.

HUMAN DATA SUGGEST POTENTIAL TOXICITY

Human data suggest a risk to a nursing infant. The drug is best avoided during breastfeeding. Depending on the drug, short-term use by the mother may be possible, but the infant should be closely monitored for potential adverse effects.

NO (LIMITED) HUMAN DATA—POTENTIAL TOXICITY (MOTHER)

Either there is no human data or the human data are limited. The characteristics of the drug suggest that breastfeeding could represent a clinically significant risk to the mother such as further loss of essential vitamins or nutrients. Breastfeeding is not recommended.

CONTRAINDICATED

There may or may not be human experience, but the combined data suggest that the drug may cause severe toxicity in a nursing infant, or breastfeeding is contraindicated because of the maternal condition for which the drug is indicated. Women should not breastfeed if they are taking the drug or have the condition.

COMPARISON OF AGENTS WITHIN THE SAME PHARMACOLOGIC CLASS

The Appendix arranges the drugs by their pharmacologic category. This allows the reader to identify all of the drugs that have been reviewed within a specific category, thus allowing, if desired, a comparison of the drugs. For example, the subsection Antihypertensives lists together those agents used for this purpose under the general heading Cardiovascular Drugs. To assist the reader in locating an agent in the Appendix, page numbers (in parentheses) referring to the location in the Appendix have been added to the generic names (shown in **bold**) in the Index.

FDA RISK CATEGORIES DEFINITIONS

Although the FDA risk categories have been excluded from this edition, readers wanting this information can obtain it from the manufacturer's product information.

*AUC = area under the plasma concentration vs. time curve; a measure of the systemic exposure of a drug

A

ABACAVIR

Antiviral

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

The animal data suggest moderate risk. Although the human pregnancy experience does not suggest a risk of structural anomalies, other potential developmental toxicities require study. Antiretroviral nucleosides have been shown to have a direct dose-related cytotoxic effect on preimplantation mouse embryos (see Didanosine, Stavudine, Zalcitabine, and Zidovudine). This toxicity has not been studied in humans. Mitochondrial dysfunction in offspring exposed in utero or postnatally to nucleoside reverse transcriptase inhibitors (NRTIs) has been reported (see Lamivudine and Zidovudine), but these findings are controversial and require confirmation. However, if indicated, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Abacavir is a synthetic carbocyclic nucleoside analog that is converted by cellular enzymes to the active metabolite, carbovir triphosphate. It is an NRTI used for the treatment of HIV type 1 (HIV-1). Other drugs in this class are didanosine, lamivudine, stavudine, zalcitabine, and zidovudine (1).

In reproduction studies, doses of abacavir up to 8 times the human therapeutic dose (HTD) based on BSA had no effect on the fertility or mating performance of male and female rats. However, embryo toxicity (increased resorptions, decreased body weight) was observed. During organogenesis, doses up to 35 times the human exposure based on AUC (about 16 times the

HTD) resulted in fetal growth restriction (reduced body weight and crown–rump length), as well as increased incidences of fetal anasarca and skeletal malformations. Offspring exposed from implantation through weaning had an increased incidence of stillbirth and survivors had decreased body weights throughout life. In contrast, no developmental toxicity or malformations were observed in rabbits at doses up to 8.5 times the human exposure based on AUC (1).

Abacavir crosses the human placenta. In four women being treated for multiple agents for HIV infection, the mean abacavir cord:maternal blood ratio was 1.03 at a mean of 3.5 hours (range 0.4–9.0 hours) after a dose (dose not specified) and the amniotic fluid concentration in one woman was 1.6 mg/L (2). These results are consistent with the relatively low molecular weight (about 671) and high lipophilic properties of abacavir. In an ex vivo human placental model, the antiviral agent readily crossed to the fetal side with a high clearance index of about 50% that of antipyrine (3). No accumulation of the drug was found on the fetal side.

The Antiretroviral Pregnancy Registry reported, for the period January 1989 through July 2009, prospective data (reported before the outcomes were known) involving 4702 live births that had been exposed during the 1st trimester to one or more antiretroviral agents (4). Congenital defects were noted in 134, a prevalence of 2.8% (95% confidence interval [CI] 2.4–3.4). In the 6100 live births with earliest exposure in the 2nd/3rd trimesters, there were 153 infants with defects (2.5%, 95% CI 2.1–2.9). The prevalence rates for the two periods did not differ significantly. There were 288 infants with birth defects among 10,803 live births with exposure anytime during pregnancy (2.7%, 95% CI 2.4–3.0). The prevalence rate did not differ significantly from the rate expected in a nonexposed population. There were 1547 outcomes exposed to abacavir (628 in the 1st trimester and 919 in the 2nd/3rd trimesters) in combination with other antiretroviral agents. There were 45 birth defects (19 in the 1st trimester and 26 in the 2nd/3rd trimesters). In reviewing the birth defects of prospective and retrospective (pregnancies reported after the outcomes were known) registered cases, the Registry concluded that except for isolated cases of neural tube defects with efavirenz exposure in retrospective reports, there was no other pattern of anomalies (isolated or syndromic) (4). (See Lamivudine for required statement.)

Two reviews, one in 1996 and the other in 1997, concluded that all women receiving antiretroviral therapy should continue to receive therapy during pregnancy and that treatment of the mother with monotherapy should be

considered inadequate therapy (5,6). The same conclusion was reached in a 2003 review with the added admonishment that therapy must be continuous to prevent emergence of resistant viral strains (7). In 2009, the updated U.S. Department of Health and Human Services guidelines for the use of antiretroviral agents in HIV-1-infected patients continued the recommendation that therapy, with the exception of efavirenz, should be continued during pregnancy (8). If indicated, abacavir should not be withheld in pregnancy because the expected benefit to the HIV-positive mother outweighs the unknown risk to the fetus. Updated guidelines for the use of antiretroviral drugs to reduce perinatal HIV-1 transmission were also released in 2010 (9). Women receiving antiretroviral therapy during pregnancy should continue the therapy but, regardless of the regimen, zidovudine administration is recommended during the intrapartum period to prevent vertical transmission of HIV to the newborn (9).

BREASTFEEDING SUMMARY

No reports have been located that describe the use of abacavir during human lactation. The molecular weight (about 671) suggests that the drug will be excreted into breast milk. The effect on a nursing infant is unknown.

Reports on the use of abacavir during human lactation are unlikely because the drug is used in the treatment of HIV-1 infections. HIV-1 is transmitted in milk, and in developed countries, breastfeeding is not recommended (5,6,8,10–12). In developing countries, breastfeeding is undertaken despite the risk because there are no affordable milk substitutes available. Until 1999, no studies had been published that examined the effect of any antiretroviral therapy on HIV-1 transmission in milk. In that year, a study involving zidovudine was published that measured a 38% reduction in vertical transmission of HIV-1 infection despite breastfeeding when compared with controls (see Zidovudine).

ABATACEPT

Immunologic Agent (Immunomodulator)/Antirheumatic Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although the animal data suggest low risk, the human pregnancy experience is too limited to assess the embryo–fetal risk. Several reviews have discussed the potential risk of abatacept in human pregnancy (1–5). Some recommend discontinuing the drug 10–18 weeks before pregnancy because the drug has a long elimination half-life (2,4,5). It is not known if in utero exposure could result in autoimmune diseases in later life (6). Moreover, use in pregnancy is contraindicated if abatacept is combined with methotrexate or leflunomide. Until more data are available, the safest course is to avoid abatacept during gestation. If abatacept is used in pregnancy for the treatment of rheumatoid arthritis, health care professionals are encouraged to call the toll-free number (877-311-8972) for information about patient enrollment in the Organization of Teratology Information Specialists (OTIS) Rheumatoid Arthritis study.

FETAL RISK SUMMARY

Abatacept, a soluble fusion protein, is a selective costimulation modulator that inhibits T-lymphocyte activation, thereby decreasing T-cell proliferation and inhibiting the production of the cytokines tumor necrosis factor- α , interferon- γ , and interleukin-2. It is administered as an IV infusion. Abatacept is indicated, either as monotherapy or in combination with other agents, for the treatment of rheumatoid arthritis in patients with moderately to severely active rheumatoid arthritis that has not responded to other drug therapy. The elimination half-life after a single 10 mg/kg IV dose in a healthy subject was 16.7 days (range 12–23 days), whereas in rheumatoid arthritis patients after multiple 10 mg/kg IV infusions, it was 13.1 days (range 8–25 days) (6).

Reproduction studies have been conducted in mice, rats, and rabbits. In these species, daily doses (route not specified but assumed to be SC) were not teratogenic. The dose comparisons were about 29 times the maximum recommended human dose of 10 mg/kg dose based on AUC (MRHD). There were no adverse effects in the offspring when rats were treated every 3 days from early gestation and throughout lactation with doses up to 3 times the MRHD. However, at a dose 11 times the MRHD, alterations of immune function were observed in female pups and one female pup (of 10 male and 10 female pups evaluated) had inflammation of the thyroid (6).

In carcinogenicity studies, weekly SC doses of abatacept for about 2 years in mice were associated with increased incidences of malignant lymphomas and mammary gland tumors at doses ≤ 3 times the HD. However, the mice were infected with viruses known to cause these cancers in immunosuppressed mice. In cynomolgus monkeys, an IV dose given once weekly that was 9 times the HD was not associated with any significant adverse effects. No evidence of lymphomas or preneoplastic morphologic changes was observed despite the presence of a virus known to cause these lesions in immunosuppressed monkeys. Abatacept was not mutagenic and did not cause chromosomal aberrations, nor did it impair the fertility of male and female monkeys given doses every 3 days up to 11 times the HD (6).

Abatacept crosses the human placenta, despite its high molecular weight (about 92,000) (6). However, the amount reaching the embryo and/or fetus was not quantified.

Several reviews have discussed the potential risks of abatacept in pregnancy (1–5). As discussed in a 2012 review, eight patients became pregnant while receiving abatacept during clinical trials in rheumatoid arthritis, seven of whom were also receiving methotrexate and one was also receiving leflunomide (4). A spontaneous abortion (SAB) occurred during the 1st trimester in three (two had a prior history of SAB) and two had an elective abortion (EAB). The remaining three women were still pregnant. In another case, the wife of a man treated with abatacept became pregnant and gave birth to a healthy baby. In a phase II trial of abatacept in multiple sclerosis, two women became pregnant and a third woman became pregnant by a abatacept-treated man. The outcomes of these pregnancies were a healthy baby, an EAB, and a SAB (4).

A 2013 case report described the outcome of a pregnancy exposed to abatacept in the 1st trimester (7). A 33-year-old woman with rheumatoid arthritis conceived while receiving abatacept (10 mg/kg every 4 weeks) and methotrexate (15 mg/week). The dose given in pregnancy occurred at

2.5 weeks'. Both drugs were stopped, but a daily 5 mg dose of an unspecified corticosteroid was allowed. At 40 weeks', the woman gave birth vaginally to a healthy 3180-g infant (sex not specified) with Apgar scores of 10 and 10 at 5 and 10 minutes, respectively. The child was doing well at 3.5-year follow-up (7).

BREASTFEEDING SUMMARY

No reports describing the use of abatacept during human lactation have been located. Although the molecular weight is high (about 92,000), excretion into breast milk is a possibility, especially because of the long elimination half-life (13 days; range 8–25 days). However, the amount in milk and the systemic bioavailability are unknown as are the effects on a nursing infant, but the potential for adverse effects on an infant's developing immune system should be considered.

ABCIXIMAB

Hematologic Agent (Antiplatelet)

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Two case reports have described the use of abciximab during human pregnancy. In addition, the reproduction effects of the drug, if any, have not been studied in animals. However, a placental perfusion study suggests that abciximab does not reach the fetus in clinically significant amounts. The primary risk, therefore, appears to be from maternal hemorrhage during drug administration. If this is adequately controlled, the benefits of the drug to the mother appear to far outweigh the unknown risks to the embryo–fetus.

FETAL RISK SUMMARY

Abciximab, the Fab fragment of the chimeric human-murine monoclonal antibody 7E3, binds to the GP IIb/IIIa receptor on human platelets and inhibits platelet aggregation. It also binds to vessel wall endothelial and smooth muscle cells. It is in the same subclass of antiplatelet agents as eptifibatid and tirofiban. Abciximab is indicated as an adjunct to percutaneous coronary intervention for the prevention of cardiac ischemic complications. It increases the risk of bleeding, especially when used with heparin and other anticoagulants or thrombolytics (1).

Animal reproduction studies have not been conducted with abciximab. No mutagenicity was observed with in vitro and in vivo tests, but long-term animal studies to detect carcinogenicity or adverse effects on fertility have not been conducted (1).

Using an in vitro perfused human placenta, researchers found that only pharmaceutically insignificant amounts of abciximab could be detected in the fetal circuit. Minute amounts of abciximab were found on fetal platelets, but not on the endothelium or smooth muscle of fetal blood vessels, indicating that

some transfer had taken place (2).

A 1998 case described the treatment of an acute myocardial infarction (AMI) in a 30-year-old woman at 38 weeks' gestation (3). Because her condition did not improve with aspirin, heparin, nitrates, or balloon angioplasty after an abciximab infusion was started, a stent was placed in the partially occluded left anterior descending coronary artery. The drug infusion was continued for 12 hours. Adequate blood flow was reestablished in the artery. Postoperatively, the woman was treated with ticlopidine, aspirin, and an unspecified β -blocker. Two weeks later, she delivered a healthy baby boy vaginally, with no evidence of bleeding and a normal ductus arteriosus. No excessive maternal bleeding was observed (3).

A brief 2009 case report described a 39-year-old woman at 6 weeks' who developed an AMI and was started on clopidogrel, aspirin, and heparin (4). Following placement of a stent, the woman again experienced chest pain and thrombus were discovered in three coronary arteries that were removed under coverage of abciximab (dose not specified) and intracoronary adenosine. She was maintained on clopidogrel and aspirin throughout the pregnancy. At 41 weeks', she was given platelet concentrates and a cesarean section delivered a female infant with appropriate weight (weight not specified). Defects in the infant included a patent foramen ovale, a muscular ventricular septal defect, and moderate mitral regurgitation. The authors considered the anomalies relatively common with a benign prognosis (4).

BREASTFEEDING SUMMARY

No reports describing the use of abciximab during lactation have been located. Because of the indications for abciximab, it is doubtful that such reports will be forthcoming. The very high molecular weight of the drug (about 48,000) suggests that it will not be excreted into milk in clinically significant amounts. Therefore, the risk to a nursing infant appears to be nil.

ABIRATERONE ACETATE

Antineoplastic

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Abiraterone acetate, given in combination with prednisone, is indicated for the treatment of prostate cancer. No reports describing its use in human pregnancy have been located, but such reports are unlikely because of the indication. Reproduction studies in pregnant animals have not been conducted. Because of the risk of embryo and fetal harm, the drug is classified as contraindicated in pregnancy.

FETAL RISK SUMMARY

Abiraterone acetate is converted in vivo to abiraterone, an inhibitor of the enzyme (CYP17) that is expressed in testicular, adrenal, and prostatic tumor tissues and is required for androgen biosynthesis. It is indicated for use in combination with prednisone for the treatment of patients with metastatic castration-resistant prostate cancer who have received prior chemotherapy containing docetaxel. The active metabolite abiraterone is further metabolized to inactive metabolites. Abiraterone is highly bound (>99%) to human plasma proteins, albumin, and α_1 -acid glycoprotein and the mean terminal half-life is 12 hours (1).

Reproduction and carcinogenesis studies with abiraterone acetate in animals have not been conducted. However, neither abiraterone acetate nor abiraterone was mutagenic or clastogenic in multiple assays. In rats and monkeys, abiraterone caused atrophy, aspermia/hypospermia, and hyperplasia in the reproductive system at doses that were 1.14 and 0.6 times, respectively, the human clinical exposure based on AUC. These effects were consistent with the antiandrogenic pharmacologic action of the agent (1).

It is not known if abiraterone acetate or its active metabolite abiraterone crosses the human placenta. The molecular weight of abiraterone acetate (about 392) and abiraterone (about 333) and the long terminal half-life of

abiraterone suggest that both agents will cross to the embryo–fetus, but the high plasma protein binding of abiraterone might limit the exposure.

BREASTFEEDING SUMMARY

No reports describing the use of abiraterone acetate during human lactation have been located. Because of the indication, it is unlikely that such reports will occur. The molecular weight of abiraterone acetate (about 392) and the active metabolite abiraterone (about 333), and the long terminal half-life of abiraterone (12 hours) suggest that the both agents will be excreted into breast milk. However, the high plasma protein binding (>99%) of abiraterone might limit the exposure. The effects of exposure to the drug on a nursing infant are unknown but, because of the potential for severe toxicity, breastfeeding is classified as contraindicated.

ACAMPROSATE

Antialcoholic Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest High Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Although no published reports describing the use of acamprosate in human pregnancy have been located, there are human data from a Teratology Information Service (TIS) in France. The animal data suggest high risk, but the very limited human pregnancy experience prevents an assessment of the embryo–fetal risk. However, the use of ethanol (alcohol) in pregnancy is well known to cause dose-related developmental toxicity (see Ethanol). Even in the absence of obvious structural defects, alcohol use during gestation is associated with marked neurotoxicity in the offspring. Therefore, in pregnant women with alcohol dependency, the risk:benefit ratio may favor the use of acamprosate.

FETAL RISK SUMMARY

The synthetic compound acamprosate has a chemical structure similar to that of the endogenous amino acid homotaurine, a structural analog of the amino acid neurotransmitter γ -aminobutyric acid and the amino acid neuromodulator taurine. Acamprosate is indicated to maintain abstinence from alcohol in patients with alcohol dependence who are abstinent at treatment initiation. The mechanism of action is not completely understood, but acamprosate is thought to act differently than disulfiram, another agent in the class. Moreover, acamprosate and disulfiram have completely different chemical structures. Acamprosate is not metabolized and protein binding is negligible. It has a long elimination half-life ranging from about 20 to 33 hours (1).

Reproduction studies have been conducted in rats, rabbits, and mice. In rats, acamprosate was teratogenic at doses about equal to the maximum recommended human daily dose based on BSA (MRHDD). The dose-related

defects were hydronephrosis, malformed iris, retinal dysplasia, and retroesophageal subclavian artery. The no-effect dose in rats was about 0.2 times the MRHDD. In Burgundy Tawny rabbits, hydronephrosis was observed at about 3 times the MRHDD. However, no defects were observed in New Zealand white rabbits at doses about 8 times the MRHDD. In mice, a dose about 2 times the MRHDD administered from day 15 of gestation through the end of lactation on postnatal day 28 was associated with an increased incidence of stillbirths. The no-effect dose in mice was about 0.5 times the MRHDD (1).

No carcinogenicity was observed in studies with rats, and no evidence of mutagenicity or clastogenicity was noted in several tests and assays. Acamprosate had no effect on the fertility of male and female rats at doses up to about 4 times the MRHDD, or in female mice at doses up to about 5 times the MRHDD (1).

It is not known if acamprosate crosses the human placenta. The molecular weight (about 400), lack of metabolism and protein binding, and long elimination half-life suggest that it will cross to the embryo and/or fetus.

A TIS in France has gathered information on 18 pregnancies exposed to acamprosate during the 1st trimester (T. Vial, personal communication, Teratology Information Service, Lyon, France, 2010). The outcomes of these pregnancies included 2 spontaneous abortions, 3 elective abortions, 10 normal newborns (1 premature and 1 died at 1 month of age probably from sudden infant death syndrome), 1 newborn with minor facial anomalies, and a fetus and a newborn with major malformations. The fetus was electively aborted because of an omphalocele and found also to have microretrognathism, cleft palate, and a ventricular septal defect. The major defect in the infant was a cleft lip. Concomitant exposure to alcohol and other drugs occurred in several of the pregnancies.

BREASTFEEDING SUMMARY

No reports describing the use of acamprosate during human lactation have been located. The molecular weight (about 400), lack of metabolism and protein binding, and prolonged elimination half-life (20–33 hours) suggest that the drug will be excreted in breast milk. The effect on a nursing infant from exposure in milk is unknown. However, alcohol is excreted into milk and is known to be a neurotoxin (see Ethanol). Thus, if a lactating woman requires acamprosate to refrain from drinking, the benefit to the nursing infant appears to outweigh the unknown risk from the drug.

ACARBOSE

Antidiabetic Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Less than 2% of acarbose is absorbed systemically, but several metabolites are absorbed in much greater proportions, and the embryo or fetal risk from any of these is unknown. Acarbose is normally used in combination with oral hypoglycemic agents, and these hypoglycemic drugs might not be indicated for the pregnant diabetic. Carefully prescribed insulin therapy will provide better control of the mother's blood glucose, thereby preventing the fetal and neonatal complications that occur with this disease. High maternal glucose levels, as may occur in diabetes mellitus, are closely associated with a number of maternal and fetal effects, including fetal structural anomalies if the hyperglycemia occurs early in gestation. To prevent this toxicity, the American College of Obstetricians and Gynecologists recommends that insulin be used for type 1 and type 2 diabetes occurring during pregnancy and, if diet therapy alone is not successful, for gestational diabetes (1,2).

FETAL RISK SUMMARY

Acarbose is an oral α -glucosidase inhibitor that delays the digestion of ingested carbohydrates within the gastrointestinal tract, thereby reducing the rise in blood glucose after meals. It is used in the management of non-insulin-dependent diabetes mellitus (type 2). Less than 2% of a dose is absorbed as active drug in adults, but the systemic absorption of metabolites is much higher (approximately 34% of the dose) (3).

Reproductive studies in rats found no evidence of impaired fertility or reproductive performance. Doses of acarbose up to 9 and 32 times the human dose (HD) in pregnant rats and rabbits, respectively, were not teratogenic in

either species or, at 10 times the HD, embryotoxic in rabbits (3).

A 1998 noninterventional observational cohort study described the outcomes of pregnancies in women who had been prescribed 1 or more of 34 newly marketed drugs by general practitioners in England (4). Data were obtained by questionnaires sent to the prescribing physicians 1 month after the expected or possible date of delivery. In 831 (78%) of the pregnancies, a newly marketed drug was thought to have been taken during the 1st trimester with birth defects noted in 14 (2.5%) singleton births of the 557 newborns (10 sets of twins). In addition, two birth defects were observed in aborted fetuses. However, few of the aborted fetuses were examined. Acarbose was taken during the 1st trimester in five pregnancies. The outcomes of these pregnancies included two spontaneous abortions and three normal newborns (one premature) (4).

A 2002 abstract reported the pregnancy outcomes (birth weight and gestational age at delivery) of 91 women at ≥ 20 weeks' gestation who were treated with either acarbose (N = 45) or insulin (N = 46) for gestational diabetes mellitus (5). The women had failed to achieve glucose goals with diet alone. In the oral group, 6% were changed to insulin because they were unable to tolerate acarbose (gastrointestinal complaints). There was no difference in the pregnancy outcomes between the groups.

A 2002 report described the use of acarbose (200 mg/day) in early pregnancy (6). A 35-year-old woman with several diseases (hypertension, diabetes mellitus, hypercholesterolemia, anxiety disorder, epilepsy, and morbid obesity) conceived while being treated with multiple drugs: rosiglitazone, gliclazide (a sulfonylurea), atorvastatin, spironolactone, hydrochlorothiazide, carbamazepine, thioridazine, amitriptyline, chlordiazepoxide, and piperzolate bromide (an antispasmodic). Her pregnancy was diagnosed in the 8th week of gestation and all medications were stopped. She was treated with methyldopa and insulin for the remainder of her pregnancy. At 36 weeks' gestation, a repeat cesarean section delivered a healthy, 3.5-kg female infant with Apgar scores of 7 and 8 at 1 and 5 minutes, respectively. The infant was developing normally after 4 months (6).

BREASTFEEDING SUMMARY

No studies describing the use of acarbose during human lactation have been located. Because the drug acts within the gastrointestinal tract to slow the absorption of ingested carbohydrates, and $< 2\%$ of a dose is absorbed systemically, the amount of unmetabolized drug in the mother's circulation available for transfer to the milk is probably clinically insignificant. As with all

drugs, however, the safest course while taking acarbose is not to breastfeed until data on its safety during lactation are available.

ACEBUTOLOL

Sympatholytic (Antihypertensive)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Some β -blockers may cause growth restriction, including intrauterine growth restriction (IUGR), and reduced placental weight, especially those lacking intrinsic sympathomimetic activity (ISA) (i.e., partial agonist). Treatment beginning early in the 2nd trimester results in the greatest weight reductions, whereas treatment restricted to the 3rd trimester primarily affects only placental weight. Acebutolol does possess ISA. However, IUGR and reduced placental weight may potentially occur with all agents within this class. Although growth restriction is a serious concern, the benefits of maternal therapy with β -blockers, in some cases, might outweigh the risks to the fetus and must be judged on a case-by-case basis.

FETAL RISK SUMMARY

Acebutolol, a cardioselective β -adrenergic blocking agent, has been used for the treatment of hypertension occurring during pregnancy (1–5). The drug undergoes extensive first-pass hepatic metabolism after oral administration (absolute bioavailability about 40%). The major metabolite, diacetolol, is equipotent to acebutolol (6).

In animal reproduction studies, no teratogenic effects were observed in pregnant rats and rabbits with doses up to about 32 times the maximum recommended human dose (MRHD) and up to about 7 times the MRHD, respectively. The maximum dose in rabbits produced slight intrauterine growth restriction that was thought to be secondary to maternal toxicity (6).

Acebutolol crosses the placenta, producing a maternal:cord ratio of 0.8 (3). The corresponding ratio for the active metabolite, diacetolol, was 0.6. Newborn

serum levels of acebutolol and the metabolite were <5–244 and 17–663 ng/mL, respectively (3). A cord:maternal ratio of 0.7 for acebutolol has also been reported (4).

No human malformations attributable to acebutolol have been observed, but experience with the drug during the 1st trimester is lacking. In a study comparing three β -blockers, the mean birth weight of 56 newborns was slightly lower than 38 pindolol-exposed infants but higher than 31 offspring of atenolol-treated mothers (3160 vs. 3375 vs. 2745 g) (2). Growth restriction has been associated with β -blockers and the weight reduction may have been drug induced.

In a comparison of 20 pregnant women treated with either acebutolol or methyldopa for mild-to-moderate hypertension, no differences between the drugs were found for pregnancy duration, birth weight, Apgar scores, or placental weight (5). In addition, no evidence of bradycardia, hypoglycemia, or respiratory problems was found in the acebutolol-exposed newborns. In an earlier study, however, 10 newborns exposed to acebutolol near term had blood pressures and heart rates significantly lower than similar infants exposed to methyldopa (7). The hemodynamic differences were still evident 3 days after birth. Mean blood glucose levels were not significantly lower than those of similar infants exposed to methyldopa, but transient hypoglycemia was present 3 hours after birth in four term newborns (5). The mean half-life of acebutolol in the serum of newborns has been calculated to be 10.1 hours, but the half-life based on urinary excretion was 15.6 hours (7). The manufacturer cites the elimination half-life of acebutolol in newborns as 6–14 hours, compared with a half-life for diacetolol of 24–30 hours during the first 24 hours, then 12–16 hours thereafter (6). Therefore, newborn infants of women consuming the drug near delivery should be closely observed for signs and symptoms of β -blockade for at least 3–4 days to allow for elimination of the parent and active metabolite from the infant. Long-term effects of in utero exposure to β -blockers have not been studied but warrant evaluation.

BREASTFEEDING SUMMARY

Acebutolol and its active metabolite, diacetolol, are excreted into breast milk (3,8). Milk:plasma ratios for the two compounds were 7.1 and 12.2, respectively (3). Absorption of both compounds was demonstrated in breastfeeding infants, but no adverse effects were mentioned (3).

In a study of seven nursing, hypertensive mothers treated with 200–1200 mg/day within 13 days of delivery, milk:plasma acebutolol ratios in three of the

mothers varied from 2.3 to 9.2, whereas similar ratios of the metabolite ranged from 1.5 to 13.5 (8). The highest milk concentration of acebutolol, 4123 ng/mL, occurred in a mother taking 1200 mg/day. Two to three days after treatment was stopped, milk:plasma ratios of acebutolol and the metabolite in the seven women were 1.9–9.8 and 2.3–24.7, respectively. Symptoms of β -blockade (hypotension, bradycardia, and transient tachypnea) were observed in one nursing infant, although the time of onset of the adverse effects was not given. Neonatal plasma concentrations of the drug and metabolite (specific data not given), which were already high from in utero exposure, rose sharply after nursing commenced. The mother was taking 400 mg/day, and her milk:plasma ratios of acebutolol and metabolite during treatment were 9.2 and 13.5, respectively, the highest observed in this study (8).

Breastfed infants of mothers taking acebutolol should be closely observed for hypotension, bradycardia, and other signs or symptoms of β -blockade. Long-term effects of exposure to β -blockers from milk have not been studied but warrant evaluation. The American Academy of Pediatrics classifies acebutolol as a drug that has been associated with adverse effects in nursing infants (9).

ACETAMINOPHEN

Analgesic/Antipyretic

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Acetaminophen is commonly used in all stages of pregnancy. Although originally thought not to cause risk in offspring, some recent reports have questioned this assessment, especially with frequent maternal use or in cases where genetic variability exists. Additional data are needed to confirm these risks but, as with all drug use in pregnancy, routine use of acetaminophen should be avoided.

FETAL RISK SUMMARY

Acetaminophen is routinely used during all stages of pregnancy for pain relief and to lower elevated body temperature. The drug crosses the placenta (1). In therapeutic doses, it is apparently safe for short-term use. However, continuous, high daily dosage in one mother probably caused severe anemia (possibly hemolytic) in her and fatal kidney disease in her newborn (2).

The pharmacokinetics of acetaminophen in pregnancy have been reported (3,4). In six healthy women who ingested a 1000-mg dose at 36 weeks' gestation and again 6 weeks after delivery, the mean serum half-lives were similar, 3.7 and 3.1 hours, respectively (3). The absorption, metabolism, and renal clearance of the drug were similar in the pregnant and nonpregnant states. A 1994 study compared the pharmacokinetics of a single 650-mg acetaminophen oral dose in 10 nonpregnant women (controls) with 8 women at a mean gestational age of 11.1 weeks (4). Among the pharmacokinetic parameters evaluated, significant differences between the pregnant and controls were found for elimination constant (0.431 vs. 0.348/hour), serum half-life (1.62 vs. 2.02 hours), and clearance (7.14 vs. 5.22 L/hour-kg).

The potential for acetaminophen-induced fetal liver toxicity after a toxic maternal dose was first suggested in 1979 (5). Two recent reports have described such toxicity (6,7). A woman, in her 27th–28th week of pregnancy,

ingested 29.5 g of acetaminophen over <24 hours for severe dental pain (6). Fetal movements were last felt about 23 hours after the first dose, and on presentation to the hospital 16 hours later, no fetal heart beat was heard. The mother eventually recovered, although her serum levels of acetaminophen by extrapolation were thought to exceed 300 mcg/mL, a toxic level. Autopsy of the 2190-g female fetus revealed a liver acetaminophen concentration of 250 mcg/g of tissue. The extensive lysis of the fetal liver and kidneys, which may have been caused by autolysis before delivery (approximately 3 days after the mother last felt fetal movement), prevented documentation of the characteristic lesions observed in acetaminophen overdose (6).

A 1997 report described the fatal outcomes of a 38-year-old woman and her fetus at 31 weeks' gestation after she consumed an acute 35-g acetaminophen dose (7). The woman presented to the hospital 26 hours after the overdose with signs and symptoms of hepatorenal failure. On admission, she had a toxic acetaminophen serum level (40.43 mcg/mL) that was predictive of a very high risk of hepatocellular damage and subsequent fulminant liver failure (7). IV administration of N-acetylcysteine was started 30 minutes after admission. Severe fetal distress was diagnosed 30 minutes later and a cesarean section under spinal anesthesia was performed to deliver a 1620-g female infant who had Apgar scores of 0, 0, and 1 at 1, 5, and 10 minutes, respectively. The infant's acetaminophen serum level was 41.42 mcg/mL. Despite intensive therapy, the infant died 34 hours after birth and the mother died 66 hours after the overdose. Although the infant's laboratory data indicated hepatorenal toxicity, the actual cause of death could not be determined because permission for autopsy was refused (7).

In four other cases of acute overdosage, acetaminophen-induced fetal liver toxicity was apparently not observed, although such damage may have resolved before delivery in some cases (8–11). One woman, at 36 weeks' gestation, consumed a single dose of 22.5 g of acetaminophen, producing toxic blood levels of 200 mcg/mL (8). She delivered a normal infant approximately 6 weeks later. In another case, a woman at 20 weeks' gestation consumed a total of 25 g in two doses during a 10-hour period (9). She gave birth at 41 weeks to a normal infant with an occipital cephalohematoma as a result of birth position. At 24 hours of age, the infant had jaundice that responded to phototherapy. No evidence of permanent liver damage was observed. The jaundice was thought to have been caused by the cephalohematoma. A third case of acute maternal overdose occurred at 15.5 weeks' gestation when a mother ingested 64 g of the drug (10). Her acetaminophen level 10 hours after

the ingestion was 198.5 mcg/mL. Marked hepatic necrosis and adult respiratory distress syndrome (because of aspiration pneumonia) ensued and then gradually resolved. The patient was discharged home approximately 3 weeks after ingestion and subsequently delivered a healthy 2000-g male infant at 32 weeks' gestation. The infant had physiologic hyperbilirubinemia with a peak level on the fourth day of life of 10.3 mg/dL, but phototherapy was not required. Follow-up evaluation at 4 months indicated normal development. One case involved a 22-year-old woman in her 31st week of pregnancy who consumed a 15-g dose, followed by a 50-g dose 1 week later (11). Fetal distress was observed 16 hours after the second overdose, as evidenced by a complete lack of fetal movements and breathing, a marked decrease in fetal heart rate beat-to-beat variability with no accelerations, and a falling baseline rate. Because of the fetal condition, labor was induced (cesarean section was excluded because of the mother's incipient hepatic failure). Eighty-four hours after the overdose, a healthy 2198-g female infant was delivered with Apgar scores of 9 and 10 at 1 and 5 minutes, respectively. Except for hypoglycemia, mild respiratory disease, and mild jaundice, the newborn did well. Liver enzymes were always within the normal range, and the jaundice was compatible with immaturity. Acetaminophen was not detected in the cord blood. Follow-up examinations of the infant at 6 weeks and again at 6 months were normal. In each of these instances, protection against serious or permanent liver damage was probably afforded by the prompt administration of IV N-acetylcysteine.

A 1993 report described a 25-year-old woman at 27 weeks' gestation who consumed 12.5–15 g of acetaminophen as a single dose 36 hours before admission for premature labor (12). She had also consumed an unknown amount of the drug over a few days before the acute overdose. Because of severe fetal distress, a cesarean section was performed under general anesthesia before her preoperative laboratory tests indicating liver failure were available. A 1300-g male infant was delivered who had Apgar scores of 1, 4, and 4 at 1, 5, and 10 minutes, respectively. No mention was made of hepatic or other toxicity in the infant and his course was thought to be satisfactory for his gestational age. The mother was treated for progressive liver failure and eventually recovered.

The Rocky Mountain Poison and Drug Center reported the results of a nationwide study on acetaminophen overdose during pregnancy involving 113 women (13). Of the 60 cases that had appropriate laboratory and pregnancy outcome data, 19 occurred during the 1st trimester, 22 during the 2nd

trimester, and 19 during the 3rd trimester. In those cases with a potentially toxic serum level of acetaminophen, early treatment with N-acetylcysteine was statistically associated with an improved pregnancy outcome by lessening the incidence of spontaneous abortion and fetal death. Only one congenital anomaly was observed in the series and that involved a 3rd trimester overdose with nontoxic maternal acetaminophen serum levels (13). Based on these observations, neither acetaminophen nor N-acetylcysteine was likely a teratogen, although follow-up data on the infants were not available (13).

A Teratology Information Service in England conducted a prospective study of the pregnancy outcomes of 300 women who had consumed an overdose of acetaminophen, either alone or as a combination product (14). The overdoses occurred in all trimesters: 118 (39.3%), 103 (34.3%), and 79 (26.3%) in the 1st, 2nd, and 3rd trimesters, respectively. Systemic antidote treatment consisted of N-acetylcysteine (N = 33), ipecac (N = 52), and methionine (N = 16). In the remaining 199 cases, treatment was not recorded or not given, or a variety of nonsystemic treatments (charcoal, gastric lavage, or miscellaneous) were used. The fetal outcomes included 219 (72%) normal infants (two sets of twins), 16 (5%) spontaneous abortions (10 within 3 weeks of the overdose), 2 (1%) late fetal deaths, 54 (18%) elective abortions (1 with a diaphragmatic hernia), and 11 (4%) newborns with malformations (exposed between 16 and 32 weeks' gestation). All of the spontaneous abortions and one late fetal death occurred after 1st trimester overdoses. The other late fetal death followed a 2nd trimester overdose. The majority of the elective abortions were conducted for "social," rather than medical reasons. Malformations included one each of systolic murmur, small port wine stain on occiput, cleft lip and palate, bilateral inguinal hernia, soft palate defect, spina bifida occulta/bilateral squint, hypospadias, and ptosis of left eye. There were three cases of talipes. The malformation rate was within the expected rate in England and none of the cases, including the one with diaphragmatic hernia, could be related to acetaminophen (14). Seven full-term newborns had neonatal complications (all exposed during the 2nd or 3rd trimester). The complications did not appear to be related to acetaminophen overdose (14). Moreover, evaluations up to at least 6 weeks of age did not demonstrate any clinical signs of renal or hepatotoxicity.

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 226 of whom had 1st trimester exposure to acetaminophen (15, pp. 286–295). Although no evidence was found to suggest a relationship to large categories of major or minor malformations, a possible association with congenital dislocation

of the hip based on three cases was found, but independent confirmation is required (15, p. 471). For use anytime during pregnancy, 781 exposures were recorded (15, p. 434). As with the qualifications expressed for 1st trimester exposure, possible associations with congenital dislocation of the hip (eight cases) and clubfoot (six cases) were found (15, p. 484).

A 1982 report described craniofacial and digital anomalies in an infant exposed in utero to large daily doses of acetaminophen and propoxyphene throughout pregnancy (16). The infant also exhibited withdrawal symptoms as a result of propoxyphene (see also Propoxyphene). The authors speculated with caution that the combination of propoxyphene with other drugs, such as acetaminophen, might have been teratogenic. In a study examining 6509 women with live births, acetaminophen with or without codeine was used by 697 (11%) during the 1st trimester (17). No evidence of a relationship to malformations was observed.

In a surveillance study of Michigan Medicaid recipients conducted between 1985 and 1992 involving 229,101 completed pregnancies, 9146 newborns had been exposed to acetaminophen during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 423 (4.6%) major birth defects were observed (416 expected). Specific data were available for six defect categories, including (observed/expected) 87/91 cardiovascular defects, 16/16 oral clefts, 4/7 spina bifida, 30/27 polydactyly, 14/16 limb reduction defects, and 16/22 hypospadias. These data do not support an association between the drug and the defects.

Using data from the North Jutland Pharmaco-Epidemiological Prescription Database in Denmark, investigators identified 123 women who had received a prescription for acetaminophen during pregnancy and/or 30 days before conception (18). The pregnancy outcomes of these women were compared with 13,329 controls who had received no prescriptions. Among the offspring of the 55 women who had received an acetaminophen prescription up to 30 days before conception and/or during the 1st trimester, there were six (10.9%) infants with congenital malformations compared with 697 (5.2%) from controls. The odds ratio (OR) for malformations was 2.3 (95% confidence interval [CI] 1.0–5.4). The six malformations were ventricular septal defect, two congenital dislocations of the hip, stenosis of tear canal, diaphragmatic hernia, and megalocornea (keratoglobus). The nature of the defects does not indicate a causal relationship to acetaminophen (18). No increased risk of malformation was found when the analysis was restricted to primigravidas (OR 0.7, 95% CI 0.1–5.5) (18). In addition, no effect was observed on fetal growth.

Unlike aspirin, acetaminophen does not affect platelet function, and there is no increased risk of hemorrhage if the drug is given to the mother at term (19,20). In a study examining intracranial hemorrhage in premature infants, the incidence of bleeding after exposure of the fetus to acetaminophen close to birth was no different from that in nonexposed control infants (21) (see also Aspirin).

A 1993 study examined the effect of therapeutic levels of acetaminophen on prostacyclin (PGI₂) production by endothelial cells isolated from human umbilical veins in culture and during the 3rd trimester in women with either hypertension or various complications of pregnancy (22). The drug reduced the production of PGI₂ in culture and during pregnancy, but thromboxane (TxA₂) production was not affected in the women. A balance between PGI₂ and TxA₂ is thought to be critical during pregnancy. PGI₂, derived from endothelial cells, is vasodilatory and antiaggregatory, whereas the platelet-derived TxA₂ is vasoconstrictive and proaggregatory (22). PGI₂ production increases normally during pregnancy, but this increase is markedly inhibited in pregnancy-induced hypertension (PIH) (22). Thus, a significant acetaminophen-induced reduction in PGI₂ production could adversely affect pregnancies complicated by PIH, including those treated with low-dose aspirin (see Aspirin). Because the effects of acetaminophen on PGI₂ are known to be tissue-specific, the authors of this study cautioned that additional studies, such as those measuring the effect of acetaminophen on placental PGI₂ and in patients being treated with low-dose aspirin for PIH, are required before the clinical significance of their findings can be determined (22).

In a prospective study of 1529 pregnant women in the mid-1970s, acetaminophen was used in the first half of pregnancy by 41% (23). A computerized system for stratifying on maternal alcohol and smoking histories was used to select 421 newborns for follow-up. Of this group, 43.5% had been exposed in utero to acetaminophen in the first half of pregnancy. After statistical control of numerous potentially confounding covariates, the data indicated that acetaminophen was not significantly related to child IQ at 4 years of age or to attention variables (see Aspirin for opposite results). Three physical growth parameters (height, weight, and head circumference) were also not significantly related to in utero acetaminophen exposure.

Acetaminophen has been used as an antipyretic just before delivery in women with fever secondary to chorioamnionitis (24). A significant improvement in fetal and newborn status, as measured by fetal heart rate tracings and

arterial blood gases, was observed after normalization of the mother's temperature.

In a 2004 case–control study, 168 infants who had a nonsyndromic muscular ventricular septal defect were compared with 692 infants without birth defects (25). No significant associations were found between the occurrence of the ventricular septal defect and maternal use of acetaminophen or nonsteroidal anti-inflammatory agents after adjusting for maternal fever nor were they detected between maternal fever and the defect.

Use of acetaminophen during pregnancy was not associated with an increased risk of congenital anomalies in a 7-year prospective cohort study of 101,041 Danish women (26). Similar results were found in a 2010 report from the National Birth Defects Prevention Study (27). Moreover, use of acetaminophen appeared to decrease the risk of selected malformations when used for febrile illness.

In contrast to the above two studies, male offspring of Danish mothers who had used mild analgesics (acetaminophen, aspirin, ibuprofen) for >2 weeks, especially in the 2nd trimester, had a significant risk of cryptorchidism diagnosed at birth. The greatest risk observed was when more than one mild analgesic was used. The findings of this study were supported by antiandrogenic effects in rat models (28).

An in vitro study was conducted to determine the primary hepatic enzymes responsible for acetaminophen sulfation (29). The study found that the sulfotransferase isoform, SULT1A3/4, was the primary determinant of this activity. Genetic variation in this enzyme could lead to reduced fetal biotransformation of acetaminophen and persistence of the drug in the fetus. The investigators hypothesized that this could be a risk factor for the development of fetal gastroschisis (29).

A 2013 study evaluated the effect of prolonged use of acetaminophen during pregnancy on the neurodevelopment of 3-year-old offspring (30). The cases came from the prospective Norwegian Mother and Child Cohort Study. Data on acetaminophen use were obtained from a follow-up questionnaire sent to the mothers who were asked about their use of acetaminophen at gestational weeks 17 and 30. Among the 48,631 children whose mothers returned the questionnaire, 2919 same-sex sibling pairs were identified. In the sibling-controlled analysis, children exposed to prenatal acetaminophen for >28 days had significantly poorer gross motor development, communication, externalizing behavior, internalizing behavior, and higher activity levels than their nonexposed siblings. In those exposed prenatally to short-term use (1–27 days), poorer

gross motor outcomes were found but the effects were smaller than with long-term use. Ibuprofen prenatal exposure was not associated with adverse neurodevelopment outcomes (30).

In a 2009 study, 1505 pregnant women and their children were prospectively followed up until 6 months of life (31). The use of acetaminophen during gestation did not increase the risk of asthma in the children. Use of the drug in the 1st and 3rd trimesters significantly reduced the risk of asthma. There was no evidence of a dose response, even with very high doses, such as >32 tablets (10,400 mg) per month (31).

BREASTFEEDING SUMMARY

Acetaminophen is excreted into breast milk in low concentrations (32–36). A single case of maculopapular rash on a breastfeeding infant's upper trunk and face was described in 1985 (32). The mother had taken 1 g of the drug at bedtime for 2 days before the onset of the symptoms. The rash resolved 24 hours after discontinuing acetaminophen. Two weeks later, the mother took another 1-g dose, and the rash recurred in the infant after breastfeeding at 3, 8, and 12 hours after the dose. Milk levels at 2.25 and 3.25 hours after the dose were 5.78/7.10 (right/left breasts) and 3.80/5.95 mcg/mL (right/left breasts), respectively. These represented milk:plasma ratios of 0.76 and 0.50, respectively (32).

Unpublished data obtained from one manufacturer showed that after an oral dose of 650 mg, an average milk level of 11 mcg/mL occurred (McNeil Laboratories, personal communication, 1979). Timing of the samples was not provided.

In 12 nursing mothers (nursing 2–22 months) given a single oral dose of 650 mg, peak levels of acetaminophen occurred at 1–2 hours in the range of 10–15 mcg/mL (33). Assuming 90 mL of milk were ingested at 3-, 6-, and 9-hour intervals after ingestion, the amount of drug available to the infant was estimated to range from 0.04% to 0.23% of the maternal dose.

After ingestion of a single analgesic combination tablet containing 324 mg of phenacetin, average milk levels of acetaminophen, the active metabolite, were 0.89 mcg/mL (34). Milk:plasma ratios at 1 and 12 hours were 0.91 and 1.42, with a milk half-life of 4.7 hours, as compared with 3.0 hours in the serum. Repeated doses at 4-hour intervals were expected to result in a steady-state concentration of 2.69 mcg/mL (34).

In three lactating women, a mean milk:plasma ratio of 0.76 was reported after a single oral dose of 500 mg of acetaminophen (35). In this case, the

mean serum and milk half-lives were 2.7 and 2.6 hours, respectively. Peak milk concentrations of 4.2 mcg/mL occurred at 2 hours. In a more recent study, the calculated milk:plasma ratio was approximately 1.0 (36). Based on a dose of 1000 mg, the estimated maximum dose the infant could ingest was 1.85% of the maternal dose.

Except for the single case of rash, no other adverse effects of acetaminophen ingestion via breast milk have been reported. The American Academy of Pediatrics classifies acetaminophen as compatible with breastfeeding (37).

ACETAZOLAMIDE

Diuretic (Carbonic Anhydrase Inhibitor)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Although some animal data have shown toxicity in offspring, a comparison to the human dose has not been provided and most studies found no adverse effects. Moreover, despite widespread use, the human data do not suggest a risk of developmental toxicity. The drug can be considered compatible in pregnancy.

FETAL RISK SUMMARY

Acetazolamide is an inhibitor of the enzyme carbonic anhydrase. It is indicated as adjunctive treatment of chronic simple (open-angle) glaucoma, secondary glaucoma, and preoperatively in acute angle-closure glaucoma where delay of surgery is desired in order to lower intraocular pressure. It also is indicated for the prevention or amelioration of symptoms associated with acute mountain sickness despite gradual ascent (1). The drug also is used off-label for idiopathic intracranial hypertension (IIH) (2–5).

Shepard (6) reviewed six reproduction studies using acetazolamide in mice, rats, hamsters, and monkeys. Forelimb defects were observed in the fetuses of rodents, but not in those of monkeys. One of the studies found that potassium replacement reduced the risk of congenital defects in rats (6). A study with pregnant rabbits found that, with doses producing maternal acidosis and electrolyte changes, acetazolamide produced a dose-related increase in axial skeletal malformations (7). The combination of acetazolamide and amiloride was found to produce abnormal development of the ureter and kidney in fetal mice when given at the critical moment of ureter development (8).

It is not known if acetazolamide crosses the human placenta. However, the molecular weight (about 222) suggests that the drug will cross to the embryo–fetus.

Despite widespread usage, no reports linking the use of acetazolamide with

congenital defects have been located. A single case of a neonatal sacrococcygeal teratoma has been described (9). The mother received 750 mg daily for glaucoma during the 1st and 2nd trimesters. A relationship between the drug and carcinogenic effects in the fetus has not been supported by other reports. Retrospective surveys on the use of acetazolamide during gestation have not demonstrated an increased fetal risk (10,11).

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 12 of whom had 1st trimester exposure to acetazolamide (12, p. 372). No anomalies were observed in the exposed offspring. For use anytime during pregnancy, 1024 exposures were recorded (12, p. 441), and 18 infants were found to have malformations (18.06 expected). Thus, no evidence was found to suggest a relationship to large categories of major or minor malformations or to individual defects.

A woman with glaucoma was treated throughout pregnancy with acetazolamide, 250 mg twice daily, and topical pilocarpine and timolol (13). Within 48 hours of birth at 36 weeks' gestation, the infant's condition was complicated by hyperbilirubinemia and asymptomatic hypocalcemia, hypomagnesemia, and metabolic acidosis. The deficiencies of calcium and magnesium resolved quickly after treatment, as did the acidosis, even though the mother continued her medications while breastfeeding the infant. Mild hypertonicity of the lower limbs requiring physiotherapy was observed at 1-, 3-, and 8-month examinations. Two healthy infants of an epileptic mother, treated throughout two pregnancies with acetazolamide 250 mg/day and carbamazepine, were delivered at term and showed no effects of exposure to the drugs (13).

Four reports described the use of acetazolamide for treatment of IIH in a large number of pregnant women (2–5). No embryo or fetal adverse effects attributable to the drug were noted in any of the cases.

BREASTFEEDING SUMMARY

Acetazolamide is excreted into breast milk (14). A mother, 6 days postpartum, was given 500 mg (sustained-release formulation) twice daily for glaucoma, and she breastfed her infant for the following week. Nursing was stopped after that time because of the mother's concerns about exposing the infant to the drug. However, no changes attributable to drug exposure were noted in the infant. Breast milk levels of acetazolamide on the fourth and fifth days of therapy, 1–9 hours after a maternal dose, varied between 1.3 and 2.1 mcg/mL. A consistent relationship between concentration and time from last dose was

not apparent. A milk:plasma ratio 1 hour after a dose was 0.25. Three plasma levels of acetazolamide in the infant were 0.2, 0.2, and 0.6 mcg/mL. The authors estimated that the infant ingested about 0.6 mg/day (i.e., 0.06% of the maternal dose) (15).

The American Academy of Pediatrics classifies acetazolamide as compatible with breastfeeding (15).

ACETYLCYSTEINE

Respiratory Agent (Mucolytic), Antidote

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefits >> Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Acetylcysteine is not teratogenic or embryotoxic in animals and, although the data are limited, do not appear to represent a risk to the human fetus when IV doses are used as an antidote for acute acetaminophen overdose. After IV administration, the drug crosses the placenta to achieve protective serum levels in the fetus. A 1999 report concluded that acetaminophen overdose in pregnant women should be managed the same way as in nonpregnant patients and that acetylcysteine therapy was protective to both the mother and the fetus (1). There is no reported human pregnancy experience after use of acetylcysteine as a mucolytic agent.

FETAL RISK SUMMARY

Acetylcysteine (N-acetyl-L-cysteine) is a mucolytic agent indicated as adjuvant therapy in the treatment of abnormal, viscid, or inspissated mucous secretions in a variety of pulmonary conditions. It is also indicated as an antidote to prevent or lessen hepatic injury following the ingestion of potentially hepatic toxic doses of acetaminophen (2). Acetylcysteine has been used as an ophthalmic solution to treat keratoconjunctivitis sicca (dry eye) and as an enema for bowel obstruction due to meconium ileus (3), although these indications are not approved by the FDA. In mice, the agent has also demonstrated efficacy as a chelating agent to reduce organic mercury-induced developmental toxicity (4).

Reproductive studies with acetylcysteine have been conducted in rats and rabbits. Pregnant rabbits were given oral doses about 3 times the human mucolytic dose on days 6–16 of gestation. Additional pregnant rabbits were exposed to an aerosol of 10% acetylcysteine and 0.05% isoproterenol for 30–

35 minutes twice daily from the 16th to the 18th day of gestation. No teratogenic effects were observed in either the oral or the aerosol studies. In pregnant rats, an aerosol combination of acetylcysteine and isoproterenol was given in a manner similar to that used in rabbits from the 6th to the 15th day of gestation. Other pregnant rats were exposed to the aerosol from the 15th to the 21st day of gestation. No teratogenic effects or maternal or fetal toxicity was observed in these studies (2).

Consistent with its low molecular weight (about 163), acetylcysteine crosses the human placenta. In a study of three pregnant women who delivered viable infants while undergoing treatment for acetaminophen toxicity, the mean acetylcysteine cord blood concentrations was 9.4 mcg/mL (range 8.6–10.9 mcg/mL) (5). The corresponding maternal serum concentrations (trough levels, 4 hours after a dose) ranged from 7.2–11.8 mcg/mL. In a fourth nonviable infant delivered at 22 weeks' gestation, the acetylcysteine level in a postmortem cardiac blood sample obtained 48 hours after death was 55.8 mcg/mL. The mean cord blood level was within the range associated with therapeutic acetylcysteine doses in adults. No adverse effects attributable to acetylcysteine or acetaminophen were observed in the three viable infants, nor was there evidence of acetaminophen toxicity in the fourth infant (5).

The only published reports describing the use of acetylcysteine during human pregnancy involve the agent's use as an antidote following acute acetaminophen overdose (1,6–10). A case report published in 1982 described a woman at 36 weeks' gestation who took an overdose of acetaminophen (6). A few hours after the ingestion, acetylcysteine was administered (140 mg/kg IV, then 70 mg/kg IV every 4 hours for 17 doses). The mother made an uneventful recovery and 6 weeks later delivered a healthy 3.29-kg female infant with Apgar scores of 9 and 9 (6).

Two other case reports of maternal acetaminophen overdose, at 15 and 32 weeks' gestation, respectively, appeared in 1986 and 1989 (7,8). Both women were successfully treated with IV acetylcysteine. In the first case, a 2.00-kg male infant was eventually delivered at 32 weeks' gestation. He was developing normally at 4 months of age (7). Because of severe toxicity in the second woman and fetal distress, delivery was induced 84 hours after the overdose resulting in the birth of a healthy 2.198-kg female infant (8). Acetaminophen was not detected in the cord blood (no test for acetylcysteine was done). Except for hyperbilirubinemia of prematurity, the infant did well with no evidence of toxicity at follow-up examinations at 6 weeks and 6 months of age (8).

In a 1989 study from the Rocky Mountain Poison and Drug Center, covering

1976–1985, pregnancy outcomes were available for 60 of the 110 women who had an acute acetaminophen overdose during gestation (9). Of the 60 women, 24 were treated with IV acetylcysteine (4 in the 1st trimester) for toxic acetaminophen serum levels. The outcomes of the 24 cases were 14 viable infants (2 premature), 3 spontaneous abortions (SABs), 5 elective abortions, 1 stillbirth, and 1 maternal death. In the stillbirth case, the mother overdosed at 33 weeks' gestation with fetal death occurring 2 days later. An autopsy of the fetus revealed massive centrilobular hepatic necrosis that was consistent with acetaminophen-induced hepatotoxicity. Of the five potential independent variables evaluated, only two were significantly predictive of pregnancy outcome: time to start of acetylcysteine and gestational age. The probability of fetal death increased the longer it took to receive the antidote and the lower the gestational age. One infant was reported to have a mild positional deformity of the feet. No other congenital defects were reported (9).

A 1997 study from a teratology information service in England reported the pregnancy outcomes of 300 cases of acute acetaminophen overdose (10). A total of 33 mothers were treated with IV acetylcysteine. The outcomes of these cases were 24 normal infants, 3 SABs or fetal deaths, 5 elective terminations, and 1 infant with hypospadias. There was no relationship between the defect and either acetaminophen or acetylcysteine due to the timing of exposure. None of the other adverse outcomes were related to acetylcysteine (10).

BREASTFEEDING SUMMARY

No reports have described the use of acetylcysteine during lactation. Although the molecular weight of the drug (about 163) is low enough for excretion into breast milk, the various conditions in which acetylcysteine is used suggest that the drug will rarely be prescribed during breastfeeding. Moreover, IV acetylcysteine has been administered directly to preterm neonates for therapeutic indications, at doses far above those that would be obtained from milk, without causing toxicity (11,12).

ACETYLDIGITOXIN

Cardiac Glycoside

[See Digitalis.]

ACITRETIN

Vitamin

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Like all retinoids, acitretin, the active metabolite of etretinate, is a potent teratogen. It represents not only a significant fetal risk during pregnancy, but also a risk for an unknown time after therapy has ceased. This added fetal risk results because acitretin can be converted back to the parent drug, etretinate, which can persist, along with acitretin and 13-cis-acitretin, in SC fat for prolonged periods, perhaps for >3 years. Measuring plasma levels of the retinoids does not appear to be beneficial in determining the risk of fetal harm. Effective contraception must be used for at least 1 month before beginning acitretin, during therapy, and for at least 3 years after acitretin therapy (1). Women of childbearing age who are considering treatment with acitretin must be informed of this very slow elimination and the possibility of adverse pregnancy outcome if they conceive within 3 years of therapy. There apparently is no risk of acitretin-induced developmental toxicity when only the father is being treated (2).

FETAL RISK SUMMARY

Acitretin, an oral active synthetic retinoid and vitamin A derivative, is the active metabolite of etretinate (see also Etretinate). It is used for the treatment of severe psoriasis resistant to other forms of therapy and for severe congenital ichthyosis and keratosis follicularis (Darier disease).

Similar to vitamin A and its derivatives, acitretin may cause congenital defects at human dosage levels in various animal species, including the mouse, rat, and rabbit. Fertility of rats was not impaired at the highest dose tested (about 3 times the maximum recommended human dose [MRHD]). Chronic administration to male dogs (30 mg/kg/day) produced testicular changes: reversible mild-to-moderate spermatogenic arrest and the appearance of multinucleated giant cells (1).

After oral absorption, acitretin undergoes extensive metabolism and interconversion by simple isomerization to 13-cis-acitretin. When consumed with alcohol, acitretin may be converted back to etretinate, a retinoid with a very long elimination half-life (mean 120 days, but may be as long as 168 days). Because the prolonged elimination would increase the teratogenic potential for women of childbearing age (see also Etretinate), the manufacturer states that alcohol must not be ingested during therapy with acitretin and for 2 months after cessation of therapy because of the long elimination period of acitretin (1).

In a 1994 reference, the concentrations of etretinate, acitretin, and 13-cis-acitretin were measured in plasma and SC fat samples from 37 women of childbearing age (3). Twenty of the women were receiving acitretin and 17 had stopped. Sixteen of the 20 women current acitretin users had taken etretinate but had stopped that drug a mean 45 months before sampling, whereas 4 women had never received etretinate. Among current acitretin users, detectable etretinate levels in the plasma and SC fat were found in 45% and 83%, respectively. The 17 women who had stopped taking acitretin had been off the drug a mean 12 months. Eleven of these women had also used etretinate but had stopped a mean 43 months before sampling. The 6 women who had never taken etretinate stopped acitretin 17 months before testing. Among these 17 women, etretinate was detected in 18% and 86%, respectively, of the plasma and SC fat samples. In some cases, acitretin and/or etretinate were detectable in plasma or SC fat up to 29 months after acitretin therapy had ceased. Thus, plasma concentrations correlated poorly with concentrations in fat. The findings led the authors to conclude that the recommended contraception period of 2 years after acitretin treatment (in 1994) was too short to avoid the risk of teratogenicity (3). Currently, the manufacturer recommends a contraception period of 3 years, but the human threshold concentration of acitretin below which the drug is not teratogenic has not been established (1).

A case report of a pregnancy exposed to acitretin starting 10 days after conception and throughout the 1st trimester was published in 1995 (4). The 34-year-old woman was treated with acitretin (50 mg/day) for severe palmoplantar epidermolytic keratoderma. Pregnancy was diagnosed 6 weeks after stopping acitretin therapy. The pregnancy was terminated at 20 weeks' gestation with delivery of a stillborn, 210-g, 24-cm-long male fetus with severe symmetric defects of the upper and lower limbs and craniofacial malformations. The extremity defects included bilateral short arms with pterygium formation in the elbows, shortened thumbs and little fingers without nails, contractures of both

lower limbs in the groins and knees, irregularly thickened femora and tibiae, and point-shaped feet with only two small toes without nails. X-ray of the limbs revealed bilateral humeroradial synostosis and bone defects in the hands and feet. Craniofacial malformations included underdeveloped maxilla and mandibula, a small mouth with a high, arched and narrow palate, low-set ears, bilateral microtia, agenesis of the external ear canals, and bilateral preauricular tags. Except for an atrioventricular septal defect type II, no other anomalies were discovered on autopsy. Concentrations of acitretin, 13-cis-acitretin, and etretinate, in the maternal plasma, fetal brain and liver, and amniotic fluid 48 days after stopping therapy, were either undetectable (<0.3 ng/mL) or unquantifiable. An attempted chromosomal analysis of the fetus failed. Because the authors could find no other explanation for the malformations, including potential genetic defects, and the craniofacial malformations were similar to previous cases of retinoic acid embryopathy (e.g., see Isotretinoin), they concluded that the defects were caused by acitretin. In addition, the authors were aware of the poor correlation between plasma and fat concentrations of the vitamin A derivatives (3); thus the failure to detect the retinoids in the plasma did not affect their conclusion (4).

A 1994 study attempted to determine if there was a threshold dose or plasma concentration of acitretin below which there was no teratogenic risk in females (5). In various species, the highest nonteratogenic oral doses (mg/kg/day) were 1 (mouse), 7.5 (rat), and 0.2 (rabbit). No data were available for cynomolgus monkeys or humans. The authors also summarized the outcomes of pregnancies that had occurred during or after acitretin therapy and been reported to the manufacturer since human therapy with the drug began in 1983. A total of 75 women were exposed to acitretin either during pregnancy (N = 8) or before pregnancy (N = 67) (median time before pregnancy 5 months, range 6 weeks to 23 months). Among those exposed during pregnancy, there were four spontaneous abortions, one induced abortion (no information on the fetus), one induced abortion with typical malformations, one newborn with a nontypical anomaly, and one normal newborn. The mother of the fetus with typical malformations took 50 mg/day of acitretin during the first 19 weeks of gestation. Malformations in the fetus were microtia and defects of the face and extremities. The mother of the infant with a nontypical anomaly took acitretin (20 mg/day) during the first 8 months of pregnancy. The infant had a hearing impairment for high frequencies. The outcomes of the 67 pregnancies exposed before conception were 9 spontaneous abortions, 18 induced abortions (15 fetuses with no information, 3 normal fetuses), 4 newborns with nontypical

abnormalities, and 36 normal newborns. One of the mothers who delivered an infant with nontypical malformations had received 1 week of acitretin, 25 mg/day, 18 months before conception. The abnormalities, considered incompatible with life, included macrocephaly, low-set ears, microphthalmia, low-inserted thumb, ventricular and atrial septal defects, total duodenal obstruction, and cystic kidneys. The malformations were thought to be due to a chromosomal abnormality (partial trisomy 1) and a history of maternal drug abuse. The nontypical abnormalities in the other three newborns were transitory neonatal icterus and hypocalcemia, left testis ectopia, and slight transitory hypotonia (5).

In 1999, a report from the manufacturer summarized the worldwide data relating to acitretin and human pregnancy exposures that had been reported to the manufacturer since acitretin became available (6). Some of these data may have also been reported in the study discussed above. There were 123 reports of acitretin exposure either before or during pregnancy, 88 of which were prospective reports. Details on malformations were provided in only one case. Outcomes that did not involve congenital malformations were classified as “other abnormalities,” defined as pregnancy-related, placental, perinatal, or neonatal disorders, such as hyperbilirubinemia, abnormal growth, and delayed motor skills. There were 11 exposures during pregnancy, five reported prospectively and six retrospectively. Among the prospective cases, there was one spontaneous abortion (SAB) (no information on the fetus), three elective abortions (EABs) (no information on the fetuses), and one newborn with malformations (no details provided, but reference 3 above was included whereas reference 4 was not). Among those reported retrospectively, there was one SAB (no information), three EABs (two with malformations and one with other adverse conditions), and two newborns with other adverse conditions. For exposures that occurred 0–2 years before pregnancy, there were 97 cases, 77 of them prospective. Outcomes in these cases were 8 SABs (1 normal embryo–fetus, and 7 with no information), 25 EABs (3 normal, 2 with malformations, and 20 with no information), and 44 newborns (41 normal, 1 with an undescended testicle, 1 hypotonic, and 1 with hypocalcemia and jaundice). The outcomes in the 20 retrospective cases were 5 SABs (no information), 4 EABs (1 normal, 1 with malformations, and 2 with no information), and 11 newborns (9 normal, 2 with malformations). Two of the five cases in which exposure occurred more than 2 years before pregnancy were prospective. Their outcomes were one SAB (no information) and one normal newborn. The three retrospective cases all involved newborns with

malformations. Finally, 10 cases involved exposure at an unknown time before conception, 4 of which were prospective. The outcomes were one SAB (no information), one EA (no information), and two normal neonates. For the six retrospective cases, there was one SAB (no information), two EABs (one normal and one with no information), and three normal newborns (6).

A 2004 case described the pregnancy outcome of a woman who had taken acitretin 10 mg/day until the 10 completed weeks of pregnancy (7). The 1450-g (25th percentile) female infant was born at 32 weeks' with Apgar scores of 8 and 10 at 1 and 5 minutes, respectively. Evaluation up to 11 months of age revealed growth restriction (length and head circumference <3rd percentile, weight 50th percentile), epicanthal folds, low nasal bridge, high palate, cup-shaped ears, anteverted nostrils, prominent heels, atrial septal defect (closed spontaneously), and bilateral sensorineural deafness. At 18 months of age, the infant was microcephalic, hypotonic, and had neurodevelopmental delay. The pattern of defects resembled those observed with isotretinoin and etretinate (7).

An interaction between acitretin and a very low-dose progestin contraceptive (levonorgestrel 0.03 mg) was observed in one woman undergoing treatment with acitretin 0.4 mg/kg/day (8). Her plasma progesterone level increased from 2.15 ng/mL before acitretin or contraceptive to 3.87–13.46 ng/mL while receiving both drugs. The increase in plasma concentration was thought to indicate failure of contraception and development of a corpus luteum after ovulation. No interaction, as evidenced by a rise in plasma progesterone concentration, was observed in nine other women who received combined oral contraceptives (normal or mini-dose) (8).

Acitretin has been measured in the seminal fluid of men consuming either acitretin or etretinate (1). In men administered 30–50 mg/day for at least 12 weeks, the sperm count, concentration, motility, and morphology were unchanged. In addition, no adverse effects were observed with regard to testosterone production, luteinizing hormone, follicle-stimulating hormone, or on the hypothalamic–pituitary axis. The maximum concentration of acitretin found in seminal fluid was 12.5 ng/mL. The amount of acitretin transferred in semen, assuming an ejaculate volume of 10 mL, would be 125 ng or 1/200,000th of a single 25-mg capsule. Of five pregnancies in which the father was receiving acitretin therapy, two ended in SABs, one fetus had bilateral cystic hygromas and multiple cardiopulmonary anomalies, one normal newborn was delivered, and one was lost to follow-up. The relationship between acitretin and the fetal malformations is unknown. However, no teratogenicity was observed in the

offspring of male rats treated with 5 mg/kg/day (about 5 times the MRHD) for 10 weeks (approximate duration of one spermatogenic cycle) before and during mating with untreated females (1).

BREASTFEEDING SUMMARY

Acitretin is excreted into the milk of humans. A woman 8 months postpartum was treated with a single daily 40 mg dose of acitretin (0.65 mg/kg/day) for extensive plaque psoriasis and acral pustulosis (9). Nursing was stopped before the therapy was started. Milk was collected each day by an electric pump before the dose and again 12 hours later. At steady state, milk concentrations of the drug and its main metabolite were 30–40 ng/mL, corresponding to a milk:serum ratio of 0.18. The estimated infant dose was 1.5% of the maternal dose (9).

The plasma elimination half-lives of acitretin and 13-cis-acitretin may be as long as 96 and 157 hours, respectively (1). Because of storage in subcutaneous fat, the actual elimination of these compounds may take much longer. The manufacturer recommends a contraception period of 3 year after acitretin therapy is stopped, but a similar recommendation for breastfeeding has not been made. Although there is a potential for toxicity, the American Academy of Pediatrics classifies the drug as compatible with breastfeeding (10).

ACLIDINIUM BROMIDE

Respiratory (Bronchodilator)

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of acclidinium in human pregnancy have been located. The animal data suggest low risk, but the absence of human pregnancy experience prevents a more complete assessment of embryo–fetal risk. However, the low (unspecified) plasma concentrations suggest that the drug, if indicated, represents a low, if any, risk in pregnancy.

FETAL RISK SUMMARY

Acclidinium bromide, a dry powder for inhalation, is indicated for the long-term, maintenance treatment of bronchospasm associated with chronic obstructive pulmonary disease, including chronic bronchitis and emphysema. It is an antimuscarinic agent that is often referred to as an anticholinergic. Acclidinium is rapidly and extensively hydrolyzed to inactive metabolites so that plasma concentrations (not specified) are low. The estimated effective half-life is 5–8 hours (1).

Reproduction studies have been conducted in rats and rabbits. No evidence of structural anomalies was observed in rats exposed during organogenesis to about 15 times the recommended human daily dose based on summed AUC of acclidinium and its metabolites (RHDD) (based on inhaled doses ≤ 5 mg/kg/day). However, during lactation, exposures that were about 5 times the RHDD (based on inhaled doses ≥ 0.2 mg/kg/day) resulted in decreased pup weights. These doses also caused maternal toxicity. In rabbits during organogenesis, no evidence of structural anomalies was observed at exposures that were about 20 times the RHDD (based on inhaled doses ≤ 3.6 mg/kg/day). Compared with controls, an increased incidence of liver lobes was noted at exposures that were about 1400 times the RHDD (based on oral doses ≥ 150 mg/kg/day) and

decreased fetal body weights occurred at exposures that were about 2300 times the RHDD (based on oral doses ≥ 300 mg/kg/day). Both exposures caused maternal toxicity (1).

Long-term studies for carcinogenicity in mice and rats were negative. In various tests for mutagenicity, both positive and negative assays were noted. In male and female rats given inhaled doses that were about 15 times the RHDD, impaired fertility and reproductive performance were observed, as well as paternal toxicity. However, in other rat studies (treated males mated with untreated females; treated females mated with untreated males), no effects on fertility were observed at inhaled doses resulting in exposures that were about 30 and 15 times the RHDD, respectively (1).

It is not known if acridinium or its metabolites cross the human placenta. The molecular weight of the parent drug (about 565) and the long half-life suggest that the drug will cross to the embryo–fetus. However, the low (unspecified) plasma concentrations indicate that the amount crossing will also be low.

BREASTFEEDING SUMMARY

No reports describing the use of acridinium during human lactation have been located. The molecular weight of the parent drug (about 565) and the long effective half-life (5–8 hours) suggest that the drug will be excreted into breast milk. However, the low (unspecified) plasma concentrations indicate that the amount excreted into milk will also be low. The most common adverse reactions ($\geq 3\%$ incidence) among adults were headache, nasopharyngitis, and cough (1). Although the drug appears to be compatible during breastfeeding, nursing infants of mothers receiving the drug should be monitored for these effects.

ACYCLOVIR

Antiviral

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No adverse effects in the fetus or newborn attributable to the use of acyclovir during pregnancy have been reported. Congenital malformations have been reported in infants exposed during pregnancy, but they do not appear to be related to the drug. Systemic IV treatment is indicated for life-threatening disseminated herpes simplex virus (HSV) infections to reduce the maternal, fetal, and infant mortality of these infections. Oral acyclovir treatment of primary genital HSV infections also appears to be indicated to prevent adverse fetal outcomes, such as prematurity, intrauterine growth restriction (IUGR), and neonatal HSV infection.

FETAL RISK SUMMARY

Acyclovir is a synthetic acyclic purine nucleoside analog used as an antiviral agent against the herpes viruses. Three studies observed no teratogenic effects in animals at nontoxic doses (1–3). One study, however, observed abnormal thymus development and functional deficits of the immune system in rats exposed in utero to acyclovir (4). Chromosome breaks were observed in some tests with cultured human lymphocytes, but only with prolonged exposure and at doses much higher than those obtainable in clinical use (5). A 1997 publication, however, cited studies that gave SC doses of 100 mg/kg once, twice, or 3 times to pregnant rats on day 10 of gestation (6). Altered development was observed in fetuses examined on day 11.5 (reduced crown–rump length, number of somites, and protein content) or on day 21 (skull, eye, and tail defects). The SC doses caused slight and reversible maternal nephropathia, but this was not thought to have induced the fetal anomalies (6).

Reproduction studies in mice, rats, and rabbits, as reported by the manufacturer, did not observe teratogenic effects (7). The doses used in the three species produced plasma levels that were the same as human levels, 1–2

times human levels, and 4 and 9 times human levels, respectively.

Although there are no approved indications for acyclovir in pregnancy, the principal clinical use of acyclovir during this period is for the treatment of primary genital HSV type 2 infection and for the prophylaxis against recurrent genital HSV infection. The Acyclovir in Pregnancy Registry found that, of the American women reported to the Registry as exposed during pregnancy, 62% and 70% of their prospective and retrospective samples, respectively, had been treated for genital herpes (8). They estimated that as many as 7500 live births per year in the United States may be exposed to acyclovir (8).

The treatment of genital herpes is intended to prevent the adverse outcomes on the fetus and newborn that the primary infection may cause, such as prematurity, IUGR, and neonatal HSV infection, and to reduce the incidence of cesarean section with recurrent disease. Reviews evaluating the various indications for acyclovir in pregnancy concluded that life-threatening maternal HSV infection and varicella pneumonia were the most justifiable indications (9,10). Some evidence was cited that the benefits of treatment of primary genital herpes, under certain conditions, might outweigh the risks, but the lack of controlled studies prevented any conclusion (9,10). Similarly, the treatment of uncomplicated varicella infections and the prophylaxis against recurrent genital HSV were unproven indications because of the absence of supporting data (9,10). Some authors have proposed the use of acyclovir for the prophylaxis of genital HSV during pregnancy, although all qualify their proposals with statements that controlled studies are needed to assess efficacy and safety (11–13).

A 1998 randomized, placebo-controlled study was conducted to determine if oral acyclovir (800 mg/day) could reduce the rate of cesarean section in women with recurrent genital herpes infection at <36 weeks' gestation (14). A total of 63 women were enrolled (acyclovir N = 31, placebo N = 32) in the study. Except for a significant reduction in clinical recurrences (odds ratio [OR] 0.10, 95% confidence interval [CI] 0.00–0.86), the other outcome measures showed no significant difference from placebo: cesarean section (OR 0.44, 95% CI 0.09–1.59), and clinical recurrence or asymptomatic shedding (OR 0.32, 95% CI 0.05–1.56). None of the newborns were infected with HSV and no abnormal findings were detected in the 19 exposed infants examined 1 year later. The investigators concluded that acyclovir should not be used for recurrent genital herpes infection during pregnancy outside of randomized controlled trials (14).

The CDC 1998 Sexually Transmitted Diseases Treatment Guidelines states,

in part:

The first clinical episode of genital herpes during pregnancy may be treated with oral acyclovir. In the presence of life-threatening maternal HSV infection (e.g., disseminated infection, encephalitis, pneumonitis, or hepatitis), acyclovir administered IV is indicated. Investigations of acyclovir use among pregnant women suggest that acyclovir treatment near term might reduce the rate of abdominal deliveries among women who have frequently recurring or newly acquired genital herpes by decreasing the incidence of active lesions. However, routine administration of acyclovir to pregnant women who have a history of recurrent genital herpes is not recommended at this time. (15)

The drug readily crosses the placenta to the fetus (16–23). After IV dosing, acyclovir levels in cord blood were higher than those in maternal serum with ratios of 1.4 and 1.25 reported (16,17). A 1992 study concluded that the placental transfer of acyclovir was most consistent with a carrier-dependent, nucleobase-type uptake of the drug, but that the overall net transfer was passive and dependent on solubility characteristics (16).

The pharmacokinetics of oral acyclovir in term pregnant women were reported in 1991 (21). Fifteen women with a history of active recurrent genital HSV type 2 infection antedating and during pregnancy, but without currently active disease, were given either 200 mg (N = 7) or 400 mg (N = 8) orally every 8 hours from 38 weeks' gestation until delivery. The mean steady-state plasma peak and trough levels in the 200-mg group were 1.9 and 0.7 $\mu\text{mol/L}$, respectively; those in the 400-mg group were 3.3 and 0.8 $\mu\text{mol/L}$, respectively. Acyclovir was concentrated in the amniotic fluid with concentrations ranging from 1.87 to 6.06 $\mu\text{mol/L}$ in the low-dose group compared with 4.20–15.5 $\mu\text{mol/L}$ in the high-dose group. The maternal:cord plasma ratio was similar in both groups with a mean of 1.3, a value comparable to that observed after IV dosing (21).

Acyclovir has been administered orally and intravenously during all stages of pregnancy (8,9,14,17–61). Topical acyclovir, which may produce low levels of the drug in maternal serum, urine, and vaginal excretions, has been used in pregnancy, and the manufacturer is aware of two women treated topically during the 3rd trimester who delivered normal infants (A. Clark, personal communication, Burroughs-Wellcome, 1985). However, no published reports of these cases have been located.

Favorable maternal and fetal outcomes were observed in two cases of isolated HSV encephalitis treated with IV and oral acyclovir (36,37). Treatment

in the two mothers began at 29 and 26 weeks' gestation, respectively, and continued until term. In the only other reported cases occurring during pregnancy, none of whom were treated with acyclovir, four mothers and three fetuses died (37). The onset of the encephalitis in the mother of the surviving fetus was at term. A 1996 case report described the successful treatment with IV acyclovir of a woman with herpes simplex hepatitis at 24 weeks' gestation (38). A viable 1013-g male infant was delivered at 28 weeks because of severe preeclampsia. Both the mother and her infant were doing well at the time of the report.

A 1991 case report and review cited data indicating that varicella pneumonia occurring during pregnancy resulted in a maternal mortality up to 44% (47). In 15 cases treated with IV acyclovir, however, only two (13%) mothers died, one fetus was stillborn, and one infant expired. Another 1991 reference added 5 new cases and a review of 16 cases from the literature to total 21 women treated during pregnancy with acyclovir for varicella pneumonia (48). Twelve women were treated during the 2nd trimester and nine during the 3rd trimester. The mean duration of acyclovir treatment was 7 days. Maternal mortality occurred in four cases, but two of the deaths occurred after delivery. One mother died of multiorgan failure 11 days after delivery, and one mother died after surgery for intestinal obstruction 1 month after delivery. The three maternal deaths directly attributable to varicella pneumonia were in the 3rd trimester at the onset of disease. Two fetal or infant deaths occurred, one from prematurity after birth at 26 weeks' gestation, and one stillborn at 34 weeks' (both cases also described in reference 47). No adverse effects were observed in the surviving infants. None of the infants had features of congenital varicella infection, nor did any develop active perinatal varicella infection. A 1993 abstract briefly described data collected retrospectively (1988–1992) on 14 pregnant women with varicella pneumonia, 11 of whom were treated with acyclovir (58). No specific information was given on the outcome of the 11 treated pregnancies. A 1998 case report described a woman at 32 weeks' gestation that was treated with IV acyclovir for varicella pneumonia (59). A healthy female infant was delivered approximately 3 days later because of fetal distress secondary to cord compression and prolapse into the right uterine segment. The infant was given varicella immunoglobulin and a 5-day course of IV acyclovir and was discharged home at 20 days of age without ever showing signs of varicella.

Data gathered for the period 1984–1999, by the Acyclovir in Pregnancy Registry, a group sponsored by the manufacturer and the CDC, were published

in 2004 (8). Excluding 461 patients with exposure to topical acyclovir only, 1234 pregnancies (12 sets of twins; 1246 outcomes) with known outcomes were followed up prospectively. The trimester of initial exposure was as follows: 1st—756 (7 sets of twins), 2nd—197 (2 sets of twins), 3rd—291 (3 sets of twins), and unknown—2. Among the 1st trimester exposures, there were 76 spontaneous abortions (SABs), 1 stillbirth, 83 elective abortions (EABs), 19 infants with birth defects, and 577 live births without birth defects. In the remaining exposures, there were no SABs, 2 EABs, 2 stillbirths, 9 infants with birth defects, and 477 live births without birth defects. For exposures during the 1st trimester with known outcomes (excluding SABs, EABs, and stillbirths), the rate of birth defects was 3.2% (19 of 596). For all trimesters, the rate was 2.6% (28 of 1082). These rates are no different from the rates expected in a nonexposed population (8). As for pregnancies reported retrospectively (i.e., in which the outcome was known before reporting), there were 47 birth defects that, in general, were similar to those reported prospectively. There was no uniqueness or pattern among the malformations, reported prospectively or retrospectively, that suggested a common cause (8).

In a surveillance study of Michigan Medicaid recipients conducted between 1985 and 1992 involving 229,101 completed pregnancies, 478 newborns had been exposed to acyclovir during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 18 (3.8%) major birth defects were observed (20 expected). Specific data were available for six defect categories, including (observed/expected) 5/5 cardiovascular defects, 0/1 oral clefts, 0/0 spina bifida, 1/1 polydactyly, 1/1 limb reduction defects, and 2/1 hypospadias. These data do not support an association between the drug and the defects.

A 1998 noninterventional observational cohort study described the outcomes of pregnancies in women who had been prescribed ≥ 34 newly marketed drugs by general practitioners in England (60). Data were obtained by questionnaires sent to the prescribing physicians 1 month after the expected or possible date of delivery. In 831 (78%) of the pregnancies, a newly marketed drug was thought to have been taken during the 1st trimester with birth defects noted in 14 (2.5%) singleton births of the 557 newborns (10 sets of twins). In addition, two birth defects were observed in aborted fetuses. However, few of the aborted fetuses were examined. Acyclovir was taken during the 1st trimester in 24 pregnancies. The outcomes of these pregnancies included 1 SAB, 5 EABs, and 18 normal term babies (60).

Because there is more human pregnancy experience with acyclovir than with similar antiviral agents (e.g., valacyclovir or famciclovir) and this experience

does not demonstrate a major risk, some authors consider acyclovir to be the drug of choice when indicated (62,63). However, for the management of herpes in pregnancy, either valacyclovir or acyclovir is recommended for primary or first-episode infection (for 7–10 days), symptomatic recurrent episode (for 5 days), and daily suppression (from 36 weeks' gestation until delivery), but only acyclovir is recommended for severe or disseminated disease (64). Long-term follow-up of children exposed in utero to these agents is warranted.

BREASTFEEDING SUMMARY

Acyclovir is concentrated in human milk with levels usually exceeding those found in maternal serum (65–69). In an in vitro experiment, the transfer of acyclovir from the plasma to breast milk was determined to be due to passive diffusion (65).

A woman, breastfeeding a 4-month-old infant, was treated with acyclovir 200 mg orally every 3 hours (5 times daily) for presumed oral herpes (66). She had taken 15 doses of the drug before the study dose. Approximately 9 hours after her 15th dose, she was given another 200-mg dose and paired maternal plasma and breast milk samples were drawn at 0, 0.5, 1.5, 2.0, and 3.0 hours. Breastfeeding was discontinued during the study interval. Milk:plasma ratios ranged from 0.6–4.1. Milk concentrations were greater than those in maternal serum at all times except at 1.5 hours, the time of peak plasma concentration (4.23 $\mu\text{mol/L}$). (Note: 1 $\mu\text{mol/L}$ = 0.225 mcg/mL [9].) The initial level in the milk was 3.3 $\mu\text{mol/L}$, reflecting the doses taken prior to the study period. The highest level measured in milk was 5.8 $\mu\text{mol/L}$ at 3.2 hours, but this was not the peak concentration because it was still rising at the time of sampling. Acyclovir was demonstrated in the infant's urine. Based on the poor lipid solubility of the drug, the pK_a 's, and other known pharmacokinetic parameters, the calculated theoretical milk:plasma ratio was 0.15. Because the actual measured ratio was much greater than this value, it was concluded that acyclovir entered the milk by an active or facilitated process that would make it unique from any other medicinal agent. The maximum ingested dose, based on 750 mL of milk/day, was calculated to be 1500 mcg/day, approximately 0.2 mg/kg/day in the infant, or about 1.6% of the adult dose. This was thought not to represent an immediate risk to the infant, and, in fact, no adverse effects of the exposure were observed in the infant (66).

In a second case, a woman 1 year postpartum was treated with oral acyclovir, 200 mg 5 times a day, for presumed herpes zoster (67). The mean concentrations in the milk and serum were 1.06 and 0.33 mcg/mL, respectively,

a milk:plasma ratio of 3.24. Detectable amounts were present in both serum and milk 48 hours after the last dose with an estimated half-life in the milk of 2.8 hours. The estimated amount of acyclovir ingested by the infant consuming 1000 mL/day of milk was about 1 mg (67).

Two recent studies measured the excretion of acyclovir in milk (68,69). In one, a woman 6 weeks postpartum suffering from eczema herpeticum received acyclovir IV 300 mg 3 times daily for 5 days (68). Breastfeeding was interrupted during the treatment. Serum and milk samples were collected after the last dose at 6-hour intervals for 4 days. Acyclovir levels in the milk exceeded those in the serum at every analysis and within the first 72 hours the milk concentration was 2.25 times higher than that in the serum. During the 88 hours that acyclovir was detectable in breast milk, a total of 4.448 mg was excreted (79% was recovered during the first 24 hours) (68).

In the other study, a woman was taking 800 mg 5 times daily for herpes zoster (69). She continued to breastfeed her 7-month-old infant. Three random milk samples were obtained (0.25–9.42 hours after a dose) with acyclovir levels ranging from 18.5 (4.16 mcg/mL) to 25.8 μ mol/L (5.81 mcg/mL). The highest level occurred 9.42 hours after a dose. No adverse effects were observed in the infant who had ingested from the milk, what was thought to be, a clinically insignificant amount of acyclovir (0.73 mg/kg/day or about 1% of the maternal dose in mg/kg/day) (69).

Because acyclovir has been used to treat herpes virus infections in the neonate, and because of the lack of adverse effects in reported cases, mothers undergoing treatment with acyclovir can breastfeed safely. The American Academy of Pediatrics classifies acyclovir as compatible with breastfeeding (70).

ADALIMUMAB

Immunologic Agent (Immunomodulator)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

The maternal benefits from treatment with adalimumab appear to far outweigh the unknown embryo–fetal risks (1,2). No developmental toxicity attributable to adalimumab has been observed in a limited number of cases and the animal data suggest low risk. In 2011, the World Congress of Gastroenterology stated “Adalimumab in pregnancy is considered low risk and compatible with use during conception and pregnancy in at least the first two trimesters” (3). Theoretically, tumor necrosis factor-alpha (TNF- α) antagonists could interfere with implantation and ovulation, but this has not been shown clinically (4). Because of the long elimination half-life, use before conception may result in inadvertent exposure of an unplanned pregnancy. If adalimumab is used in pregnancy for the treatment of rheumatoid arthritis, health care professionals are encouraged to call the toll-free number (877-311-8972) for information about patient enrollment in the Organization of Teratology Information Specialists (OTIS) Rheumatoid Arthritis study and pregnancy registry.

FETAL RISK SUMMARY

Adalimumab is a recombinant IgG1 monoclonal antibody that binds specifically to human TNF- α to block its action on cell surface TNF receptors. TNF- α is a pro-inflammatory cytokine with a central role in inflammatory processes. Adalimumab is in the same subclass of immunomodulators (blockers of TNF activity) as etanercept, certolizumab pegol, golimumab, and infliximab. It is indicated for reducing the signs and symptoms and inhibiting the progression of structural damage in adult patients with moderate to severe active rheumatoid arthritis who have had an inadequate response to one or more disease-modifying antirheumatic drugs. It has also been used in Crohn’s disease. The

mean terminal elimination half-life is about 14 days (range 10–20 days) (5).

An animal reproduction study for perinatal development toxicity was conducted in pregnant cynomolgus monkeys. Doses up to 266 times the human AUC (SC 40 mg with methotrexate every week) or 373 times the human AUC (SC 40 mg without methotrexate) revealed no fetal harm (the timing of the exposure was not specified). No clastogenic or mutagenic effects were observed in various tests, but adalimumab has not been tested for carcinogenic or fertility effects (5).

Although the molecular weight is very high (about 148,000), adalimumab crosses the human placenta to the fetus in late gestation (6). As an IgG1 antibody, the drug would be transported actively across the placenta, especially in the 3rd trimester, but with minimal transfer in the 1st trimester. In 10 cases at a mean gestational age of 39 weeks (range 38–41 weeks), the median of infliximab concentrations in cord blood as a percentage of maternal concentration was 179% (range 98%–293%). The last dose was given a median of 5.5 weeks (range 0.14–8 weeks) before birth. Infant or cord blood concentrations were higher than maternal levels in every case. Moreover, infliximab was detected in the infants for at least 11 weeks. No birth defects, infections, or neonatal intensive care unit stays occurred in any infant (6).

A 2005 case report described a 34-year-old woman with long-standing Crohn's disease who was treated throughout gestation with adalimumab and prednisone (7). The woman received 38 weekly SC doses of adalimumab (40 mg/dose). Normal fetal growth was documented during the uncomplicated pregnancy. An elective cesarean section at 38.5 weeks' delivered a normal infant with Apgar scores of 8 and 9, presumably at 1 and 5 minutes, respectively. The infant was growing and developing normally at 6 months of age (7).

The preliminary results of an on-going prospective cohort study and pregnancy registry involving adalimumab that is being conducted by OTIS were reported at an October 2006 meeting (D. Johnson, personal communication, University of California, San Diego, 2006). Of the 95 women enrolled in the study or registry, 26 involved exposure in the 1st trimester. Thirteen outcomes were known, 12 of which resulted in healthy, full-term infants without birth defects. In the 13th case, a woman with twins, one fetus was aborted and the other was delivered prematurely without defects.

A 35-year-old woman with Crohn's disease was treated with adalimumab (SC 40 mg every other week) throughout gestation (8). She delivered a normal infant (details not provided) that had normal growth and development at 6

months of age.

A 34-year-old woman with Crohn's disease was treated with budesonide, then prednisone only from 6 to 20 weeks' gestation (9). At that point, she was started on azathioprine 100 mg/day and adalimumab 80 mg (one dose), then 40 mg every other week. Prednisone was tapered and stopped by the 32nd week. Labor was induced at 38 weeks' and she delivered a healthy, 2.89-kg, male infant who was well and developing normally at 1 year of age (9).

A 2006 communication from England described the pregnancy outcomes of 23 women directly exposed to TNF- α agents at the time of conception (17 etanercept, 3 adalimumab, and 3 infliximab) (10). Additional therapy included methotrexate in nine women and leflunomide in two. There also were nine patients (four etanercept, five infliximab) that discontinued therapy before conception. The outcomes for the 32 pregnancies were 7 spontaneous abortions (SABs), 3 elective abortions (EABs), and 22 live births. No major anomalies were observed in the live births, including one infant exposed to adalimumab and methotrexate early in gestation (10).

A 2007 case report and literature review described the use of adalimumab in a 41-year-old woman with rheumatoid arthritis (11). The woman had received a single dose of 40 mg after conception when an unplanned pregnancy at 5 weeks' was discovered. A healthy 2.6-kg infant was delivered at 32 weeks' gestation. At 25 months of age, the child was growing and developing normally (11).

A 2008 report described a 22-year-old woman with Takayasu arteritis who conceived while taking adalimumab 40 mg SC every 4 weeks, leflunomide 10 mg/day, prednisolone 5 mg/day, and dalteparin 500 IU/day (12). Leflunomide was discontinued by the patient at 8 weeks' gestation but the other agents were continued throughout. At 37 weeks', a cesarean section was performed to deliver a healthy 2550-g male infant with Apgar scores of 9, 9, and 10 at 1, 5, and 10 minutes, respectively (12).

A woman with lupus nephritis took mycophenolate mofetil (1000 mg/day) and adalimumab (40 mg every other week) during the first 8 weeks of pregnancy (13). She underwent a cesarean section for transverse position at 32 weeks' gestation to give birth to a 4422-g female infant with normal karyotype (46,XX). The infant had multiple birth defects including arched eyebrows, hypertelorism, epicanthic folds, micrognathia, thick everted lower lip, cleft palate, bilateral microtia with aural atresia, congenital tracheomalacia, and brachydactyly. Shortly after birth, a tracheostomy was done for respiratory distress and a G-tube was placed because of feeding difficulties. The cleft palate was repaired

surgically. At 20 months of age, the infant had normal growth and slightly delayed motor development. The tracheostomy was still required as were G-tube feedings. She seemed to have some hearing, but had significant expressive speech delay. The defects were attributed to mycophenolate (13).

A 2009 study from France reported the outcomes of 15 women who took anti-TNF drugs during pregnancy (10 etanercept, 3 infliximab, and 2 adalimumab) (14). The drugs were given in the 1st, 2nd, and 3rd trimesters in 12, 3, and 2 cases, respectively. The outcomes were 2 SABs, 1 EAB, and 12 healthy babies without malformation or neonatal illness. They also reviewed the literature regarding the use of anti-TNF agents in pregnancy and found more than 300 cases. It was concluded that, although only 29 were treated throughout gestation, the malformation rate was similar to the general population (14).

A 32-year-old woman with Crohn's disease was treated with adalimumab 40 mg every other week for a total of 18 doses (15). Therapy at that time was stopped when her pregnancy was diagnosed. She had received 40 mg doses at 2, 4, and 6 weeks' gestation. She eventually delivered at term a healthy 3360-g female infant with Apgar scores of 10, 10, and 10. The child was doing well at 2 years of age (15).

In 2008, investigators reviewed >120,000 adverse events involving TNF- α agents that had been reported to the FDA in 1999–2005 (16). There were 61 congenital anomalies in 41 children born to mothers taking etanercept or infliximab. There were no cases of birth defects involving adalimumab (16).

In a 2010 case report, a 34-year-old woman was treated for psoriasis with adalimumab from 3 months before conception through 5 weeks of pregnancy (17). An elective cesarean section at 38.5 weeks gave birth to a low-birth-weight infant (weight and sex not specified). The child was developing normally at 12 months of age (17).

A 26-year-old woman with Crohn's ileitis was treated with adalimumab before and during gestation up to week 30 of gestation (18). At that time the drug was discontinued, and she gave birth at 38 weeks' to a healthy infant (weight and sex not specified).

In subfertile women with T helper 1/T helper 2 cytokine elevations undergoing in vitro fertilization, adalimumab and IV immunoglobulin significantly improved the rates of implantation, clinical pregnancies, and live births (19).

BREASTFEEDING SUMMARY

Adalimumab is excreted into breast milk. In a case described above,

adalimumab therapy was discontinued at 30 weeks' gestation and the woman gave birth to a healthy infant at term (18). The mother did not require therapy while breastfeeding her infant during the first 4 weeks after birth but, at that time, she experienced a flare-up of Crohn's disease. Nursing was discontinued when a 40-mg SC dose was given. Immediately before the dose, maternal serum and breast milk concentrations of adalimumab were undetectable. Postdose, the serum level peaked at 4300 ng/mL at 3 days, whereas the peak milk concentration of 31 ng/mL was reached on day 6 (18).

In another study described above, 9 of 10 mothers continued to take adalimumab after birth and 6 of 10 infants were breastfed (6). No other details were provided.

The very low adalimumab concentration in breast milk is consistent with its high molecular weight (about 148,000). The systemic bioavailability of the drug from milk and any effect of this exposure on a nursing infant are unknown. However, two mothers, described above, did continue adalimumab during breastfeeding and no adverse effects in their infants were mentioned (7,8).

ADAPALENE

Dermatologic Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Adapalene is not teratogenic in two experimental animal species. After chronic use in humans, trace amounts of adapalene have been detected in the systemic circulation. The adverse pregnancy outcome described below is the only report of adapalene exposure in human pregnancy. The combination of animal data and very low systemic bioavailability suggests that any risk to a fetus from inadvertent exposure would be very low, but the nearly complete absence of human data prevents further assessment. Until more experience in pregnancy has been reported, the safest course is to avoid use of this agent in the 1st trimester.

FETAL RISK SUMMARY

Adapalene is used topically (cream, gel, or solution) for the treatment of acne vulgaris. The agent is a retinoid-like compound that is a modulator of cellular differentiation, keratinization, and inflammatory processes. It binds to specific retinoic acid nuclear receptors. Plasma concentrations are very low after chronic topical application (<0.25 ng/mL) (1).

No teratogenic effects were noted in pregnant rats given oral doses up to 120 times the maximum daily human dose (MDHD). Topical application of adapalene to pregnant rats and rabbits up to 150 times the MDHD demonstrated no fetotoxicity and only minimal increases in supernumerary ribs in rats (1).

It is not known if adapalene crosses the human placenta. The molecular weight (about 413) and low plasma concentrations suggest that minimal amounts of drug would be available to cross the placenta.

Only one report describing the use of adapalene during human pregnancy

has been located (2). At 22 weeks' gestation, a small-for-date fetus with anophthalmia was detected by ultrasound examination and the pregnancy was terminated. Anophthalmia and agenesis of the optic chiasma were observed in the aborted fetus. The mother had been treated with adapalene gel (0.3 mg/day) from 1 month before conception until 13 weeks' gestation. The defects were not thought to be typical of retinoid-induced malformations (heart, central nervous system, thymus, limbs, and craniofacial) (2).

BREASTFEEDING SUMMARY

No reports describing the use of adapalene during lactation have been located. The systemic availability of this drug from topical administration is very low (<25 ng/mL) (1). The amount in breast milk, therefore, should also be very low. It is doubtful that this level, if it is excreted in milk, represents any risk to a nursing infant.

ADEFOVIR

Antiviral

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential
Toxicity (Hepatitis B) Contraindicated (HIV)

PREGNANCY SUMMARY

The animal data suggest low risk, but the human data are limited and prevent an assessment of the embryo–fetal risk. If indicated, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Adefovir, an acyclic nucleotide analog of adenosine monophosphate, is used for the treatment of chronic hepatitis B, especially in patients with clinical evidence of lamivudine-resistant hepatitis B virus. The mechanism involves the inhibition of hepatitis B virus DNA polymerase (reverse transcriptase) (1). It has also been used in patients infected with HIV (1,2). The antiviral agent is available as a prodrug, adefovir dipivoxil, which is rapidly converted to adefovir after oral administration (1). Adefovir is then phosphorylated to the active metabolite, adefovir diphosphate, by cellular kinases. Serum protein binding is very low ($\leq 4\%$) and the terminal elimination half-life is about 7.5 hours (1).

Reproduction studies have been conducted in rats and rabbits. No evidence of embryotoxicity or teratogenicity was observed in rats after oral dosing that produced systemic exposures up to 23 times the human exposure achieved with the therapeutic dose of 10 mg/day (HE) or in rabbits at 40 times the HE. In rats given maternal toxic IV doses (systemic exposures 38 times the HE), embryotoxicity and an increase in the incidence of fetal malformations (anasarca, depressed eye bulge, umbilical hernia, and kinked tail) were observed. The no-effect exposure from IV doses in pregnant rats was 12 times the HE (1). Intraperitoneal doses of adefovir in mice resulted in dose-related resorptions, low birth weight, neonatal death, and severe lymphoid depletion of the thymus (3).

It is not known if adefovir crosses the human placenta. The molecular weight (about 501) of the prodrug, adefovir dipivoxil, the relative lack of protein binding, and the moderately long terminal elimination half-life suggest that adefovir will cross to the fetal compartment.

The Antiretroviral Pregnancy Registry reported, for the period January 1989 through July 2009, prospective data (reported before the outcomes were known) involving 4702 live births that had been exposed during the 1st trimester to one or more antiretroviral agents (4). Congenital defects were noted in 134, a prevalence of 2.8% (95% confidence interval [CI] 2.4–3.4). In the 6100 live births with earliest exposure in the 2nd/3rd trimesters, there were 153 infants with defects (2.5%, 95% CI 2.1–2.9). The prevalence rates for the two periods did not differ significantly. There were 288 infants with birth defects among 10,803 live births with exposure anytime during pregnancy (2.7%, 95% CI 2.4–3.0). The prevalence rate did not differ significantly from the rate expected in a nonexposed population. There were 37 outcomes exposed to adefovir all in the 1st trimester in combination with other antiretroviral agents. There were no birth defects. In reviewing the birth defects of prospective and retrospective (pregnancies reported after the outcomes were known) registered cases, the Registry concluded that, except for isolated cases of neural tube defects with efavirenz exposure in retrospective reports, there was no other pattern of anomalies (isolated or syndromic) (4). (See Lamivudine for required statement.)

For HIV infection, two reviews, one in 1996 and the other in 1997, concluded that all women currently receiving antiretroviral therapy should continue to receive therapy during pregnancy and that treatment of the mother with monotherapy should be considered inadequate therapy (5,6). The same conclusion was reached in a 2003 review with the added admonishment that therapy must be continuous to prevent emergence of resistant viral strains (7). In 2009, the updated U.S. Department of Health and Human Services guidelines for the use of antiretroviral agents in HIV type 1 (HIV-1)-infected patients continued the recommendation that therapy, with the exception of efavirenz, should be continued during pregnancy (8). If indicated, adefovir should not be withheld in pregnancy because the expected benefit to the HIV-positive mother outweighs the unknown risk to the fetus. Updated guidelines for the use of antiretroviral drugs to reduce perinatal HIV-1 transmission also were released in 2010 (9). Women receiving antiretroviral therapy during pregnancy should continue the therapy; however, regardless of the regimen, zidovudine administration is recommended during the intrapartum period to prevent vertical

transmission of HIV to the newborn (9).

BREASTFEEDING SUMMARY

No reports describing the use of adefovir during lactation have been located. The molecular weight (about 501) of the prodrug, adefovir dipivoxil, the relative lack of protein binding, and the moderately long terminal elimination half-life suggest that the adefovir will be excreted into breast milk. Women infected with hepatitis B can breastfeed without additional risk for the transmission of hepatitis B. However, if adefovir is used during nursing for the treatment of the maternal infection, there is a potential risk of serious toxicity for the nursing infant, such as the nephrotoxicity seen in adults.

Reports on the use of adefovir during human lactation in women infected with HIV are unlikely because HIV-1 is transmitted in milk, and in developed countries, breastfeeding is not recommended (5,6,8,10–12). In developing countries, breastfeeding is undertaken, despite the risk, because there are no affordable milk substitutes available. Until 1999, no studies had been published that examined the effect of any antiretroviral therapy on HIV-1 transmission in milk. In that year, a study involving zidovudine was published that measured a 38% reduction in vertical transmission of HIV-1 infection in spite of breastfeeding when compared with controls (see Zidovudine).

ADENOSINE

Antiarrhythmic

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably
Compatible

PREGNANCY SUMMARY

Adenosine has been used in all stages of pregnancy for maternal and embryo–fetal indications without harming the embryo or fetus. If indicated, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Adenosine, an endogenous purine-based nucleoside found in all cells of the body, is used for the treatment of paroxysmal supraventricular tachycardia. Adenosine phosphate and adenosine triphosphate have been used as vasodilators. Ordinarily, adverse fetal effects secondary to adenosine would not be expected because of the widespread, natural distribution of this substance in the body and its very short (<10 seconds) half-life after IV administration. However, the maternal administration of large IV doses of adenosine may potentially produce fetal toxicity, as has been observed with other endogenous agents (e.g., see Epinephrine).

A reproduction study in chick embryos did not observe teratogenicity (1). Injection into the fourth cerebral ventricle of fetal sheep resulted in depressed fetal respiratory drive (2). In pregnant sheep, constant infusions and single injections of adenosine produced alterations in maternal heart rate and a decrease in diastolic pressure, but no changes in maternal systolic pressure or arterial blood gases, and had no effect on fetal heart rate, arterial pressure, or arterial blood gases (3,4). Another experiment using near-term sheep demonstrated that angiotensin II-induced maternal–placental vasoconstriction could not be reversed by a high-dose infusion of adenosine (5).

Endogenous adenosine cord blood levels, measured in 14 fetuses of 19–34 weeks' gestation, were not related to gestational age, but were significantly

increased in anemic fetuses and were positively associated with blood oxygen tension (6). The investigators concluded that the results were compatible with a fetal response to tissue hypoxia.

The first case describing the use of adenosine in human pregnancy appeared in 1991 (7). Recurrent narrow complex tachycardia occurred suddenly in a 40-year-old woman in her 39th week of gestation. She had been hospitalized 6 months before the current episode for a similar condition secondary to mitral valve prolapse and had been taking atenolol for tachyarrhythmia prophylaxis since that occurrence. Maternal blood pressure was 80 mm Hg systolic with a pulse of 240 beats/minute. Fetal heart rate was 140 beats/minute. Two IV bolus doses of adenosine (6 and 12 mg) were administered resulting in conversion to sinus rhythm with a rate of 80 beats/minute. A nonstress test, conducted after stabilization of the mother, was normal. Two weeks later, a healthy 3.6-kg infant was delivered. Both mother and baby were doing well 1 month postpartum.

Since the above case, a number of reports have described the safe use of adenosine to treat maternal or fetal supraventricular tachycardia (8–20) during all phases of gestation, including one woman in active labor (15), eight during the 1st trimester (16), and four cases of direct fetal administration (18–20). The first three of the maternal reports and the first fetal case are described below.

A 19-year-old woman was treated at 38 weeks' gestation for the arrhythmia during labor (8). Conversion to a normal sinus rhythm required two IV bolus doses (6 and 12 mg). No effect was observed on uterine contractions, fetal heart rate, or variability. A cesarean section was required for failure of the labor to progress. The second case occurred in a 34-year-old woman with onset of supraventricular tachycardia at 30 weeks' gestation (9). She responded within 30 seconds to a single 6-mg IV adenosine dose with no changes observed in the fetal heart rate tracing. A normal infant was delivered at term. The third woman was a 26-year-old patient with a history of Wolff-Parkinson-White syndrome who was initially treated successfully with 6 mg IV adenosine at 7 months' gestation (10). She was subsequently treated with atenolol and eventually admitted at term for labor induction. During labor the supraventricular tachycardia recurred and two doses (6 and 12 mg) of adenosine were required to convert to a normal sinus rhythm. During the mother's arrhythmia, fetal distress demonstrated by recurrent, deep variable decelerations with loss of short-term variability was observed, but fetal bradycardia resolved with a return to a fetal heart rate of 130 beats/minute on

conversion of the mother. A third recurrence of the mother's tachycardia occurred shortly before a cesarean section and this was successfully converted with a 12-mg dose of adenosine. A male infant was delivered with Apgar scores of 1 and 5 at 1 and 5 minutes, respectively. No adverse effects in the fetus or newborn attributable to adenosine were observed in any of the above cases or in the other cited cases.

A 1995 reference described the direct fetal administration of adenosine for the treatment of persistent supraventricular tachycardia with massive hydrops at 28 weeks' gestation (18). Treatment with digoxin and flecainide for 5 weeks had not been successful in reversing the condition. Based on estimated fetal weight, 0.2 mg/kg of adenosine was given by bolus injection into the umbilical vein and a normal rhythm occurred within seconds. The umbilical serum levels of digoxin and flecainide were determined at the same time and further loading of the fetus with digoxin (0.05 mg/kg) and flecainide (1.0 mg/kg) were administered via the umbilical vein (18). After about 20 minutes of intermittent atrial arrhythmia and tachycardia, the fetal heart converted to a stable, normal rhythm. One week later, the fetus died in utero from what was thought to be a recurrence of the tachycardia or the onset of a drug-induced arrhythmia (18). Massive hydrops fetalis with a structurally normal heart was found at autopsy.

BREASTFEEDING SUMMARY

Because adenosine is used only by IV injection in acute care situations, it is doubtful that any report will be located describing the use of adenosine during human lactation. Moreover, the serum half-life is so short that it is unlikely that any of the drug will pass into milk.

AGALSIDASE ALFA

Endocrine/Metabolic Agent (Enzyme)

See Agalsidase Beta.

AGALSIDASE BETA

Endocrine/Metabolic Agent (Enzyme)

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably
Compatible

PREGNANCY SUMMARY

The successful use of agalsidase- β or agalsidase- α in human pregnancy has been described in a few reports. The animal data, involving only one species, suggest low risk, but the limited human pregnancy experience prevents a more complete assessment of the embryo–fetal risk. However, Fabry disease is a debilitating condition that can be markedly improved by the use of enzyme replacement therapy. If a woman requires enzyme replacement therapy and gives informed consent, the enzyme should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Agalsidase- β , a glycoprotein, is a recombinant α -galactosidase A enzyme that has the same amino acid sequence as the endogenous enzyme. It is indicated for patients with Fabry disease, an X-linked genetic disorder of glycosphingolipid metabolism. Agalsidase- β reduces globotriaosylceramide deposition in capillary endothelium of the kidney and certain other cells. It is given as an IV infusion every 2 weeks. The terminal plasma half-life of agalsidase- β is dose-dependent with a range of 45–102 minutes (1).

Agalsidase- α is available in Europe and the United States (as an orphan drug). The α - and β -products are produced by different protein expression systems (2). Another commercial product, α -galactosidase A, also is an orphan drug in the United States that is available elsewhere. All three formulations contain the same enzyme, α -galactosidase A.

Reproduction studies have been conducted with agalsidase- β in rats. Doses up to 30 times the human dose were not associated with impaired fertility or embryo–fetal harm. Studies for carcinogenicity and mutagenicity have not been

conducted (1).

It is not known if agalsidase- β crosses the human placenta. The molecular weight (about 100,000) and short elimination half-life suggest that the enzyme will not cross to the embryo or fetus.

A 2005 case report described the use of agalsidase- α throughout gestation in a 34-year-old woman (3). Fabry disease had been diagnosed at 15 years of age and treatment with the enzyme, 0.2 mg/kg every 2 weeks infused over 40 minutes, was started 18 months before pregnancy. When pregnancy was diagnosed, the patient requested continuation of the therapy. Analysis of the amniotic fluid showed normal α -galactosidase A activity so the male fetus was not expected to have Fabry disease. After an uneventful pregnancy, the woman gave birth at 37 weeks' to a healthy, 3010-g male infant with Apgar scores of 9, 10, and 10, presumably at 1, 5, and 10 minutes, respectively. The infant's length and head circumference were 52 and 32 cm, respectively (3). A brief 2009 report described two pregnant women with Fabry disease who were treated with agalsidase- α (4). The outcomes of both pregnancies were healthy infants.

Three reports have described successful pregnancy outcomes that were treated with agalsidase- β for Fabry disease (5–7).

BREASTFEEDING SUMMARY

No reports describing the use of agalsidase- β , agalsidase- α , or α -galactosidase A during human lactation have been located. The molecular weight of the enzyme (about 100,000) and short plasma elimination half-life (45–102 minutes) suggest that it will not be excreted into breast milk. Even if excretion does occur, the enzyme probably would be digested in the nursing infant's gut. α -Galactosidase A is a native enzyme and should be present in the infant. Moreover, the indication for enzyme replacement therapy implies that the mother would have received it during pregnancy. Thus, the risk to a nursing infant from maternal use of any of the three formulations appears to be nil.

ALBENDAZOLE

Anthelmintic

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Albendazole is a broad-spectrum anthelmintic that is used both in humans and in mass treatments of farm animals (1,2). The human use of albendazole is apparently widespread (1). The animal data suggest risk, but the poor oral bioavailability in humans suggests low risk. One source stated that the developmental toxicity of albendazole observed in animals was attributable to the active metabolite, albendazole sulfoxide (1). Moreover, in rats, the bioavailability is much higher than in humans (20%–30% vs. 1%). There is a potential, though, for much higher plasma concentrations of the metabolite if the drug is consumed with a fatty meal. If albendazole is required during pregnancy, avoiding the 1st trimester should be considered (2).

FETAL RISK SUMMARY

Albendazole is an orally administered, benzimidazole class, broad-spectrum anthelmintic used in the treatment of parenchymal neurocysticercosis caused by larval forms of the pork tapeworm, *Taenia solium*. It is also active against the larval forms of *Echinococcus granulosus*. Plasma concentrations of albendazole are negligible or undetectable because of poor systemic absorption attributable to low water solubility and its rapid hepatic metabolism to the active metabolite, albendazole sulfoxide. However, administration of albendazole with a fatty meal will markedly increase the levels of the metabolite in human plasma (up to fivefold on average) (3).

Reproduction studies have been conducted in mice, rats, and rabbits. In rats, albendazole did not adversely affect male or female fertility at oral doses 0.32 times the recommended human dose based on BSA (RHD). The drug was embryotoxic and teratogenic (skeletal malformations) in pregnant rats given

oral doses during organogenesis that were 0.10 and 0.32 times the RHD, respectively. Similar toxicity was observed in pregnant rabbits at 0.60 times the RHD, but the dose was maternally toxic (33% mortality). No teratogenicity was observed in mice given oral doses up to 0.16 times the RHD during organogenesis (3).

A reproductive study in rats examined the effect of oral albendazole (0, 10, or 20 mg/kg/day) administered on gestational days 9–11. Compared with controls, the 10 mg/kg dose resulted in a decrease in crown–rump length, a small increase in resorptions, but no teratogenicity. The high dose, however, caused marked fetal growth restriction, an increase in the number of resorptions, and craniofacial and skeletal malformations. Because the severity of the toxic effects differed significantly among the litters, the results suggested that differences in maternal metabolism of albendazole might be involved (4).

In another report by the above researchers, pregnant rats were administered albendazole 0, 10, 20, or 30 mg/kg/day on gestational days 10–12 (1). Dose-related resorptions and growth restriction were observed in the three groups receiving albendazole. At 10 mg/kg/day, increased development delay of limb buds was observed, but <5% of the embryos had abnormal heads or shapes. At the two higher doses, however, >20% of the embryos had morphologic alterations in head shapes and in the development of forelimb buds, branchial bars, eyes, and telencephalon. As in their initial communication, the researchers concluded that differences in maternal metabolism might have accounted for the observed interlitter differences in adverse fetal outcomes (1).

It is not known if albendazole or its active metabolite, albendazole sulfoxide, cross the placenta. The molecular weight of the parent compound (about 265) is low enough for transfer, but the poor oral bioavailability suggests that little, if any, of this agent reaches the plasma. No information is available on the metabolite other than that portions of it undergo further oxidative metabolism before elimination (3).

A brief 1993 publication reported the “accidental” exposure to “high doses” (specific doses not given) of albendazole for systemic infections during the 1st trimester in 10 women (5). The women were followed up to term, and all delivered normal infants. Moreover, some of the offspring have been followed up for up to 1 year without noting any adverse effects from the exposure (5).

In a randomized, placebo-controlled field trial in western Sierra Leone, anthelmintic treatment was studied as part of a strategy to control maternal anemia caused by parasitic infections (6). A single oral dose of albendazole (400 mg) was given to 61 pregnant women in the 2nd trimester. No adverse

pregnancy outcomes attributable to the drug were observed (6).

Several reports have described the use of albendazole during human pregnancy as either single dose or multiple doses. No adverse effects of the drug were observed in the offspring (7–13).

BREASTFEEDING SUMMARY

Consistent with its molecular weight (about 265) and negligible bioavailability, very low amounts of albendazole and its active metabolite are excreted into breast milk. In a 2009 report, 33 women who were breastfeeding healthy full-term infants between 2 weeks and 6 months after birth received a single 400-mg dose of albendazole (14). Milk samples were collected at 6, 12, 24, and 36 hours after the dose and maternal blood samples were obtained at 6 hours. The mean peak milk concentrations of the parent drug and active metabolite, occurred at 6 hours, 31.9 and 312.8 ng/mL, respectively. At 36 hours, the parent drug was not detected in milk. The milk:maternal serum ratios (range) for the parent drug and active metabolite were 0.9 (0.2–6.5) and 0.6 (0.1–1.5), respectively. The authors concluded that the low concentrations in milk were unlikely to cause harm in a nursing infant (14).

A 2002 reference concluded that a single oral dose could be given to pregnant and lactating women (15).

ALBUTEROL

Sympathomimetic/Bronchodilator

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Albuterol (salbutamol) has not caused structural anomalies, but there is evidence of an association with functional and neurobehavioral toxicity with prolonged use. Similar to other β -mimetics, the drug can cause maternal and fetal tachycardia and hyperglycemia. Nevertheless, the drug should not be withheld because of pregnancy, but excessive use should be avoided. If albuterol is used in pregnancy for the treatment of asthma, health care professionals are encouraged to call the toll-free number (877-311-8972) for information about patient enrollment in an Organization of Teratology Information Specialists (OTIS) study.

FETAL RISK SUMMARY

Albuterol is a β_2 -sympathomimetic used to prevent premature labor (see also Terbutaline and Ritodrine) and for the treatment of asthma (1–12). The inhaled formulation is indicated for the relief of bronchospasm in patients with reversible obstructive airway disease and acute attacks of bronchospasm (13). It is in the same subclass of β_2 -adrenergic bronchodilators as arformoterol, formoterol, metaproterenol, pirbuterol, salmeterol, and terbutaline.

In twins, however, a double-blind, controlled study involving 144 women (74 treated with albuterol and 70 treated with placebo) observed no difference between the groups in the length of gestation, birth weight, or fetal outcome, except fewer infants in the albuterol group had respiratory distress syndrome (14).

In an in vitro experiment using perfused human placentas, 2.8% of infused drug crossed to the fetal side, but the method only used about 5% of the exchange area of the total placenta (15). Maternal serum concentrations during IV and oral albuterol therapy have been reported (16).

Reproduction studies in mice observed an increase in the incidence of cleft palate at a SC dose 0.4 times the maximum recommended human oral dose (MRHD) and higher (17). Cranioschisis was observed in 37% of the fetuses from pregnant rabbits treated with a dose 78 times the MRHD) (16).

No published reports linking the use of albuterol to human congenital anomalies have been located, but the majority of reports do not involve 1st trimester exposures. However, in a surveillance study of Michigan Medicaid recipients conducted between 1985 and 1992 involving 229,101 completed pregnancies, 1090 newborns had been exposed to albuterol during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 48 (4.4%) major birth defects were observed (43 expected). Specific data were available for six defect categories, including (observed/expected) 9/11 cardiovascular defects, 2/2 oral clefts, 2/0.6 spina bifida, 1/2 limb reduction defects, 0/3 hypospadias, and 6/3 polydactyly. Only with the latter defect is there a suggestion of a possible association, but other factors, including the mother's disease, concurrent drug use, and chance, may be involved.

A brief 1980 report described a patient who was treated with a continuous IV infusion of albuterol for 17 weeks via a catheter placed in the right subclavian vein (10,18,19). A normal male infant was delivered within a few hours of stopping the drug. A 1982 report described the use of albuterol in two women with incompetent cervix from the 14th week of gestation to near term (20). Both patients delivered normal infants.

Adverse reactions observed in the fetus and mother after albuterol treatment are secondary to the cardiovascular and metabolic effects of the drug. Albuterol may cause maternal and fetal tachycardia with fetal rates >160 beats/minute (1–3,12,21). Major decreases in maternal blood pressure have been reported with both systolic and diastolic pressures dropping >30 mmHg (2,4,6). Fetal distress after maternal hypotension was not mentioned. One study observed a maximum decrease in diastolic pressure of 24 mm Hg (34% decrease) but a rise in systolic pressure (21). Other maternal adverse effects associated with albuterol have been acute congestive heart failure, pulmonary edema, and death (22–30).

Like all β -mimetics, albuterol may cause transient fetal and maternal hyperglycemia followed by an increase in serum insulin (4,31–34). Cord blood levels of insulin are about twice those of untreated control infants and are not dependent on the duration of exposure, gestational age, or birth weight (33,34). These effects are more pronounced in diabetic patients, especially in juvenile diabetics, with the occurrence of significant increases in glycogenolysis and

lipolysis (21,35,36). Maternal blood glucose should be closely monitored and neonatal hypoglycemia prevented with adequate doses of glucose.

A group of 20 women in premature labor, treated with oral albuterol (4 mg every 4 hours for several weeks), was matched with a control group of women who were not in premature labor (37). The mean gestational ages at delivery for the treated and nontreated patients were 36.4 and 37.0 weeks, respectively. No significant differences were found between the groups for cord blood concentrations of insulin, triiodothyronine (T3), thyroxine (T4), and thyroid-stimulating hormone (TSH). However, growth hormone levels were significantly higher in the treated group than in control patients (36.5 vs. 17.4 ng/mL, respectively, $p < 0.001$). The investigators did not determine the reason for the elevated growth hormone level but speculated that it could be caused by either the use of β -methasone for fetal lung maturation in some women of the albuterol group (and resulting fluctuations in fetal blood glucose and insulin levels) or direct adrenergic stimulation of the fetal pituitary (37). Of interest, of the 12 women who received β -methasone, cord blood growth hormone levels in 11 were compared with those of 8 untreated control women. Although the levels in the treated patients were higher (39.5 vs. 31.4 ng/mL), the difference was not significant.

Albuterol decreases the incidence of neonatal respiratory distress syndrome similar to the way that other β -mimetics do (14,38,39). Long-term evaluation of infants exposed to in utero β -mimetics has been reported but not specifically for albuterol (40,41). No harmful effects were observed in these infants. However, a brief 1994 reference described the use of β -sympathomimetics (albuterol, $N = 1$; ritodrine $N = 7$) in eight infants from a group of 16 with retinopathy of prematurity (42). In a matched control group with retinopathy, only 1 of 16 infants was exposed to ritodrine ($p < 0.008$). The authors speculated that the β -sympathomimetics had compromised retinal perfusion in utero leading to ischemia and eventually to the ophthalmic complication (42).

The effects of inhaled albuterol on maternal and fetal hemodynamics were first published as an abstract (43) and then as a full report (44). Twelve pregnant asthmatic women between 33 and 39 weeks' gestation received two deep inhalations of a 0.05% solution as recommended by the manufacturer. No effects on the mean maternal, uterine, or fetal hemodynamics were observed.

In contrast, a 1997 case report described fetal tachycardia from the inadvertent administration of a double dose of inhaled albuterol over 24 hours (45). The 34-year-old woman at 33 weeks' gestation received a metered-dose inhaler (two 90-mcg actuations every 4–6 hours; five doses over 24 hours) and

albuterol nebulizer treatment (2.5 mg) every 4 hours (five doses over 24 hours). Three hours after the last dose, fetal tachycardia (>200 beats/minute) was detected (maternal heart rate was 90–100 beats/minute). Atrial flutter of 420 beats/minute was detected by fetal echocardiography with a predominate 2:1 conduction. Eight hours later, spontaneous conversion to a normal rate occurred. A normal infant was delivered at term and did well during the 4 days of hospitalization.

A 2009 report examined the evidence for the use and toxicity of β_2 -agonists in pregnancy, particularly for terbutaline and ritodrine as tocolytic agents and albuterol for asthma (46). Based on animal and human reports, the authors concluded that there was a biologic plausible basis for associating prolonged in utero exposure to β_2 -agonists with functional and behavioral teratogenesis, specifically increased risks for autism spectrum disorders, psychiatric disorders, poor cognitive and motor function, and poor school performance. There also were increased risks in offspring for elevated heart rate and hypertension. The mechanisms for these effects appeared to be a decrease in parasympathetic activity resulting in an increase in sympathetic activity. A genetic predisposition for the toxicity was supported by data. The available data suggested that albuterol use in the 1st and 2nd trimesters was associated with a modest increase in the risk of autism spectrum disorders. The authors concluded that excessive treatment with albuterol should be avoided (46).

BREASTFEEDING SUMMARY

No reports describing the use of albuterol during human lactation have been located. However, the inhaled formulation is probably compatible with breastfeeding because of the low maternal systemic concentrations. Other drugs in the class (see Terbutaline) are considered compatible with breastfeeding and albuterol, most likely, is compatible.

ALCAFTADINE

Ophthalmic Antihistamine

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of alcaftadine in human pregnancy have been located. The animal data suggest low risk. Moreover, antihistamines, in general, are considered compatible with pregnancy.

FETAL RISK SUMMARY

Alcaftadine is an antihistamine indicated for the prevention of itching associated with allergic conjunctivitis. It is available as a 0.25% ophthalmic solution. Minimal amounts are measured in the plasma and concentrations of alcaftadine were below the level of detection (10 pg/mL) at 3 hours. The drug is metabolized to an active carboxylic acid metabolite that was undetectable in the plasma 12 hours after a dose. Plasma protein binding for the parent drug and active metabolite were about 39% and 63%, respectively. The elimination half-life of the active metabolite was about 2 hours (1).

Reproduction studies have been conducted in rats and rabbits. No evidence of impaired female reproduction or fetal harm was observed in these species at oral doses that produced plasma exposures that were about 200 and 9000 times, respectively, the human plasma exposure at the recommended human ocular dose (RHOD) (1).

No evidence of mutagenic or genotoxic effects was observed in multiple assays. There also was no evidence of fertility impairment in male and female rats at oral doses producing plasma exposures that were about 200 times the human plasma exposure at the RHOD (1).

It is not known if alcaftadine or its active metabolite crosses the human placenta. The molecular weight of the parent drug (about 307) and moderate protein binding imply that exposure of the embryo and/or fetus is possible, but

the minimal amounts in the plasma suggest that any exposure would be clinically insignificant.

BREASTFEEDING SUMMARY

No reports describing the use of alcaftadine during human lactation have been located. The molecular weight of the parent drug (about 307) and moderate protein binding imply that the drug and possibly the active carboxylic acid metabolite will be excreted into breast milk. However, the minimal plasma concentrations that occur after ocular use suggest that the risk to a nursing infant will be nil. Moreover, antihistamines, in general, are considered compatible with breastfeeding.

ALDESLEUKIN

Antineoplastic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of aldesleukin in human pregnancy have been located. The limited animal reproduction data, although based on body weight and at doses causing maternal toxicity, suggest low risk. In addition, the biologic effects of aldesleukin are the same as endogenous interleukin-2. Nevertheless, until human pregnancy experience is available, the best course is to avoid use of this agent in pregnancy. However, metastatic renal carcinoma and melanoma are potentially fatal, so if a woman requires aldesleukin and informed consent is obtained, it should not be withheld because of pregnancy. If an inadvertent pregnancy occurs, the woman should be advised of the unknown risk to her embryo–fetus.

FETAL RISK SUMMARY

Aldesleukin, a biologic response modifier, is a human recombinant interleukin product produced by recombinant technology. The protein possesses the biologic activities of human native interleukin-2. Aldesleukin is in the same antineoplastic subclass as denileukin. Aldesleukin is indicated for the treatment of metastatic renal carcinoma and metastatic melanoma. After IV infusion, aldesleukin undergoes rapid distribution into the extravascular space and elimination by metabolism. The distribution and elimination half-lives are 13 and 85 minutes, respectively (1).

In a reproduction study in rats, embryo-lethal effects were observed at IV doses that were 27–36 times the human dose based on body weight (HD). However, IV doses 2.1–36 times higher than the HD caused significant maternal toxicity. No evidence of teratogenicity other than that caused by maternal toxicity was observed. Studies for carcinogenicity, mutagenicity, or

effects on fertility have not been conducted (1).

It is not known if aldesleukin crosses the human placenta. The molecular weight of the protein, about 15,300, suggests that it does not. However, other proteins, such as the immunoglobulins cross the placenta. Moreover, the protein rapidly distributes into tissues (e.g., into the lung, liver, kidney, and spleen in rats). The very short distribution and elimination half-lives may limit the amount reaching the embryo and fetus.

BREASTFEEDING SUMMARY

No reports describing the use of aldesleukin during human lactation have been located.

The molecular weight, about 15,300, suggests that it will not be excreted into breast milk. However, other proteins, such as the immunoglobulins, are excreted into milk and so may aldesleukin. The very short distribution (13 minutes) and elimination (85 minutes) half-lives may limit the amount reaching the embryo and fetus. Waiting about 4 hours after a dose to breastfeed should limit the potential exposure of the infant even more. The effects, if any, on a nursing infant are unknown.

ALEFACEPT

Immunologic Agent (Immunosuppressant)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of alefacept in human pregnancy have been located. The animal data suggest that the human embryo and fetal risk are low, but the absence of human pregnancy experience prevents a full assessment of the risk. Psoriasis is common in women of childbearing potential (1). Combined with the very long elimination half-life, this suggests that exposure of inadvertent pregnancies is highly probable. Although the effects on pregnancy are unknown, there is a potential that alefacept could adversely affect the development of the fetal immune system and the immune function of the infant. Health care professionals are encouraged to enroll women who became pregnant while being treated with alefacept in the Biogen Pregnancy Registry by calling 1-866-263-8483 (1).

FETAL RISK SUMMARY

Alefacept is an immunosuppressive dimeric fusion protein consisting of a portion of the human leukocyte function antigen-3 linked to the Fc portion of immunoglobulin G (IgG1) produced by recombinant DNA technology. Alefacept is indicated for the treatment of moderate to severe chronic plaque psoriasis in patients who are candidates for systemic therapy or phototherapy. The drug is administered either IM or IV. After an IV dose, the mean elimination half-life was about 270 hours (about 11 days) (1).

Reproduction studies with alefacept have been conducted in cynomolgus monkeys. At doses about 62 times the human dose based on body weight (HD), no evidence of impaired fertility or fetal harm was observed. Weekly IV bolus doses administered during organogenesis were not abortifacient or teratogenic. Alefacept crossed the placenta in monkeys producing fetal

concentrations that were 23% of the maternal concentrations. No evidence of fetal toxicity or adverse effects on immune system development was observed in the exposed fetuses (1).

In long-term studies in cynomolgus monkeys with weekly IV doses that were 12 or 248 times the HD, one animal in the high-dose group developed a β -cell lymphoma. Other animals in both groups developed β -cell hyperplasia of the spleen and lymph nodes. All animals were positive for an endemic primate gammaherpesvirus. It is known that the immune suppression of animals infected with this virus may lead to β -cell lymphomas (1). Hyperplasia of β -cell-dependent regions in baboon spleens was observed in another low-dose study. Carcinogenicity and fertility studies were not conducted with alefacept, but mutagenicity assays, both in vitro and in vivo, were negative (1).

It is not known if alefacept crosses the human placenta. The monkey and human placentas are classified as hemomonochorial and, since the drug crosses the monkey placenta, it probably crosses the human placenta as well. The human fetal exposure to the drug should be similar to that observed in monkeys.

BREASTFEEDING SUMMARY

No reports describing the use of alefacept during human lactation have been located. As an immune globulin, the drug is probably excreted into breast milk. Moreover, because of the very long elimination half-life (about 11 days), holding breastfeeding after a dose to allow clearance from the mother's system is not practical. The effect of this exposure on a nursing infant is unknown, but the dimeric fusion protein would most likely undergo some degree of digestion in the infant's gut. However, suppression of a nursing infant's immune function is a potential complication. Until data are available, avoiding nursing during the use of alefacept is the safest course.

ALEMTUZUMAB

Antineoplastic

PREGNANCY RECOMMENDATION: No Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of alemtuzumab in human or animal pregnancies have been located. It is not known if the antibody crosses the placenta but, if it did, a potential fetal consequence of this exposure could be the depletion of B and T lymphocytes (1). Because of the potential for embryo and fetal harm, the antibody should be avoided, if possible, during pregnancy. In addition, based on the very long half-life, a woman should not conceive for several months after the last dose. The manufacturer recommends that men of reproductive potential and women of childbearing potential should use effective contraceptive methods during treatment and for a minimum of 6 months after therapy is stopped (1). However, leukemia can be fatal, so if a woman requires alemtuzumab and informed consent is obtained, it should not be withheld because of pregnancy. If an inadvertent pregnancy occurs, the woman should be advised of the potential risk for severe adverse effects in the embryo and fetus.

FETAL RISK SUMMARY

Alemtuzumab is a recombinant DNA-derived humanized monoclonal antibody (Campath-1H) that is given by IV infusion. It is indicated for the treatment of B-cell chronic lymphocytic leukemia. The mean plasma half-life changes with time, increasing from 11 hours (range 2–32 hours) after the first 30 mg dose to 6 days (range 1–14 days) after the last 30 mg dose (1).

Alemtuzumab may cause severe, infusion-related toxicity, including hypotension and other adverse effects. Premedication with acetaminophen and antihistamines is recommended (1). Hypotension in a pregnant woman could have deleterious effects on placental perfusion resulting in embryo and fetal

harm.

Animal reproduction studies have not been conducted with alemtuzumab. Neither have studies been conducted for carcinogenicity, mutagenicity, or fertility (1).

It is not known if alemtuzumab crosses the human placenta. The very high molecular weight (about 150,000 for the Campath-1H antibody) suggests that it will not cross. However, human immunoglobulin G (IgG) does cross and, therefore, alemtuzumab may also cross (1).

BREASTFEEDING SUMMARY

No reports describing the use of alemtuzumab during lactation have been located. The very high molecular weight (about 150,000 for the Campath-1H antibody) suggests that it will not be excreted into breast milk. However, human IgG is excreted into milk and, therefore, alemtuzumab may also be excreted (1). The effects of this potential exposure on a nursing infant are unknown, but immunosuppression and other severe adverse effects are potential complications.

ALENDRONATE

Bisphosphonate

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Alendronate does not cause structural anomalies in animals but does produce dose-related maternal and fetal toxicity. Several reports have described its use in or near pregnancy. Although one report did find significantly shorter gestations, reduced birth weight, and an increased rate of spontaneous abortions, these outcomes may have been due to the underlying maternal disease and/or the use of corticosteroids (1). Because the oral bioavailability is very low and the plasma clearance is rapid, clinically significant amounts may not cross the placenta. The drug is slowly released from bone; thus, the use before pregnancy may result in low-level, continuous exposure throughout gestation. The use of alendronate in women who may become pregnant or during pregnancy is not recommended. However, inadvertent exposure during early pregnancy does not appear to present a major risk to the embryo or fetus.

FETAL RISK SUMMARY

Bisphosphonates are synthetic analogs of pyrophosphate that bind to the hydroxyapatite found in bone. Alendronate, a specific inhibitor of osteoclast-mediated bone resorption, is indicated for the treatment and prevention of osteoporosis in postmenopausal women and men. Alendronate is also indicated for the treatment of Paget's disease of bone and for glucocorticoid-induced osteoporosis. The oral bioavailability, relative to an IV reference dose, is very low with only about 0.6% absorbed under fasting conditions. Alendronate is not metabolized in animals or humans. Approximately 78% of the drug is bound to protein in human plasma. After an IV dose, the plasma half-life is about 1 hour (plasma concentrations fell by >95% within 6 hours). However, the terminal

elimination half-life is >10 years because of its slow release from bone (2).

In pregnant rats, a dose 0.26 times the maximum recommended daily dose for Paget's disease of 40 mg based on BSA (MRHD) caused decreased body weight in otherwise-normal pups. Decreased postimplantation survival occurred at 0.52 times the MRHD. With higher doses (2.6 times the MRHD), there was an increase in the incidence of incomplete fetal ossification in vertebrae, skull, and sternebrae. (Note: The daily doses for prevention and treatment of osteoporosis are 5 and 10 mg, respectively.) None of these adverse effects was observed in pregnant rabbits treated with doses up to 10.3 times the MRHD (2).

Delays and failure of delivery secondary to maternal hypocalcemia (both total and ionized calcium) were observed in pregnant rats at 3.9 times the MRHD. Normal calcium levels were measured in the fetuses. Late maternal pregnancy deaths also were observed at this dose. When the rats were treated from before mating through gestation, doses as small as 0.13 times the MRHD resulted in protracted parturition. Oral calcium supplementation did not prevent the hypocalcemia or prevent maternal and fetal deaths secondary to delays in delivery. However, IV calcium did prevent maternal, though not fetal, deaths (2,3).

In a study published in 1999, pregnant rats were treated with a daily SC dose of alendronate (0.1 mg/kg) during days 11–20 of pregnancy (4). Based on body weight, the dose was comparable to a human oral dose of 10 mg/day, but the systemic bioavailability was much higher than that obtained in humans. The gestational period was chosen because it covered the time of active bone development in rat fetuses. Alendronate passed through the placenta and accumulated in the fetuses. A significant increase in fetal bone calcium content (i.e., bone mass) with an accompanying significant decrease in bone marrow volume was found (4).

It is not known if alendronate crosses the placenta to the human fetus, but the molecular weight (about 325) is low enough that fetal exposure should be expected. Although the low maternal plasma concentration and short plasma half-life should reduce the amount of drug available for passage to the fetus, any drug that crosses the placenta probably will accumulate in fetal bones, as it does in rat fetuses.

A 2003 case report has described the use of alendronate in human pregnancy (5). A 49-year-old woman, who was amenorrheic and thought to be postmenopausal, was treated with oral alendronate 10 mg/day for osteoporosis. Treatment was begun before and continued throughout her

gestation. An apparently normal female infant with a birth weight of 2390 g (50th percentile) was born at 36 weeks' gestation. Laboratory tests were within normal limits. X-ray studies of the skull and wrists revealed normal bone structure and density without abnormal calcifications. At 1 year of age, the girl's weight was 8 kg (10th percentile), her height was 73 cm (50th percentile), and her physical examination and psychomotor development were normal (5).

In a 2006 case series, 24 pregnancies were exposed to alendronate, 8 of the women took the drug 1–6 months before pregnancy, 15 before and during the first 3–8 weeks', and 1 through week 21 (1). Because of the long elimination half-life, the three groups were combined and compared with 790 nonexposed controls. In the subjects, there were 19 liveborn infants with a median gestational age of 38 weeks ($p = 0.001$ vs. controls [40 weeks]). The median birth weight also was significantly lower in subjects, 2910 vs. 3290 g ($p = 0.002$), and there were more spontaneous abortions 20.8 vs. 7% ($p = 0.026$). However, 13 of the women were also taking corticosteroids. No major anomalies were observed in the subjects (1).

A 2008 review described 51 cases of exposure to bisphosphonates before or during pregnancy: alendronate ($N = 32$) pamidronate ($N = 11$), etidronate ($N = 5$), risedronate ($N = 2$), and zoledronic acid ($N = 1$) (6). The authors concluded that although these drugs may affect bone modeling and development in the fetus, no such toxicity has yet been reported.

BREASTFEEDING SUMMARY

No reports describing the use of alendronate during nursing have been located. The molecular weight (about 325) is low enough for excretion into breast milk, but the low plasma concentrations and rapid plasma clearance suggest that minimal amounts will be excreted into milk. Moreover, since the oral bioavailability of this drug in the nonfasting state is negligible, systemic levels in a nursing infant should also be negligible (2).

ALFENTANIL

Narcotic Agonist Analgesic

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 3rd Trimester

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Alfentanil is not teratogenic in animals and, based on the experience with similar agents, teratogenicity in humans is unlikely. However, there are no reports describing the use of this drug during organogenesis. As with all opioid agonist analgesics, alfentanil may cause neonatal respiratory depression if used close to delivery.

FETAL RISK SUMMARY

No reports linking the use of alfentanil during pregnancy with congenital abnormalities have been located, but experience in the 1st trimester has not been reported. The narcotic is not teratogenic in rats and rabbits (1,2). An embryocidal effect was observed with doses 2.5 times the upper human dose administered for 10–30 days, but this may have been related to maternal toxicity (1).

Alfentanil rapidly crosses the placenta to the fetus (3–5). A 1986 report described the pharmacokinetics and placental transfer of alfentanil after a single 30-mcg/kg IV dose administered to 5 women scheduled for cesarean section (group A) and during a continuous epidural infusion (30-mcg/kg loading dose followed by 30-mcg/kg/hour infusion) given to five women for vaginal delivery (group B) (3). The ratio of total alfentanil in umbilical vein to maternal blood in the combined 10 women was 0.29 (0.31 and 0.28 for groups A and B, respectively). The fetal:maternal ratio of free (unbound) alfentanil, however, was 0.97, reflecting the decreased α_1 -acid glycoprotein (the most important binding protein for the drug) levels in the fetuses compared with the mothers (3).

Alfentanil was administered as a continuous infusion (30 mcg/kg/hour with as-

needed bolus doses of 30 mcg/kg) via an extradural catheter to 16 women undergoing vaginal delivery (4). The umbilical vein:maternal ratios in six women varied between 0.221 and 0.576 (mean 0.33). For all 16 newborns, the mean (range) Apgar scores at 1, 3, and 5 minutes were 8.56 (range 7–10), 9.60 (range 8–10), and 9.80 (range 9–10), respectively, and were comparable to a control group. However, neurobehavioral assessment of the newborns using the Amiel-Tison score at 15–30 minutes of life indicated a significant decrease, compared with that of control newborns, in passive and active tone and total score. Primary reflexes and general assessment were not statistically different from those of control newborns. No abnormal feeding habits or behavior changes were noted on later evaluation, presumably after the effects of the narcotic had dissipated.

In 21 women scheduled for elective cesarean section, alfentanil (10 mcg/kg IV) administered before the induction of anesthesia significantly decreased the pressor response to laryngoscopy and endotracheal intubation in comparison to 16 control patients ($p < 0.01$) (5). At delivery, the mean total alfentanil fetal:maternal ratio was 0.32, but based on the lower α_1 -acid glycoprotein levels in the newborns (33% of maternal levels), the calculated unbound alfentanil concentrations in the newborns and mothers were approximately equal (5).

Other reports have described the use of IV alfentanil immediately before the induction of anesthesia for cesarean section to lessen the hypertensive effects of tracheal intubation in women with preeclampsia (6–8) or as a single epidural injection (1 mg) in combination with a continuous epidural infusion of bupivacaine before vaginal delivery (9). As with other opioid agonist analgesics, neonatal respiratory depression is a potential complication, but it can be quickly reversed with naloxone.

BREASTFEEDING SUMMARY

Alfentanil is excreted into breast milk. Nine nonbreastfeeding women undergoing postpartum tubal ligation were administered alfentanil, 50 mcg/kg IV (10). An additional 10 mcg/kg was given if needed. Colostrum was collected from the right breast 4 hours after the last injection of alfentanil and from the left breast at 28 hours. The mean level of alfentanil in the colostrum at 4 hours was 0.88 ng/mL (range 0.21–1.56 ng/mL), and the mean level at 28 hours was 0.05 ng/mL (range 0.11–0.26 ng/mL). The clinical significance of the drug level in milk to the nursing infant at either time is unknown but is probably nil.

ALGLUCERASE

Endocrine/Metabolic Agent (Gaucher Disease)

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

No alglucerase-related adverse effects in embryos and fetuses have been reported in the limited data on pregnancies complicated by type I Gaucher disease. Pregnancy may exacerbate existing disease or result in new disease manifestations, but the data suggest that treatment may reduce the risk of spontaneous abortion and bleeding complications. However, systematic human or animal studies have not been conducted. The manufacturer has replaced alglucerase with imiglucerase and the last commercially available alglucerase expired in March 2011.

FETAL RISK SUMMARY

Alglucerase, an enzyme given by IV infusion, is used in the treatment of patients with type I Gaucher disease. It is in the same pharmacologic subclass as imiglucerase, taliglucerase- α , and velaglucerase- α . Alglucerase replaced the endogenous enzyme β -glucocerebrosidase. Alglucerase is prepared from pooled human placental tissue. After infusion, the terminal elimination half-life ranges from 3.6 to 10.4 minutes (1).

Reproduction studies with alglucerase have apparently not been conducted. Moreover, the carcinogenic and mutagenic potential of alglucerase has not been studied. Histopathology studies to detect effects on spermatogenesis in rats revealed no testicular changes (1).

It is not known if alglucerase crosses the human placenta. The relatively high molecular weight (about 55,600) and the short terminal half-life suggest that exposure of the embryo–fetus will be limited, if it occurs at all.

A 1996 case report and review involved a 24-year-old woman with Gaucher disease who was treated with alglucerase 40 U/kg every 2 weeks (2). She

received two doses of the enzyme during the 1st trimester and then additional doses were held until 12 weeks' gestation when therapy was reinstated. She gave birth at term to 3.65-kg, female infant with Apgar scores of 9 and 9 at 1 and 5 minutes, respectively. No additional information on the condition of the infant was provided (2).

A 1997 report described six pregnancies exposed to alglucerase (3). In one pregnancy, a low-dose, high-frequency regimen (30 U/kg/month, administered 3 times weekly) was discontinued before conception and then restarted at 12 weeks' gestation. At term, a normal, 2.84-kg female infant was delivered. A second pregnancy was similarly treated but with a dose of 60 U/kg/month. This patient gave birth at term to a healthy, 3.65-kg male infant. Two women were treated throughout pregnancy on the low-dose, high-frequency regimen and gave birth at term to healthy, but small-for-gestational-age, female infants (2.56 and 2.50 kg, respectively). In a fifth pregnancy, a low-dose regimen was started at 5 months' gestation but, about 1 month later, the woman delivered a female infant who died within 24 hours. The sixth case involved a woman with symptomatic pulmonary hypertension who had been treated with alglucerase for 3 years. At 10 weeks' gestation, the pregnancy was terminated because of the lung condition. The conceptus was normal and appropriate for gestational age (3).

Another case report described a 25-year-old woman with avascular necrosis of the femur complicating Gaucher disease (4). She conceived 4 months later while receiving alglucerase 3200 U every 2 weeks (body weight not specified). She gave birth at term to a 4.19-kg, male infant who was doing well at 6 months of age (4).

Outcomes of exposed pregnancies treated with either alglucerase or imiglucerase have been summarized from surveys gathered from international treatment centers, from reports in the literature, as well as the manufacturer's pharmacovigilance database. The total number of exposed patients is unclear as there could be overlap between the various sources of reports. However, as reviewed in a 2010 publication, among 43–78 treated pregnancies compared with 71–388 untreated pregnancies with the same disease, the risk of spontaneous abortion, disease-related bleeding complications at delivery, and disease-related complications postpartum was reduced. No evidence of teratogenic risk was noted (5,6).

BREASTFEEDING SUMMARY

Alglucerase has been detected in breast milk even though the relatively high

molecular weight (about 55,600) and the short terminal half-life (3.6–10.4 minutes) suggest that excretion will be limited.

In a woman receiving an IV infusion of 60 U/kg, milk concentrations of the enzyme ranged from 69 to 187 ng/mL above baseline for 2–48 hours postinfusion (7). A 1998 case report described successful breastfeeding in a mother being treated with alglucerase (8).

The glycoprotein is largely destroyed in the digestive tract suggesting that even if small amounts are transferred into breast milk, the enzyme is unlikely to reach the systemic circulation of a breastfed infant (1).

ALGLUCOSIDASE ALFA

Endocrine/Metabolic Agent (Enzyme)

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably
Compatible

PREGNANCY SUMMARY

One report describing the use of alglucosidase alfa in human pregnancy has been located. The animal data suggest low risk, but the dose used was very low. Untreated Pompe disease is a fatal condition with death usually related to respiratory failure (1). If a woman requires alglucosidase alfa, it should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Alglucosidase alfa, a glycoprotein produced by recombinant DNA technology, consists of the enzyme α -glucosidase (GAA) encoded by the most predominant of nine haplotypes of this gene. It is given by IV infusion every 2 weeks. Alglucosidase is indicated for patients with Pompe disease (GAA deficiency). The plasma half-life is dose-dependent ranging from 2.3 to 2.9 hours (1).

Reproduction studies have been conducted in mice. IV doses, given every other day, up to about 0.2 times the recommended bi-weekly human dose based on BSA revealed no evidence of fetal harm. A similar dose had no effect on fertility or reproductive performance in mice. Studies for carcinogenicity and mutagenicity have not been conducted (1).

It is not known if alglucosidase alfa crosses the human placenta. The molecular weight (about 99,377–109,000) and the short plasma half-life suggest that little, if any, of the glycoprotein will cross to the embryo or fetus.

A 2011 case report described the use of alglucosidase alfa (20 mg/kg every other week) throughout pregnancy in 40-year-old woman with adult-onset Pompe disease (2). Because of worsening disease, an elective cesarean section was performed at about 38 weeks' to deliver a healthy male infant with Apgar scores of 8, 9, and 10. The infant's weight, length, and head

circumference were normal and there were no congenital anomalies. The infant was developing normally at 1 year of age (2).

BREASTFEEDING SUMMARY

One report describing the use of alglucosidase alfa during lactation has been located. In the above case report, a mother treated throughout pregnancy with the enzyme continued therapy while breastfeeding her infant (2). Before a dose, enzyme activity in her milk was 3 nmol/mL/hr, about 10% of what is measured in the milk of an unaffected mother. After infusion, the highest activity (245 nmol/mL/hr) was reached at 2.5 hours postinfusion (2). As expected, because alglucosidase alfa is a native enzyme and would be present in the infant, no adverse effects were reported in the nursing infant.

If a woman requires alglucosidase alfa for the treatment of Pompe disease, it should not be withheld because of breastfeeding.

ALISKIREN

Antihypertensive

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Although there is no human pregnancy experience, the animal reproduction data suggest low risk in the 1st trimester. Because aliskiren acts directly on the renin–angiotensin system, exposure in the 2nd and 3rd trimesters should be avoided except in those rare incidences in which the mother requires therapy with this agent. Two other classes of agents that act on this system, angiotensin-converting-enzyme (ACE) inhibitors and angiotensin II receptor antagonists (ARA), are known to cause marked fetal toxicity in the 2nd and 3rd trimesters. (See Captopril and Losartan for representative agents.) Therefore, use of aliskiren during the 2nd and 3rd trimesters may cause teratogenicity and severe fetal and neonatal toxicity identical to that seen with ACE inhibitors and ARA drugs. Fetal toxic effects may include anuria, oligohydramnios, fetal hypocalvaria, intrauterine growth restriction, prematurity, and patent ductus arteriosus. Anuria-associated anhydramnios/oligohydramnios may be associated with fetal limb contractures, craniofacial deformation, and pulmonary hypoplasia. Severe anuria and hypotension, resistant to both pressor agents and volume expansion, may occur in the newborn following in utero exposure to aliskiren. Newborn renal function and blood pressure should be closely monitored.

FETAL RISK SUMMARY

Aliskiren is a nonpeptide renin inhibitor. It is indicated for the treatment of hypertension either alone or in combination with other antihypertensive agents. Aliskiren is partially metabolized to inactive metabolites apparently by the CYP450 isoenzyme CYP3A4. Oral bioavailability is poor with only about 2.5%

absorbed systemically (1). The mean elimination half-life is 30 hours (range 23–36 hours) and plasma protein binding is about 50% (2).

Reproduction studies have been conducted in rats and rabbits. In pregnant rats and rabbits, there was no evidence of teratogenicity with oral doses ≤ 20 and ≤ 7 times, respectively, the maximum recommended human dose of 300 mg/day (MRHD) on a BSA basis (MRHD-BSA). However, in rabbit offspring fetal birth weights were reduced at 3.2 times the MRHD-BSA. In rabbits, the drug was present in the placenta, amniotic fluid, and fetuses (1).

Carcinogenic studies in mice and rats with doses producing exposures that were about 1.5 and 4 times, respectively, the MRHD based on AUC (MRHD-AUC) observed no significant increases in tumor incidence. However, tumors that are considered rare in the strain of rat studied were observed in two animals; a colonic adenoma in one and a cecal adenocarcinoma in the other. Mucosal epithelial hyperplasia of the lower gastrointestinal tract, with or without erosion/ulceration, was noted in both species at exposures that were about 0.75 and 2 times, respectively, the MRHD-AUC. No genotoxic potential was observed in multiple assays. In addition, no effect on the fertility of male and female rats was observed with doses ≤ 8 times the MRHD-BSA (1).

Although aliskiren crosses the placenta in rabbits (1), this has not been studied in humans. The molecular weight (about 552 for the free base), long elimination half-life, and moderate plasma protein binding suggest that the drug will cross to the embryo and fetus. However, the low lipid solubility should limit the amount transferred.

No reports have described the use of aliskiren in human pregnancy. However, use of the drug in the 2nd and 3rd trimesters is not recommended because of the potential for severe toxicity in the fetus and newborn.

BREASTFEEDING SUMMARY

No reports describing the use of aliskiren during human lactation have been located. The molecular weight (about 552 for the free base), long elimination half-life (mean 30 hours), and moderate plasma protein binding (about 50%) suggest that the drug will be excreted into breast milk. However, the low lipid solubility should limit the amount excreted. The effect on a nursing infant is unknown. The American Academy of Pediatrics, however, classifies ACE inhibitors, a closely related group of antihypertensive agents, as compatible with breastfeeding. (See Captopril or Enalapril.)

ALLOPURINOL

Antineoplastic/Antigout

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

The human pregnancy experience with allopurinol is limited because the conditions for which it is indicated are relatively rare in women of childbearing age. No adverse effects were observed in rats and rabbits but, in one study, severe toxicity was noted in mice. However, the only dose comparisons to the human dose were based on body weight and are not interpretable. In one study, the use of allopurinol throughout gestation was associated with multiple major defects in the newborn. Additional data are needed before the association can be classified as causal.

FETAL RISK SUMMARY

Allopurinol, a xanthine oxidase inhibitor, is used for the treatment of symptomatic primary or secondary hyperuricemias. It is in the same antineoplastic subclass of antimetabolites that reduce uric acid levels as rasburicase. Allopurinol is indicated for the management of patients with (a) signs and symptoms of primary or secondary gout; (b) leukemia, lymphoma, and malignancies who are receiving cancer therapy which causes elevations of serum and urinary uric acid levels; and (c) recurrent calcium oxalate calculi whose daily uric acid excretion exceeds 800 mg/day in male patients and 750 mg/day in female patients. Allopurinol is rapidly metabolized to oxipurinol, an active metabolite. Allopurinol has a plasma half-life of about 1–2 hours, whereas oxipurinol has a half-life of about 15 hours (1).

Reproduction studies by the manufacturer have been conducted in rats and rabbits. At doses up to 20 times the usual human dose based on body weight, no evidence of impaired fertility or fetal harm was observed (1). In a 1972 study, doses of 50 mg/kg and 100 mg/kg of allopurinol were given

intraperitoneally to mice (2). The high dose, but not the low dose, resulted in a significant increase in the number of dead offspring. Both doses were associated with cleft palate and skeletal defects (2). However, it was not determined if the toxicity was a fetal effect or an effect secondary to maternal toxicity (1). In studies involving other animal species, no fetal harm was observed (3).

Consistent with the low molecular weight (about 136 for allopurinol), as well as the plasma half-lives for allopurinol and oxipurinol, both cross the placenta. A group of mothers were given allopurinol 500 mg IV 18–190 minutes before birth (4). The median maternal concentration of allopurinol and oxipurinol were 3.8 mcg/mL (1.2–7.9 mcg/mL) and 3.2 mcg/mL (1.5–6.4 mcg/mL), respectively, whereas arterial cord blood levels were 2.0 mcg/mL (0.2–7.3 mcg/mL) and 1.5 mcg/mL (0.6–7.6 mcg/mL), respectively (4).

The manufacturer is aware of two unpublished reports of women receiving the drug during pregnancy who gave birth to normal infants (1).

Allopurinol, in daily doses of 300–400 mg (unspecified dose in one patient), was combined with cancer chemotherapeutic agents in six patients for the treatment of leukemia occurring during pregnancy (5–9). Treatment in each of these cases was begun in the 2nd or 3rd trimester. The outcomes of these pregnancies were as follows: four normal healthy infants (5–7); one intrauterine fetal death probably a result of severe preeclampsia (8); and one growth-restricted infant with absence of the right kidney, hydronephrosis of the left kidney, and hepatic subcapsular calcifications (9). The cause of the defects in the latter infant was unknown but, because drug therapy was not started until the 20th week of gestation, any relationship to allopurinol can be excluded. The intrauterine growth restriction was thought to be caused by the chemotherapeutic agent, busulfan, that the mother received (9).

A 1976 case report described the use of allopurinol in a woman with type I glycogen storage disease (von Gierke's disease) (10). One of the characteristics of this inherited disease is hyperuricemia as a result of decreased renal excretion and increased production of uric acid. The woman was receiving allopurinol, 300 mg/day, at the time of conception and during the early portion of the 1st trimester (exact dates were not specified). The drug was stopped at that time. A term female infant was delivered by cesarean section for failed labor. Phenylketonuria, an autosomal recessive disorder, was subsequently diagnosed in the infant (10).

A woman with primary gout and gouty nephropathy was treated with 300 mg/day of allopurinol throughout gestation (11). She delivered an appropriate-

for-gestational-age 2510-g healthy female infant at 35 weeks' gestation. The infant's weight gain was normal at 10 weeks of age, but other developmental milestones were not provided (11).

A 1997 randomized, double-blind, placebo controlled trial, allopurinol (200 mg/day) was combined with vitamin E (800 IU/day) and vitamin C (1000 mg/day) for women with severe preeclampsia diagnosed between 24 and 32 weeks of gestation (12). The outcomes evaluated were prolongation of pregnancy, infant outcomes, and other factors. The results did not suggest a benefit of the therapy (12).

A 2009 feasibility study evaluated whether allopurinol given to mothers with signs of fetal distress immediately before birth would reduce free radical formation in the fetus, a potential first step to reduce or prevent fetal hypoxia-induced brain injury (4). The study found that therapeutic doses of allopurinol reduced cord blood levels of the protein S-100B, a marker of brain injury. Two other reports described the rationale for this intervention and a new study that was just beginning (13,14).

A 2011 case report described multiple major birth defects in an infant born at 41 weeks' (15). Birth weight, length, and head circumference were appropriate for gestational age. The mother had taken allopurinol 300 mg/day for recurrent kidney stones and methyldopa for hypertension throughout gestation. External anomalies were as follows: hypertelorism, left-sided microphthalmia and coloboma of upper eyelid, left-sided microtia and absent left external auditory canal, simplified right ear with a preauricular tag, left-sided cleft lip and palate, and bilateral undescended testes. The infant died at 8 days of age. The following internal defects were found at autopsy: hypoplasia of corpus callosum, left optic nerve atrophy, left microphthalmia, small frontal fossa, agenesis of the left diaphragm with intrusion of liver, stomach, and spleen into the diaphragmatic space, mildly enlarged right-sided kidney, absent left kidney, small accessory spleen, and profound left pulmonary hypoplasia. The cerebellum and gyral pattern of the brain surface appeared to be normal, as was the cardiovascular system and skeleton. The infant's karyotype was a normal 46,XY, but a chromosome microdeletion/duplication syndrome could not be ruled out. Because the anomalies shared some features with those caused by mycophenolate mofetil (see Mycophenolate), and because both allopurinol and mycophenolate interrupt purine synthesis, the authors concluded that allopurinol should be considered a potential teratogen (15).

In contrast to the above report, a 2012 case described a 27-year-old woman with ulcerative colitis who was treated throughout pregnancy with allopurinol

100 mg/day, mercaptopurine 25 mg/day, and mesalazine 4 g/day (16). Pregnancy was complicated by diarrhea and blood loss in the 2nd trimester. An elective cesarean section was performed at 39 weeks' to give birth to a healthy 3550-g infant (sex not specified) with Apgar score of 9, 10, and 10 at 1, 5, and 10 minutes, respectively. No anomalies were observed in the infant (16).

BREASTFEEDING SUMMARY

Allopurinol and its active metabolite, oxipurinol, are excreted into human milk. A woman with hyperuricemia was taking allopurinol 300 mg/day for 4 weeks while breastfeeding her 5-week-old infant (17,18). Maternal plasma and milk samples were drawn 2 and 4 hours after a 300-mg dose. Her plasma levels of allopurinol and oxipurinol at these times were 1.0 and 13.8 mcg/mL, and 1.0 and 19.9 mcg/mL, respectively. Milk levels of the drug and metabolite at 2 and 4 hours were 0.9 and 53.7 mcg/mL, and 1.4 and 48.0 mcg/mL, respectively. At these times, the milk:plasma ratios for allopurinol were 0.9 and 1.4, respectively, and for oxipurinol were 3.9 and 2.4, respectively. The mother breastfed her infant 2 hours after her dose and a single infant plasma sample was taken 2 hours later. Allopurinol was not detected (detection limit 0.5 mcg/mL) in the infant's plasma but the concentration of oxipurinol was 6.6 mcg/mL. The average daily dose of allopurinol and oxipurinol ingested by the infant from the milk (based on 150 mL/kg/day) was 0.14–0.20 and 7.2–8.0 mg/kg, respectively. No adverse effects in the nursing infant were observed (18). However, 4 hours after a dose and 2 hours after feeding, the infant's oxipurinol plasma level was 48% and 33% of the mother's levels at 2 and 4 hours. As such, the infant should be monitored for allergic reactions, such as rash, periodic blood counts, and other common toxicities observed in adults.

The American Academy of Pediatrics classifies allopurinol as compatible with breastfeeding (19).

ALMOTRIPTAN

Antimigraine

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of almotriptan in human pregnancy have been located. The animal data are suggestive of low risk, but an assessment of the actual risk cannot be determined until human pregnancy experience is available. Although a 2008 review of triptans in pregnancy found no evidence for teratogenicity, the data did suggest a possible increase in the rate of preterm birth (1).

FETAL RISK SUMMARY

Almotriptan is an oral selective serotonin (5-hydroxytryptamine; 5-HT_{1B/1D}) receptor agonist that has high affinity for 5-HT_{1B}, 5-HT_{1D}, and 5-HT_{1F} receptors. The drug is closely related to eletriptan, frovatriptan, naratriptan, rizatriptan, sumatriptan, and zolmitriptan (see also Eletriptan, Frovatriptan, Naratriptan, Rizatriptan, Sumatriptan, and Zolmitriptan). It is indicated for the acute treatment of migraine with or without aura in adults. Protein binding is minimal (about 35%). Almotriptan is metabolized to inactive metabolites, but about 40% is excreted unchanged in the urine. The mean elimination half-life is approximately 3–4 hours (2).

Reproduction studies have been conducted in rats and rabbits. Rats were given doses throughout organogenesis that produced maternal exposures up to about 958 times the human exposure from the maximum recommended daily dose (MRDD) of 25 mg based on AUC (MRDD-AUC). At the highest dose (958 times the MRDD-AUC), increased embryo deaths were observed. Doses >80 times the MRDD-AUC resulted in an increased incidence of fetal skeletal variations (decreased ossification). When almotriptan was administered to pregnant rats throughout gestation and lactation, a dose 160 times the MRDD

based on BSA (MRDD-BSA) caused an increase in gestational length and a decrease in litter size and pup birth weight. The decreased pup weight persisted throughout lactation. The no-observed-effect-level (NOEL) was 40 times the MRDD-BSA. In pregnant rabbits, a dose 50 times the MRDD-BSA resulted in an increase in embryo deaths (2).

It is not known if almotriptan crosses the human placenta to the fetus. The molecular weight (about 336 for the free base) is low enough that passage to the fetus should be expected. In addition, the minimal plasma protein binding, incomplete metabolism, and moderate elimination half-life suggest that substantial amounts of the drug will be available for transfer at the maternal:fetal interface.

BREASTFEEDING SUMMARY

No reports describing the use of almotriptan during human lactation have been located. The molecular weight (about 336 for the free base) suggests that the drug will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown.

ALOSETRON

Antidiarrheal/Antiemetic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of alosetron in human pregnancy have been located. Because the drug is restricted by the manufacturer to severe diarrhea-predominant irritable bowel syndrome, pregnancy exposures are probably infrequent. The animal data suggest low risk, but the absence of human pregnancy experience prevents an assessment of the embryo–fetal risk. Limited information for other agents in this class (e.g., see Ondansetron) does not suggest a risk of teratogenicity. Therefore, if indicated, alosetron should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Alosetron is a selective antagonist of the serotonin 5-HT₃ receptor type. It is the same pharmacologic class as dolasetron, granisetron, ondansetron, and palonosetron. Although classified as an antiemetic, alosetron is indicated for the treatment of irritable bowel syndrome in women whose primary symptom is severe chronic diarrhea. Alosetron is extensively metabolized to metabolites with unknown biologic activity. About 82% is bound to plasma proteins and the terminal elimination half-life is very short (about 1.5 hours) (1).

Reproduction studies have been conducted in rats and rabbits. In rats, doses up to about 160 times the recommended human dose based on BSA (RHD) revealed no evidence of impaired fertility or fetal harm. Similar findings were observed in rabbits given doses up to about 240 times the RHD. In addition, dose up to about 160 times the RHD had no effect on reproductive performance in male or female rats (1).

It is not known if alosetron crosses the human placenta. The molecular weight of the free base (about 295) and moderate plasma protein binding

suggest that the drug will cross to the embryo–fetus, but the very short terminal elimination half-life will limit the amount of drug at the maternal:fetal interface.

BREASTFEEDING SUMMARY

No reports describing the use of alosetron during human lactation have been located. The molecular weight of the free base (about 295) and moderate plasma protein binding suggest that the drug will be excreted into breast milk. However, the very short terminal elimination half-life (about 1.5 hours) suggests that the amount of drug in milk will be minimal. The effects of this exposure on a nursing infant are unknown. However, because of the potential for severe toxicity (e.g., gastrointestinal symptoms that have caused deaths in adults), alosetron should probably not be used in women who are breastfeeding.

ALPRAZOLAM

Sedative

PREGNANCY RECOMMENDATION: Human and Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

No structural anomalies have been attributed to the use of alprazolam during human pregnancy but in some reports, large numbers of patients were lost to follow-up. When used close to delivery, neonatal withdrawal has been reported. The long-term effects of in utero exposure on neurobehavior, especially when the exposure occurs in the latter half of pregnancy, have not been studied but are of concern.

FETAL RISK SUMMARY

Alprazolam, a member of the benzodiazepine class of agents, is used for the treatment of anxiety. Although no congenital anomalies have been attributed to the use of alprazolam during human pregnancies, other benzodiazepines (e.g., see Diazepam) have been suspected of producing fetal malformations after 1st trimester exposure. In pregnant rats, the drug produced thoracic vertebral anomalies and increased fetal death only at the highest dose (50 mg/kg) tested (1).

Researchers described the effects of alprazolam exposure on gestational day 18 (i.e., near term) on the neurodevelopment of mice in a series of reports (2–4). In one strain of mice, exposure induced persistent imbalance in the newborn and hind limb impairment in the adult offspring suggesting a defect in cerebellar development (2). In the second part of this study, in utero exposure to the drug (0.32 mg/kg orally) did not increase anxiety in adult offspring but did reduce motivation (3). A decrease in the tendency to engage in group activity and an increase in male aggression was observed in the third part of the study (4).

No data have been located on the placental passage of alprazolam. However, other benzodiazepines, such as diazepam, freely cross the placenta

and accumulate in the fetus (see Diazepam). A similar distribution pattern should be expected for alprazolam.

One manufacturer has received 441 reports of in utero exposure to alprazolam or triazolam, two short-acting benzodiazepines, almost all of which occurred in the 1st trimester (5,6). Although most of the women discontinued the drugs when pregnancy was diagnosed, 24 continued to use alprazolam throughout their gestations (5). At the time of publication, about one-fifth of the 441 cases were still pregnant; one-sixth had been lost to follow-up, and one-sixth had been terminated by elective abortion for various reasons (5). Spontaneous abortion or miscarriage (no congenital anomalies were observed in the abortuses) occurred in 16 women; 2 pregnancies ended in stillbirths; and 1 newborn infant died within 24 hours of birth. Most of the remainder of the reported exposures ended with the delivery of a normal infant. The manufacturer also received two retrospective reports of congenital defects after alprazolam exposure (5). One of the cases involved an infant with Down's syndrome after maternal consumption of a single 5.5-mg dose of alprazolam and an unknown amount of doxepin during pregnancy (5). The second report involved a mother who had ingested 0.5 mg/day of alprazolam during the first 2 months of gestation. She delivered an infant with cat's eye with Pierre Robin syndrome. Neither of these outcomes can be attributed to alprazolam.

A 1992 reference reported the prospective evaluation of 542 pregnancies involving 1st trimester exposure to alprazolam gathered by a manufacturer from worldwide surveillance (7). These data were an extension of the data provided immediately above. Of the total, 131 (24.2%) were lost to follow-up. The outcome of the remaining 411 pregnancies was 42 (10.2%) spontaneous abortions, 5 (1.2%) stillbirths, 88 (21.4%) induced abortions, and 263 (64.0%) infants without and 13 (3.2%) infants with congenital anomalies. A total of 276 live births occurred, but two of these infants, both born prematurely, died shortly after birth. One, included in the group with congenital anomalies, had bilateral hydroceles and ascites, whereas the other died after intraventricular hemorrhage. The type and incidence of defects were comparable to those observed in the Collaborative Perinatal Project with no pattern of defects or excess of defects or spontaneous abortions apparent (7).

A second 1992 study reported on heavy benzodiazepine exposure during pregnancy from Michigan Medicaid data collected during 1980–1983 (8). Of the 2048 women, from a total sample of 104,339, who had received benzodiazepines, 80 had received ≥ 10 prescriptions for these agents. The records of these 80 women indicated frequent alcohol and substance abuse.

Their pregnancy outcomes were 3 intrauterine deaths, 2 neonatal deaths in infants with congenital malformations, and 64 survivors. The outcome for 11 infants was unknown. Six of the surviving infants had diagnoses consistent with congenital defects. The investigators concluded that the high rate of congenital anomalies was suggestive of multiple alcohol and substance abuse. The outcome may not have been related to benzodiazepine exposure (8).

Single case reports of pyloric stenosis, moderate tongue-tie, umbilical hernia and ankle inversion, and clubfoot have been received by the manufacturer after in utero exposure to either alprazolam or triazolam (5). In addition, the manufacturer has received five reports of paternal use of alprazolam with pregnancy outcomes of two normal births, one elective abortion, one unknown outcome, and one stillbirth with multiple malformations (5). There is no evidence that the drug affected any of these outcomes.

Neonatal withdrawal after in utero exposure to alprazolam throughout gestation has been reported in three infants (5,9). In two cases involving maternal ingestion of 3 mg/day and 7–8 mg/day, mild withdrawal symptoms occurred at 2 days of age in the infant exposed to 3 mg/day (5). No details were provided on the onset or severity of the symptoms in the infant exposed to the higher dose. The third neonate was exposed to 1.0–1.5 mg/day (9). The mother continued this dosage in the postpartum interval while breastfeeding. Restlessness and irritability were noted in the infant during the 1st week. The symptoms worsened 2–3 days after breastfeeding was stopped on the seventh day because of concerns over drug excretion into the milk. Short, episodic screams and bursts of crying were observed frequently. Treatment with phenobarbital was partially successful, allowing the infant to sleep for longer periods. However, on awakening, jerking movements of the extremities and crying continued to occur. The infant was lost to follow-up at approximately 3 weeks of age.

BREASTFEEDING SUMMARY

Alprazolam is excreted into breast milk. Eight lactating women, who stopped breastfeeding their infants during the study, received a single 0.5 mg oral dose and multiple milk and serum samples were collected up to 36 hours after the dose (9). Transfer into milk was consistent with passive diffusion. The mean milk:serum concentrations ratio (using area under the drug concentration-time curve) was 0.36, indicating that a nursing infant would have received 0.3–5 mcg/kg/day, or about 3% (body weight adjusted) of the maternal dose (9).

A brief 1989 report citing information obtained from the manufacturer

described a breastfed infant whose mother took alprazolam (dose not specified) for 9 months after delivery but not during pregnancy (10). The mother tapered herself off the drug over a 3-week period. Withdrawal symptoms consisting of irritability, crying, and sleep disturbances were noted in the nursing infant. The symptoms resolved without treatment after 2 weeks.

Because of the potent effects, the drug may have on a nursing infant's neurodevelopment, the case of probable alprazolam withdrawal, and the lethargy and loss of body weight observed with the chronic use of other benzodiazepines (see Diazepam), alprazolam should be avoided during lactation. The American Academy of Pediatrics classifies alprazolam as an agent for which the effect on a nursing infant is unknown but may be of concern (11).

ALTEPLASE

Thrombolytic

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

The limited use of alteplase during pregnancy does not suggest a significant fetal risk. Although only one of the reported human exposures occurred during organogenesis, the high molecular weight probably precludes the transfer of alteplase to the embryo. Moreover, teratogenicity was not observed in animals. Hemorrhage is a risk of therapy at any time during gestation, but careful monitoring of the mother can prevent this from becoming a significant risk to the fetus. Therefore, it appears that alteplase may be used during gestation if the mother's condition requires this therapy.

FETAL RISK SUMMARY

Alteplase (tissue plasminogen activator; t-PA; rt-PA), an enzyme formed by recombinant DNA technology, is a thrombolytic agent used for the treatment of acute conditions such as myocardial infarction, pulmonary embolism, and ischemic stroke. The agent is a glycoprotein composed of 527 amino acids (1).

No maternal or fetal toxicity was observed in rats and rabbits dosed with 1 mg/kg (approximately 0.65 times the human dose for acute myocardial infarction [HD]) during organogenesis (1). An embryocidal effect was noted in rabbits administered an IV dose of 3 mg/kg (about 2 times the HD) (1). Shepard (2) cited two studies in which no teratogenicity or other toxicity was observed in the offspring of pregnant rats and rabbits administered t-PA during organogenesis.

Ten case reports have described the use of alteplase in human pregnancy (3–12). A 27-year-old woman in premature labor at 31 weeks' gestation was treated with urokinase and heparin, supplemented with continuous dobutamine to maintain a stable hemodynamic state, for massive pulmonary embolism (3). Because she failed to improve, low-dose alteplase therapy was initiated at 10

mg/hour for 4 hours, followed by 2 mg/hour for 1.5 hours (total dose 43 mg). The patient's clinical condition markedly improved with complete reperfusion of the right upper and middle lobe and partial reperfusion of the left lower lobe. Coagulation tests (prothrombin time, partial thromboplastin time, and thrombin time) during alteplase therapy remained within or close to the normal range. A healthy, premature, 2100-g male infant was delivered 48 hours after thrombolysis. A 38-year-old woman at 32 weeks' gestation developed a superior vena caval thrombosis during total parenteral hyperalimentation (4). Treatment with alteplase, 2 mg/hour for 48 hours resulted in clinical resolution of her symptoms (swelling of face and arms) within 24 hours. No evidence of placental bleeding was observed. Labor was induced 2 days later, and a healthy premature infant was delivered. A 29-year-old woman with severe pulmonary embolism and congenital antithrombin III deficiency was treated at 35 weeks' gestation with 100 mg alteplase for 3 hours followed by IV heparin (5). Nearly complete reperfusion of the right lung and the lower two-thirds of the left lung was observed at the end of the alteplase infusion. No placental bleeding was noted. The male infant, delivered by cesarean section 20 hours later, died at 14 days of age secondary to intracranial hemorrhage, a complication thought to be caused by prematurity and unrelated to the thrombolytic therapy.

Brief details of a case (6) of t-PA therapy during pregnancy were described in a 1995 review (8). A 30-year-old woman in her 11th week of gestation was treated with alteplase for pulmonary embolism. No complications were observed, and she had a normal, term delivery (6). A 30-year-old woman at 21 weeks' gestation had an acute myocardial infarction that was treated with a total dose of 100 mg alteplase given IV for 90 minutes (7). Immediate relief of her chest pain occurred and the other effects of cardiac reperfusion (arrhythmias and hypotension) were successfully treated. A cesarean section was performed at 33 weeks' gestation for premature labor unresponsive to magnesium sulfate, and a 1640-g male infant who has done well was delivered. A 20% abruptio placentae was noted during surgery. The cause of the abruption was thought to be either alteplase or the aspirin (81 mg/day) the mother had received after her initial treatment (7).

A 32-year-old pregnant woman had two episodes of a thrombosed St. Jude mitral valve prosthesis (8). The first event, at 20 weeks' gestation, was successfully treated by clot removal under cardiopulmonary bypass. About 8 weeks later, another clot formed on the valve and it was treated with 50 mg alteplase. An anterior placental hematoma was noted on ultrasound during

treatment, but it resolved spontaneously within 2 weeks. At 38 weeks' gestation, the patient delivered vaginally a healthy girl with Apgar scores of 10 at 1 and 5 minutes (8). A 31-year-old patient developed a pulmonary embolism at 12 weeks' gestation (9). The woman was initially treated with IV heparin. However, because of continued hemodynamic deterioration, IV alteplase 100 mg over 2 hours was administered with rapid clinical improvement. SC heparin was given for the remainder of the pregnancy. At 33 weeks' gestation, placental abruption was diagnosed and a cesarean section delivered a normal 2325-g female infant with Apgar scores of 7 and 8 at 1 and 5 minutes, respectively (9). The last case report involved a 28-year-old woman who underwent in vitro fertilization because of long-standing infertility (10). Approximately 7 days after embryo transfer, she experienced a middle cerebral artery thrombosis secondary to ovarian hyperstimulation syndrome induced by the fertility medications. Treatment with 15.5 mg of intra-arterial alteplase over 68 minutes dissolved the clot but a hematoma developed in the right basal ganglia resulting in worsening the stroke. She improved over the next 3 months with only mild residual effects of the stroke and eventually delivered a healthy male infant by spontaneous vaginal delivery at term (10).

A 2005 report described the use of alteplase in an 18-year-old woman with nephritic syndrome who was treated with cyclosporine and prophylactic enoxaparin from 9 weeks' gestation (11). At 26 weeks', a subtotal thrombus of the right main renal vein was found. Enoxaparin was stopped and a continuous infusion of alteplase and low-dose heparin was begun. After 24 hours, the thrombus had decreased by 25%. On hospital day 7 (27 weeks'), a cesarean section performed for a prolonged fetal heart rate deceleration delivered a 720-g female infant with Apgar scores of 5 and 6 at 1 and 5 minutes, respectively. Alteplase and heparin were discontinued intraoperatively. The infant, with repeated normal head ultrasound scans, went home on the 83rd day of life with no evidence of focal neural deficits (11).

A 2006 report described the use of alteplase in a 34-year-old woman at 10 weeks' gestation who developed a fulminate pulmonary thromboembolism (12). Treatment with alteplase removed most of the thrombotic material in the pulmonary arteries. The patient was treated with heparin and then danaparoid and gave birth to a healthy female infant at term (12).

A 1995 review found no increased risk for preterm rupture of membranes, placental hemorrhage, or premature labor from thrombolytic agents (streptokinase, urokinase, or alteplase) (13). In seven women administered thrombolytic therapy before 14 weeks' gestation, pregnancy loss occurred in

one case. Because of the small number of exposures, the concern that thrombolytics may interfere with placental implantation cannot be completely excluded and, indeed, one such case has been reported, although the exact cause was not determined (13).

BREASTFEEDING SUMMARY

It is not known whether alteplase (t-PA) crosses into human milk. Because of the nature of the indications for this agent and its very short initial half-life (<5 minutes), the opportunities for its use during lactation or the possibility of exposure of a nursing infant is minimal.

ALVIMOPAN

Gastrointestinal Agent (Peripheral Opioid Antagonist)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of alvimopan in human pregnancy have been located. The animal reproduction data suggest low risk, but the absence of human pregnancy experience prevents further assessment of the risk to the embryo–fetus. Alvimopan is available only for short-term use (15 doses or 7 days) in patients who are in hospitals registered to use the drug. Moreover, the indication suggests that use in pregnancy will be uncommon.

FETAL RISK SUMMARY

Alvimopan, a peripheral-acting selective antagonist with high affinity for the μ -opioid receptor, has no measurable opioid-agonist effects. It is in the same class as methylnaltrexone, a drug used for opioid-induced constipation. It achieves its action without reversing the central analgesic effects of μ -opioid agonists. Alvimopan is indicated to accelerate the time to upper and lower gastrointestinal recovery after partial large- or small-bowel resection surgery with primary anastomosis. The agent is metabolized to an active metabolite. Plasma protein binding to albumin of alvimopan and its metabolite is 80% and 94%, respectively. The mean terminal phase half-lives of the parent drug and metabolite are 10–17 and 10–18 hours, respectively (1).

Reproduction studies have been conducted in rats and rabbits. In pregnant rats, oral and IV doses that were about 68–136 and 3.4–6.8 times, respectively, the recommended human oral dose based on BSA (RHOD) revealed no evidence of fetal harm. Similar findings were observed in pregnant rabbits given IV doses that were about 5–10 times the RHOD (1).

In 2-year carcinogenicity studies, significant increases in the incidences of fibromas, fibrosarcoma and sarcoma in the skin/subcutis, and

osteoma/osteosarcoma in bones were observed in female mice. No tumors were observed in rats. Neither alvimopan nor its active metabolite was genotoxic in multiple assays. No adverse effects on fertility in male and female rats were observed with alvimopan IV doses that were about 3.4–6.8 times the RHOD (1).

It is not known if alvimopan or its metabolite crosses the human placenta. The molecular weight of the parent drug (about 425 for nonhydrated molecule), and moderate plasma protein binding and long half-lives for the parent drug and metabolite suggest that both will cross to the embryo and/or fetus.

BREASTFEEDING SUMMARY

No reports describing the use of alvimopan during human lactation have been located. The molecular weight of the parent drug (about 425 for the nonhydrated molecule), moderate plasma protein binding (80% parent drug; 94% active metabolite), and long half-lives (10–17 and 10–18 hours, respectively) suggest that both alvimopan and its active metabolite will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown.

AMANTADINE

Antiviral/Antiparkinson

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Amantadine is teratogenic and embryotoxic in one animal species, but the human pregnancy data are too limited for a complete risk assessment. However, complex cardiac defects were reported in three cases, and five other outcomes involved various malformations. The drug is best avoided in the 1st trimester.

FETAL RISK SUMMARY

Amantadine is indicated for the treatment of Parkinson disease and for the treatment and prophylaxis of influenza A. The plasma half-life is approximately 16–17 hours (range 10–31 hours) and the drug is moderately (about 67%) bound to plasma proteins (1). In a 1975 correspondence, one author thought the drug was a potential human teratogen and the absence of published reports at the time had more to do with its infrequent use in pregnancy than to its teratogenic potency (2).

Amantadine was teratogenic in pregnant rats at a dose that was equivalent to the estimated human dose based on BSA conversion (EHD) of 7.1 mg/kg/day and embryotoxic at a dose that was equivalent to the EHD of 14.2 mg/kg/day. No embryo or fetal harm was observed at a dose that was equivalent to the EHD of 5.3 mg/kg/day. No teratogenic or embryotoxic effects were seen in pregnant rabbits given a dose that was equivalent to the EHD of 9.6 mg/kg/day (1).

No reports describing the placental passage of amantadine in humans have been located. The low molecular weight (about 152 for the free base), moderate plasma protein binding, and long plasma half-life suggest that the drug will cross to the embryo–fetus.

A cardiovascular defect (single ventricle with pulmonary atresia) has been reported in an infant exposed to amantadine during the 1st trimester (3). The mother was taking 100 mg/day for a Parkinson-like movement disorder.

A 1987 retrospective report described the use of amantadine, starting before conception in four women, one of whom had a probable molar pregnancy (4). In the remaining three cases, 1st trimester spotting was observed in one (apparently normal outcome), one newborn had an inguinal hernia (also exposed to levodopa/carbidopa), and one pregnancy aborted a fetus without apparent anomalies at 4 months (also exposed to levodopa) (4).

A 1991 report described the outcomes of consecutive pregnancies in a woman with multiple sclerosis who was treated with amantadine throughout each pregnancy (5). The infants were born at 34 and 36 weeks', respectively, with birth weights of 2640 and 2954 g, respectively. At the time of the report, the ages of the infants were 2.8 years and 3 months, respectively, and both were physically and developmentally normal (5).

Tibial hemimelia and tetralogy of Fallot was reported in an infant born from a mother exposed during early organogenesis to amantadine (6). The 37-year-old mother had taken the drug 100 mg daily for 7 days during the fourth and sixth postconception weeks for a para-influenza virus infection. Chromosome analysis of the infant revealed a normal female karyotype. In addition to this case, the investigators reported two other pregnancies exposed to amantadine throughout, both with normal outcomes. Both children, aged 4.4 and 3.2 years, had normal growth and development (6).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 51 newborns had been exposed to amantadine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Five (9.8%) major birth defects were observed (2 expected). Among six categories of defects for which specific data were available, one cardiovascular defect (0.5 expected) and one limb reduction defect (0 expected) were observed. No cases of oral clefts, spina bifida, polydactyly, or hypospadias were recorded. Although the incidence of defects is high, the number of exposures is too small to draw any conclusions.

Rosa expanded the above communication with additional data in 1994 (7). In addition to the six types of defects surveyed, brain and eye defects were added for a new total of eight defects. Among 333,000 pregnancies, 64 had 1st trimester prescriptions for amantadine. Five defects (same as in his 1993 communication) were now linked to the drug (3.1 expected), including one cardiovascular defect, but no limb reduction defects were found in the new

analysis. Because heart defects were common among nonexposed cases in Medicaid data (1 in 98 births), and considering the above reports, he cautioned that if amantadine did cause the cardiac defects, the available data suggested that the risk was not high (7).

A retrospective cohort study, covering the period 2003–2008, described 239 pregnancies that were treated with antiviral agents during pregnancy (8). Of these, 104 women received M2 ion channel inhibitors (rimantadine, amantadine, or both) and 135 received oseltamivir. The pregnancy outcomes of these patients were compared with 82,097 controls from the site's overall obstetric patient population. The exposure timing for the combined treated groups was 13% 1st trimester, 32% 2nd trimester, and 55% 3rd trimester. There were no significant differences between the treated groups and controls in terms of maternal and delivery characteristics except that M2 inhibitors had more multiple gestations. For M2 inhibitors, oseltamivir vs. controls, there were also no differences in stillbirths (0%, 0% vs. 1%), major defects (1% [trisomy 21], 0% vs. 2%), and minor defects (19%, 15% vs. 22%). The only significant finding in the characteristics of liveborn, singleton neonates, after exclusion of twins and major anomalies, was a higher risk of necrotizing enterocolitis in both treatment groups compared to controls—1.0%, 0.8% vs. 0.02%. (8).

BREASTFEEDING SUMMARY

Amantadine is excreted into breast milk in low concentrations (1). This is consistent with its low molecular weight (about 152 for the free base), moderate plasma protein binding, and long plasma half-life. Although no reports of adverse effects in nursing infants have been located, one manufacturer recommended that the drug be used with caution in lactating mothers because of the potential for urinary retention, vomiting, and skin rash in a nursing infant (9). The current manufacturer recommends that amantadine should not be used during breastfeeding (1).

AMBENONIUM

[Withdrawn from the market. See 9th edition.]

AMBRISENTAN

Vasodilator

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of ambrisentan in human pregnancy have been located. The animal data suggest risk if the drug is used in human pregnancy. In a black-box warning, the manufacturer classifies ambrisentan as contraindicated in women who are or may become pregnant (1). Pregnancy must be excluded before the initiation of therapy and women of reproductive potential must use two reliable methods of contraception. Monthly pregnancy tests are required. In addition, ambrisentan is available only through a special restricted distribution program because of the dual risk of teratogenicity and the potential for liver injury. Only physicians and pharmacies registered in this program can prescribe and distribute the drug.

FETAL RISK SUMMARY

Ambrisentan is an oral endothelin receptor antagonist in the same class as bosentan. It is indicated for the treatment of pulmonary arterial hypertension (WHO group 1) in patients with WHO class II or III symptoms to improve exercise capacity and delay clinical worsening. The molecule is a carboxylic acid with a pK_a of 4.0 and is water soluble at higher pH. Plasma protein binding is 99%. The terminal elimination half-life is 15 hours but the effective half-life is 9 hours (1).

Animal reproduction studies have been conducted in rats and rabbits, but the doses used were not compared with the human dose. The drug was teratogenic in both species causing abnormalities of the lower jaw and hard and soft palate, malformation of the heart and great vessels, and failure of formation of the thymus and thyroid. The malformations were similar to those observed with other endothelin receptor antagonists and were thought to be a

class effect. In rats given doses that were 17, 51, and 170 times, respectively, the maximum oral human dose of 10 mg based on BSA during late gestation and through weaning, decreased newborn pup survival was observed with the middle and high doses. The high dose was also associated with adverse effects on testicle size and fertility of pups (1).

It is not known if ambrisentan crosses the human placenta. Although the molecular weight (about 378) and the elimination half-life suggest that the drug will cross the placenta, the low lipid solubility and the high plasma binding might mitigate the amount reaching the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use of ambrisentan during human lactation have been located. Although the molecular weight (about 378) and the elimination half-life (15 hours) suggest that the drug will be excreted into breast milk, the low lipid solubility and the high plasma binding (99%) might mitigate the amount in milk. The effect of exposure on a nursing infant is unknown, but the potential for toxicity is a concern. Therefore, until human data are available, the safest course is to not breastfeed during treatment with ambrisentan.

AMIFOSTINE

Antineoplastic Cytoprotectant

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably
Compatible

PREGNANCY SUMMARY

No reports describing the use of amifostine in human pregnancy have been located. The animal reproduction data suggest risk, but the absence of human pregnancy experience prevents a more complete assessment. However, one of the indications for amifostine is the prevention of cisplatin-induced renal toxicity in women being treated for ovarian cancer. Thus, if a pregnant woman requires amifostine and gives informed consent, the maternal benefit from amifostine appears to outweigh the potential embryo–fetal risk. If inadvertent exposure occurs during pregnancy, the woman should be advised of the potential risk for adverse effects in the embryo and fetus.

FETAL RISK SUMMARY

Amifostine is an organic thiophosphate cytoprotective agent that is administered as an IV infusion. It is a prodrug that is dephosphorylated by a tissue enzyme to the active free thiol metabolite. Amifostine is indicated to reduce the cumulative renal toxicity associated with repeated doses of cisplatin in patients with ovarian cancer. It also is indicated to reduce the incidence of moderate to severe xerostomia in patients undergoing postoperative radiation treatment for head and neck cancer, where the radiation port includes a substantial portion of the parotid gland. Amifostine is rapidly metabolized to the active metabolite and subsequently to a less active metabolite. The plasma elimination half-life is very short, about 8 minutes.

Reproduction studies have been conducted in rabbits. Amifostine was embryotoxic in pregnant rabbits at a dose that was about 60% of the recommended human dose based on BSA (1).

Long-term studies have not been done to determine the carcinogenic or fertility impairment potential of amifostine, but the agent was not mutagenic in two tests. The active metabolite was mutagenic in some, but not other, tests and was not clastogenic (1).

It is not known if amifostine crosses the human placenta. The molecular weight of the prodrug (about 214) suggests that it will distribute to the embryo and/or fetus, but the very short plasma elimination half-life should limit the amount available for transfer.

BREASTFEEDING SUMMARY

No reports describing the use of amifostine during human lactation have been located. The molecular weight of the prodrug (about 214) suggests that it will be excreted into breast milk, but the very short plasma elimination half-life (about 8 minutes) should limit the amount. The effects of this potential exposure on a nursing infant are unknown. However, because the drug is given as a short IV infusion immediately before chemotherapy or radiation, and breastfeeding would be unlikely at this time, the risk of exposing an infant to amifostine when nursing is later resumed appears to be nil.

AMIKACIN

Antibiotic (Aminoglycoside)

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No reports linking the use of amikacin to congenital defects have been located. Ototoxicity, which is known to occur after amikacin therapy in humans, has not been reported as an effect of in utero exposure. However, eighth cranial nerve toxicity in the human fetus is well known after exposure to other aminoglycosides (see Kanamycin and Streptomycin) and amikacin could potentially cause this.

FETAL RISK SUMMARY

Amikacin is an aminoglycoside antibiotic. The drug causes dose-related nephrotoxicity in pregnant rats and their fetuses (1). Reproduction studies were conducted in mice and rats and no evidence of impaired fertility or teratogenicity was observed (2).

The drug rapidly crosses the placenta into the fetal circulation and amniotic fluid (3–6). Studies in patients undergoing elective abortions in the 1st and 2nd trimesters indicate that amikacin distributes to most fetal tissues except the brain and cerebrospinal fluid (3,5). The highest fetal concentrations were found in the kidneys and urine. At term, cord serum levels were one-half to one-third of maternal serum levels whereas measurable amniotic fluid levels did not appear until almost 5 hours after injection (4).

BREASTFEEDING SUMMARY

Amikacin is excreted into breast milk in low concentrations. After 100- and 200-mg IM doses, only traces of amikacin could be found for 6 hours in two of four patients (4,7). Because oral absorption of this antibiotic is poor, ototoxicity in the infant would not be expected. However, three potential problems exist for the nursing infant: modification of bowel flora, direct effects on the infant, and interference with the interpretation of culture results if a fever workup is

required.

AMILORIDE

Diuretic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Similar to other diuretics, amiloride does not appear to pose a risk to the embryo–fetus when used for indications other than gestational hypertension or preeclampsia.

FETAL RISK SUMMARY

Amiloride is a potassium-conserving diuretic. In general, diuretics are not recommended in the treatment of gestational hypertension because of the maternal hypovolemia characteristic of this disease.

Reproduction studies using amiloride alone in mice at 25 times the maximum recommended human dose (MRHD) and in rabbits at 20 times the MRHD found no evidence of fetal harm (1). The combination of acetazolamide and amiloride was found to produce abnormal development of the ureter and kidney in fetal mice when given at the critical moment of ureter development (2).

Amiloride crosses the placenta in modest amounts in mice and rabbits (1). No reports describing the human placenta passage of amiloride have been located. The molecular weight (about 230 for the free base) suggests that drug will cross the placenta.

Seven reports of fetal exposure to amiloride have been located (3–9). In one case, a malformed fetus was discovered after voluntary abortion in a patient with renovascular hypertension (3). The patient had been treated during the 1st trimester with amiloride, propranolol, and captopril. The left leg of the fetus ended at midthigh without distal development and no obvious skull formation was noted above the brain tissue. The authors attributed the defects to captopril (3), but this agent is not thought to cause birth defects in the 1st trimester.

A second case involved a 21-year-old woman with Bartter's syndrome who was maintained on amiloride (20–30 mg/day) and potassium chloride (160–300 mEq/day) throughout pregnancy (4). Progressive therapy with the two agents was required to maintain normal potassium levels. Mild intrauterine growth restriction was detected at 30 weeks' gestation with eventual vaginal delivery of a 2800-g female infant at 41 weeks' gestation. No abnormalities were noted in the infant. A normal 3500-g female infant was delivered by cesarean section at 37 weeks' gestation from a mother who had been treated throughout pregnancy with amiloride, hydrochlorothiazide, and amiodarone for severe chronic atrial fibrillation (5). A second case with Bartter's syndrome was reported in 2004 (6). Amiloride was used throughout the pregnancy and a healthy 3.300-kg female infant was born at term.

Two cases of Gitelman syndrome, an inherited hypokalemic salt-losing renal tubular disorder that is closely related to Bartter's syndrome, that were treated with amiloride have been located (7,8). Both pregnancy outcomes were normal babies born at 37 weeks' gestation.

A woman with primary aldosteronism had two pregnancies that were treated with amiloride (9). Both pregnancies ended with the birth of a healthy infant.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 28 newborns had been exposed to amiloride during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Two (7.1%) major birth defects were observed (one expected), one of which was a hypospadias. No anomalies were observed in five other categories of defects (cardiovascular, oral clefts, spina bifida, polydactyly, and limb reduction defects) for which specific data were available.

BREASTFEEDING SUMMARY

No reports describing the use of amiloride during human lactation have been located. The molecular weight (about 230 for the free base) suggests that excretion into breast milk will occur.

AMINOCAPROIC ACID

Hemostatic

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: Hold Breastfeeding

PREGNANCY SUMMARY

The human pregnancy experience with this agent is too limited to assess the embryo–fetal risk. There are no animal reproduction data to assist in an assessment.

FETAL RISK SUMMARY

Aminocaproic acid is used to enhance hemostasis when fibrinolysis contributes to bleeding. Animal reproduction studies have not been conducted with the drug (1).

No reports describing the placental passage of aminocaproic acid have been located. The molecular weight (about 131) is low enough that passage to the fetus should be expected.

Aminocaproic acid was used during the 2nd trimester in a patient with subarachnoid hemorrhage as a result of multiple intracranial aneurysms (2). The drug was given for 3 days preceding surgery (dosage not given). No fetal toxicity was observed.

BREASTFEEDING SUMMARY

No reports describing the use of aminocaproic acid during lactation have been located. Although the molecular weight (about 131) is low enough that excretion into breast milk should be expected, the indication for the drug probably implies that the chance of its use during nursing is very small.

para-AMINOSALICYLIC ACID

Antitubercular

PREGNANCY RECOMMENDATION: Human and Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Reports have associated para-aminosalicylic acid with structural anomalies, but confirming studies are required. The best course is to avoid this agent, if possible, in the 1st trimester.

FETAL RISK SUMMARY

para-Aminosalicylic acid is a bacteriostatic agent used for the treatment of *Mycobacterium tuberculosis*. It is most frequently used in combination with other agents for the treatment of multidrug-resistant tuberculosis.

In reproduction studies with rats at doses within the human dose range, occipital malformations were observed (1). No adverse effects on the fetus were observed in rabbits treated with 5 mg/kg/day throughout gestation (1).

No reports describing the placental transfer of para-aminosalicylic acid have been located. The molecular weight (approximately 153) is low enough that passage to the fetus should be expected.

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 43 of whom had 1st trimester exposure to para-aminosalicylic acid (4-aminosalicylic acid) (2). Congenital defects were found in five infants. This incidence (11.6%) was nearly twice the expected frequency. No major category of malformations or individual defects were identified. An increased malformation rate for ear, limb, and hypospadias has been reported for 123 patients taking 7–14 g/day of para-aminosalicylic acid with other antitubercular drugs (3). An increased risk of congenital defects has not been found in other studies (4–6).

BREASTFEEDING SUMMARY

para-Aminosalicylic acid is excreted into breast milk. In one nonbreastfeeding

patient given an oral 4-g dose of the drug, a peak milk concentration of 1.1 mcg/mL was measured at 3 hours with an elimination half-life of 2.5 hours (7). The peak maternal plasma concentration, 70.1 mcg/mL, occurred at 2 hours.

AMIODARONE

Antiarrhythmic

PREGNANCY RECOMMENDATION: Human and Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Fetal adverse effects directly attributable to amiodarone have been observed. Congenital goiter/hypothyroidism and hyperthyroidism may occur after in utero exposure. Newborns exposed to amiodarone in utero should have thyroid function studies performed because of the large proportion of iodine contained in each dose.

FETAL RISK SUMMARY

Amiodarone is an antiarrhythmic agent used for difficult or resistant cases of arrhythmias. The drug contains about 75 mg of iodine per 200 mg dose (1–3).

Amiodarone was maternal and embryo toxic (increased fetal resorptions, decreased live litter size, growth restriction, and restricted sternum and metacarpal ossification) in rats administered an IV infusion about 1.4 times the maximum recommended human dose based on BSA (MRHD) (4). Lower doses, about 0.4 and 0.7 times the MRHD, produced no embryo toxicity (4). In pregnant rabbits administered IV doses about 0.1, 0.3, and 0.7 times the MRHD, embryo toxicity was observed at 0.3 times the MRHD and above. At about 2.7 times the MRHD, >90% of the animals aborted. No teratogenic effects were observed in any of the rabbit groups (4).

Amiodarone and its metabolite, desethylamiodarone, cross the placenta to the fetus (1–3,5–9). In the 10 infants described in these reports, cord blood concentrations of the parent compound were 0.05–0.35 mcg/mL, representing cord:maternal ratios of 0.10–0.28 in nine cases (1–3,5–9) and 0.6 in one case (9). Cord blood concentrations of the metabolite varied between 0.05 and 0.55 mcg/mL, about one-fourth of the maternal levels in 9 of the 10 cases. In one study, the amount of amiodarone crossing the placenta to the fetus was dependent on the degree of hydrops fetalis (10). The expected fetal concentrations of the drug were not achieved until substantial compensation of

the fetus had occurred.

In 22 cases of amiodarone therapy during pregnancy, the antiarrhythmic was administered for maternal indications (1–3,5,7–9,11–16). One patient in the last 3 months of pregnancy was treated with 200 mg daily for resistant atrial tachycardia (1). She delivered a 2780-g female infant at 40 weeks' gestation. Both the mother and the infant had a prolonged QT interval on electrocardiogram (ECG). A second woman was also treated by these investigators under similar conditions. Both infants were normal (infant sex, weight, and gestational age were not specified for the second case), including having normal thyroid function. In another report, a woman was treated at 34 weeks' gestation when quinidine failed to control her atrial fibrillation (2). After an initial dose of 800 mg/day for 1 week, the dose was decreased to 400 mg/day and was continued at this level until delivery at 41 weeks' gestation. The healthy 3220-g infant experienced bradycardia during labor induction (104–120 beats/minute [bpm]) and during the first 48 hours after birth. No other adverse effects were observed in the infant, who had normal thyroid and liver function tests. A woman was treated during the 37th–39th weeks of pregnancy with daily doses of 600, 400, and 200 mg, each for 1 week, for atrial tachycardia that was resistant to propranolol, digoxin, and verapamil (3). No bradycardia or other abnormalities were noted in the newborn. The infant's thyroid-stimulating hormone (TSH) level on the 4th day was 9 mU/L, a normal value. Goiter was not observed and the infant was clinically euthyroid.

A 1985 report described the treatment of two women with amiodarone for maternal heart conditions (5). One of these patients, a 31-year-old woman with atrial fibrillation, was treated with amiodarone, 200 mg/day, and diuretics throughout gestation. She delivered a healthy 3500-g female without goiter or corneal changes at 37 weeks' gestation. A cord blood thyroxine (T4) level was elevated (209 nmol/L) and was still elevated 1 week later (207 nmol/L), but TSH concentrations at these times were 3.2 mU/L and <1 mU/L (both normal), respectively. The second woman, a 27-year-old primigravida, was treated with amiodarone, 400–800 mg/day, starting at 22 weeks' gestation. Fetal bradycardia, 100–120 bpm, was observed at approximately 33 weeks' gestation. Spontaneous labor ensued at 39 weeks with delivery of a healthy 2900-g male. Thyroid function studies were not reported, but the neonatal examinations were normal (5).

A woman in her 16th week of pregnancy presented with severe atrial fibrillation (7). She was treated with amiodarone, 800 mg/day for 1 week followed by 200 mg/day for the remainder of her pregnancy (7). She delivered

a growth-restricted 2660-g male in the 39th week of gestation who had no goiter and whose free T4 index, serum-free triiodothyronine (T3), and serum TSH concentrations were all within normal limits. An ECG at 1 day of age showed a prolonged QT interval. Follow-up of the infant at 6 months was normal.

A healthy 3650-g male infant was delivered at term from a mother who had taken 200–400 mg/day of amiodarone throughout gestation (8). The infant's thyroid function was normal at birth; no goiter or corneal deposits were noted; and subsequent growth and thyroid function remained within normal limits. In another case, a woman was treated with propranolol and amiodarone, 400 mg/day for 4 days each week, throughout gestation (11). A healthy 2670-g female infant was delivered, but the gestational age was not specified. No goiter or corneal microdeposits were present in the infant and clinically she was euthyroid. The T4 and TSH levels in cord blood were both normal although a total serum iodine level (290 mcg/dL) was markedly elevated (normal 5.5–17.4 mcg/dL).

A 1991 report described the use of amiodarone in one woman with a history of symptomatic ventricular arrhythmia, and mitral and tricuspid valve prolapse through two complete pregnancies (12). She also had a history of right upper lobectomy for drug-resistant pulmonary tuberculosis. She was treated with 400 mg/day of amiodarone during the first 12 weeks of gestation of one pregnancy before the dose was reduced to 200 mg/day. She continued this dose during the remainder of this pregnancy and through a successive pregnancy. One of the newborns, a 2500-g female delivered at 38 weeks' gestation, was growth-restricted. The second infant, a 2960-g male, was delivered prematurely at 35.5 weeks' gestation. Except for the growth restriction in the one infant, the newborns were physically normal and had no clinical or biochemical signs of hypothyroidism (12). The concentrations of amiodarone and its metabolite desethylamiodarone were <0.3 mcg/mL in the first-born infant (not determined in the second newborn).

In two other reports, treatment was begun at 25 and 32 weeks' gestation (13,14). Delivery occurred at 31 weeks in one case (sex and birth weight not given), and the infant died 2 days after delivery (13). In the second report, the infant (sex and birth weight not given) was born at 37 weeks' gestation (14). Amiodarone and desethylamiodarone concentrations in the cord blood were 0.1 and 0.2 mcg/mL, respectively. The drug and its metabolite were not detected in the infant's serum at 3 and 6 days after birth. A prolonged QT interval was observed on the infant's ECG.

Five pregnancies in four women treated with amiodarone for various cardiac arrhythmias were described in a 1992 reference (9). The drug was used throughout gestation in four pregnancies and during the last 6 weeks in a fifth. One infant delivered at 34 weeks' gestation was growth-restricted (birth weight, length, and head circumference were all at the 10th percentile or less), but the other four newborns were of normal size. No adverse effects—such as goiter, corneal microdeposits, pulmonary fibrosis, and dermatologic or neurologic signs—were observed (9). The infants were clinically euthyroid, but one of the five newborns had transient biochemical signs of hypothyroidism (low T4 concentration) that responded to treatment. This latter infant, whose mother had taken the β -blocker, metoprolol, throughout gestation and amiodarone only during the last 6 weeks, had delayed motor development and impaired speech performance at 5 years of age. He had been delivered at 40 weeks' gestation with a birth weight of 2880 g (10th percentile) and a length of 50 cm (50th percentile). The other four infants had normal follow-up examinations at periods ranging from 8 months to 5 years.

Congenital hypothyroidism with goiter was described in a growth-restricted 2450-g male newborn whose mother had taken 200 mg/day of amiodarone from the 13th week of gestation until delivery at 38 weeks for treatment of Wolff-Parkinson-White syndrome (15). The mother had no signs or symptoms of hypothyroidism. Thyroid tests of cord blood revealed a TSH level of >100 mU/L (normal 10–20 mU/L), a T4 level of 35.9 mcg/L (normal 60–170 mcg/L), and no thyroid antibodies. In addition to a homogeneous goiter, the newborn had persistent hypotonia and bradycardia, large anterior and posterior fontanelles, and macroglossia, but no corneal microdeposits. The bradycardia resolved after several days. Greater than normal amounts of urinary iodine were measured from birth (144 mcg/dL; normal <15 mcg/dL) until the sixth week of life. The infant's plasma concentrations of amiodarone and desethylamiodarone on day 5 were 140 and 260 ng/mL, respectively, and were still detectable after 1 month. His bone age at birth and at 20 months of age was estimated to be 28 weeks and 12 months, respectively. Treatment with levothyroxine during the first 20 months resulted in the complete disappearance of the goiter at about 3 months of age, but his psychomotor development was held back.

A 1994 report described three pregnancies in two women who were being treated with amiodarone (16). Recurrent ventricular fibrillation was treated in one woman with an implanted defibrillator and amiodarone, 400 mg/day. She became pregnant 4 years after beginning this therapy and eventually delivered

a premature, 2540-g male infant at 35 weeks' gestation with a holosystolic murmur and an umbilical hernia. At 2 weeks of age, the infant experienced mild congestive heart failure with labored breathing. A large midmuscular ventricular septal defect, with marked left ventricular and left atrial dilatation and left ventricular hypertrophy, was observed by echocardiogram (16). The defect was still present at 21 months of age. A second pregnancy in this woman, at the same amiodarone dose, was electively terminated at approximately 11 weeks' gestation. The thorax and limbs of the fetus were normal and contained 1.55 and 5.8 mcg/g of amiodarone and desethylamiodarone, respectively. The second woman had been treated with amiodarone, 600 mg/day, for 2 years for recurrent sustained ventricular tachycardia (Chagas disease) before conception. She eventually delivered a term 3300-g male infant with mild bradycardia (110 bpm) at birth. Both liveborn infants were clinically euthyroid without goiter or corneal changes.

Six cases of amiodarone therapy for refractory fetal tachycardia have been described in the literature (6,10,17–20). In the first of these, a fetus at 27 weeks' gestation experienced tachycardia (260 bpm) that was unresponsive to digoxin and propranolol (17). Lidocaine and procainamide lowered the heart rate somewhat but were associated with unacceptable maternal toxicity. Amiodarone combined with verapamil was successful in halting the tachycardia and reversing the signs of congestive heart failure. An amiodarone maintenance dose of 400 mg/day was required for control. Spontaneous labor occurred after 39 days of therapy, with delivery of a 2700-g male infant at 33 weeks' gestation. Atrial flutter with a 2:1 block and a ventricular rate of 200 bpm were converted on the third day by electrical cardioversion. No adverse effects from the drug therapy were mentioned.

A fetus with supraventricular tachycardia (220 bpm) showed evidence of congestive heart failure at 32 weeks' gestation (6). Maternal therapy with digoxin alone or in combination with sotalol (a β -blocker) or verapamil failed to stop the abnormal rhythm. Digoxin was then combined with amiodarone, 1600 mg/day for 4 days, then 1200 mg/day for 3 days, then 800 mg/day for 6 weeks. The fetal heart rate fell to 140 bpm after 14 days of therapy, and the signs of congestive heart failure gradually resolved. Neonatal thyroid indices at birth (about 38 weeks' gestation) and at 1 month were as follows (normal values are shown in parentheses): free T3 index, 3.4 and 5.6 pmol/L (4.3–8.6 pmol/L); free T4 index, 5.4 and 25 pmol/L (9–26 pmol/L); T3, 1.7 and 2.7 nmol/L (1.2–3.1 nmol/L); T4, 196 and 300 nmol/L (70–175 nmol/L); and TSH, 30 and 4.12 mU/L (<5 mU/L). The elevated T4 level returned to normal at a

later unspecified time. It was not mentioned whether a goiter was present at birth. At 10 months of age, all thyroid function tests were within normal limits.

A third case involved a fetus at 30 weeks' gestation with tachycardia (220 bpm) and congestive heart failure that had not responded to digoxin and propranolol (18). At 32 weeks' gestation, digoxin and amiodarone lowered the rate to 110–180 bpm with improvement in the congestive failure. Amiodarone was given at 1200 mg/day for 3 days, then 600 mg/day until delivery 3 weeks later. The newborn had tachycardia of up to 200 bpm that was treated with digoxin, furosemide, and propranolol. Hypothyroidism was diagnosed based on the presence of a goiter and abnormal thyroid tests (normal values are in parentheses): T4, 48 mcg/mL (70–180 mcg/mL); free T4, 0.5 mcg/mL (>1.5 mcg/mL); and TSH, >240 mU/L (<30 mU/L). The infant was treated with 10 mcg/day of T4 until 3 months of age, at which time his cardiac and thyroid functions were normal. Follow-up at 15 months was normal.

A 27-week fetus with refractory supraventricular tachycardia and hydrops fetalis was treated with repeated injections of amiodarone into the umbilical vein after maternal therapy with amiodarone, and multiple other antiarrhythmic drugs failed to resolve the fetal condition (10). Subtherapeutic transplacental passage of amiodarone and digoxin was documented that did not improve until substantial resolution of the hydrops had occurred with direct administration of amiodarone to the fetus. A male infant was delivered at 37 weeks' gestation because of growth restriction, but thyroid function and other tests were within normal limits, and no corneal deposits were observed.

In a similar case, a 27-week fetus with severe hydrops secondary to congenital sinoatrial disease-induced sinus bradycardia and atrial flutter was treated with amiodarone via the IV, intraperitoneal, and transplacental routes (19). Prior maternal therapy with oral sotalol and flecainide had failed to reverse the worsening right heart failure. A 15-mg IV dose was administered to the fetus concurrently with initiation to the mother of 200 mg orally every 8 hours. Approximately 24 hours later, an additional 15-mg dose of amiodarone was given intraperitoneally to the fetus. The fetal ascites resolved over the next 3 weeks. A 2686-g female infant in good condition was eventually delivered at 37 weeks' gestation. Cardiac function was normal in the neonatal period and at 3-month follow-up, as were thyroid tests at 6 days of age.

A 1994 report described the use of amiodarone, 1600 mg/day (25 mg/kg/day), for the treatment of fetal supraventricular tachycardia that had failed to respond to flecainide at 33 weeks' gestation (20). The tachycardia recurred 2 weeks later and a cesarean section was performed under epidural

anesthesia with lidocaine to deliver a 3380-g male infant (follow-up of the infant not specified).

A historic cohort study, first published as an abstract (21) and then as a full report (22), described the fetal effects of maternal treatment with amiodarone. Twelve women, with various heart conditions requiring amiodarone therapy, were treated with individualized therapeutic doses (mean dose 321 mg/day) during gestation. Seven patients were treated throughout their pregnancies with one suffering a spontaneous abortion at 10 weeks. β -Blockers were used concurrently in the six pregnancies that delivered live newborns, but in one the β -blocker was stopped after 14 weeks. In the other five women, treatment with amiodarone was begun in the 2nd or 3rd trimester, and concurrent β -blockers were used in three for various intervals. The 11 infants were delivered at term (>37 weeks' gestation). Amiodarone was detected in two of three cord blood samples. The level in one was 0.2 mcg/mL (maternal serum not detectable), and the cord blood level in the other was 21.3% of the maternal concentration. One of the newborns was hyperthyroid (asymptomatic, transient) and one was hypothyroid. Fetal bradycardia occurred in three of the infants, two of whom had been exposed to β -blockers (acebutolol and propranolol). Four infants were small for gestational age (<3rd percentile corrected for gestational age) and three of these had been exposed to β -blockers throughout pregnancy. Two infants had birth defects, only one of whom had been exposed during the 1st trimester. This infant had congenital jerk nystagmus with synchronous head titubation (exposed to amiodarone and propranolol throughout, and quinidine during the 1st 3 weeks). The other newborn had hypotonia, hypertelorism, and micrognathia (exposed to amiodarone from the 20th week, atenolol from 18 to 20 weeks, and phenoxybenzamine during week 39), as well as delayed motor development assessed at 18 months (normal speech but milestone delay of about 3 months as indicated by lifting head, sitting unaided, crawling, standing, and walking). The child's birth weight and Apgar scores had been normal for gestational age and his neonatal course, other than a meconium plug, had been unremarkable. Other than this case, the other exposed infants had normal development (mean age at follow-up 30 months, range 0 months to 11.5 years) (22).

Congenital defects have been observed in two newborns, but any association between amiodarone and the defects may be fortuitous. Ventricular septal defects reportedly occur at an incidence of 1–3/1000 live births (16). The transient bradycardia and prolonged QT interval observed in some amiodarone-newborns are direct effects of the drug but apparently lack clinical significance.

Intrauterine growth restriction occurs frequently in infants exposed in utero to amiodarone, but it is uncertain whether this is a consequence of amiodarone, the mother's disease, other drug therapy (such as β -blockers), or a combination of these and other factors. Growth restriction has also been observed in animal studies. Because of the above outcomes and the limited data available, the drug should be used cautiously during pregnancy. As a result of the potential for fetal and newborn toxicity, it is not recommended as a first-line drug in uncomplicated cases of fetal supraventricular tachycardia (23).

Following chronic administration, amiodarone has a very long elimination half-life of 14–58 days (24). Therefore, the drug must be stopped several months before conception to avoid exposure in early gestation. A 1987 review of the management of cardiac arrhythmias during pregnancy recommends that amiodarone be restricted to refractory cases (25). Similarly, a 1992 review of maternal drug therapy for fetal disorders suggests caution, if it is used at all, before amiodarone is prescribed during pregnancy (26).

BREASTFEEDING SUMMARY

Amiodarone is excreted into breast milk (2,3,8,9). The drug contains about 75 mg of iodine/200 mg dose (2,3,5). One woman consuming 400 mg/day had milk levels of amiodarone and its metabolite, desethylamiodarone (activity unknown), determined at varying times between 9 and 63 days after delivery (2). Levels of the two substances in milk were highly variable during any 24-hour period. Peak levels of amiodarone and the metabolite ranged from 3.6 to 16.4 and from 1.3 to 6.5 mcg/mL, respectively. The milk:plasma ratio of the active drug at 9 weeks postpartum ranged from 2.3 to 9.1 and that of desethylamiodarone from 0.8 to 3.8. The authors calculated that the nursing infant received about 1.4–1.5 mg/kg/day of active drug. Plasma levels of amiodarone in the infant remained constant at 0.4 mcg/mL (about 25% of maternal plasma) from birth to 63 days. In a second case, a mother taking 200 mg/day did not breastfeed, but milk levels of the drug and the metabolite on the second and third days after delivery were 0.5–1.8 and 0.4–0.8 mcg/mL, respectively (3). A mother taking 400 mg/day had milk concentrations of amiodarone and the metabolite during the first postpartum month ranging from 1.06 to 3.65 and from 0.50 to 1.24 mcg/mL, respectively (8). No adverse effects were observed in her nursing infant.

Mothers of three breastfeeding infants had taken amiodarone, 200 mg/day, during pregnancy and continued the same dose in the postpartum period (9). Milk concentrations of the drug at various times after delivery in the three

mothers were 1.70 (2 days postpartum) and 3.04 mcg/mL (3 weeks postpartum), 0.55 (4 weeks postpartum) and 0.03 mcg/mL (6 weeks postpartum), and 2.20 mcg/mL (at birth), respectively. The milk:plasma ratios at these times varied widely from 0.4 to 13.0, as did the milk concentrations of the metabolite (0.002–1.81 mcg/mL). Two of the infants had concentrations of amiodarone in their plasma of 0.01–0.03 mcg/mL.

Although no adverse effects were observed in the one breastfed infant, relatively large amounts of the drug and its metabolite are available through the milk. Amiodarone, after chronic administration, has a very long elimination half-life of 14–58 days in adults (24). Data in pediatric patients suggest a more rapid elimination, but the half-life in newborns has not been determined. The effects of chronic neonatal exposure to this drug are unknown. Because of this uncertainty and because of the high proportion of iodine contained in each dose (see also Potassium Iodide), breastfeeding is not recommended if the mother is currently taking amiodarone or has taken it chronically within the past several months.

The American Academy of Pediatrics, noting that hypothyroidism is a potential complication, classifies amiodarone as a drug for which the effect on nursing infants is unknown but may be of concern (27).

AMITRIPTYLINE

Antidepressant

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although occasional reports have associated the therapeutic use of amitriptyline with congenital malformations, the bulk of the evidence indicates that these widely used drugs are relatively safe during pregnancy. The single case of gross overdose is suggestive of an association between amitriptyline, perphenazine, or both, and malformations, but without confirming evidence no conclusions can be determined. Because of the experience with tricyclic antidepressants, one review recommended that they were preferred during gestation over other antidepressants (1).

FETAL RISK SUMMARY

Two reviews found reports of amitriptyline-induced teratogenicity in animals: encephaloceles and bent tails in hamsters (2) and skeletal malformations in rats (1). However, reproduction studies conducted by the manufacturer in mice, rats, or rabbits with oral doses up to 13 times the maximum recommended human dose revealed no evidence of teratogenicity (3). The manufacturer does cite the teratogenicity of amitriptyline in mice, hamsters, rats, and rabbits when higher doses were used (3).

The manufacturer states that amitriptyline crosses the placenta (3). The relatively low molecular weight (approximately 314) is consistent with this finding.

In humans, limb reduction anomalies have been reported with amitriptyline (4,5). However, analysis of 522,630 births, 86 with 1st trimester exposure to amitriptyline, did not confirm an association with this defect (6–13). Reported malformations other than limb reduction defects after therapeutic dosing included: micrognathia, anomalous right mandible, left pes equinovarus (1 case); swelling of hands and feet (1 case); hypospadias (1 case); and bilateral

anophthalmia (1 case) (8,12–14).

A case of maternal suicide attempt with a combination of amitriptyline (725 mg) and perphenazine (58 mg) at 8 days' gestation was described in a 1980 abstract (15). An infant was eventually delivered with multiple congenital defects. The abnormalities included microcephaly, "cotton-like" hair with pronounced shedding, cleft palate, micrognathia, ambiguous genitalia, foot deformities, and undetectable dermal ridges (15).

Thanatophoric dwarfism was found in a stillborn infant exposed throughout gestation to amitriptyline (>150 mg/day), phenytoin (200 mg/day), and phenobarbital (300 mg/day) (16). The cause of the malformation could not be determined, but both drug and genetic etiologies were considered.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 467 newborns had been exposed to amitriptyline during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 25 (5.4%) major birth defects were observed (20 expected). Specific data were available for six defect categories, including (observed/expected) 6/5 cardiovascular defects, 0/1 oral clefts, 0/0 spina bifida, 2/1 polydactyly, 2/1 limb reduction defects, and 1/1 hypospadias. These data do not support an association between the drug and the defects.

In a 1996 descriptive case series, the European Network of the Teratology Information Services (ENTIS) prospectively examined the outcomes of 689 pregnancies exposed to antidepressants (17). Multiple drug therapy occurred in about two-thirds of the mothers. Amitriptyline (118 exposures; one set of twins) was the second most commonly used tricyclic antidepressant. The outcomes of these pregnancies were 18 elective abortions, 10 spontaneous abortions, 2 stillbirths, 79 normal newborns (including 7 premature infants), 5 normal infants with neonatal disorders, 4 infants with congenital defects, and 1 premature infant with other complications. The defects (all exposed in the 1st trimester or longer) were small ventricular septal defect; single palmar crease and small palpebral fissure; facial microangioma and right hydrocele (exposed also to clobazam, as well as diphtheria, tetanus, and typhoid vaccines); and facial muscle asymmetry and glucose-6-phosphate dehydrogenase (G6PD) deficiency (exposed also to clonazepam and oxazepam) (17).

Neonatal withdrawal after in utero exposure to other antidepressants (see Imipramine), but not with amitriptyline, has been reported. However, the potential for this complication exists because of the close similarity among these compounds. Urinary retention in the neonate has been associated with maternal use of nortriptyline, an amitriptyline metabolite (see Nortriptyline) (18).

A 2002 prospective study compared two groups of mother–child pairs exposed to antidepressants throughout gestation (46 exposed to tricyclics—18 to amitriptyline; 40 to fluoxetine) to 36 nonexposed, not depressed controls (19). Offspring were studied between the ages 15 and 71 months for effects of antidepressant exposure in terms of IQ, language, behavior, and temperament. Exposure to antidepressants did not adversely affect the measured parameters, but IQ was significantly and negatively associated with the duration of depression, and language was negatively associated with the number of depression episodes after delivery (19).

BREASTFEEDING SUMMARY

Amitriptyline and its active metabolites are excreted into breast milk (20–24). A recent study has measured the amount of a second active metabolite, E-10-hydroxynortriptyline, in milk (23).

Serum and milk concentrations of amitriptyline in one patient were 0.14 and 0.15 mcg/mL, respectively, a milk:plasma ratio of 1.0 (20). No drug was detected in the infant's serum. In another patient, it was estimated that the baby received about 1% of the mother's dose (22). No clinical signs of drug activity were observed in the infant.

In another study, the mother was treated with 175 mg/day of amitriptyline (23). Milk and maternal serum samples were analyzed for active drug and active metabolites on postpartum days 1–26. Amitriptyline serum levels ranged from 24 (day 1) to 71 ng/mL (days 3–26), whereas those in the milk ranged from 24 ng/mL (day 1) to only 54% of the serum levels on days 2–26. Nortriptyline serum levels ranged from 17 (day 1) to 87 ng/mL (day 26) with milk levels 74% of those in the serum. Mean concentration of the second metabolite, E-10-hydroxynortriptyline, was 127 ng/mL (days 1–26) in the serum and 70% of that in the milk. The total dose (parent drug plus metabolites) consumed by the male infant on day 26 was estimated to be 35 mcg/kg (80 times lower than the mother's dose). The compounds were not detected in the nursing infant's serum on day 26 and no adverse effects, including sedation, were observed in him (23).

Ten nursing infants of mothers taking antidepressants (two with amitriptyline 100–175 mg/day) were compared with 15 bottle-fed infants of mothers with depression who did not breastfeed (24). Concentrations of clomipramine in fore- and hind-milk were 30 ng/mL (one patient) and 113 and 197 ng/mL (two patients), respectively. The milk:maternal plasma ratios were 0.2 and 0.9, respectively. One infant had a plasma level of 7.5 ng/mL when the mother was

taking 100 mg/day. No toxic effects or delays in development were observed in the infants. The estimated daily dose consumed by the infants was about 1% of the mother's weight-adjusted dose (24).

A 1996 review of antidepressant treatment during breastfeeding found no information that amitriptyline exposure of the infant during nursing caused adverse effects (25).

Although amitriptyline and its metabolite have not been detected in infant serum, the effects of exposure to small amounts in the milk are unknown (26). The American Academy of Pediatrics classifies amitriptyline as a drug whose effect on the nursing infant is unknown but may be of concern (27).

AMLODIPINE

Calcium Channel Blocker

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Three reports, totaling five pregnancies, have described the use of amlodipine in human pregnancy. The outcomes of these pregnancies were two normal term-infants, one growth-restricted newborn (no relationship to drug because of timing of exposure), one fetal death (cause unknown, but possibly related to other exposures), and one neonate with a rare skin disease (doubtful relationship to drug).

FETAL RISK SUMMARY

Amlodipine is a calcium channel blocking agent used in the treatment of hypertension and angina. It is the same calcium channel blocker subclass as nine other agents (see Appendix). Amlodipine is extensively converted to inactive metabolites. Plasma protein binding is about 93% and the terminal elimination half-life is about 30–50 hours (1).

The drug is not teratogenic or embryotoxic in rats and rabbits given doses up to 8 and 23 times, respectively, the maximum recommended human dose based on BSA (MRHD) during organogenesis. However, rats administered 8 times the MRHD for 14 days before mating and throughout gestation had a significant decrease in litter size (by about 50%), a significant increase in intrauterine deaths (about fivefold), and prolonged labor and gestation. This dose, however, had no effect on fertility in the rat (1).

It is not known if amlodipine crosses the human placenta. The molecular weight (about 567 for the besylate salt) and the long terminal elimination half-life suggest that it will cross to the embryo–fetus.

A 1998 case report described an unusual condition in a neonate whose mother had been treated for hypertension with amlodipine throughout gestation

(2). The 3.97-kg male infant had been born at 39 weeks' with meconium staining of the amniotic fluid at Apgar scores of 3 and 8 at 1 and 5 minutes, respectively, and required oxygen therapy. At 24 hours of age, the infant developed firm, red, pea-sized nodular lesions over most of his body. The skin lesions were extremely tender requiring morphine analgesia. A skin biopsy revealed needle-like crystals within adipocytes of the SC fat. On the second day of life, he had two generalized tonic-clonic seizures. Although his general clinical condition improved over the 1st week of life with no further seizures, the skin changes, diagnosed as SC fat necrosis of the newborn, persisted until 9 months of age. The cause of the infant's condition was unknown (2).

A 2007 report described three hypertensive women exposed to amlodipine in the 1st trimester (3). In the first case, the mother took amlodipine 5 mg/day until 7 weeks' gestation and then declined further treatment. Her blood pressure remained in good control throughout gestation. At about 38 weeks, she delivered a healthy, 3750-g female infant with Apgar scores of 9 and 10 at 1 and 5 minutes, respectively. The infant was healthy at 3 months of age with normal development (see also Breastfeeding Summary). The second case involved treatment with amlodipine until about 2 weeks' gestation at which time the therapy was changed to atenolol 50 mg/day. Just before the seventh week the woman declined further treatment. Her blood pressure remained in good control throughout pregnancy. The growth-restricted (2600 g; <10th percentile), but otherwise-normal female infant was born at about 39 weeks' with Apgar scores of 8 and 9 at 1 and 5 minutes, respectively. At 20 months of age, the 10-kg child was still growth-restricted, and intellectual delay and weakness in the left arm and hand grasp were noted. The cause of the condition was unknown but not thought to be related to the drug therapy. The third case involved a woman with polycystic kidney disease and hypertension that was being treated with imidapril 5 mg/day (an ACE inhibitor) and barnidipine 10 mg/day (a calcium channel blocker) in an unknown pregnancy. Because of uncontrolled blood pressure, her therapy was changed at about 8 weeks' to amlodipine 5 mg/day. The mother also was taking sucralfate for acute gastritis and lorazepam for anxiety, and reported occasional use of 1 ounce of alcohol. At 12 weeks', an ultrasound revealed no cardiac activity and she underwent dilatation and evacuation of a dead fetus (3).

A 26-year-old woman with pulmonary arterial hypertension conceived while taking amlodipine (dose not specified) and warfarin (4). Warfarin was discontinued (exact gestational timing not specified) and replaced with enoxaparin. The patient remained on amlodipine and enoxaparin throughout

pregnancy. At about 38 weeks', a cesarean section was performed to deliver a 3123-g male infant with Apgar scores of 9 and 9. The infant went home with his mother, and no other information was provided on the infant (4).

BREASTFEEDING SUMMARY

The molecular weight (about 567 for the besylate salt) and the long terminal elimination half-life (30–50 hours) suggest that it will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown. However, no adverse effects were reported in the case below.

A mother 2 weeks postpartum, who was exclusively breastfeeding her infant, was restarted on amlodipine 5 mg/day to control her hypertension (3). At 3 months of age, the healthy female infant weighed 6.3 kg (25th–50th percentile) and had normal physical and neurodevelopment.

Although not mentioning amlodipine, the American Academy of Pediatrics classifies nifedipine, another calcium channel blocker, as compatible with breastfeeding (5).

AMMONIUM CHLORIDE

Respiratory Drug (Expectorant), Urinary Acidifier

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Although the data are limited and there are no animal reproduction data, there is no evidence suggesting that usual doses of ammonium chloride present an embryo or fetal risk.

FETAL RISK SUMMARY

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 365 of whom had 1st trimester exposure to ammonium chloride as an expectorant in cough medications (1, pp. 378–381). For use anytime during pregnancy, 3401 exposures were recorded (1, p. 442). In neither group was evidence found to suggest a relationship to large categories of major or minor malformations. Three possible associations with individual malformations were found but independent confirmation is required to determine the actual risk: inguinal hernia (1st trimester only) (11 cases); cataract (6 cases); and any benign tumor (17 cases) (1, pp. 478, 496)

When consumed in large quantities near term, ammonium chloride may cause acidosis in the mother and the fetus (2,3). In some cases, the decreased pH and pCO₂, increased lactic acid, and reduced oxygen saturation were as severe as those seen with fatal apnea neonatorum. However, the newborns did not appear in distress.

BREASTFEEDING SUMMARY

No reports describing the use of ammonium chloride during lactation have been located.

AMOBARBITAL

Sedative/Hypnotic

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although the data are limited, there is evidence of structural anomalies in newborns exposed to amobarbital during organogenesis. The absolute risk is unknown but may be low. The drug also is eliminated slowly in newborns. If possible, the drug should be avoided during organogenesis and near delivery.

FETAL RISK SUMMARY

Amobarbital is a member of the barbiturate class. The drug crosses the placenta, achieving levels in the cord serum similar to those in the maternal serum (1,2). Single or continuous dosing of the mother near term does not induce amobarbital hydroxylation in the fetus as demonstrated by the prolonged elimination of the drug in the newborn (half-life 2.5 times maternal). An increase in the incidence of congenital defects in infants exposed in utero to amobarbital has been reported (3,4, pp. 336, 344). In one survey of 1369 patients exposed to multiple drugs, 273 received amobarbital during the 1st trimester (3). Ninety-five of the exposed mothers delivered infants with major or minor abnormalities. Malformations associated with barbiturates, in general, were as follows:

| | |
|---------------------------|-----------------------------------|
| Anencephaly | Congenital dislocation of the hip |
| Congenital heart disease | Soft-tissue deformity of the neck |
| Severe limb deformities | Hypospadias |
| Cleft lip and palate | Accessory auricle |
| Intersex | Polydactyly |
| Papilloma of the forehead | Nevus |
| Hydrocele. | |

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 298 of whom had 1st trimester exposure to amobarbital (4, pp. 336, 344). For use anytime during pregnancy, 867 exposures were recorded (4, p. 438). A possible association was found between the use of the drug in the 1st trimester and the following: cardiovascular malformations (7 cases), polydactyly in blacks (2 cases in 29 blacks), genitourinary malformations other than hypospadias (3 cases), inguinal hernia (9 cases), and clubfoot (4 cases).

In contrast to the above reports, a 1964 survey of 187 pregnant patients who had received various neuroleptics, including amobarbital, found a 3.1% incidence of malformations in the offspring (5). This is approximately the expected incidence of abnormalities in a nonexposed population. Arthrogyrosis and multiple defects were reported in an infant exposed to amobarbital during the 1st trimester (6). The defects were attributed to immobilization of the limbs at the time of joint formation, multiple drug use, and active tetanus.

BREASTFEEDING SUMMARY

No reports describing the use of amobarbital during lactation have been located. Similar to other barbiturates, the drug probably is excreted into breast milk. The effects of this exposure are unknown, but toxicity is possible (e.g., see Phenobarbital).

AMOXAPINE

Antidepressant

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

The animal data suggest risk, but the human pregnancy experience is too limited to assess the embryo–fetal risk. Until such data are available, the safest course may be to avoid amoxapine during organogenesis.

FETAL RISK SUMMARY

No published reports linking the use of amoxapine with congenital defects have been located. Reproductive studies in mice, rats, and rabbits have found no teratogenicity, but embryotoxicity was observed in rats and rabbits given oral doses approximating the human dose (1). Intrauterine death, stillbirths, decreased weight, and decreased neonatal survival (days 0–4) were seen with oral doses at 3–10 times the human dose.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 19 newborns had been exposed to amoxapine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Three (15.8%) major birth defects were observed (one expected). Data on the specific types of defects were not available, but no cases of cardiovascular defects, oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias were observed. Although the total incidence of anomalies is high, the number of exposures is too small to draw a conclusion.

BREASTFEEDING SUMMARY

Amoxapine and its metabolite are excreted into breast milk. A 29-year-old woman suffering from depression was treated with approximately 250 mg/day of amoxapine (2). She developed galactorrhea and oligomenorrhea. Milk

samples were collected after 10 and 11 months of therapy and analyzed for amoxapine and the active metabolite, 8-hydroxyamoxapine. The levels of the parent compound at the sample collection times were both <20 ng/mL, but the metabolite was present in both samples, 45 minutes after the last dose at 10 months and 11.5 hours after the last dose at 11 months. Levels of the active metabolite at these times were 113 and 168 ng/mL, respectively. A venous blood specimen obtained simultaneously with the first milk sample had concentrations of amoxapine and 8-hydroxyamoxapine of 97 and 375 ng/mL, respectively. The American Academy of Pediatrics classifies amoxapine as a drug whose effect on the nursing infant is unknown but may be of concern (3).

AMOXICILLIN

Antibiotic (Penicillin)

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 1st and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Penicillins are generally considered low risk at any stage of pregnancy. This assessment may have to be modified for the aminopenicillins (ampicillin and amoxicillin) because there is some evidence that exposure to these two antibiotics during organogenesis is associated with oral clefts (see also Ampicillin). However, even if the association is causal, the absolute risk is very low. In addition, one study reported an association between amoxicillin–clavulanic acid and necrotizing enterocolitis (NEC) when the antibiotic combination was used near preterm birth. Both of these associations require confirmation.

FETAL RISK SUMMARY

Amoxicillin is an aminopenicillin antibiotic similar to ampicillin. The antibiotic is known to cross the placenta.

Reproduction studies have been conducted in mice and rats at doses up to 10 times the human dose. No effect on fertility or fetal harm was observed at this dose (1).

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 3546 of whom had 1st trimester exposure to penicillin derivatives (2, pp. 297–313). For use anytime during pregnancy, 7171 exposures were recorded (2, p. 435). In neither group was evidence found to suggest a relationship to large categories of major or minor malformations or to individual defects. Amoxicillin has been used as a single 3-g dose to treat bacteriuria in pregnancy without causing fetal harm (3,4).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 8538 newborns had been exposed to amoxicillin during the 1st trimester (F. Rosa, personal

communication, FDA, 1993). A total of 317 (3.7%) major birth defects were observed (363 expected). Specific data were available for six defect categories, including (observed/expected) 76/85 cardiovascular defects, 16/14 oral clefts, 6/7 spina bifida, 17/24 polydactyly, 9/16 limb reduction defects, and 22/22 hypospadias. These data do not support an association between the drug and the defects.

Several reports have described the use of amoxicillin in pregnancy, either for preterm pre-labor rupture of membranes (5,6) or for the treatment of prenatal Chlamydia infection (7–10). The latter reference is of particular interest because of the potential for fetal–newborn harm when amoxicillin–clavulanic acid (ACA) was used. A 2001 randomized study (ORACLE 1) was conducted in patients with preterm, pre-labor rupture of fetal membranes to determine neonatal health benefits of three antibiotic regimens (10). The regimens, compared with a placebo group (N = 1225) were erythromycin (250 mg) (N = 1197), amoxicillin (250 mg)–clavulanic acid (125 mg) (N = 1212), or both (N = 1192) four times daily for 10 days or until delivery. The primary outcome measures were specific outcomes or a composite of neonatal death, chronic lung disease, or major cerebral abnormality. For these neonatal outcomes, the two groups with ACA had no benefit over placebo, whereas erythromycin use resulted in significantly better outcomes (both composite and specific). When any-ACA exposure was compared with no-ACA for outcomes with suspected or proven NEC, the results were 92 (3.8%) and 58 (2.4%) ($p = 0.004$). The authors thought that a possible mechanism for this outcome was that the ACA combination selected for *Clostridium difficile* and that abnormal colonization of the neonatal intestinal tract was one possible mechanism for NEC (10).

A population based from Denmark examined the association between amoxicillin use in pregnancy and birth weight, preterm birth, congenital anomalies, perinatal death, and spontaneous abortion (SAB) (11). During the study period (1991–2000), 401 primiparous women obtained a prescription for the antibiotic. The control group consisted of 10,237 primiparous women who did not redeem any prescriptions from 3 months before pregnancy until the end of pregnancy. The mean birth weight of subjects was 57 g (95% confidence interval [CI] 9–105) higher than controls. The odds ratio and 95% CI for the other outcomes were as follows: low birth weight (0.63, 0.26–1.53); preterm birth (0.77, 0.49–1.21); congenital anomalies (1.16, 0.54–2.50); and SAB (0.89, 0.66–1.18) (11).

In a 2004 study, 191 women treated with ACA (subjects) in the 1st trimester were matched with 191 controls exposed to amoxicillin only (12). Maternal age,

birth weight, gestational age at birth, and rates of live births and abortions were comparable between the two groups. The rates of major malformations in subjects (3/158, 1.9%) and controls (5/163, 3%) ($p = 0.49$; relative risk 0.62, 95% CI 0.15–2.55) were within the expected baseline risk for the general population. There were no cases of oral clefts (12).

A retrospective cohort study using data from Tennessee Medicaid included 30,049 infants born in 1985–2000 was published in 2009 (13). Infants with fetal exposures in the 1st trimester to four antibiotics recommended for potential bioterrorism attacks (amoxicillin, ciprofloxacin, azithromycin, and doxycycline) were compared to infants with no fetal exposure to any antibiotic. Erythromycin was included as a positive control. In the 7216 infants exposed to amoxicillin and no other antibiotics, the number of cases, risk ratios, and 95% CI were as follows: any malformation (232, 1.09, 0.55–1.37), cardiac (89, 1.15, 0.79–1.68); musculoskeletal (52, 1.05, 0.66–1.69); genitourinary (52, 1.38, 0.78–2.43); gastrointestinal (26, 0.63, 0.35–1.16); CNS (23, 1.08, 0.50–2.32); and orofacial (15, 1.67, 0.56–5.04). The authors concluded that the four antibiotics should not result in a greater incidence of overall major malformations (see also Azithromycin, Ciprofloxacin, and Doxycycline) (13).

A 2012 study used data from the Slone Epidemiology Center Birth Defects Study (1994–2008) to identify 877 infants with cleft lip with/without cleft palate and 471 with cleft palate alone (14). Controls included 6952 infants without defects, 2.1% of whom were exposed to amoxicillin. The adjusted odds ratio (OR) for cleft lip with/without cleft palate for exposure in the 1st trimester was 2.0 (95% CI 1.0–4.1). For third gestational month exposure, the results were OR 4.3 (95% CI 1.4–13.0). For cleft palate, the results for the two exposure periods were OR 1.0 (95% CI 0.4–2.3) and OR 7.1 (95% CI 1.4–36). No elevated risks were observed for other penicillins or cephalosporins, but the risk for ampicillin could not be evaluated because there were fewer than five exposed subjects. Because the risk for oral clefts among penicillins appeared to be related only to the aminopenicillins (ampicillin and amoxicillin), the authors speculated that the aminobenzyl group has a role in the development of oral clefts. Even so, the background risk for oral clefts is about 1–2 per 1000 and a twofold risk would increase the risk to only 2–4 per 1000 (14).

BREASTFEEDING SUMMARY

Amoxicillin is excreted into breast milk in low concentrations. Following a 1-g oral dose given to six mothers, peak milk levels occurred at 4–5 hours, averaging 0.9 mcg/mL (range 0.68–1.3 mcg/mL) (15). Mean milk:plasma ratios

at 1, 2, and 3 hours were 0.014, 0.013, and 0.043, respectively. Although no adverse effects have been observed, three potential problems exist for the nursing infant: modification of bowel flora, direct effects on the infant (e.g., allergy or sensitization), and interference with the interpretation of culture results if a fever workup is required.

In a 1993 cohort study, diarrhea was reported in 32 (19.3%) nursing infants of 166 breastfeeding mothers who were taking antibiotics (16). For the 25 women taking amoxicillin, diarrhea was observed in 3 (12%) infants. The diarrhea was considered minor because it did not require medical attention (16).

The American Academy of Pediatrics classifies amoxicillin as compatible with breastfeeding (17).

AMPHETAMINE

Central Stimulant

PREGNANCY RECOMMENDATION: Human and Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity Contraindicated (Nonmedical Use)

PREGNANCY SUMMARY

Although medicinal use of amphetamines appears to be low risk for embryo–fetal harm, abuse of the agent is associated with significant toxicity for the embryo, fetus, and newborn. Such use is contraindicated in pregnancy.

FETAL RISK SUMMARY

The amphetamines are a group of sympathomimetic drugs that are used to stimulate the central nervous system. Members of this group include amphetamine, dextroamphetamine, and methamphetamine. A number of studies have examined the possible relationship between amphetamines and adverse fetal outcome. Women were using these drugs for appetite suppression, narcolepsy, or illicit abuse purposes.

In near-term pregnant sheep administered IV doses at or below what is commonly regarded as abuse, methamphetamine rapidly crossed the placenta and accumulated in the fetus (1). Fetal blood pressure was increased 20%–37% with a decrease in fetal oxyhemoglobin saturation and arterial pH. Approximately similar results were reported in a 1993 abstract that also used pregnant sheep (2). Fetal concentrations of the drug were approximately the same as maternal levels during a 6-hour interval.

The question as to whether amphetamines are teratogenic in humans has been examined in a number of studies and single-patient case histories. Cardiac malformations and other defects were produced in mice injected with very large doses (about 200 times the usual human dose) of dextroamphetamine (3). These same investigators then retrospectively and prospectively examined human infants whose mothers had ingested the drug (4). In the retrospective portion of the study, 219 infants and children under 2

years of age with congenital heart disease were compared with 153 similar-age infants and children without heart defects. Neither maternal exposure to dextroamphetamine during pregnancy nor exposure during the vulnerable period differed statistically between the groups. However, a positive family history of congenital heart disease occurred in 31.1% of the infants with the defects compared with only 5.9% of the control group ($p = 0.001$). The prospective study compared 52 mothers with a documented exposure to dextroamphetamine during the vulnerable period with 50 nonexposed mothers. Neither group produced an infant with congenital heart disease, and the numbers of other congenital abnormalities were similar (nine vs. seven). Thus, this study found no evidence for an association between congenital heart defects and dextroamphetamine. However, in a follow-up study published 3 years later, the investigators reported a significant relationship between dextroamphetamine exposure and heart defects (5). Comparing 184 infants under 1 year of age with congenital heart disease with 108 control infants, significant differences were found for maternal exposure to dextroamphetamine (18% vs. 8%, $p < 0.05$), exposure during the vulnerable period (11% vs. 3%, $p = 0.025$), and positive family history of congenital heart disease (27% vs. 6%, $p < 0.001$). Infants who were both exposed during the vulnerable period and had a positive family history were statistically similar for the groups (5% vs. 1%).

In a fourth study by the above investigative group, 240 women were followed prospectively during their pregnancies to determine exposure to medicinal agents, radiation, and other potential teratogens (6). Thirty-one (13%) women consumed an appetite suppressant (usually dextroamphetamine) during the 1st trimester and an additional 34 (14%) were exposed later in pregnancy. Eight (3.3%) babies had a major congenital defect noted at birth, which is approximately the expected incidence in the United States. Three of the affected infants had been exposed during the 1st trimester to an appetite suppressant. Although the authors identified a wide range of maternal drug consumption during the 1st trimester, no conclusions as to the cause of the defects can be drawn from the data.

Four other reports have related various defects with amphetamine exposure (7–10). An infant with a bifid exencephalia was delivered from a mother who took 20–30 mg of dextroamphetamine daily throughout pregnancy (7). The infant died after an attempt was made at surgical correction. A second case involved a mother who ingested dextroamphetamine daily for appetite suppression and who delivered a full-term infant. The infant died 6 days later as a result of a congenital heart defect (8). Drug histories were obtained from

mothers of 11 infants with biliary atresia and compared with the histories of 50 control mothers (9). Amphetamine exposure occurred in five women in the study group and in three of the controls. A 1966 report described a mother with two infants with microcephaly, mental retardation, and motor dysfunction (10). The mother had taken an appetite suppressant containing methamphetamine and phenobarbital during the 1st and 2nd trimesters of both pregnancies (pregnancy numbers 1 and 3). A spontaneous abortion occurred in pregnancy number 2, but no details were given of the mother's drug intake. Her fourth pregnancy, in which she did not take the appetite suppressant, resulted in the delivery of a normal child. There was no family history of developmental disorders, congenital defects, mental retardation, cerebral palsy, or epilepsy.

Fetal structural defects have been associated with maternal abuse of drugs in a large volume of literature (see also Ethanol, Cocaine, Heroin, Lysergic Acid Diethylamide [LSD], Marijuana, and Methadone). For example, in a 1972 case, multiple brain and eye anomalies were observed in an infant exposed in utero to amphetamines, LSD, meprobamate, and marijuana (11). In this and similar cases, the cause of the structural abnormalities is probably multifactorial, involving drug use, life-styles, infections, poor maternal health, and other factors.

In a retrospective study, 458 mothers who delivered infants with major (N = 175) or minor (N = 283) abnormalities were compared with 911 matched controls (12). Appetite suppressants were consumed during pregnancy by significantly more mothers of infants with anomalies than by controls (3.9% vs. 1.1%, $p < 0.01$). Dextroamphetamine consumption accounted for 13 of the 18 maternal exposures in the anomaly group. During the first 56 days of pregnancy, dextroamphetamine-containing compounds were used by 10 mothers in the anomaly group compared with only 5 of the controls (2.2% vs. 0.5%; $p < 0.05$). The abnormalities (3 major and 7 minor) observed in the 10 infants were urogenital system defects (4 cases), and 1 case each of congenital heart disease, cleft lip, severe limb deformity, accessory auricles, congenital dislocation of hip, and pilonidal sinus. Although statistically significant results were found in this study, the results must be interpreted cautiously due to the retrospective collection of drug histories and the lack of information pertaining to past and present maternal medical and obstetric histories.

A prospective study of 1824 white mothers who took anorectic drugs (primarily amphetamines) during pregnancy compared with 8989 white mothers who did not take such drugs measured rates of severe congenital defects of 3.7% and 3.4%, respectively, in infants with a gestational age of at least 37

weeks (13). When children of all known gestational ages were included, amphetamine usage occurred in 85% (1694 of 1992) of the group consuming anorectic drugs. The incidence of severe congenital defects in the amphetamine group was 3.4%. Fourteen infants were exposed in the first 84 days after the last menstrual period, and except for three infants with cleft lip and/or palate, no pattern of malformations was observed.

The effects of amphetamine abuse on fetal outcome and subsequent development were described in a series of reports from Sweden (14–18). Twenty-three women who ingested amphetamine during the 1st trimester were divided into two groups: 6 who claimed that they stopped use of the drug after they became aware of their pregnancy or after the 1st trimester, and 17 who continued use of the drug throughout gestation (14). Two of the infants (group not specified) had congenital defects: a stillborn infant had myelomeningocele, and one had extensive telangiectasis (considered to be an inherited disorder). The outcome of the infants exposed throughout gestation included six preterm (<37 weeks), three small-for-gestational-age (all with poor prenatal care), one of whom had a seizure on the first day, and two full-term but extremely drowsy infants. In a later report, 66 infants born to amphetamine-addicted mothers were followed during their first year of life (16). Except for temporary drowsiness in the first few months, all children had normal somatic and psychomotor development at 12 months of age. In the final report from these investigators, the fetal outcome of 69 amphetamine-addicted women who delivered 71 children (1 delivered twice and 1 delivered twins) was described (17). Seventeen of the women claimed to have stopped amphetamine ingestion as previously described, and 52 continued use of amphetamines throughout pregnancy. Three women in the first group and 17 in the second group were alcoholics (18). Four infants had congenital defects: intestinal atresia (two cases—both died and one also had hydrocephalus), congenital heart defect (one case), and epidermolysis bullosa without known heredity (one case). In one of the four cases, the mother was an alcoholic, but the particular case was not specified. Drowsiness was observed in 8 infants and jitteriness in 11 infants; 4 full-term infants required tube feedings. The four studies (14–17) were combined into a single article published in 1980 (18).

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 671 of whom had 1st trimester exposure to amphetamines (19, pp. 346–347). For use anytime during pregnancy, 1898 exposures were recorded (19, p. 439). In neither group was evidence found to suggest a relationship to large categories of major or minor malformations. Two case reports failed to observe any

neonatal effects from the treatment of narcolepsy with large doses of amphetamine (20,21). A 1988 report described a mother who had used amphetamines, barbiturates, cocaine, LSD, alcohol, and marijuana during pregnancy who delivered a female infant with bilateral cerebrovascular accident and resulting porencephaly (22). The infant expired at 2.5 months of age. The fetal injury was thought to be caused by cocaine (see also Cocaine).

A 1992 case report described the use of dextroamphetamine and lovastatin in a human pregnancy (23). A woman was treated for 5 weeks with the combination, starting approximately 6 weeks from her last menstrual period, for progressive weight gain and hypercholesterolemia. Therapy was discontinued when her pregnancy was diagnosed at 11 weeks' gestation. A female infant was delivered by cesarean section at 39 weeks' gestation. Gestational age was confirmed by an ultrasound examination at 21 weeks' gestation and the Dubowitz score at birth. The infant had a constellation of malformations termed the VATER association (vertebral anomalies, anal atresia, tracheoesophageal fistula with esophageal atresia, renal and radial dysplasias). Specific anomalies included an asymmetric chest, thoracic scoliosis, absent left thumb, foreshortened left forearm, left elbow contracture, fusion of the ribs on the left, butterfly vertebrae in the thoracic and lumbar spine, left radial aplasia, and a lower esophageal stricture. Chromosomal analysis was normal, and the family history was noncontributory (23).

The effects of IV methamphetamine abuse on the fetus were evaluated in a 1988 report (24). Maternal use of the drug was identified by self-reporting before delivery in 52 women, and an equal number of controls were selected for comparison. Although self-reporting of illegal drug use is prone to underreporting, the drug histories were validated by social worker interviews and were thought to represent actual drug use in the study population. Other drugs used in the study and control groups were tobacco (24 vs. 6), marijuana (20 vs. 1), cocaine (14 vs. 0), and one each in the study group for alcohol, lorazepam, dextroamphetamine, heroin, opium, LSD, and diazepam. No statistical differences were measured between the groups in the rate of obstetric complications (12% vs. 27%) or neonatal complications (21% vs. 17%). The latter category included meconium (10% vs. 12%), fetal heart rate decelerations (4% vs. 0) and tachycardia (2% vs. 0%), tachypnea (4% vs. 2%), and withdrawal symptoms (2% vs. 0%). Mean birth weight, length, and head circumference were all lower in the study infants compared with controls ($p = 0.001$). Six (12%) of the infants in the study group had a congenital defect compared with seven (14%) of the controls. Statistically, however, the

investigators could only conclude that methamphetamine abuse does not cause a ≥ 12 -fold increase in congenital anomalies (24).

A 1992 abstract described the effects of methamphetamine abuse in 48 newborns in comparison to 519 controls (25). Offspring of women positive for opiates, cocaine, alcohol, and toluene were excluded from both groups. Except for a significantly lower birth weight, 3173 vs. 3327 g ($p = 0.03$), all other parameters studied were similar, including birth length, head circumference, Apgar scores, gestational age at delivery, and the incidence of both major and minor malformations.

Intrauterine death occurred at 34 weeks' gestation in the fetus of a 29-year-old amphetamine addict who had injected 500 mg of amphetamine (26). The mother was exhibiting toxic signs and symptoms of amphetamine overdose when she was brought to the hospital. An initial fetal bradycardia of 90–100 beats/minute worsened over the next 50 minutes when the heart sounds became inaudible. Approximately 24 hours later, a 3000-g female stillborn infant without congenital abnormalities was delivered.

Amphetamine withdrawal has been described in newborns whose mothers were addicted to amphetamines during pregnancy (27–29). In a report of four mothers using methamphetamine, symptoms consisting of shrill cries, irritability, jerking, and sneezing were observed in two infants (27). One of the infants was evaluated at 4 months of age and appeared normal except for small size (weight 3rd percentile, head circumference 10th percentile). The author speculated that the symptoms in the newborns may have been caused by hidden narcotic addiction (27). Another report of four women with methamphetamine dependence described one newborn with marked drowsiness lasting for 4 days (28). The mother had not been taking narcotics. The third report of neonatal withdrawal involved an infant delivered from a mother who was a known amphetamine addict (29). Beginning 6 hours after birth, the female infant had diaphoresis, agitation alternating with periods of lassitude, apnea with feedings, a seizure on the 6th day, vomiting, miotic pupils, and a glassy-eyed stare. Her first 3 months were marked by slow development, but at 2.5 years of age, there was no evidence of neurologic disability and intelligence was considered above normal.

Methamphetamine withdrawal characterized by abnormal sleep patterns, poor feeding, tremors, and hypertonia was reported in a 1987 study (30). Infants exposed to methamphetamine or cocaine, either alone or in combination, were combined into a single group ($N = 46$) because of similar maternal and neonatal medical factors. Mothers in the drug group had a

significantly greater incidence of prematurity compared with drug-free controls (28% vs. 9%), and a significantly greater incidence of placental hemorrhage and anemia compared with narcotic-using mothers and controls (13% vs. 2% vs. 2.2%, and 13% vs. 2% vs. 0%). Maternal methamphetamine abuse was significantly associated with lower gestational age, birth weight, length, and occipitofrontal circumference (30).

Echoencephalography (ECHO) was performed within 3 days of birth on 74 term (>37 weeks) infants who had tested positive for cocaine or methamphetamine, but who otherwise had uncomplicated perinatal courses (31). The infants had no other known risk factors for cerebral injury. The 74 newborns were classified into three groups: 24 (32%) exposed to methamphetamine, 32 (43%) exposed to cocaine, and 18 (24%) exposed to cocaine plus heroin or methadone, or both. Two comparison groups were formed: a group of 87 term, drug-free infants studied by ECHO because of clinical concerns for hypoxic–ischemic encephalopathy, and a normal group of 19 drug-free term newborns. Both groups of comparison infants were also studied by ECHO within 3 days of birth. Only one structural anomaly, consisting of an absent septum pellucidum, was observed in the infants examined. The affected newborn, exposed to methamphetamine, was also found to have bilateral optic nerve atrophy and diffuse attenuation of the white matter. Twenty-six (35.1%) of the drug-exposed infants had cranial abnormalities detected by ultrasonography, which was similar to the 27.6% (24 of 87) incidence in the group suspected of encephalopathy ($p = 0.7$). The normal controls had an incidence of 5.3% (1 of 19) ($p < 0.01$ in comparison to both of the other groups). The lesions observed in the drug-exposed infants were intraventricular hemorrhage, echodensities known to be associated with necrosis, and cavitory lesions. Lesions were concentrated in the basal ganglion, frontal lobes, and posterior fossa (31). The ECHO abnormalities were not predicted by standard neonatal clinical assessment and were believed to be consistent with those observed in adult abusers of amphetamines and cocaine (31).

Amphetamines do not appear to be human teratogens (32–34). Mild withdrawal symptoms may be observed in the newborns, but the few studies of infant follow-up have not shown long-term sequelae, although more studies of this nature are needed. Illicit maternal use of amphetamines, on the other hand, presents significant risks to the fetus and newborn, including intrauterine growth restriction, premature delivery, and the potential for increased maternal, fetal, and neonatal morbidity. These poor outcomes probably reflect several factors,

including multiple drug use, lifestyles, and poor maternal health. However, cerebral injuries occurring in newborns exposed in utero appear to be directly related to the vasoconstrictive properties of amphetamines (31).

BREASTFEEDING SUMMARY

Amphetamine, the racemic mixture of levo—and dextroamphetamine, is concentrated in breast milk (21). After continuous daily dosing of 20 mg, milk concentrations ranged from 55 to 138 ng/mL with milk:plasma ratios varying between 2.8 and 7.5. Amphetamine was found in the urine of the nursing infant. No adverse effects of this exposure were observed over a 24-month period. In a second study, no neonatal insomnia or stimulation was observed in 103 nursing infants whose mothers were taking various amounts of amphetamine (35). The American Academy of Pediatrics classifies amphetamines as contraindicated during breastfeeding because of irritability and poor sleeping pattern (36).

AMPHOTERICIN B

Antifungal Antibiotic

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Although animal reproduction data suggest risk, no adverse effects have been reported in exposed human embryos and fetuses. The drug crosses the human placenta with cord blood concentrations up to those measured in the mother.

FETAL RISK SUMMARY

No reports linking the use of amphotericin B with congenital defects have been located. Reproduction studies of amphotericin B liposome were conducted with maternal nontoxic doses in rats (0.16–0.8 times the recommended human clinical dose range of 1–5 mg/kg based on BSA [RHCD]) and rabbits (0.2–1 times the RHCD) (1). Rabbits administered doses 0.5–2 times the RHCD had a higher rate of spontaneous abortions than did controls (1). No fetal harm was observed in reproduction studies of amphotericin B lipid complex in rats and rabbits at doses up to 0.64 times the human dose (2).

The antibiotic crosses the placenta to the fetus with cord blood:maternal serum ratios ranging from 0.38 to 1.0 (3–5). In a term (42 weeks) infant whose mother was treated with amphotericin B 0.6 mg/kg every other day, cord and maternal blood levels at delivery were both 2.6 mcg/mL, with a cord blood:maternal serum ratio of 1.0 (3). Amniotic fluid concentration was 0.08 mcg/mL at delivery. The time interval between the last dose and delivery was not specified. Concentrations in the cord blood and maternal serum of a woman treated with 16 mg of amphotericin B just before delivery (one-fifth of a planned total dose of 80 mg had infused when delivery occurred) were 0.12 and 0.32 mcg/mL, respectively, a ratio of 0.38 (4). The woman's last dose before this time was 7 days previously when she had received 80 mg. In a third case, a mother was receiving 20 mg IV every other day (0.5 mg/kg) (5). The cord and

maternal serum concentrations were 1.3 and 1.9 mcg/mL, respectively, a ratio of 0.68. The levels were determined 26 hours after her last dose.

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 9 of whom had 1st trimester exposure to amphotericin B (6). Numerous other reports have also described the use of amphotericin B during various stages of pregnancy, including the 1st trimester (4–22). No evidence of adverse fetal effects was found by these studies. Amphotericin B can be used during pregnancy in those patients who will clearly benefit from the drug.

BREASTFEEDING SUMMARY

No reports describing the use of amphotericin B during human lactation have been located. The drug probably is excreted into breast milk, but the risk, if any exists, to a nursing infant is unknown.

AMPICILLIN

Antibiotic (Penicillin)

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 1st Trimester

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Penicillins are considered low risk at any stage of pregnancy. This assessment may have to be modified for the aminopenicillins (ampicillin and amoxicillin) because there is some evidence that exposure to these two antibiotics during organogenesis is associated with oral clefts (see also Amoxicillin). However, even if the association is causal, the absolute risk is very low. The association requires confirmation.

FETAL RISK SUMMARY

Ampicillin is an aminopenicillin antibiotic (see also Amoxicillin). The drug rapidly crosses the placenta into the fetal circulation and amniotic fluid (1–6). Fetal serum levels can be detected within 30 minutes and equilibrate with maternal serum in 1 hour. Amniotic fluid levels can be detected in 90 minutes, reaching 20% of the maternal serum peak in about 8 hours. The pharmacokinetics of ampicillin during pregnancy have been reported (7,8).

Ampicillin depresses both plasma-bound and urinary-excreted estriol by inhibiting steroid conjugate hydrolysis in the gut (9–13). Urinary estriol was formerly used to assess the condition of the fetoplacental unit, with depressed levels being associated with fetal distress. This assessment is now made by measuring plasma unconjugated estriol, which is not usually affected by ampicillin. An interaction between ampicillin and oral contraceptives resulting in pregnancy has been suspected (14,15). Two studies, however, failed to confirm this interaction and concluded that alternate contraceptive methods were not necessary during ampicillin therapy (16,17).

The use of ampicillin in early pregnancy was associated with a prevalence ratio estimate of 3.3 (90% confidence interval [CI] 1.3–8.1, $p = 0.02$) for congenital heart disease in a retrospective study (18). A specific defect,

transposition of the great arteries, had a risk of 7.7 (90% CI 1.3–38) based on exposure in 2 of the 29 infants with the anomaly. The investigators did note, however, that the results had to be viewed cautiously because the data were subject to recall bias (drug histories were taken by questionnaire or telephone up to a year after presumed exposure) and the study could not distinguish between the fetal effects of the drug versus those of the infectious agent(s) for which the drugs were used. Others have also shared this concern (19). Other reports linking the use of ampicillin with congenital defects have not been located.

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 3546 of whom had 1st trimester exposure to penicillin derivatives (20, pp. 297–313). For use anytime during pregnancy, 7171 exposures were recorded (20, p. 435). In neither group was evidence found to suggest a relationship to large categories of major or minor malformations or to individual defects. Based on these data, it is unlikely that ampicillin is teratogenic.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 10,011 newborns had been exposed to ampicillin during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 441 (4.4%) major birth defects were observed (426 expected). Specific data were available for six defect categories, including (observed/expected) 116/100 cardiovascular defects, 13/16 oral clefts, 6/8 spina bifida, 36/29 polydactyly, 9/17 limb reduction defects, and 27/24 hypospadias. These data do not support an association between the drug and the defects.

Ampicillin is often used in the last half of pregnancies in which either the woman or her fetus is at risk for infections because of premature rupture of the membranes or other risk factors (21–23). In one report, a mother with ruptured membranes at 40 weeks' gestation had an anaphylactic reaction to ampicillin (24). A markedly distressed infant was delivered with severe metabolic acidosis (arterial cord blood pH 6.71). Multifocal clonic seizures and brain edema occurred during the neonatal period, and pronounced neurologic abnormalities were evident at 6 months of age.

A 2001 study from Hungary evaluated the association between ampicillin and birth defects (25). Of 38,151 controls (no defects), 2632 (6.9%) had been treated with ampicillin. In 22,865 cases (with defects), 1643 (7.2%) had been treated with ampicillin. For ampicillin use in the second and third months of gestation, the only significant difference was for cleft palate (odds ratio 4.2, 95% confidence interval 1.4–16.3). However, the authors concluded that the

lack of evidence for the association in other studies and in animals suggested that the apparent risk was not real and instead a chance association (25).

BREASTFEEDING SUMMARY

Ampicillin is excreted into breast milk in low concentrations. Milk:plasma ratios have been reported up to 0.2 (26,27). Candidiasis and diarrhea were observed in one infant whose mother was receiving ampicillin (28).

In a 1993 cohort study, diarrhea was reported in 32 (19.3%) nursing infants of 166 breastfeeding mothers who were taking antibiotics (29). For the five women taking ampicillin, diarrhea was observed in one (20%) infant. The diarrhea was considered minor because it did not require medical attention (29).

Although adverse effects are apparently rare, three potential problems exist for the nursing infant: modification of bowel flora, direct effects on the infant (e.g., allergic response or sensitization), and interference with the interpretation of culture results if a fever workup is required.

AMPRENAVIR

Antiviral

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

The limited human data do not allow a prediction as to the risk of amprenavir during pregnancy. The developmental toxicity observed in animals at doses less than the human clinical dose is a potential concern for human pregnancies. However, if indicated, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Amprenavir is an inhibitor of HIV type 1 (HIV-1) protease. Protease is an enzyme that is required for the cleavage of viral polyprotein precursors into active functional proteins found in infectious HIV. Amprenavir, in combination with other antiretroviral agents, is indicated for the treatment of HIV-1 infections.

In reproduction studies with amprenavir, doses two times the human clinical exposure based on AUC comparisons (HCE) in male and female rats had no effect on fertility or mating (1). During embryo and fetal development, doses 1/2 the HCE produced thymic elongation and incomplete ossification of bones. When administered from day 7 of gestation to day 22 of lactation, a dose two times the HCE was associated with reduced body weights. However, subsequent development of the offspring, including fertility and reproductive performance, was not affected (1). In rabbits, doses up to 1/20th the HCE were associated with abortions and minor skeletal variations resulting from deficient ossification of the femur, humerus trochlea, and humerus (1).

Amprenavir is transferred across rat and rabbit placentas to the fetus (1). In an ex vivo human placental model, the antiviral agent also readily crossed to the fetus but with a clearance index less than abacavir. No accumulation of the drug was measured (2). The placental transfer is consistent with the molecular

weight of amprenavir (about 506).

The Antiretroviral Pregnancy Registry reported, for the period January 1989 through July 2009, prospective data (reported before the outcomes were known) involving 4702 live births that had been exposed during the 1st trimester to one or more antiretroviral agents (3). Congenital defects were noted in 134, a prevalence of 2.8% (95% confidence interval [CI] 2.4–3.4). In the 6100 live births with earliest exposure in the 2nd/3rd trimesters, there were 153 infants with defects (2.5%, 95% CI 2.1–2.9). The prevalence rates for the two periods did not differ significantly. There were 288 infants with birth defects among 10,803 live births with exposure anytime during pregnancy (2.7%, 95% CI 2.4–3.0). The prevalence rate did not differ significantly from the rate expected in a nonexposed population. There were 38 outcomes exposed to amprenavir (28 in the 1st trimester and 10 in the 2nd/3rd trimesters) in combination with other antiretroviral agents. There was one birth defect among those exposed in the 1st trimester and none in those exposed in the 2nd/3rd trimesters. In reviewing the birth defects of prospective and retrospective (pregnancies reported after the outcomes were known) registered cases, the Registry concluded that, except for isolated cases of neural tube defects with efavirenz exposure in retrospective reports, there was no other pattern of anomalies (isolated or syndromic) (3). (See Lamivudine for required statement.)

A public health advisory was issued by the FDA on the association between protease inhibitors and diabetes mellitus (4). Because pregnancy is a risk factor for hyperglycemia, there was concern that these antiviral agents would exacerbate this risk. An abstract published in 2000 described the results of a study involving 34 pregnant women treated with protease inhibitors (none with amprenavir) compared with 41 controls that evaluated the association with diabetes (5). No association between protease inhibitors and an increased incidence of gestational diabetes was found.

Two reviews, one in 1996 and the other in 1997, concluded that all women currently receiving antiretroviral therapy should continue to receive therapy during pregnancy and that treatment of the mother with monotherapy should be considered inadequate therapy (6,7). The same conclusion was reached in a 2003 review with the added admonishment that therapy must be continuous to prevent emergence of resistant viral strains (8). In 2009, the updated U.S. Department of Health and Human Services guidelines for the use of antiretroviral agents in HIV-1-infected patients continued the recommendation that the therapy, with the exception of efavirenz, should be continued during pregnancy (9). If indicated, therefore, protease inhibitors, including amprenavir,

should not be withheld in pregnancy because the expected benefit to the HIV-positive mother outweighs the unknown risk to the fetus. Pregnant women taking protease inhibitors should be monitored for hyperglycemia. The updated guidelines for the use of antiretroviral drugs to reduce perinatal HIV-1 transmission also were released in 2010 (10). Women receiving antiretroviral therapy during pregnancy should continue the therapy but, regardless of the regimen, zidovudine administration is recommended during the intrapartum period to prevent vertical transmission of HIV to the newborn (10).

BREASTFEEDING SUMMARY

No reports describing the use of amprenavir during human lactation have been located. The antiviral agent is excreted into the milk of lactating rats (1). In addition, the molecular weight (about 506) is low enough that excretion into human breast milk should be expected.

Reports on the use of amprenavir during human lactation are unlikely because the antiviral agent is used in the treatment of HIV infections. HIV-1 is transmitted in milk, and in developed countries, breastfeeding is not recommended (6,7,9,11–13). In developing countries, breastfeeding is undertaken, despite the risk, because there are no affordable milk substitutes available. Until 1999, no studies had been published that examined the effect of any antiretroviral therapy on HIV-1 transmission in milk. In that year, a study involving zidovudine was published that measured a 38% reduction in vertical transmission of HIV-1 infection in spite of breastfeeding when compared with controls (see Zidovudine).

AMRINONE

Cardiac Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The data are too limited to assess the risk to the embryo–fetus. The drug probably crosses the placenta. If the maternal condition requires amrinone, it should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Amrinone is a cardiac inotropic agent that also has a vasodilatory effect (1). The drug is unrelated to cardiac glycosides or catecholamines. The principal indication for amrinone is the short-term management of congestive heart failure.

Amrinone is teratogenic in some animal species, producing skeletal and gross external malformations in one type of rabbits but not in other types, and having no effect on fetal rats (1). In pregnant baboons, amrinone infusion did not significantly affect uterine artery blood flow (2).

A single case report has described the use of amrinone in a human pregnancy (3). A 34-year-old woman at 18 weeks' gestation was treated with an amrinone IV infusion (0.5 mg/kg loading dose followed by 2 mcg/kg/minute) for refractory congestive heart failure secondary to bacterial endocarditis. A higher dose was not used because of premature ventricular contractions. Although no fetal adverse effects attributable to the drug were noted, fetal death occurred 11 days after discontinuance of amrinone because of the deteriorating medical condition of the mother (3).

BREASTFEEDING SUMMARY

No reports describing the use of amrinone during lactation have been located. The molecular weight of amrinone (about 187) is low enough, however, that

passage into milk should be expected.

AMYL NITRITE

Vasodilator

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The absence of specific human pregnancy experience prevents an assessment of the embryo–fetal risk. However, another vasodilator has limited data and does not appear to cause developmental toxicity (see Nitroglycerin). Transient decreases in maternal blood pressure may occur.

FETAL RISK SUMMARY

Amyl nitrite is a rapid-acting, short-duration vasodilator used primarily for the treatment of angina pectoris. Because of the nature of its indication, experience in pregnancy is limited. The Collaborative Perinatal Project recorded seven 1st trimester exposures to amyl nitrite and nitroglycerin, as well as eight other patients exposed to other vasodilators (1). From this small group of 15 patients, four malformed children were observed. It was not stated whether amyl nitrite was taken by any of the mothers of the affected infants. The number of cases is too small to assess the risk of amyl nitrite in pregnancy.

BREASTFEEDING SUMMARY

No reports describing the use of amyl nitrite during lactation have been located. It is doubtful if maternal use would represent any risk to a nursing infant.

ANAGRELIDE

Hematologic Agent (Antiplatelet)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Human pregnancy experience with anagrelide is limited. Except for one spontaneous abortion (SAB), all other outcomes were normal babies. Moreover, the animal data suggest low risk. The manufacturer recommends that women should not become pregnant while taking anagrelide, but the benefits of therapy must be weighed against the unknown risks on a case-by-case basis.

FETAL RISK SUMMARY

Anagrelide, an antiplatelet agent, is indicated for the reduction of elevated platelet counts and resulting risk of thrombosis in patients with thrombocythemia.

An animal teratology study observed no congenital abnormalities in pregnant rats given oral doses up to 730 times the maximum recommended human dose based on BSA (MRHD) or in pregnant rabbits administered doses up to 32 times the MRHD (1). In a fertility and reproductive performance study of female rats, however, doses 49 times the MRHD or higher disrupted implantation and produced an adverse effect on embryo–fetal survival (1). The same dosage in a perinatal and postnatal study with pregnant rats caused a delay in parturition, deaths of undelivered dams and their fetuses, and increased mortality in pups that were born (1).

No reports describing the placental transfer of anagrelide in animals or humans have been located. The molecular weight of the drug (about 275 for the free base) is low enough that passage to the embryo and/or fetus should be expected.

The first reported human pregnancy exposure to anagrelide appears to be

that described by the manufacturer in its product information (1). Five women became pregnant while receiving the drug at doses of 1–4 mg/day. Therapy was stopped when the pregnancies were diagnosed (timing not specified), and all the women delivered normal, healthy babies.

A 2001 report described 43 pregnancies in 20 women with essential thrombocythemia (ET) (2). Only one pregnancy involved exposure to anagrelide and that one ended in a 1st trimester SAB.

A 2004 case report described the outcome of a pregnancy in which anagrelide was used throughout (3). A 25-year-old woman had been diagnosed with essential thrombocythemia (ET) several years before conception and, because she did not tolerate interferon- α , she was maintained on anagrelide 4 mg/day. She was a heterozygous carrier of the factor V Leiden mutation. When pregnancy was recognized, her dose was reduced to 1 mg/day and low molecular weight heparin was started. Because preeclampsia developed at 32 weeks', an elective cesarean section was performed to deliver a 1400-g baby (no other data given). The infant had normal blood count parameters (3).

A 2005 report described two women with ET who became pregnant while receiving anagrelide (4). A 32-year-old woman was maintained on 1–4 mg/day, the dose adjusted to maintain a normal platelet count. She conceived against medical advice and eventually gave birth to a healthy 2.87-kg baby girl with no congenital defects and a normal full blood count. The second patient was a 28-year-old woman who was maintained on anagrelide 1.5–2.0 mg/day. Her pregnancy was discovered at 12 weeks' gestation. The drug was discontinued and she was maintained on low-molecular-weight heparin until she gave birth to a healthy full-term, 2.1-kg male baby with no congenital defects and a normal blood count (4).

A 32-year-old woman positive for the JAK2V617F mutation ET became pregnant while receiving anagrelide (5). The drug was discontinued in the third week and she was treated with aspirin for the remainder of pregnancy. At 39 4/7 weeks, a normal, healthy 2.8-kg baby girl was born with Apgar scores of 9 and 10. The infant's blood count was normal (5).

BREASTFEEDING SUMMARY

No reports describing the use of anagrelide during lactation have been located. The molecular weight of the compound (about 275 for the free base) is low enough that excretion into milk should be expected. The effect of this exposure on a nursing infant is unknown.

ANAKINRA

Immunologic Agent (Immunomodulator)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

One report has described the use of anakinra throughout pregnancy. The infant was severely growth-restricted, probably due to the mother's disease. No other developmental toxicity was noted. The animal data do not suggest a risk of structural defects, but the agent prevented embryo implantation in one study. Although the near absence of data prevents an assessment of the risk for the human embryo–fetus, interleukin-1 receptor antagonist (IL-1ra) is a natural occurring cytokine that appears to have a role in the protection of the placenta/embryo–fetus from the maternal immune response mechanisms. Therefore, it is doubtful if recommended doses of recombinant IL-1ra will cause direct toxicity to the embryo or fetus. Until human pregnancy data are available, however, the safest course is to avoid anakinra during gestation. Planned or inadvertent pregnancy exposure appears to represent a low risk for the embryo and fetus. If anakinra is used in pregnancy for the treatment of rheumatoid arthritis, health care professionals are encouraged to call the toll-free number (877-311-8972) for information about patient enrollment in the Organization of Teratology Information Specialists (OTIS) Rheumatoid Arthritis Study.

FETAL RISK SUMMARY

Anakinra is a nonglycosylated form of the human cytokine IL-1ra produced by recombinant DNA technology. Anakinra (recombinant IL-1ra) is indicated for the reduction in signs and symptoms of moderate to severe rheumatoid arthritis. By binding to interleukin-1 receptors, IL-1ra competitively inhibits interleukin-1 activity, such as the stimulation of several inflammatory mediators. The terminal

elimination half-life ranges from 4 to 6 hours (1).

Native IL-1ra is a normal constituent in the maternal, fetal, and amniotic fluid compartments (2,3). Endogenous IL-1ra has been measured in amniotic fluid and newborn urine. Fetal urine is a major source of the cytokine and is gender-dependent with the highest levels found in females. The investigators of one study concluded that the higher concentrations contributed to the better resistance of female fetuses against preterm birth and perinatal infections (3). Conversely, IL-1ra also has been shown to have partial agonist properties because it increases the prostaglandin E₂ (PGE₂) production of interleukin-1 β in fetal membranes that is involved in the initiation of parturition at term (4).

Reproduction studies have been conducted in rats and rabbits. No evidence of impaired fertility or fetal harm was observed in either species at doses up to 100 times the human dose (assumed to be based on weight). Animal carcinogenic studies have not been conducted with anakinra, but it was not mutagenic with in vitro and in vivo tests (1).

In contrast to the above animal data, recombinant IL-1ra has been shown in mice to impair embryonic implantation by a direct inhibitory effect on transformation of the epithelial plasma membrane (5,6). Further, the embryos were morphologically normal and were viable when transferred to pseudopregnant mice (6).

In a 1992 mouse study, interleukin-1-induced preterm delivery was blocked by IL-1ra (7). However, IL-1ra did not prevent preterm delivery or prolong pregnancy in mice with endotoxin-induced preterm labor (8).

A 2001 Australian study found evidence that polymorphisms in the gene encoding for endogenous IL-1ra were associated with recurrent miscarriage (three or more consecutive pregnancy losses before 20 weeks' gestation) (9). The study investigated 105 women with idiopathic recurrent miscarriage compared with 91 controls with a history of normal pregnancies and no pregnancy losses. Three alleles of IL-1ra polymorphisms were measured. Study subjects had a significantly higher level of polymorphic allele 2, suggesting that this was a genetic determinant of idiopathic recurrent miscarriage and that IL-1ra acted as a physiologic mediator. The study could not determine the degree of genetic IL-1ra deficiency that was associated with idiopathic recurrent miscarriage (9). In contrast, a 2003 Finnish study found that significantly higher levels of polymorphic allele 3 were associated with recurrent spontaneous abortion, suggesting that the allele frequencies varied considerably in different ethnic groups (10).

Anakinra crosses the rabbit placenta. The cervixes of pregnant rabbits were

inoculated with *Escherichia coli* and then the rabbits were given a 5-hour infusion of anakinra (10 mg/kg) (11). Although the treatment did not affect clinical or microbiological outcomes or amniotic fluid levels of tumor necrosis factor-alpha or prostaglandins (PGE₂), amniotic fluid concentrations of anakinra were markedly elevated compared with controls (14.8 ng/mL vs. none detected) (11).

An in vitro study was conducted using term human placentas obtained at cesarean section from uncomplicated pregnancies to determine if recombinant IL-1ra crossed the placenta (12). Both maternal-to-fetal and fetal-to-maternal directions were studied. Minimal transfer occurred in either direction. The findings appear to be consistent with the high molecular weight (17,300) of the 153-amino acid protein.

A 2009 case report described a 33-year-old woman with adult-onset Still disease who was treated with anakinra 100 mg/day throughout pregnancy (13). She gave birth at term to a severely growth-restricted (5th percentile), otherwise-normal 2700-g female infant with Apgar scores of 7, 8, and 9. Intrauterine growth restriction is a known complication of Still disease (see also Breastfeeding Summary) (13).

BREASTFEEDING SUMMARY

A 2009 report (see above) described the use of anakinra 100 mg/day during breastfeeding (13). The mother was treated throughout gestation and continued the therapy while breastfeeding. The small-for-gestational-age infant had appropriate growth (10th to 25th percentile) and normal psychomotor development (13).

Even though the molecular weight of the 153-amino acid cytokine is high (17,300), endogenous IL-1ra is excreted into colostrum and mature milk. In a 1996 study, concentrations of IL-1ra in colostrum were higher than those in milk (14). Both colostrum and milk had significantly higher concentrations than did maternal serum or plasma. The measurements of another 1996 study mirrored these findings of IL-1ra in colostrum, transitional milk, and mature milk (15). In the first study, the high milk concentrations persisted over a sequential collection period of 2–6 months (14). It was thought that the presence of natural IL-1ra contributed to the known anti-inflammatory properties of breast milk. Indeed, in a 2001 study, milk levels of IL-1ra in eight lactating women with acute mastitis were markedly increased (16). Because of the presence of native IL-1ra in milk, there appears to be no risk to a nursing infant from maternal administration of anakinra.

ANIDULAFUNGIN

Antifungal

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of anidulafungin in human pregnancy have been located. The animal reproduction data suggest low risk, but the absence of human pregnancy experience prevents a complete assessment of embryo–fetal risk. Moreover, there are no reports of human pregnancy experience with caspofungin and micafungin, the other agents in the class. Thus, the best course is to avoid anidulafungin in pregnancy, however, if the woman's condition requires it, the benefit probably outweighs the unknown risk. The lowest possible dose should be used.

FETAL RISK SUMMARY

Anidulafungin is a semisynthetic lipopeptide antifungal agent administered by IV infusion. It is an echinocandin, a class of antifungal agents that also includes caspofungin and micafungin. Anidulafungin is indicated for the treatment of candidemia and other forms of *Candida* infections. Although it does not undergo hepatic metabolism, anidulafungin does undergo chemical degradation at physiologic temperature and pH to inactive peptidic compounds that are subsequently degraded and eliminated. The *in vitro* degradation half-life of the drug under physiologic conditions is about 24 hours. The terminal elimination half-life is 40–50 hours, with excretion primarily in the feces. Plasma protein binding of anidulafungin is moderate (84%) (1).

Reproduction studies have been conducted in rats and rabbits. In pregnant rats given a dose up to two times the recommended human dose based on BSA (RHD), skeletal changes in rat fetuses were observed that included incomplete ossification of various bones and wavy, misaligned, or misshapen ribs. These effects, however, were not dose-related and were within the range of the

laboratory's historical control database. In pregnant rabbits, doses four times the RHD (the highest dose) were associated with slightly reduced fetal weights, but maternal toxicity was also noted (1).

Anidulafungin was not genotoxic in several tests. Carcinogenicity studies have not been conducted. There were no adverse effects on fertility from the drug in male and female rats given IV doses that were two times the RHD (1).

It is not known if anidulafungin can cross the human placenta. The molecular weight (about 1140) is high, but the long degradation half-life and moderate plasma protein binding suggest that transfer to the embryo and/or fetus might occur. Moreover, the recommended course of therapy involves daily IV doses for at least 14 days. Anidulafungin does cross the rat placenta and has been detected in fetal plasma (1).

BREASTFEEDING SUMMARY

No reports describing the use of anidulafungin during human lactation have been located.

The molecular weight (about 1140) is high, but the long degradation half-life and moderate plasma protein binding suggest that excretion into breast milk might occur. Moreover, the recommended course of therapy involves daily IV doses for at least 14 days. The effect on a nursing infant from potential exposure to the drug in milk is unknown. Dose-related histamine-mediated symptoms (rash, urticaria, flushing, pruritus, dyspnea, and hypotension) have been observed in adults receiving IV anidulafungin.

ANTHRALIN

Dermatologic Agent (Anti-Psoriatic)

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of anthralin in human pregnancy have been located. The lack of animal reproduction data and human pregnancy experience prevents an assessment of the embryo–fetal risk. However, a 2002 review of psoriasis in pregnancy stated that there was no evidence of systemic absorption or toxicity with topical anthralin (1). Thus, the embryo–fetal risk probably is nil.

FETAL RISK SUMMARY

Anthralin (dithranol) is a synthetic product used in creams and ointments for the topical treatment of psoriasis. It has been used in the treatment of psoriasis since 1916 (1). Reproduction studies in animals have not been conducted (2).

Either there is no systemic absorption of anthralin or the plasma concentrations are too low to detect. In either case, exposure of the embryo–fetus to clinically significant amounts of anthralin appears to be nil, despite the low molecular weight (about 226).

A case of contact dermatitis to dithranol (anthralin) in a woman at 7 months gestation was reported in 2003 (3). The dermatitis, due to inadvertent exposure, cleared rapidly after exposure was eliminated. No information on the pregnancy outcome was given.

BREASTFEEDING SUMMARY

No reports describing the use of anthralin during human lactation have been located. The molecular weight (about 226) is low enough for excretion into breast milk. However, either there is no systemic absorption of anthralin or the plasma concentrations are too low to detect. In either case, exposure of the

nursing infant to clinically significant amounts of anthralin appears to be nil.

ANTIPYRINE

Analgesic/Antipyretic

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

The absence of relevant animal reproduction data and the limited human pregnancy experience prevent an assessment of the embryo–fetal risk. The drug is best avoided in pregnancy because of its known toxicity in adults.

FETAL RISK SUMMARY

Because of its rare association with hemolytic anemia and agranulocytosis (1), antipyrine (phenazone), a prostaglandin synthesis inhibitor, is no longer available as a single agent. However, the drug is still available in some topical ear drops and in the prodrug, dichloralphenazone (see also Dichloralphenazone). This latter agent, a combination of chloral hydrate and antipyrine, is a component, along with isometheptene and acetaminophen, of several proprietary mixtures commonly used for tension and vascular (migraine) headaches (see also Isometheptene and Acetaminophen).

Although animal reproductive studies involving antipyrine have not been located, the drug has been used extensively in investigations of fetal metabolism in pregnant sheep as reviewed in a 1993 reference (2). That investigation found that antipyrine did not affect umbilical metabolism but did alter metabolism and blood flow distribution in the fetal lamb (2).

Eight cases of antipyrine exposure (presumably oral), among 27 women using a miscellaneous group of non-narcotic analgesics during the 1st trimester, were reported by the Collaborative Perinatal Project (3). From the 27 mother–child pairs, one infant had a congenital malformation (standard relative risk 0.46), but the specific agent the mother had taken was not identified.

In a double-blind, randomized study of neonatal jaundice prophylaxis, either antipyrine (N = 24), 300 mg/day or placebo (N = 24) was given from the 38th

week of gestation until delivery (4). The average duration of treatment in both groups was 15.5 days. The mean bilirubin concentration in the infants 4 days after birth was 62.6 $\mu\text{mol/L}$ in those exposed to antipyrine compared with 111.5 $\mu\text{mol/L}$ in the placebo group ($p < 0.005$). The authors attributed the decrease in bilirubin to the induction of glucuronyltransferase in the fetal liver, a known effect of antipyrine (4). No adverse effects in the newborns were observed.

BREASTFEEDING SUMMARY

Antipyrine (phenazone), a nonelectrolyte with a molecular weight <200 , freely diffuses into the aqueous phase of milk with a milk:plasma ratio of approximately 1.0 (5,6). No reports of its use during lactation have been located.

ANTITHROMBIN III (HUMAN)

Hematologic Agent (Thrombin Inhibitor)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Antithrombin III (human) has been used in the 2nd and 3rd trimesters for the treatment of preeclampsia. Preliminary evidence suggests that this treatment may be beneficial, but further studies are needed to confirm these outcomes. Although the limited animal data are reassuring, there is no human 1st trimester experience with this agent.

FETAL RISK SUMMARY

This product is prepared from pooled units of human plasma from screened normal plasma donors. Although the risk of transmitting infectious agents, such as viruses, has been reduced by measures taken during production, there is still a potential for transmitting disease (1). Antithrombin III is an α_2 -glycoprotein that normally is present in human plasma at a concentration of approximately 12.5 mg/dL (1). It is the major plasma inhibitor of thrombin.

Reproduction studies have been conducted with antithrombin III in pregnant rats and rabbits. No evidence of impaired fertility or fetal harm was observed with doses up to four times the human dose (1).

It is not known whether there are physiologic processes that can carry maternal antithrombin to the embryo or fetus. The molecular weight of the protein, about 58,000, should prevent passive diffusion.

Two reports have described the use of antithrombin III in the treatment of preeclampsia (2,3). In both cases, the beneficial effects of antithrombin III were theorized to be related to the inhibition of thrombin, resulting in a reduction in maternal hypertension and an increase in placental circulation (2,3). In a nonrandomized study, women with severe early-onset preeclampsia (mean gestational age at onset 28–29 weeks) with intrauterine growth restriction were

treated for 7 days with antithrombin III 1500 IU/day and heparin 5000 U/day (N = 14) or heparin 5000 U/day alone (N = 15) (2). None of the women received antihypertensive agents. The mean gestational age at the beginning of treatment was 30–31 weeks with delivery in both groups occurring at about 32 weeks' gestation. There was no difference in the mean birth weights (1280 vs. 1135 g), but the estimated fetal weight gain (g/day) was higher in the antithrombin group (29.5 vs. 15.3 g, $p < 0.05$). No information was provided on the status of the newborns, but there were no differences between the groups in the fetal biochemical profile score (2).

A total of 133 women with severe preeclampsia (24–35 weeks' gestation) were enrolled in a randomized, double-blind, placebo-controlled trial (3). The patients received either antithrombin III 3000 units once daily for 7 days (N = 66) or albumin once daily for 7 days (N = 67). The mean gestational age at the start of treatment was about 32 weeks in both groups. Treatment was interrupted in 23 and 29 patients in the antithrombin III and placebo groups, respectively, because of worsening of maternal and fetal findings. Patients in each group received antihypertensive agents and/or magnesium sulfate when indicated. There were no significant differences between the groups in the fetal biochemical profile score, but the antithrombin III group had a greater estimated fetal gain ($p = 0.029$). Pregnancy outcomes all favored the treatment group: gestational age at delivery (34.1 vs. 33.0 weeks, $p = 0.007$), birth weight (1749 vs. 1409 g, $p = 0.004$), and number of small-for-gestational-age newborns (65.6% vs. 83.3%, $p = 0.020$). No adverse effects in the newborns were observed (3).

BREASTFEEDING SUMMARY

No reports describing the use of antithrombin III during lactation have been located. The high molecular weight of the protein (about 58,000) suggests that it will not be excreted into breast milk. However, even if small amounts did enter the milk they likely would be digested in the infant's stomach. Therefore, the risk to a nursing infant from this agent appears to be nil.

APIXABAN

Anticoagulant

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of apixaban in human pregnancy have been located. The animal reproduction data suggest low risk, but the absence of human pregnancy experience prevents a complete assessment of the embryo–fetal risk. Maternal bleeding during pregnancy and at delivery, as well as fetal or newborn bleeding, is a risk because there is no established way to reverse the anticoagulant effect that may persist for about 24 hours. The treatment of deep venous thrombosis or pulmonary embolism is not an approved indication, and apixaban should not be used as heparin is the treatment of choice for these indications (1). However, if apixaban is the treatment of choice for its approved indication, it should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Apixaban is an oral, reversible, selective active site inhibitor of factor Xa in the same pharmacologic class as rivaroxaban. It is indicated to reduce the risk of stroke and systemic embolism in patients with nonvalvular atrial fibrillation. The agent is partially metabolized (about 25%) to inactive metabolites. Plasma protein binding is about 87%. The half-life is about 6 hours but, because of prolonged absorption, repeated dosing results in an effective half-life of about 12 hours (2).

Reproduction studies have been conducted in mice, rats, and rabbits. In these species that were given apixaban from implantation to the end of gestation, fetal exposures occurred but were not associated with an increased risk of fetal malformations or toxicity, or maternal or fetal deaths due to bleeding. However, an increased incidence of maternal bleeding in mice, rats,

and rabbits was observed at maternal exposures that were 19, 4, and 1 times, respectively, the human exposure of unbound drug based on AUC at the maximum human dose of 5 mg twice daily (MHD) (2).

Two-year studies in mice and rats observed no carcinogenicity. Various assays for mutagenic and clastogenic effects also were negative. No effect on fertility was observed in male or female rats given doses up to 3 and 4 times, respectively, the MHD. In rats given doses up to 5 times the MHD from implantation through the end of lactation, no adverse findings were observed in male offspring. Adverse effects in female offspring were decreased mating and fertility indices (2).

It is not known if apixaban crosses the human placenta. The molecular weight (about 460), partial metabolism, moderate plasma protein binding, and long effective half-life suggest that the drug will cross to the embryo–fetus. The drug does cross the rat placenta and distributes in fetal blood, liver, and kidney (3).

BREASTFEEDING SUMMARY

No reports describing the use of apixaban during human lactation have been located. The molecular weight (about 460), partial metabolism, moderate plasma protein binding (about 87%), and long effective half-life (about 12 hours) suggest that the drug will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown. However, bleeding (e.g., gastrointestinal, intracranial, intraocular) has been reported in adults and is potentially fatal. Therefore, the safest course is to not breastfeed if apixaban is taken.

APREPITANT

Antiemetic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of aprepitant in human pregnancy have been located. The animal data suggest low risk, even though low doses relative to the human dose were studied. Use of higher doses was not possible because of saturation of absorption in the animals. The absence of human pregnancy experience prevents a full assessment of the risk. Until additional data are available, the use of aprepitant, if indicated, should be restricted to the 2nd and 3rd trimesters. However, if inadvertent exposure does occur during organogenesis, the embryo–fetal risk appears to be low.

FETAL RISK SUMMARY

Aprepitant is an oral antiemetic indicated, in combination with other antiemetic agents, for the prevention of acute and delayed nausea and vomiting associated with highly emetogenic cancer chemotherapy, such as cisplatin. It is a selective high-affinity antagonist of human substance P/neurokinin 1 (NK₁). Protein binding to plasma protein is >95%. Aprepitant is extensively metabolized to relatively inactive compounds by cytochrome P450 isoenzymes (primarily CYP3A4). The elimination half-life ranges from 9 to 13 hours (1).

Reproduction studies have been conducted in rats and rabbits. In rats, oral doses up to about 1.6 times the human exposure in nonpregnant patients at the recommended dose based on AUC_{0–24 h} (HERD) revealed no evidence of impaired fertility or fetal harm. Similar results were observed in rabbits at doses up to about 1.4 times the HERD. Higher doses were not used because of saturation of absorption. In 2-year carcinogenicity studies, oral doses up to 0.4–1.4 times the HERD were carcinogenic in male and female rats. Oral doses up to 2.2–2.7 times the HERD were carcinogenic in male mice. No

mutagenicity was observed in various assays (1).

It is not known if aprepitant crosses the human placenta. The drug crosses the placenta in rats and rabbits and crosses the blood–brain barrier in humans (1). Although protein binding is high, the molecular weight (about 534) and elimination half-life suggest that the drug will cross the human placenta to the embryo and/or fetus.

BREASTFEEDING SUMMARY

No reports describing the use of aprepitant during human lactation have been located. The molecular weight (about 534) and elimination half-life (9–13 hours) suggest that the drug will be excreted into breast milk. However, the high plasma protein binding (>95%) should attenuate the amount excreted. The potential effect of this exposure on a nursing infant is unknown, but consideration should be given, especially if the exposure is prolonged, to the carcinogenic effects observed in animal studies.

APROBARBITAL

[Withdrawn from the market. See 8th edition.]

APROTININ

Hemostatic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports linking the use of aprotinin and congenital defects have been located. The drug crosses the placenta and decreases fibrinolytic activity in the newborn (1). The drug has been used safely in severe accidental hemorrhage with coagulation when labor was not established (2).

FETAL RISK SUMMARY

Aprotinin, a polypeptide, is a natural, broad-spectrum protease inhibitor obtained from bovine lung that is indicated for the prophylaxis of perioperative blood loss during cardiopulmonary bypass surgery. After IV administration, aprotinin undergoes rapid distribution into the total extracellular space and the plasma half-life, after the distribution phase, is about 150 minutes. The terminal half-life is about 10 hours (3).

Reproduction studies were conducted in rats with daily IV doses for 11 days up to 2.4 times the human dose based on body weight (HD-BW) or 0.37 times the human dose based on BSA (HD-BSA). Rabbits were given daily IV doses for 13 days up to 1.2 times the HD-BW or 0.36 times the HD-BSA. No effects on fertility or fetal harm were observed in either species (3).

BREASTFEEDING SUMMARY

No reports have been located describing the use of aprotinin during lactation. Because of the indication for this drug, the opportunity for breastfeeding following its use is probably nil. The oral absorption of this polypeptide is unknown, but most likely poor.

ARFORMOTEROL

Respiratory Drug (Bronchodilator)

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of arformoterol in human pregnancy have been located. The animal data suggest low risk, but the absence of human data prevents a complete assessment of the embryo–fetal risk. Although other β -adrenergic agonists are known to interfere with uterine contractions (e.g., see Terbutaline), such an effect from arformoterol is unlikely because of the very low systemic levels obtained from oral inhalation.

FETAL RISK SUMMARY

Arformoterol is a selective long-acting β_2 -adrenergic receptor agonist that acts as a bronchodilator. It is the (R,R)-enantiomer of formoterol and has twice the potency of racemic formoterol. (See also Formoterol.) Arformoterol is formulated as a solution that is administered by nebulization. Systemic bioavailability of arformoterol is very low with concentrations in the low pg/mL range in nonpregnant patients. The drug is extensively metabolized to inactive metabolites. Plasma protein binding (52%–65%) is moderate, but the mean terminal half-life (26 hours) is prolonged (1).

Reproduction studies have been conducted in rats and rabbits. In pregnant rats, oral doses that resulted in exposures about 370 times the adult exposure (AUC) at the maximum recommended daily inhalation dose (MRDID) caused omphalocele (umbilical hernia). At exposures of about 1100 times the MRDID, increased pup loss at birth and during lactation and decreased pup weights were observed. Delays in development were evident at about 2400 times the MRDID (1).

In pregnant rabbits, fetal malpositioned right kidney was noted at doses producing exposures that were about 8400 times the MRDID. Doses that were

about $\geq 22,000$ times the MRDID based on BSA (MRDID-BSA) caused brachydactyly, bulbous aorta, liver cysts, adactyly, lobular dysgenesis of the lung, and interventricular septal defect. At the highest dose (about 43,000 times the MRDID-BSA), embryoletality was observed. Decreased pup weights were noted at doses that were about 22,000 times the MRDID-BSA. There were no teratogenic findings at exposures of about ≤ 4900 times the MRDID (1).

Two-year studies for carcinogenicity have been conducted in mice (oral) and rats (inhalation). In female mice, there was a dose-related increase in the incidence of uterine and cervical endometrial stromal polyps and stromal cell sarcoma at exposures (AUC) of about 70 times the MRDID. In female rats, exposures that were about 130 times the MRDID caused an increased incidence of thyroid gland C-cell adenoma and carcinoma. No tumor findings occurred with exposures of about 55 times the MRDID. Arformoterol was not mutagenic or clastogenic in multiple assays. There were no effects on fertility or reproductive performance in rats given oral doses up to about 2700 times the MRDID-BSA (1).

It is not known if arformoterol crosses the human placenta. The molecular weight (about 345 for the free base), moderate plasma protein binding, and prolonged terminal half-life suggest that the drug will cross the placenta. However, because of the minimal amounts in the systemic circulation, this exposure appears to be clinically insignificant.

BREASTFEEDING SUMMARY

No reports describing the use of arformoterol during human lactation have been located. The molecular weight (about 345 for the free base), moderate plasma protein binding, and prolonged terminal half-life suggest that the drug will be excreted into breast milk. However, because of the minimal amounts in the systemic circulation, this exposure appears to represent no risk to a nursing infant.

ARGATROBAN

Hematologic Agent (Thrombin Inhibitor)

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential
Toxicity

PREGNANCY SUMMARY

Animal reproductive studies have not shown developmental toxicity, but the doses used were a small fraction of the human dose. The human pregnancy experience is limited to three case reports where argatroban was used in the 2nd and 3rd trimesters. No drug-induced toxicity, such as hemorrhage, was observed in the three exposed infants. Although there are no reports describing the use of argatroban in the 1st trimester, the lack of teratogenicity in animals and another agent in this subclass (see Lepirudin) is encouraging. Thus, if a pregnant woman requires argatroban therapy the benefits to her appear to outweigh the theoretical risks to the embryo or fetus.

FETAL RISK SUMMARY

Argatroban is a synthetic reversible direct thrombin inhibitor derived from L-arginine. It is in the same anticoagulant subclass as bivalirudin, desirudin, and lepirudin. Argatroban is indicated as an anticoagulant for prophylaxis or treatment of thrombosis in patients with heparin-induced thrombocytopenia (HIT). It is also indicated as an anticoagulant in patients with or at risk for HIT undergoing percutaneous coronary intervention. The drug is administered as a continuous IV infusion and undergoes partial metabolism in the liver. Total serum protein binding is 54%, with 20% bound to albumin and 34% to α_1 -acid glycoprotein. The terminal elimination half-life is 39–51 minutes (1).

Reproduction studies with IV argatroban have been conducted in pregnant rats and rabbits at doses up to 0.3 and 0.2 times, respectively, the maximum recommended human dose based on BSA. No evidence of impaired fertility or fetal harm was observed in either species (1).

It is not known if argatroban crosses the human placenta. The molecular weight (about 527 for the hydrated form), low metabolism, and moderate serum protein binding suggest that exposure of the embryo–fetus should be expected, especially since the drug is given as a continuous infusion.

The use of argatroban in the 2nd trimester was reported in 2008 (2). A 35-year-old woman with anemia secondary to myelodysplastic syndrome developed a deep vein thrombosis (location and extent not specified) in the 18th week of pregnancy and was treated with unfractionated heparin. Severe thrombocytopenia developed, which was subsequently shown to be caused by bone-marrow dysplasia and not heparin (HIT antibody was negative), and therapy was changed to daily IV doses of danaparoid. In the 22nd week of gestation, pulmonary embolism occurred after a leg massage. An emergency pulmonary embolectomy was performed under cardiopulmonary bypass to remove emboli from the right main pulmonary artery. Anticoagulation during surgery was maintained with argatroban. The woman recovered and eventually delivered a healthy infant by cesarean section at 29 weeks' gestation. No details on the infant were provided (2).

A second 2008 report described the use of argatroban in the 3rd trimester (3). A 26-year-old woman with a nonocclusive portal vein thrombosis and thrombocytopenia secondary to idiopathic thrombocytopenic purpura was treated with enoxaparin at 31 weeks' gestation. Two weeks later, because of worsening thrombocytopenia that initially was thought to be HIT but was later found not to be, treatment was changed to a continuous infusion of argatroban. Dexamethasone was given for 4 days before a scheduled cesarean section to increase the platelet count so that epidural anesthesia could be used. Argatroban was discontinued 7 hours before epidural anesthesia was successfully placed. A 3092-g male infant with Apgar scores of 8 and 9 at 1 and 5 minutes, respectively, was delivered. Examination of the infant revealed a small muscular ventricular septal defect with a patent foramen ovale; neither was due to argatroban. The infant had a normal platelet count at birth. At 6 months of age, the ventricular septal defect had resolved but he still had a patent foramen ovale (3).

Argatroban was used in a 38-year-old woman with an upper extremity deep vein thrombosis who had developed HIT late in the 2nd trimester (4). As the thrombus resolved, her therapy was changed to SC fondaparinux 7.5 mg/day, and this agent was continued until the day before scheduled induction. During labor she was given an IV infusion of argatroban and then discontinued several hours before combined spinal–epidural analgesia. She gave birth to a healthy,

3.8-kg male infant with Apgar scores of 8 and 8 at 1 and 5 minutes, respectively. No bleeding complications were reported in the infant (4).

A 31-year-old woman in her 12th week of pregnancy completely lost her vision in her right eye for 2 minutes (5). After an extensive workup, she was diagnosed with hypereosinophilic syndrome and started on heparin and prednisone. HIT developed and her anticoagulant therapy was changed to argatroban (dose not specified). The thrombocytopenia resolved and, after 15 days, she was discharged home on fondaparinux (75 mg/day) and a tapering dose of prednisone. About 6–7 months later she gave birth to a healthy female infant (no further infant details provided) (5).

In a 2012 case report, a 33-year-old woman, with a history of hereditary antithrombin deficiency, presented at 7 weeks' gestation with a deep venous thrombosis in her left leg due to the deficiency (6). She was treated with urokinase (24,000 units/day), heparin (20,000 units/day), and antithrombin concentrate (3000 units/day). Ten days later, at 9 weeks', HIT was diagnosed; heparin was discontinued and a continuous infusion of argatroban (2.5 mcg/kg/min) was started. At 21 weeks', argatroban was stopped and fondaparinux (2.5 mg/day) was started at 24 weeks'. Argatroban (2.5–3.5 mcg/kg/min) was restarted during labor induction at 37 weeks'. The patient gave birth to a 2800-g male infant with Apgar scores of 9 and 10 at 1 and 5 minutes, respectively. The newborn had 14% of antithrombin activity. The mother and her newborn were discharged home 15 days later (6).

BREASTFEEDING SUMMARY

No studies describing the use of argatroban during human lactation have been located. The molecular weight (about 527 for the hydrated form), low metabolism, and moderate serum protein binding suggest that the drug will be excreted into breast milk, especially as it is given as a continuous infusion. Both the effect of this exposure on a nursing infant and the potential for oral absorption are unknown. Severe adverse effects have been observed in adults, such as hypotension, fever, nausea/vomiting, and diarrhea (1). Thus, until human data are available, the safest course is to not breastfeed while receiving argatroban.

ARIPIPRAZOLE

Antipsychotic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Several case reports have described the use of aripiprazole in human pregnancy. No developmental toxicity was observed in these cases. The animal data suggest a risk of developmental toxicity and possibly teratogenicity, but the very limited human pregnancy experience prevents a complete assessment of the embryo–fetal risk. Until such data are available, the safest course is to avoid the drug in pregnancy. However, if the mother’s condition requires treatment with aripiprazole, the lowest effective dose, avoiding the 1st trimester if possible, should be used. In addition, long-term evaluation of the infant is warranted.

FETAL RISK SUMMARY

Aripiprazole is an antipsychotic used in the treatment of schizophrenia. Activity is due to both the parent drug and its active metabolite. Both are extensively (>99%) bound to serum proteins, primarily albumin. The mean elimination half-lives of aripiprazole and the active metabolite are about 75 and 94 hours, respectively (1,2). The drug is in the quinolinone subclass of antipsychotics that has no other members.

Reproduction studies have been conducted in rats and rabbits. Female rats were treated for 2 weeks before mating through day 7 of gestation with doses up to six times the maximum recommended human dose based on BSA (MRHD). Fertility was not impaired but increased pre-implantation loss was seen at a dose twice the MRHD or greater and decreased fetal weight was noted at six times the MRHD. In pregnant rats, a dose 10 times the MRHD given during organogenesis caused a slightly prolonged gestation, and a slight delay in fetal development, as evidenced by decreased fetal weight,

undescended testes, and delayed skeletal ossification. The latter effect was also seen at three times the MRHD. Some maternal toxicity was observed at 10 times the MRHD, but there was no evidence that the observed adverse effects were secondary to maternal toxicity (1,2). There were no effects on embryo, fetal, or pup survival, but offspring had decreased bodyweights (at 3 and 10 times the MRHD), and increased incidences of hepatodiaphragmatic nodules and diaphragmatic hernia (at 10 times the MRHD). Adverse effects in female offspring exposed in utero at 10 times the MRHD included delayed vaginal opening and impaired reproductive performance (decreased fertility rate, corpora lutea, implants, and live fetuses, and increased post-implantation loss). In perinatal and postnatal rat studies, a dose 10 times the MRHD given from day 17 of gestation through postpartum day 21 resulted in slight maternal toxicity and prolongation of gestation, increases in stillbirths, and decreases in pup weight (persisting into adulthood) and survival. Disturbances in spermatogenesis and prostate atrophy, but not impaired fertility, were observed in male rats given doses 13–19 times the MRHD from 9 weeks before mating through mating (1,2).

In rabbits, a dose 11 times the human exposure at the maximum recommended human dose based on AUC (HE) (up to 65 times the MRHD) during organogenesis resulted in decreased maternal food consumption and increased abortions. Other adverse effects noted were increased fetal mortality (at 11 times the HE), decreased fetal weight (at 3 and 11 times the HE), and increased incidences of skeletal abnormalities (fused sternebrae at 3 and 11 times the HE) and minor skeletal variations (at 11 times the HE) (1,2).

It is not known if aripiprazole or its active metabolite crosses the human placenta early in gestation. However, consistent with the molecular weight of the parent compound (about 448), combined with the prolonged elimination half-lives of aripiprazole and the active metabolite, both cross the placenta to the fetus at term (see case report below).

A 2006 case report described the use of aripiprazole in a 22-year-old woman with a 3-year history of paranoid schizophrenia (3). She had been treated with a variety of antipsychotics, including aripiprazole, but had stopped all therapy 1 year before conception. When her disease relapsed at 29 weeks' gestation, the woman was restarted on aripiprazole 10 mg/day and subsequently increased to 15 mg/day. After 85 days of therapy, the drug was stopped 6 days before spontaneous delivery at the end of week 37 of gestation. The normal, 2.6-kg male infant had Apgar scores of 9 and 10 at 1 and 5 minutes, respectively. He remained healthy at 6 months of age (3).

A second 2006 case report described a 27-year-old woman with schizophrenia who conceived while taking aripiprazole 15 mg/day (4). The woman stopped the drug during the 8th week of gestation. After a relapse during the 20th week of gestation, she restarted aripiprazole 10 mg/day and continued this dose throughout the remainder of her pregnancy. Fetal distress, including tachycardia, was noted at term and a healthy, 3.25-kg infant (sex not specified) was delivered by cesarean section. The infant was doing well at 6 months of age (4).

In a 2008 case report, a 24-year-old woman with schizoaffective disorder took aripiprazole 20 mg/day up to the time of conception and then discontinued the drug because she did not want to expose her fetus (5). She also had stopped her intermittent use of marijuana about 2 weeks before conception. At about 8 weeks', she experienced a severe relapse and aripiprazole was restarted and continued throughout pregnancy. At 40 weeks', she gave birth to a healthy, 3.24-kg male infant with Apgar scores of 9 and 9. The infant was doing well at 12 months of age (5).

Five other reports, similar to those above, have described the use of aripiprazole in six pregnancies (6–10). No adverse effects of the drug therapy were observed in the newborns. In one case, a woman taking aripiprazole 10 mg/day had an elective cesarean section at 39 weeks' gestation (9). At birth, samples were obtained from cord blood 8.6 hours after the last dose. The cord serum concentrations of aripiprazole and the active metabolite were 17 and 8 mcg/L, respectively, while the concentrations in the mother, taken 9.6 hours after dose, were 70 and 45 mcg/L, respectively. The cord:maternal ratios were 0.64 and 0.47, respectively (9).

BREASTFEEDING SUMMARY

In a case mentioned above, a woman taking aripiprazole 15 mg/day breastfed her newborn infant (6). Breast milk samples were collected on postpartum day 3 but the analysis for the drug was unsuccessful. On day 27, milk samples were collected 24 hours after the last dose (30 minutes before the next dose) and 4 and 10 hours after a dose. On day 28, the mother's serum concentrations of the parent drug and metabolite were 207 and 42 ng/mL, respectively. Neither aripiprazole nor its metabolite was detected in any of the three milk specimens. Based on a detection limit of 10 ng/mL, the milk:plasma ratios were <0.04. The estimated relative infant dose based on the mother's weight-adjusted dose was <0.7%. At 3 months of age, the infant was growing normally (6).

Although the above case was unable to find detectable milk concentrations of aripiprazole and its metabolite, confirmation of these results is warranted. Until such data are available, if a woman taking the drug chooses to breastfeed, the infant should be closely monitored for adverse effects. Recommendations for counseling breastfeeding mothers who are taking an antipsychotic drug were listed in a 2013 reference (11). Moreover, long-term evaluation of exposed infants is warranted.

ARMODAFINIL

Central Stimulant

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Other than the three cases reported by the manufacturer, no reports describing the use of armodafinil in human pregnancy have been located. Developmental toxicity was observed in two animal species at systemic exposures that were equal to or less than human plasma exposures. The near absence of human pregnancy experience prevents a better assessment of the embryo–fetal risk. Avoiding armodafinil during pregnancy is the best course. Inadvertent exposure does not appear to represent a major risk of embryo–fetal harm but, because of the two cases of intrauterine growth restriction, closer attention than usual to fetal growth might be appropriate.

FETAL RISK SUMMARY

Armodafinil is the R-enantiomer of modafinil which is a mixture of the R- and S-enantiomers (see also Modafinil). It is indicated to improve wakefulness in patients with excessive sleepiness associated with obstructive sleep apnea/hypopnea syndrome, narcolepsy, and shift-work sleep disorder. Armodafinil is a lipophilic agent that is extensively metabolized to apparently inactive metabolites. The drug is moderately bound (about 60%) to plasma proteins, primarily albumin, and the terminal half-life is about 15 hours (1).

Reproduction studies with armodafinil have been conducted in rats and, with modafinil, in rats and rabbits. In rats, daily oral doses of armodafinil given throughout the period of organogenesis resulted in increased incidences of fetal visceral and skeletal variations and decreased fetal body weights. The no-effect dose for rat embryo–fetal developmental toxicity was associated with a plasma exposure (AUC) that was about 0.03 times the AUC in humans at the

maximum recommended daily dose of 250 mg (MRDD) (1).

Daily oral doses of modafinil given to rats throughout organogenesis caused an increase in resorptions and increased incidences of visceral and skeletal variations. The no-effect dose for embryo–fetal developmental toxicity was associated with a plasma exposure (AUC) that was about 0.5 times the AUC in humans at the recommended daily dose of 200 mg (RHD). In another study, no developmental toxicity was observed at plasma modafinil exposure about 2 times the AUC at the RHD. However, when modafinil was given to rats throughout gestation and lactation, decreased viability in the offspring occurred with plasma exposures that were about 0.1 times the AUC at the RHD. No effects on postnatal developmental and neurobehavioral parameters were observed in surviving offspring (1).

In rabbits, daily oral doses of modafinil given throughout organogenesis caused increased incidences of fetal structural alterations and embryo–fetal death at the highest dose. The highest no-effect dose for developmental toxicity was associated with a plasma modafinil exposure that was about equal to the AUC at the RHD (1).

Carcinogenicity studies conducted with modafinil in mice and rats were negative. No evidence of mutagenic or clastogenic potential was found in multiple assays with armodafinil. Fertility studies in male and female rats with modafinil observed an increase in time to mate at the highest dose. The no-effect dose resulted in a plasma exposure that was about equal to the AUC in humans at the RHD (1).

It is not known if armodafinil crosses the human placenta. The molecular weight (about 273), lipophilic nature, moderate plasma protein binding, and long terminal half-life suggest that the drug will cross to the embryo–fetus.

The manufacturer mentioned two cases of intrauterine growth restriction, and one spontaneous abortion had been reported in association with armodafinil and modafinil, but it was not known if the outcomes were drug-related (1). (See also Modafinil.)

BREASTFEEDING SUMMARY

No reports describing the use of armodafinil during human lactation have been located. The molecular weight (about 273), lipophilic nature, moderate plasma protein binding (about 60%), and long terminal half-life (about 15 hours) suggest that the drug will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown. If a lactating woman uses armodafinil, her infant should be closely observed for adverse effects that are commonly

seen in adults (i.e., headache, nausea, dizziness, anxiety, and insomnia).

ARNICA

Herb

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of arnica in human pregnancy have been located. The herb should not be used in pregnancy as it is a uterine stimulant that has been used traditionally as an abortifacient (1).

FETAL RISK SUMMARY

Arnica is a perennial plant that has bright yellow, daisy-like flowers that, when dried, are the primary parts used, but the roots and rhizomes also are used. The herb has been used medicinally for hundreds of years, especially in Europe. The herb and its extracts have been used as a topical treatment for skin conditions and wounds and are often used in cosmetic formulations. However, clinical evidence to support its use as an anti-inflammatory or analgesic is lacking. The FDA has classified arnica as an unsafe herb when used orally, in which case it is considered a poison, or applied to broken skin where absorption could occur. It is possibly safe when used in amounts commonly found in foods. A large number of chemicals are found in arnica, including flavonoids glycosides, isomeric alcohols, terpenoids (including sesquiterpene lactones), amines, coumarins, carbohydrates, volatile oils, fatty acids, and other compounds. The active ingredients are the sesquiterpene lactones (1–3).

No carcinogenicity, reproductive, or developmental toxicity data are available (3).

In homoeopathic formulations, arnica has been promoted for use before and during labor as helpful for internal and external bruising of both the mother and newborn infant (4). In a survey of 1044 Italian women, 491 (47%) reported that they had taken or were taking one or more herbals in the last year, sometimes during pregnancy (5). Arnica was among the top 10 herbs taken by the women.

BREASTFEEDING SUMMARY

Although it has not been studied, an abstract describing toxicity in a nursing infant suggests that some of the chemicals in arnica are excreted into human milk. A 9-day-old term male infant who was exclusively breastfed presented with a 1-day history of lethargy, decreased milk intake, anemia, and jaundice (6). The mother, who was asymptomatic, had started drinking a tea made from arnica flowers 48 hours before the onset of symptoms. No reason for the infant's jaundice was found on workup. A screening test in the infant for glucose-6-phosphate dehydrogenase (G6PD) was normal. Exchange transfusions were used to lower the bilirubin and correct the infant's anemia. The mother stopped drinking the tea and resumed breastfeeding, and no further hemolysis or other problems were noted in the infant (6).

ASENAPINE

Antipsychotic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of asenapine in human pregnancy have been located. There is no evidence of embryo–fetal harm with other agents in this subclass. However, because of the very limited human pregnancy experience with atypical antipsychotics, the American College of Obstetricians and Gynecologists does not recommend the routine use of these agents in pregnancy, but a risk benefit assessment may indicate that such use is appropriate (1). Until human data are available, the use of other antipsychotics in pregnancy should be considered. Nevertheless, asenapine is indicated for severe debilitating mental disease and the benefits to the mother will probably outweigh the unknown embryo–fetal risk. A 1996 review on the management of psychiatric illness concluded that patients with histories of chronic psychosis represent a high-risk group (for both the mother and the fetus) and should be maintained on pharmacologic therapy before and during pregnancy (2). Folic acid 4 mg/day has been recommended for women taking atypical antipsychotics because they may have a higher risk of neural tube defects due to inadequate folate intake and obesity (3).

FETAL RISK SUMMARY

Asenapine is an atypical antipsychotic agent that is available for sublingual administration. It is indicated for the acute treatment of schizophrenia in adults. Asenapine belongs to the antipsychotic subclass of dibenzapine derivatives that includes clozapine, loxapine, olanzapine, and quetiapine. It is metabolized and eliminated as inactive metabolites. The mean terminal half-life is about 24 hours. Asenapine is highly bound (95%) to plasma proteins, including albumin

and α 1-acid glycoprotein (4).

Animal reproduction studies have been conducted in rats and rabbits. In these species, asenapine was not teratogenic at IV doses up to 0.7 and 0.4 times, respectively, the maximum recommended human dose of 10 mg twice daily given sublingually based on BSA (MRHD). In rabbits, the highest dose produced plasma levels (AUC) that were twice the human levels resulting from the MRHD. Increases in post-implantation loss and early pup deaths were observed in rats given daily IV doses that were 0.15–0.7 times the MRHD from gestation day 6 through postpartum day 21. Decreases in pup survival and weight gain were seen at IV doses that were 0.4 and 0.7 times the MRHD. Oral dosing had the same effects. The decreases in pup survival were largely due to prenatal drug effects (4).

Lifetime carcinogenicity studies have been conducted in mice and rats. In female mice given SC doses resulting in plasma levels (AUC) that were about 5 times the human levels resulting from the MRHD, an increased incidence of malignant lymphomas was observed. However, the mouse strain used had a high and variable incidence of this cancer, and the significance of this finding to humans is unknown. The no-effect dose was about 1.5 times the human levels resulting from the MRHD. No tumors were observed in male mice or in rats. No evidence of genotoxic potential was found in several tests. In rats, doses up to 10 times the MRHD had no effect on fertility (4).

It is not known if asenapine crosses the human placenta. The molecular weight (about 286 for the free base) and the long terminal elimination half-life suggest that the drug will cross to the embryo–fetus, even though the high plasma protein binding may limit the exposure.

BREASTFEEDING SUMMARY

No reports describing the use of asenapine during human lactation have been located. The molecular weight (about 286 for the free base) and the long terminal elimination half-life (about 24 hours) suggest that the drug will be excreted into breast milk, even though the high (95%) plasma protein binding might limit the exposure. The effect of this exposure on a nursing infant is unknown, but they should be monitored for the most common adverse reactions observed in adults (somnolence, dizziness, akathisia, and oral hypoesthesia).

The manufacturer recommends women receiving asenapine should not breastfeed (4). Moreover, the American Academy of Pediatrics classifies other atypical antipsychotics (e.g., see Clozapine) as drugs whose effect on the nursing infant is unknown but may be of concern (5).

Because of the very limited human experience with atypical antipsychotics, the American College of Obstetricians and Gynecologists does not recommend the routine use of these agents during lactation, but a risk–benefit assessment may indicate that such use is appropriate (1).

ASPARAGINASE

Antineoplastic

PREGNANCY RECOMMENDATION: Human and Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Based on limited reports in humans, the use of asparaginase, in combination with other antineoplastics, does not seem to pose a major risk to the fetus when used in the 2nd and 3rd trimesters, or when exposure occurs before conception in either women or men. No reports describing the use of only asparaginase in pregnancy have been located. Because of the teratogenicity observed in animals and the lack of human data after 1st trimester exposure, asparaginase should be used cautiously during this period, if at all.

FETAL RISK SUMMARY

The antineoplastic agent asparaginase, which is used in the treatment of certain types of cancers, contains the enzyme, L-asparagine amidohydrolase, type EC-2, derived from *Escherichia coli* (1).

The drug is teratogenic in rabbits, rats, and mice (1–3). In pregnant rabbits given 50 IU/kg (5% of the human dose), asparaginase crossed the placenta and produced malformations of the lung, kidney, and skeleton; spina bifida; abdominal extrusion; and missing tail (2). Doses of 1000 IU/kg (equal to the human dose) or more in rats and mice produced exencephaly and skeletal anomalies (3). Maternal and fetal growth restriction have also been observed in pregnant rats and mice treated with 1000 IU/kg (1).

The reported use of asparaginase during human pregnancy is limited to six pregnancies, all in the 2nd trimester, resulting in the birth of seven infants (one set of twins) (4–9). In each case, multiple other chemotherapeutic agents were used with asparaginase for treatment of the acute leukemias. Therapy with asparaginase was initiated between 16.5 and 22 weeks of pregnancy. No congenital abnormalities were observed in any of the newborn infants, although

two newborns had transient, drug-induced bone marrow hypoplasia (4,5). One 34-year-old mother, with acute lymphoblastic leukemia, was treated for 18 weeks, commencing at 22 weeks' gestation, with various combinations of asparaginase, daunorubicin, vincristine, cytarabine, cyclophosphamide, mercaptopurine, and methotrexate (9). Asparaginase, 5000 U/m²/day, was administered on days 15–28 of therapy. She gave birth to a normal female infant after 40 weeks' gestation. The newborn had a normal karyotype (46,XX) but with gaps and a ring chromosome. The clinical significance of these findings is unknown, but because these abnormalities may persist for several years, the potential exists for an increased risk of cancer as well as for a risk of genetic damage in the next generation (9).

A number of reports have evaluated the reproductive histories of men and women who were exposed to asparaginase and multiple other antineoplastic agents before conception (10–15). Of the 13 men described, 9 fathered 15 children (10–13), including 1 who fathered a child while receiving therapy (10). Two congenital anomalies were observed; one infant had a birthmark (13), and one newborn had multiple anomalies (11). In the latter case, the man, who had been off therapy for at least 3.5 years, also fathered a normal child (11). No relationship between these outcomes and the fathers' exposure to either asparaginase or the other chemotherapeutic agents can be inferred from the two cases.

In 57 women treated with asparaginase and other agents 2 months to 15 years before conception, a total of 83 pregnancies occurred, resulting in 5 spontaneous abortions, 5 elective abortions, 2 stillbirths, and 71 liveborn infants (10,12–15). Among the liveborn infants, four were delivered prematurely, one was growth-restricted, and seven had congenital defects, four minor and three major. The minor abnormalities were an epidermal nevus (13), dark hair patch (14), ear tag (14), and congenital hip dysplasia (15). Infants with major defects were the offspring of women who had been treated 15–24 months before conception with asparaginase, chlorambucil, mercaptopurine, methotrexate, procarbazine, thioguanine, vinblastine, vincristine, and prednisone (14). The defects were hydrocephalus, tracheomalacia, and pelvic asymmetry. The authors concluded that the latter defect was most likely a deformation, resulting from the mother's scoliosis or from uterine scarring caused by radiation, rather than a mutagenic effect of drug therapy (14). Causes for the other two defects were not proposed, but they were not thought to be the result of germ cell damage.

BREASTFEEDING SUMMARY

No reports describing the use of asparaginase during human lactation have been located. Toxicity in a nursing infant is a potential complication if a mother receiving this drug chooses to breastfeed.

ASPARTAME

Artificial Sweetener

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible (Excluding Those with Phenylketonuria)

PREGNANCY SUMMARY

Ingestion of aspartame-sweetened products during pregnancy does not represent a risk to the fetuses of normal mothers, or of mothers either heterozygous for or who have phenylketonuria (PKU). Elevated plasma levels of phenylalanine, an amino acid that is concentrated in the fetus, are associated with fetal toxicity. Whether a toxic threshold exists for neural toxicity or the toxicity is linear with phenylalanine plasma levels is not known. Women with PKU need to control their consumption of any phenylalanine-containing product. Because aspartame is a source of phenylalanine, although a minor source, this should be considered by these women in their dietary planning. The other components of aspartame—methanol and aspartic acid—and the various degradation products have no toxicity in doses that can be ingested by humans.

FETAL RISK SUMMARY

Aspartame is a nutritive sweetening agent used in foods and beverages. It contains 4 kcal/g and is about 180–200 times as sweet as sucrose. The product was discovered in 1965 and obtained final approval by the FDA as a food additive in certain dry foods in 1981 and in carbonated beverages in 1983 (1). Aspartame is probably the most extensively studied food additive ever approved by the FDA (2,3). Chemically, the compound is N-L- α -aspartyl-L-phenylalanine, 1-methyl ester (i.e., the methyl ester of the amino acids L-phenylalanine and L-aspartic acid).

Aspartame is broken down in the lumen of the gut to methanol, aspartate, and phenylalanine (1–4). The major decomposition product when the parent compound is exposed to high temperatures or in liquids is aspartyl-phenylalanine diketopiperazine (DKP), a product formed by many dipeptides

(3–5). The rate of conversion of aspartame to degradation products depends on pH and temperature (3). In addition to methanol, the two amino acids, and DKP, other degradation products are L,L- β -aspartame (aspartame is commercially available as the L,L- α isomer), three dipeptides (α -Asp-Phe, β -Asp-Phe, and Phe-Asp), and phenylalanine methyl ester (3). The dipeptide compounds are hydrolyzed to the individual amino acids in the gut, and these, along with methanol, will be evaluated in later sections. None of the other degradation products have shown toxic effects after extensive study (3). Moreover, the DKP compound and the β -isomer of aspartame are essentially inactive biologically (3).

The projected maximum ingestion of aspartame has been estimated to be 22–34 mg/kg/day. The higher dose is calculated as the 99th percentile of projected daily ingestion (2). The 22–34 mg/kg dose range is equivalent to 2.4–3.7 mg/kg/day of methanol, 9.8 mg/kg/day of aspartate, and 12–19 mg/kg/day of phenylalanine (2). The FDA has set the allowable or acceptable daily intake (ADI) of aspartame at 50 mg/kg (1.5 times the 99th percentile of projected daily ingestion) (1,3). In Europe and Canada, the ADI is 40 mg/kg (3). The ADI is defined as an average daily ingestion that is considered harmless, even if continued indefinitely, but does not imply that amounts above this value are harmful (3).

The toxic effects of methanol ingestion are the result of its metabolism to formaldehyde and then to formic acid. Accumulation of this latter product is responsible for the acidosis and ocular toxicity attributable to methanol (1–3). The dose of methanol estimated to cause significant toxicity is estimated to be 200–500 mg/kg (4). Theoretically, since about 10% of aspartame is methanol, the toxic dose of aspartame, in terms only of methanol, would be about 2000 mg/kg, a dose considered far in excess of any possible ingestion (4). In 12 normal subjects, methanol plasma levels were below the level of detection (0.4 mg/dL) after ingestion of aspartame, 34 mg/kg (3). When abuse doses (100, 150, and 200 mg/kg) of aspartame were administered, statistically significant increases in methanol blood concentrations were measured with peak levels of 1.27, 2.14, and 2.58 mg/dL, respectively (3). Methanol was undetectable at 8 hours after the 100-mg/kg dose, but was still present after the higher aspartame doses. Blood and urine formate concentrations were measured after ingestion of 200 mg/kg of aspartame in six healthy subjects (3). No significant increases in blood formate levels were measured, but urinary formate excretion did increase significantly. This indicated that the rate of formate synthesis did not exceed the rate of formate metabolism and excretion

(3). No ocular changes or toxicity were observed in the test subjects (3). Moreover, the amount of methanol (approximately 55 mg/L) derived from aspartame-sweetened beverages, containing approximately 555 mg/L of aspartame, is much less than the average methanol content of fruit juices (140 mg/L) (2). Based on the above data, the risk to the fetus from the methanol component of aspartame is nil.

Aspartate is one of two dicarboxylic amino acids (glutamate is the other) that have caused hypothalamic neuronal necrosis in neonatal rodents fed large doses of either the individual amino acids or aspartame (2,5). In neonatal mice, plasma concentrations of aspartate and glutamate must exceed 110 and 75 micro-mol/dL, respectively, before brain lesions are produced (2). Concerns were raised that this toxicity could occur in humans, especially because glutamate is widespread in the food supply (e.g., monosodium glutamate [MSG]) (6). In addition, some aspartate is transaminated to glutamate, and the neural toxicity of the two amino acids is additive (6). However, brain lesions were not produced in nonhuman primates fed large doses of aspartame, aspartate, or MSG (2).

In normal humans, ingestion of aspartame, 34 mg/kg, or equimolar amounts of aspartate, 13 mg/kg, did not increase plasma aspartate levels (7). Adults heterozygous for PKU also metabolized aspartate normally as evidenced by insignificant increases in plasma aspartate concentrations and unchanged levels of those amino acids that could be derived from aspartate, such as glutamate, asparagine, and glutamine (8). When the dose of aspartame was increased to 50 mg/kg, again no increase in plasma aspartate levels was measured (9). When an abuse dose of aspartame, 100 mg/kg, was administered to adults heterozygous for PKU, plasma aspartate levels increased from a baseline of 0.49–0.80 micro-mol/dL (10). The increase was well within the range of normal postprandial levels. In normal adults given a higher abuse dose of aspartame (200 mg/kg), plasma levels of aspartate plus glutamate were increased from a baseline of 2.7–7 micro-mol/dL, still far below the estimated toxic human plasma level of 100 micro-mol/dL for aspartate and glutamate (7). Plasma aspartate levels at 2 hours after the 200-mg/kg dose were less than normal postprandial aspartate levels after a meal containing protein (1). Based on these data, subjects heterozygous for PKU metabolize aspartate normally (2). Moreover, neither aspartate nor glutamate is concentrated in the fetus, unlike most other amino acids (1,2,5,11,12). Human placentas perfused in vitro showed a fetal:maternal ratio of 0.13 for aspartic acid and 0.14 for glutamic acid (11). In pregnant monkeys infused with sodium aspartate, 100 mg/kg/hour,

maternal plasma aspartate levels increased from 0.36 to 80.2 micro-mol/dL, whereas fetal levels changed from 0.42 to 0.98 micro-mol/dL (12). Thus, there is no evidence of a risk of fetal aspartate toxicity resulting from maternal ingestion of aspartame, either alone or in combination with glutamate.

High plasma levels of phenylalanine, such as those occurring in PKU, are known to affect the fetus adversely. Phenylalanine, unlike aspartate, is concentrated on the fetal side of the placenta with a fetal:maternal gradient of 1.2:1–1.3:1 (13). The fetus of a mother with PKU may either be heterozygous for PKU (i.e., those who only inherit one autosomal recessive gene and who are nonphenylketonuric) or homozygous for PKU (i.e., those who inherit two autosomal recessive genes and who are phenylketonuric). The incidence of PKU is approximately 1/15,000 persons (5). In contrast, individuals heterozygous for PKU are much more common, with an estimated incidence of 1/50–1/70 persons (8). In the former case, the fetus has virtually no ($\leq 0.3\%$) phenylalanine hydroxylase activity and is unable to metabolize phenylalanine to tyrosine, thus allowing phenylalanine to accumulate to toxic levels (14). The heterozygous fetus does possess phenylalanine hydroxylase, although only about 10% of normal, with activity of the enzyme detected in the fetal liver as early as 8 weeks' gestation (13,14). Unfortunately, possession of some phenylalanine hydroxylase activity does not reduce the amount of phenylalanine transferred from the mother to the fetus (13). In a study of four families, evidence was found that the heterozygous fetus either did not metabolize the phenylalanine received from the mother or metabolism was minimal (13). This supported previous observations that the degree of mental impairment from exposure to high, continuous maternal levels of phenylalanine is often similar for both the nonphenylketonuric and phenylketonuric fetuses (13). Moreover, the exact mechanism of mental impairment induced by elevated phenylalanine plasma levels has not been determined (4,15,16).

Offspring of women with PKU often are afflicted with mental retardation, microcephaly, congenital heart disease, and low birth weight (16). Pregnancies of these women are also prone to spontaneously abort (16). In one study, maternal phenylalanine plasma levels >120 micro-mol/dL (classic PKU) were consistently associated with microcephaly, although true mental retardation was observed only when plasma levels exceeded 110 micro-mol/dL (16). However, research has not excluded the possibility that lower concentrations may be associated with less severe reductions in intelligence (16–18). For example, in the study cited above, maternal phenylalanine levels <60 $\mu\text{mol/dL}$ (mild hyperphenylalaninemia without urine phenylketones) were associated with

normal intelligence in the infants (16). When maternal levels were in the range of 60–100 micro-mol/dL (atypical PKU), most of the infants also had normal intelligence, but their mean IQ was lower than that of the infants of mothers with mild hyperphenylalaninemia. Others have interpreted these and additional data as indicating a 10.5 point reduction in IQ for each 25.0 micro-mol/dL rise in maternal phenylalanine plasma concentration (19,20). A recent study, however, examined the nonhyperphenylalaninemic offspring of 12 mothers with untreated hyperphenylalaninemia (21). The results supported the contention that a maternal plasma phenylalanine threshold of 60 micro-mol/dL existed for an adverse effect on the intelligence of the offspring (21). The investigators, however, were unable to exclude the possibility that nonintellectual dysfunction, such as hyperactivity or attention deficit disorder, may occur at concentrations below the alleged threshold (21). Thus, although this latest study is evidence for a threshold effect, additional studies are needed before the concept of a linear relationship between offspring intelligence and maternal phenylalanine levels can be set aside (19,20,22–24).

In normal subjects, fasting and postprandial (after a meal containing protein) phenylalanine levels are approximately 6 and 12 micro-mol/dL, respectively (2,8). When normal adults were administered either a 34- or 50-mg/kg aspartame dose, the mean maximum phenylalanine concentrations were 9–12 and 16 micro-mol/dL, respectively, with levels returning to baseline 4 hours after ingestion (2,7–9). Single doses of 100–200 mg/kg, representing abuse ingestions of aspartame, resulted in peak phenylalanine plasma levels ranging from 20 to 49 micro-mol/dL (2,25). These elevated levels returned to near baseline values within 8 hours. Normal adults were also dosed with an aspartame-sweetened beverage, providing a 10-mg/kg dose of aspartame, at 2-hour intervals for three successive doses (2,26). Plasma levels of phenylalanine rose slightly after each dose, indicating that the phenylalanine load from the previous dose had not been totally eliminated. However, the increases were not statistically significant, and plasma phenylalanine levels never exceeded normal postprandial limits at any time (26). The results of the above studies suggest that even large doses of aspartame do not pose a fetal risk in the normal subject.

Humans heterozygous for the PKU allele metabolize phenylalanine slower than normal persons because of a decreased amount of liver phenylalanine hydroxylase (2). The conversion of phenylalanine to tyrosine is thus impaired, and potentially toxic levels of phenylalanine may accumulate. When adults with this genetic trait were administered aspartame, 34 mg/kg, the mean peak

phenylalanine concentration was 15–16 micro-mol/dL, approximately 36%–45% higher than that measured in normal adults (11 micro-mol/dL) (2,8,27). To determine the effects of abuse doses, a dose of 100 mg/kg was administered, resulting in a mean peak plasma level of 42 micro-mol/dL, approximately 100% higher than that observed in normal individuals (20 micro-mol/dL) (2,10). In both cases, phenylalanine plasma levels were well below presumed toxic levels and returned to baseline values within 8 hours.

A 1986 study examined the effects of a 10-mg/kg dose of aspartame obtained from a commercial product on the basal concentrations of several amino acids, including phenylalanine, in four types of patients: normal, PKU, hyperphenylalaninemic, and PKU carriers (28). One hour after ingestion, mean phenylalanine levels had increased 1.35 micro-mol/dL (+30%) in normal subjects and 1.35 micro-mol/dL (+20%) in PKU carriers, decreased 4.58 micro-mol/dL (-3%) in subjects with PKU, and remained unchanged in hyperphenylalaninemic individuals. The 10-mg/kg dose was selected because it represented, for a 60-kg adult, the dose received from three cans of an aspartame-sweetened soft drink or from approximately 1 quart of aspartame-sweetened Kool-Aid (28).

BREASTFEEDING SUMMARY

Ingestion of aspartame, 50 mg/kg, by normal lactating women results in a small, but statistically significant, rise in overall aspartate and phenylalanine milk concentrations (9). Milk aspartate levels rose from 2.3 to 4.8 micro-mol/dL during a 4-hour fasting interval after the aspartame dose. The rise in phenylalanine milk levels during the same interval was approximately 0.5–2.3 micro-mol/dL. The investigators of this study concluded that these changes, even if spread over an entire 24-hour period, would have no effect on a nursing infant's phenylalanine intake (9). However, because mothers or infants with PKU need to carefully monitor their intake of phenylalanine, the American Academy of Pediatrics classifies aspartame as an agent to be used with caution during breastfeeding if the mother or the infant has PKU (29).

ASPIRIN

Nonsteroidal Anti-inflammatory

PREGNANCY RECOMMENDATION: Compatible (Low-Dose) Human Data Suggest Risk in 1st and 3rd Trimesters (Full-Dose)

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

The use of aspirin during pregnancy, especially of chronic or intermittent high doses, should be avoided. The drug may affect maternal and newborn hemostasis mechanisms, leading to an increased risk of hemorrhage. High doses may be related to increased perinatal mortality, intrauterine growth restriction (IUGR), and teratogenic effects. Low doses, such as 80 mg/day, appear to have beneficial effects in pregnancies complicated by systemic lupus erythematosus with antiphospholipid antibodies. In pregnancies at risk for the development of gestational hypertension and preeclampsia, and in fetuses with IUGR, low-dose aspirin (40–150 mg/day) may be beneficial, but more studies are required to assess accurately the risk:benefit ratio of such therapy. Near term, aspirin may prolong gestation and labor. Although aspirin has been used as a tocolytic agent, serious bleeding complications may occur in the newborn. Premature closure of the ductus arteriosus may occur in the latter part of pregnancy as a result of maternal consumption of full-dose aspirin. Persistent pulmonary hypertension of the newborn (PPHN) is a potential complication of the closure. If an analgesic or antipyretic is needed, acetaminophen should be considered.

FETAL RISK SUMMARY

Aspirin, a nonsteroidal anti-inflammatory drug (NSAID), is the most frequently ingested drug in pregnancy either as a single agent or in combination with other drugs (1). The terms “aspirin” and “salicylate” are used interchangeably in this monograph unless specifically separated. In eight surveys totaling more than 54,000 patients, aspirin was consumed sometime during gestation by slightly

more than 33,000 (61%) (2–9). The true incidence is probably much higher than this because many patients either do not remember taking aspirin or consume drug products without realizing that they contain large amounts of salicylates (2,4,8). Evaluation of the effects of aspirin on the fetus is thus difficult because of this common, and often hidden, exposure. However, some toxic effects on the mother and the fetus from large doses of salicylates have been known since 1893 (10).

Aspirin consumption during pregnancy may produce adverse effects in the mother: anemia, antepartum or postpartum hemorrhage, prolonged gestation, and prolonged labor (5,11–14). The increased length of labor and frequency of postmaturity result from the inhibition of prostaglandin synthesis by aspirin. Aspirin has been shown to significantly delay the induced abortion time in nulliparous (but not multiparous) patients by this same mechanism (15). In an Australian study, regular aspirin ingestion was also found to increase the number of complicated deliveries (cesarean sections, breech, and forceps) (5). Small doses of aspirin may decrease urinary estriol excretion (16).

Aspirin, either alone or in combination with β -mimetics, has been used to treat premature labor (17–19). Although adverse effects in the newborn were infrequent, maternal complications in one study included non-dose-related prolonged bleeding times and dose-related vertigo, tinnitus, headache, and hyperventilation (19).

Failure of intrauterine devices (IUDs) to prevent conception has been described in two patients who consumed frequent doses of aspirin (20). The anti-inflammatory action of aspirin was proposed as the mechanism of the failure.

Low-dose aspirin (about 85 mg/day) was used to treat maternal thrombocytopenia (platelet counts $<60,000/\text{mm}^3$) in 19 patients with either IUGR or toxemia (21). In five women who had a definite response to the aspirin, no improvement in plasma volume or fetal welfare was demonstrated.

In women with systemic lupus erythematosus complicated with either lupus anticoagulant or anticardiolipin antibody (i.e., antiphospholipid antibodies), low-dose aspirin (e.g., 80 mg/day) has been used in combination with prednisone to reduce the incidence of pregnancy loss (22–25) (see reference 22 for a review of this topic). This therapy has not been associated with drug-induced fetal or neonatal complications.

Several studies have investigated the effect of low-dose aspirin (e.g., 40–150 mg/day) on the prevention of gestational hypertension, preeclampsia, and eclampsia, and the associated fetal risks of IUGR and mortality (26–38) (see

reference 36 for a review of this topic). Low-dose aspirin exerts its beneficial effects in these disorders by irreversible inactivation of platelet cyclooxygenase, resulting in a greater inhibition of thromboxane A₂ synthesis than that of prostacyclin production. This inhibition restores the ratio of the two substances to a more normal value. Aspirin-induced fetal and neonatal toxicity has not been observed after the chronic use of low-dose aspirin for these indications. The lack of toxicity may be partially explained by the findings of a study published in 1989 (34). In that study, 60–80 mg of aspirin/day, starting 3 weeks before delivery and continuing until birth, inhibited maternal platelet cyclooxygenase, but not that of the newborn. These results were in agreement with other studies using 60–150 mg/day (34). Other toxicities associated with the use of full-dose aspirin near term, such as hemorrhage, premature closure of the ductus arteriosus, pulmonary hypertension, prolonged gestation, and prolonged labor, were not observed with low-dose aspirin therapy (34). Although these results are reassuring, in the opinion of some, too few studies have been reported to allow a true estimate of the fetal risk (36). However, other recent reports have observed no serious neonatal adverse effects, including hemorrhagic complications, in their series (39,40). In one of these studies, 33 women judged to be at risk for gestational hypertension were randomly assigned to either an aspirin (N = 17) or a placebo (N = 16) group during the 12th week of gestation in a single-blind study (39). Patients in the aspirin group, treated with 60 mg/day from enrollment to delivery, had a longer duration of pregnancy (39 vs. 35 weeks) and delivered heavier infants (2922 vs. 2264 g). None of the aspirin-treated women developed gestational hypertension, whereas three of the placebo group did develop the complication. In a double blind study, 65 women with increased blood pressure during the rollover test administered during the 28th or 29th week of pregnancy were randomly divided into two groups: one group was treated with 100 mg/day of aspirin (N = 34) and the other with placebo (N = 31) (40). Four women (11.8%) of the aspirin-treated group developed gestational hypertension compared with 11 (35.5%) of the placebo group.

Fetal and newborn effects, other than congenital defects, from aspirin exposure in utero, may include increased perinatal mortality, IUGR, congenital salicylate intoxication, and depressed albumin-binding capacity (2,5,12,41–43). For the latter effect, no increase in the incidence of jaundice was observed (2). Perinatal mortality in the Australian study was a result of stillbirths more often than neonatal deaths (5, 41). Some of the stillbirths were associated with antepartum hemorrhage and others may have been caused by closure of the

ductus arteriosus in utero (44). Closure of the ductus has been shown in animals to be a result of aspirin inhibition of prostaglandin synthetase. In some early cases, in utero premature closure of the ductus arteriosus was probably caused by aspirin but not suspected (45). However, a large prospective American study involving 41,337 patients, 64% of whom used aspirin sometime during gestation, failed to show that aspirin was a cause of stillbirths, neonatal deaths, or reduced birth weight (46). The difference between these findings probably relates to the chronic or intermittent use of higher doses by the patients in the Australian study (44). Excessive use of aspirin was blamed for the stillbirth of a fetus in whom salicylate levels in the fetal blood and liver were 25–30 and 12 mg/dL, respectively (47). Congenital salicylate intoxication was found in two newborns exposed to high aspirin doses before delivery (42,43). Although both infants survived, one infant exhibited withdrawal symptoms beginning on the second neonatal day consisting of hypertonia, agitation, a shrill piercing cry, and increased reflex irritability (41). The serum salicylate level was 31 mg/dL. Most of the symptoms gradually subsided over 6 weeks, but some mild hypertonia may have persisted.

A 1996 case–control study investigated the relationship between aspirin and other NSAIDs and PPHN (48). Case infants (N = 103) weighed at least 2500 g at birth and had no major congenital defects, whereas controls (N = 298) were full-term infants without congenital defects. Aspirin or other NSAIDs were used by mothers of 26 cases. Because 34% of the cases and all of the controls were born at one hospital (inborn), the investigators conducted two analyses, one for inborn infants and one for the total group. For the total group, the odds ratio and 95% confidence interval (CI) for the exposures and PPHN were aspirin 4.9 (1.6–15.3) and other NSAIDs 6.2 (1.8–21.8). For inborn cases, the findings were aspirin 9.6 (2.4–39.0) and other NSAIDs 17.5 (4.3–71.6). The timing of the exposures was earlier than expected, a median 3 months for aspirin and 1 month for NSAIDs. This result led to three potential conclusions: (a) the drugs caused early structural remodeling or functional alterations of the pulmonary vasculature, (b) the agents were also used in the 3rd trimester, or (c) there was another, unidentified primary cause of PPHN. Exposure in the 3rd trimester was the most likely conclusion because it would have been consistent with the presumed mechanism of in utero premature closure of the ductus arteriosus and resulting increased risk of PPHN. However, the investigators could not determine which of the choices was correct (48). A 2001 report also found the association between aspirin and PPHN (49).

Aspirin given in doses of 325–650 mg during the week before delivery may

affect the clotting ability of the newborn (50–56). In the initial study by Bleyer and Breckenridge (50), 3 of 14 newborns exposed to aspirin within 1 week of delivery had minor hemorrhagic phenomena vs. only 1 of 17 nonexposed controls. Collagen-induced platelet aggregation was absent in the aspirin group and, although of less clinical significance, factor XII activity was markedly depressed. A direct correlation was found between factor XII activity and the interval between the last dose of aspirin and birth. Neonatal purpuric rash with depressed platelet function has also been observed after maternal use of aspirin close to term (56). The use of salicylates other than aspirin may not be a problem because the acetyl moiety is apparently required to depress platelet function (57–59). In a 1982 study, 10 mothers consuming less than 1 g of aspirin within 5 days of delivery had excessive intrapartum or postpartum blood loss, resulting in hemoglobin levels that were markedly lower than those of controls (13,14). One mother required a transfusion. Bleeding complications seen in 9 of the 10 infants included numerous petechiae over the presenting part, hematuria, a cephalohematoma, subconjunctival hemorrhage, and bleeding from a circumcision. No life-threatening hemorrhage, effect on Apgar scores, or increased hospital stay was found, nor was bleeding observed in seven mother–infant pairs when aspirin consumption occurred 6–10 days before delivery (13,14).

An increased incidence of intracranial hemorrhage (ICH) in premature or low-birth-weight infants may occur after maternal aspirin use near birth (60). Computed tomographic screening for ICH was conducted on 108 infants 3–7 days after delivery. All of the infants were either ≤ 34 weeks in gestation or ≤ 1500 g in birth weight. A total of 53 infants (49%) developed ICH, including 12 (71%) of the 17 aspirin-exposed newborns. This incidence was statistically significant when compared with the 41 (45%) non–aspirin-exposed infants who developed ICH. The conclusions of this study have been challenged and defended (61,62). In view of the potentially serious outcome, however, full doses of aspirin should be used with extreme caution by patients in danger of premature delivery.

Aspirin readily crosses the placenta (10). When given near term, higher concentrations are found in the neonate than in the mother (63). The kinetics of salicylate elimination in the newborn have been studied (63–65).

A 2003 population-based cohort study involving 1055 pregnant women investigated the prenatal use of aspirin, other NSAIDs, and acetaminophen (66). Fifty-three women (5%) reported used of NSAIDs around the time of conception or during pregnancy, 13 of whom had a spontaneous abortion

(SAB). After adjustment, an 80% increased risk of SAB was found for other NSAIDs (adjusted hazard ratio 1.8, 95% CI 1.0–3.2). Moreover, the association was stronger if the initial use of drugs was around conception or if they were used longer than 1 week. A similar association was found with aspirin, but it was weaker because there were only 22 exposures (5 SABs). No association was observed with acetaminophen (66).

The relationship between aspirin and congenital defects is controversial. Several studies have examined this question with findings either supporting or denying a relationship. In two large retrospective studies, mothers of 1291 malformed infants were found to have consumed aspirin during pregnancy more frequently than mothers of normal infants (67,68). In a retrospective survey of 599 children with oral clefts, use of salicylates in the 1st trimester was almost three times more frequent in the mothers of children with this defect (69). A reviewer of these studies noted several biases, including the fact that they were retrospective, that could account for the results (46). Three other reports of aspirin teratogenicity involving a total of 10 infants have been located (70–72). In each of these cases, other drugs and factors were present.

A 1985 study found a possible association between the use of aspirin in early pregnancy and congenital heart disease (73). The risk for defects in septation of the truncus arteriosus was increased about twofold over nonexposed controls. In an earlier retrospective case–control comparison of the relationship between maternal drug intake and congenital heart disease, aspirin was used by 80 of 390 mothers of infants with defects vs. 203 of 1254 mothers of control infants (74). Twelve of the exposed infants had transposition of the great arteries and six had tetralogy of Fallot, but the association between the drug and these defects was weak. The study could not distinguish between the effects of the drug and the underlying condition for which the drug was used (74). A brief review of this and other investigations that have examined the relationship between aspirin and congenital heart disease was published in 1985 (75). The review concluded that too few data existed to associate aspirin with cardiac defects.

A study published in 1989, however, concluded that 1st trimester use of aspirin did not increase the risk of congenital heart defects in relation to other structural anomalies (76). The interval examined encompassed the time of major cardiac development (i.e., from the 5th week after the onset of the last menstrual period to the 9th week of gestation). The data, from the Slone Epidemiology Unit Birth Defects Study, involved 1381 infants with any structural cardiac defect and five subgroups with selected cardiac defects (subgroups

were not mutually exclusive): aortic stenosis (N = 43), coarctation of the aorta (N = 123), hypoplastic left ventricle (N = 98), transposition of the great arteries (N = 210), and conotruncal defects (N = 791). A control group of 6966 infants with other malformations was used for comparison. Infants with syndromes that included cardiac defects, such as Down's syndrome or Holt-Oram syndrome, were excluded from the data, as were mothers who were uncertain about 1st trimester aspirin use or its frequency. After adjustment for potentially confounding factors, the relative risks for the defects among aspirin users in comparison to controls were as follows: 0.9 (95% CI 0.8–1.1) for any cardiac defect, 1.2 (95% CI 0.6–2.3) for aortic stenosis, 1.0 (95% CI 0.6–1.4) for coarctation of the aorta, 0.9 (95% CI 0.6–1.4) for hypoplastic left ventricle, 0.9 (95% CI 0.6–1.2) for transposition of the great arteries, and 1.0 (95% CI 0.8–1.2) for conotruncal defects. No dose–effect relationship was observed (76).

A 2003 case–control study was conducted to identify drug use in early pregnancy that was associated with cardiac defects (77). Cases (cardiovascular defects without known chromosome anomalies) were drawn from three Swedish health registers (N = 5015). Controls were all infants born in Sweden in 1995–2001 (N = 577,730). Associations were identified for several drugs, some of which were probably due to confounding from the underlying disease or complaint or multiple testing, but some were thought to be true drug effects. The total exposed, number of cases, and odds ratio (OR, 95% CI) for NSAIDs and aspirin were 7698, 80 cases, 1.24 (0.99–1.55) and 5920, 52 cases, 1.01 (0.76–1.33), respectively. These results demonstrated no association with cardiac defects (77).

In an FDA surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 1709 newborns had been exposed to aspirin during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 83 (4.9%) major birth defects were observed (73 expected). Specific data were available for six defect categories, including (observed/expected) 19/17 cardiovascular defects, 2/3 oral clefts, 0/1 spina bifida, 3/5 polydactyly, 1/3 limb reduction defects, and 6/4 hypospadias. These data do not support an association between the drug and the defects.

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 14,864 of whom used aspirin during the 1st trimester (6). For use anytime during pregnancy, 32,164 (64%) aspirin exposures were recorded. This prospective study did not find evidence of a teratogenic effect with aspirin. However, the data did not exclude the possibility that grossly excessive doses

of aspirin may be teratogenic. An Australian study of 144 infants of mothers who took aspirin regularly in pregnancy also failed to find an association between salicylates and malformations (41). Based on these studies and the fact that aspirin usage in pregnancy is so common, it is not possible to determine the teratogenic risk of salicylates, if indeed it exists.

A 1996 case–control study of gastroschisis found a significantly elevated risk with ibuprofen (see Ibuprofen) and other medications and exposures (78). A significant association also was found for aspirin (N = 7, OR 4.67, 95% CI 1.21–18.05). The data supported a vascular hypothesis for the pathogenesis of gastroschisis (78).

Full-dose aspirin has been reported to affect adversely the IQ of children exposed in utero during the first half of pregnancy (79). In a longitudinal prospective study of the effects of prenatal alcohol exposure on child health and development conducted between 1974 and 1975, drug histories were obtained from 1529 women during the 5th month of pregnancy. At birth, 421 children were selected for later follow-up based on a system of prebirth criteria. Of these, 192 (45.6%) had been exposed to aspirin during the first half of pregnancy. A significant and negative association was discovered between aspirin and child IQ and the children's attentional decrements when they were examined at 4 years of age. The association was not changed after adjustment for a wide variety of potentially confounding covariates. Of interest, the data indicated that girls were significantly more affected than boys. The physical growth parameters, height, weight, and head circumference at 4 years of age, were not significantly related to maternal use of aspirin (79).

In a similar study, data were collected in 19,226 pregnancies by the Collaborative Perinatal Project; aspirin exposure during the first half of pregnancy was reported by 10,159 (52.8%) (80). In contrast to the earlier report, the mean child IQs at 4 years of age in the exposed and nonexposed groups were 98.3 and 96.1, respectively. Adjustment for multiple confounders reduced the difference between the groups to less than one point. No relationship between the amount of aspirin consumed and child IQ was found. The investigators concluded that an adverse effect of in utero aspirin exposure on child IQ was unlikely (80).

Women attempting to conceive should not use any NSAID, including aspirin, because of the findings in a variety of animal models that indicate these agents block blastocyst implantation (81,82). Moreover, as noted above, NSAIDs have been associated with SABs in humans (see Ibuprofen for additional studies).

A 2012 report from the National Birth Defects Prevention Study found

associations between exposures to NSAIDs (aspirin, ibuprofen, and naproxen) and several birth defects (83). The data for this case–control study came from approximately 20,470 women with expected due dates in 1997–2004. Among this group, 3173 women (15.5%) were exposed to NSAIDs in the 1st trimester. Although the results suggested that NSAIDs are not a major cause of birth defects, the study did find several small-to-moderate but statistically significant increases in nine defects. The drug, adjusted OR and 95% CI for each defect were: anencephaly/craniorachischisis— aspirin (2.1; 1.1–4.3); spina bifida— ibuprofen (1.6; 1.2–2.1); encephalocele—naproxen (3.5; 1.2–10); anophthalmia/microphthalmia— aspirin (3.0; 1.3–7.3), ibuprofen 1.9; 1.1–3.3, and naproxen 2.8; 1.1–7.3); cleft lip ± cleft palate— ibuprofen (1.3; 1.1–1.6) and naproxen (1.7; 1.1–2.5); cleft palate— aspirin (1.8; 1.1–2.9); transverse limb deficiency—naproxen (2.0; 1.0–3.8); amniotic bands/limb body wall— aspirin (2.5; 1.1–5.6) and ibuprofen (2.2; 1.4–3.5); and a heart defect (isolated pulmonary valve stenosis)—naproxen (2.4; 1.3–4.5). The analysis of the latter defect was limited to term births only. The authors acknowledged that further studies were needed because most of these associations had not been reported from other databases (83).

BREASTFEEDING SUMMARY

Aspirin and other salicylates are excreted into breast milk in low concentrations. Sodium salicylate was first demonstrated in human milk in 1935 (84). In one study of a mother taking 4 g daily, no detectable salicylate in her milk or in her infant's serum was found, but the test sensitivity was only 50 mcg/mL (85). Reported milk concentrations are much lower than this level. Following single or repeated oral doses, peak milk levels occurred at around 3 hours and ranged from 1.1 to 10 mcg/mL (86,87). This represented a milk:plasma ratio of 0.03–0.08 at 3 hours. Because salicylates are eliminated more slowly from milk than from plasma, the ratio increased to 0.34 at 12 hours (86). Peak levels have also been reported to occur at 9 hours (88). Only one report has attributed infant toxicity to salicylates obtained in mother's milk (89). A 16-day-old female infant developed severe salicylate intoxication with a serum salicylate level of 24 mg/dL on the third hospital day. Milk and maternal serum aspirin levels were not obtained, but the mother was taking 650 mg every 4 hours. Although the parents denied giving the baby aspirin or other salicylates, it is unlikely, based on the above reports, that she could have received the drug from the milk in the quantities found (89).

Adverse effects on platelet function in the nursing infant exposed to aspirin

via the milk have not been reported but are a potential risk. The American Academy of Pediatrics recommends that aspirin should be used cautiously by the mother during lactation because of potential adverse effects in the nursing infant (90).

ATAZANAVIR

Antiviral

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Although the limited human data prevent an assessment of the risk of atazanavir during pregnancy, the animal data suggest low risk to the developing fetus. Of note, the systemic exposures in two animal species were very close to those obtained clinically. However, if indicated, the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Atazanavir is an azapeptide HIV type 1 (HIV-1) protease inhibitor. The agent selectively inhibits the virus-specific processing of viral Gag and Gag-Pol polyproteins in HIV-1-infected cells, thereby preventing formation of mature virions (1). The hepatic metabolites of atazanavir are inactive. Plasma protein binding is 86% with about equal amounts bound to albumin and α_1 -glycoprotein. The mean elimination half-life is about 7 hours (1).

Reproduction studies have been conducted in rats and rabbits. In rats, doses producing systemic drug exposures that were two times the human exposure from the clinical dose of 400 mg once daily (HE) had no adverse effect on mating or fertility and were not teratogenic or embryotoxic. However, in pre- and postnatal rat development studies, the dose resulted in body weight loss or decreased weight gain in offspring and maternal toxicity. No effects on offspring were observed when the maternal exposure was equivalent to the HE. No teratogenic effects were observed in rabbits at doses producing maternal exposures equal to the HE (1).

It is not known if atazanavir crosses the human placenta. The molecular weight (about 705 for the free base) and moderately long elimination half-life suggest that passage to the embryo and fetus might occur.

The Antiretroviral Pregnancy Registry reported, for the period January 1989

through July 2009, prospective data (reported before the outcomes were known) involving 4702 live births that had been exposed during the 1st trimester to one or more antiretroviral agents (2). Congenital defects were noted in 134, a prevalence of 2.8% (95% confidence interval [CI] 2.4–3.4). In the 6100 live births with earliest exposure in the 2nd/3rd trimesters, there were 153 infants with defects (2.5%, 95% CI 2.1–2.9). The prevalence rates for the two periods did not differ significantly. There were 288 infants with birth defects among 10,803 live births with exposure anytime during pregnancy (2.7%, 95% CI 2.4–3.0). The prevalence rate did not differ significantly from the rate expected in a nonexposed population. There were 528 outcomes exposed to atazanavir (343 in the 1st trimester and 185 in the 2nd/3rd trimesters) in combination with other antiretroviral agents. There were 12 birth defects (9 in the 1st trimester and 3 in the 2nd/3rd trimesters). In reviewing the birth defects of prospective and retrospective (pregnancies reported after the outcomes were known) registered cases, the Registry concluded that, except for isolated cases of neural tube defects with efavirenz exposure in retrospective reports, there was no other pattern of anomalies (isolated or syndromic) (2). (See Lamivudine for required statement.)

Hyperbilirubinemia is a common adverse effect with atazanavir, but it is not known if this will worsen physiologic hyperbilirubinemia in the newborn or young infant and lead to kernicterus. In the prepartum period, additional monitoring and alternative therapy to atazanavir should be considered (1).

A public health advisory was issued by the FDA on the association between protease inhibitors and diabetes mellitus (3). Because pregnancy is a risk factor for hyperglycemia, there was concern that these antiviral agents would exacerbate this risk. An abstract published in 2000 described the results of a study involving 34 pregnant women treated with protease inhibitors (none with amprenavir) compared with 41 controls that evaluated the association with diabetes (4). No association between protease inhibitors and an increased incidence of gestational diabetes was found.

Two reviews, one in 1996 and the other in 1997, concluded that all women currently receiving antiretroviral therapy should continue to receive therapy during pregnancy and that treatment of the mother with monotherapy should be considered inadequate therapy (5,6). The same conclusion was reached in a 2003 review with the added admonishment that therapy must be continuous to prevent emergence of resistant viral strains (7). In 2009, the updated U.S. Department of Health and Human Services guidelines for the use of antiretroviral agents in HIV-1-infected patients continued the recommendation

that the therapy, with the exception of efavirenz, should be continued during pregnancy (8). If indicated, therefore, protease inhibitors, including atazanavir, should not be withheld in pregnancy because the expected benefit to the HIV-positive mother outweighs the unknown risk to the fetus. Pregnant women taking protease inhibitors should be monitored for hyperglycemia. Updated guidelines for the use of antiretroviral drugs to reduce perinatal HIV-1 transmission also were released in 2010 (9). Women receiving antiretroviral therapy during pregnancy should continue the therapy but, regardless of the regimen, zidovudine administration is recommended during the intrapartum period to prevent vertical transmission of HIV to the newborn (9).

BREASTFEEDING SUMMARY

No reports describing the use of atazanavir during human lactation have been located. The molecular weight (about 705 for the free base) and the moderately long elimination half-life (about 7 hours) suggest that the drug will be excreted into breast milk. The effect on a nursing infant from this exposure is unknown.

However, reports on the use of atazanavir during lactation are unlikely because of the potential toxicity, especially hyperbilirubinemia, and because the drug is indicated in the treatment of patients with HIV. HIV-1 is transmitted in milk, and in developed countries, breastfeeding is not recommended (5,6,8,10–12). In developing countries, breastfeeding is undertaken, despite the risk, because there are no affordable milk substitutes available.

ATENOLOL

Sympatholytic (Antihypertensive)

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Atenolol may cause growth restriction and reduced placental weight. The drug does not possess ISA (i.e., partial agonist). The reduced fetal growth appears to be related to increased vascular resistance in both the mother and the fetus and is a function of the length of drug exposure. Treatment starting early in the 2nd trimester is associated with the greatest decrease in fetal and placental weights, whereas treatment restricted to the 3rd trimester primarily affects only placental weight. Although growth restriction is a serious concern, the benefits of maternal therapy with β -blockers, in some cases, might outweigh the risks to the fetus and must be judged on a case-by-case basis. Because only one case has been reported, an association between atenolol and fetal retroperitoneal fibromatosis requires confirmation. Newborns exposed to atenolol near delivery should be closely observed during the first 24–48 hours for signs and symptoms of β -blockade. The long-term effects of prolonged in utero exposure to this class of drugs have not been studied but warrant evaluation.

FETAL RISK SUMMARY

Atenolol is a cardioselective β_1 -adrenergic blocking agent used for the treatment of hypertension. The drug did not cause structural anomalies in pregnant rats and rabbits, but a dose-related increase in embryo and fetal resorptions in rats was observed at doses ≥ 25 times the maximum recommended human antihypertensive dose based on 100 mg/day in a 50-kg patient (MRHD). This effect was not seen in rabbits at doses up to 12.5 times the MRHD (1).

In contrast with propranolol and sotalol, atenolol exposure during gestation

did not increase the motor activity or cause poor performance in rat offspring (2). The adverse effects observed with propranolol and sotalol, but not atenolol, were attributed to the β_2 -blocking activity of propranolol and sotalol.

A 2002 abstract, reviewing both published and nonpublished sources to assess atenolol developmental toxicity, found that fetal growth restriction occurred in both animals and humans (3). The animal–human concordance was thought to result from the reduced placental and fetal circulation induced by atenolol.

Atenolol readily crosses the placenta to the fetus producing steady-state fetal levels approximately equal to those in the maternal serum (4–11). When 11 pregnant patients were treated with 100 mg/day, the serum half-life (8.1 hours) and the 24-hour urinary excretion (52 mg) were similar to those values in nonpregnant women (8). In nine women treated with atenolol for cardiac disease, the average maternal and cord drug concentrations at delivery were 133 and 126 ng/mL, respectively (11). No evidence of altered atenolol pharmacokinetics during pregnancy was found. Atenolol transfer was one-third to one-fourth the transfer of the more lipid-soluble β -blockers propranolol, timolol, and labetalol in an in vitro experiment using perfused human placentas (12).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 105 newborns had been exposed to atenolol during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 12 (11.4%) major birth defects were observed (4 expected). Specific data were available for six defect categories, including (observed/expected) 3/1 cardiovascular defects, 1/0 oral clefts, 0/0 spina bifida, 0/0 polydactyly, 1/0 limb reduction defects, and 4/0 hypospadias. Only with the latter defect is there a suggestion of a possible association, but other factors, including the mother's disease, concurrent drug use, and chance, may be involved.

A 1997 abstract (13) and later full report (14) described a case of retroperitoneal fibromatosis in a fetus exposed in utero to atenolol from the second month of gestation through delivery at 37 weeks. The obese (134 kg at term), 25-year-old mother, in her third pregnancy, was treated for hypertension with 100-mg atenolol daily until giving birth to the 3790-g male infant. Other drug therapy included magnesium supplements and occasional metoclopramide. The mother had no familial history of cancer and both of her other children were normal. Treatment of the tumor with chemotherapy during the first 3 months of life was successful, but a severe scoliosis was present in

the child at 4 years of age. The authors attributed the rare tumor to the drug because, among other reasons, the location of the mass was similar to that of fibroses reported in adults exposed to atenolol (13,14).

The use of atenolol for the treatment of hypertension in pregnant women has been described frequently (7,10,15–28). No fetal malformations attributable to atenolol have been reported in these trials, but in most cases, the treatment with atenolol did not occur during the 1st trimester.

In a 1981 study, 13 women—11 in the 3rd trimester and 2 in the 2nd trimester—were treated for gestational hypertension with atenolol 100 mg/day until delivery (15). The birth weights of 12 of the 13 newborns were less than the 50th percentile (3 were less than the 10th percentile), but the authors thought they were consistent with severe preeclampsia. The pharmacokinetic profiles of atenolol in the pregnant subjects were similar to those measured in nonpregnant women (15).

A 1982 study described the pregnancy outcomes of 10 women with chronic hypertension who were treated with atenolol 100–200 mg/day beginning at 11–32 weeks (16). One woman delivered a stillborn infant at 41+ weeks' gestation, but the remaining nine women delivered at a median of 39 weeks. The median birth weight was 82% of the gestational mean with placental weights ranging from 235 to 795 g.

A 1983 retrospective study examined the effects of atenolol (N = 87) and metoprolol (N = 2), either alone or in combination with other antihypertensives, for the treatment of hypertension (chronic or preeclampsia) in pregnancy (17). Birth weights were not given. There were three stillbirths, but the maternal therapy in these cases was not specified.

A randomized, double-blind study published in 1983 compared atenolol (N = 46) with placebo (N = 39) for the treatment of mild-to-moderate gestational hypertension (18). Treatment was started at a mean 34 weeks' gestation in both groups. The mean gestational ages at delivery were 38 weeks (placebo) and 39 weeks (atenolol) ($p < 0.05$). No differences in the incidence of hypoglycemia, respiratory distress syndrome, or hyperbilirubinemia were observed between the groups. Although not statistically significant, both the mean birth weights (2961 vs. 3017 g) and placental weights (549 vs. 608 g) were lower in those treated with atenolol. However, significantly more atenolol-exposed newborns had bradycardia, 39% (18 of 46) vs. 10% (4 of 39) ($p < 0.01$). None of the infants required treatment for the lowered heart rate. Three intrauterine deaths occurred, two in the placebo group and one in the atenolol group (18). In the same year, the authors of this study and a previous report

(16) commented briefly on the benefits of β -blockers in the management of hypertension during pregnancy (19).

A 1992 study evaluated the effectiveness of atenolol in three groups of pregnant women having chronic hypertension (N = 12), gestational hypertension without proteinuria (N = 52), or preeclampsia (N = 6) (20). The mean doses in the three groups were 62.5, 70.0, and 100.0 mg, respectively. The drug was started at a mean gestational age of 24.5, 29.8, and 31.0 weeks, respectively. The mean birth weights observed were approximately 2902, 3059, and 2431 g, respectively.

The effect of β -blockers in pregnancy was reviewed in a 1988 article. Citing only three reports, the authors concluded that atenolol was safe and effective therapy during pregnancy (21).

Antihypertensive therapy with atenolol has been associated with fetal growth restriction in a number of studies (7,10,22–27). A nonrandomized 1983 study compared atenolol (N = 28; enrolled before May 1981) with labetalol (N = 28; enrolled after May 1981) in the treatment of chronic (N = 6) or gestational hypertension (N = 50) (7). The average daily doses were 144.6 mg (atenolol) and 614 mg (labetalol). Newborn weights were significantly higher in those exposed to labetalol, 3280 vs. 2750 g, respectively ($p < 0.001$). Two newborns were premature (<37 weeks) in the atenolol group compared with one in the labetalol group. In addition, two mothers treated with atenolol delivered stillborn infants at 29 and 38 weeks, respectively (7).

A 1984 case report described the pregnancy outcome of a woman treated with atenolol (50 mg/day increased to 100 mg/day at 33 weeks') throughout a 36-week gestation (10). Intrauterine growth restriction (IUGR) was diagnosed by ultrasound and a small (weight not given) but otherwise-normal baby girl was delivered with Apgar scores of 5, 7, and 9 at 1, 5, and 10 minutes, respectively. The maternal plasma and cord blood atenolol concentrations were 510 and 380 ng/mL, respectively. Other than a transient decrease in heart rate to 100 beats/minute at 16 hours of age, the infant had no complications (10).

A 1980 report described 60 pregnancy outcomes from 59 women treated with β -blockers for hypertension (22). The agents used were atenolol (N = 10; daily dose 100–200 mg), acebutolol (N = 28; daily dose 200–600 mg), pindolol (N = 21; daily dose 10–20 mg), and propranolol (N = 1; daily dose 40 mg). Although the birth weights were not differentiated by drug, 9 newborns weighed <2500 g, 11 were 2500–2800 g, and 40 were >2800 g (21). Two years later, this research group compared atenolol (N = 31), acebutolol (N = 56), and pindolol (N = 38) in a nonrandomized study for the treatment of hypertension

during pregnancy (23). One year later, the researchers increased the number of atenolol cases to 37 (24). The mean birth weights of the three groups were 2.82, 3.16, and 3.38 kg, respectively (23,24).

In a prospective, randomized, double-blind study, women with mild essential hypertension were given either atenolol (50–200 mg/day) or placebo starting at a mean gestational age of 15.9 weeks (25). The 15 newborns in the treated group had a significantly lower birth weight than the 14 untreated controls (2620 vs. 3530 g; $p < 0.001$). In the treated group, 5 of the newborns had weights below the 5th percentile and 10 were below the 10th percentile, compared with 1 newborn below the 25th percentile in controls. In addition, the atenolol group had significantly smaller placentas (442 vs. 635 g; $p < 0.002$) (25).

A 1992 report described the outcomes of 29 women with pregnancy-induced hypertension in the 3rd trimester (26). The women were randomized to receive either atenolol ($N = 13$) or pindolol ($N = 16$). The decrease in mean maternal arterial blood pressure in the two groups was similar. In comparing the women's status before and after therapy, several significant changes were measured in fetal hemodynamics with atenolol but, except for fetal heart rate, no significant changes were measured with pindolol. The atenolol-induced changes included a decrease in fetal heart rate; increases in the pulsatility indices (and thus the peripheral vascular resistance) of the fetal thoracic descending aorta, the abdominal aorta, and the umbilical artery; and a decrease in the umbilical venous blood flow (26). Although no difference in birth weights was observed in the two groups, the placental weight in atenolol-treated pregnancies was significantly less, 529 vs. 653 g ($p = 0.03$).

A 1997 report described an open, retrospective survey on the use of antihypertensives in 398 consecutive pregnant women who attended an antenatal hypertension clinic from 1980 to 1995 (27). The 76 women who used atenolol were compared with those using calcium channel blockers ($N = 22$), diuretics ($N = 26$), methyldopa ($N = 17$), other β -blockers ($N = 12$), or no drug therapy ($N = 235$). The mean birth weights/placental weights in the groups were atenolol 2.19 kg/390 g ($p < 0.001$); other β -blockers 2.36 kg/450 g; calcium channel blockers 2.50 kg/385 g ($p = 0.001$); diuretics 2.53 kg/500 g; methyldopa 2.70 kg/500 g; and no drug treatment 2.78 kg/535 g. The ponderal index ($\text{kg/m}^3 \times 10^4$), an indirect measure of impaired placental function in some forms of IUGR, also was calculated for each group: 2.21 ($p < 0.001$), 2.44, 2.22, 2.33, 2.67, and 2.39, respectively. The authors concluded that atenolol was associated with IUGR and reduced placental weights and should be

avoided in women who are trying to conceive or are in the early stages of gestation (27).

A 1999 retrospective cohort study reported the outcomes of 312 pregnancies in 223 women treated for gestational hypertension (N = 80), preeclampsia (N = 19), chronic hypertension (N = 179), or superimposed preeclampsia on chronic hypertension (N = 34) (28). The women were treated with atenolol monotherapy (N = 78), other monotherapy (N = 53), combination therapy (N = 90; atenolol in 57), or no treatment (N = 91). The atenolol outcomes were statistically significant when compared with other monotherapy or with no treatment. (Combination therapy implied more severe disease and consistently had the worst outcomes.) Birth weights were as follows: atenolol 2372 g vs. other monotherapy 2756 g or no treatment 3068 g ($p < 0.05$), and combination therapy 2220 g; birth lengths were as follows: atenolol 47.9 cm vs. other monotherapy 48.3 cm, no treatment 50.4 cm, ($p < 0.05$), and combination therapy 46.3 cm. There were two nonsignificant trends: higher prevalence of preterm delivery (<37 weeks) atenolol 33% vs. other monotherapy 26%, no treatment 15%, and combination therapy 46%; and higher prevalence of small-for-gestational-age (<10th percentile) atenolol 49% vs. other monotherapy 34%, no treatment 21%, and combination therapy 52%. The adverse fetal effects of atenolol were more pronounced when the therapy was started early in pregnancy and were duration-dependent (28).

A prospective randomized study compared 24 atenolol-treated women with 27 pindolol-treated women (29). No differences between the groups were found in gestational length, birth weight, Apgar scores, rates of cesarean section, or umbilical cord blood glucose levels. Treatment in both groups started at about 33 weeks' gestation. Placentas in the atenolol group weighed less than those from pindolol-treated women, 440 vs. 533 g, $p < 0.02$.

A 1987 study used Doppler ultrasound to evaluate maternal and fetal circulation during atenolol therapy in 14 women (9 nulliparous) with pregnancy-induced hypertension at a mean gestational age of 35 weeks (range 33–38 weeks) (30). The studies were conducted before and during the first and third days of treatment. During treatment, the volume of blood flow remained unchanged in the fetal descending aorta and the umbilical vein. In contrast, the pulsatility index increased in the fetal descending aorta and the maternal arcuate artery, suggesting that peripheral vascular resistance had increased on both the maternal and fetal sides of the placenta. No effect on placental or fetal weight occurred because of the short treatment period (delivery occurred a mean 18 days after the start of the study) (30). The study design and

techniques were criticized based on concerns for reproducibility, including day-to-day variability in Doppler measurements, the lack of controls, and the uncertainty of the clinical significance of velocity waveform measurements (31).

A 1995 randomized study examined the short-term effects of IV 15- to 20-minute infusions of atenolol or pindolol in 24 women with gestational hypertension (32). Comparisons were made for uterine and umbilicoplacental vascular impedance, fetal hemodynamics, and cardiac function. Both drugs significantly decreased maternal blood pressure and maternal heart rate immediately after infusion, but the effect of atenolol still was evident 30 minutes after the end of the infusion. Pindolol produced no changes in uteroplacental or umbilicoplacental vascular impedance, whereas atenolol increased vascular impedance in the nonplacental uterine artery. The umbilical artery pulsatility indices, an indication of increased vascular resistance, were higher after atenolol than after pindolol. Pindolol had no effects on fetal hemodynamics whereas atenolol decreased pulsatility indices in the fetal renal artery. In addition, atenolol significantly decreased peak systolic velocity in the fetal pulmonary trunk. The investigators concluded that both drugs were equally effective in lowering maternal blood pressure, that atenolol increased uteroplacental vascular impedance, and that atenolol had direct effects on fetal hemodynamics. Based on these findings, pindolol was the preferred agent (32).

A 1995 review of vasoactive drugs in pregnancy stated that pregnancy-induced hypertension (now known as gestational hypertension) was associated with increased vascular resistance that could reduce uteroplacental blood flow by 40%–70% (33). In addition, atenolol treatment was associated with increased resistance in uterine arteries and decreased peak velocity in the fetal pulmonary trunk, but that pindolol lacked these effects (32). They concluded that the use of vasoconstricting β -blockers during pregnancy should be reconsidered (33).

Normotensive women at risk for preeclampsia (cardiac output > 7.4 L/minute before 24 weeks' gestation) were enrolled in a 1999 double-blind, randomized, controlled trial to determine if atenolol could reduce this risk (34). The treatment groups were nulliparous: atenolol (N = 21) or placebo (N = 19); diabetics: atenolol (N = 7) or placebo (N = 9); and controls: no treatment (N = 18). A significant decrease ($p = 0.04$) in the incidence of preeclampsia was noted in the atenolol-treated women, but their offspring had a birth weight of 440 g less than that of placebo infants ($p = 0.02$). However, no increase in the rate of small-for-gestational-age fetuses was observed. Previous research by these investigators had suggested that in women with hypertension, fetal

growth restriction occurred primarily when increased vascular resistance was present but not when hypertension was mediated by increased cardiac output (34). They concluded that a change in therapy was indicated if the maternal cardiac output was less than the mean for gestational age or if peripheral resistance was greater than 1150 dyne second/cm⁵. If these guidelines had been followed, atenolol therapy would have been changed in seven subjects, including four cases involving the smallest infants (34).

A 2001 retrospective review of pregnancies (N = 235) at risk for preeclampsia that were treated with atenolol (25–100 mg/day) early in gestation was reported by the same authors as those of the above study (35). The goals of therapy were to reduce cardiac output to 1 standard deviation above the mean for gestational age and to lower mean arterial pressure to <90 mmHg. To maintain fetal growth, this was modified to maintaining cardiac output above the mean for gestational age and maintaining peripheral vascular resistance at <1150 dyne second/cm⁵. Low birth weight was associated with (a) prior pregnancy with IUGR (p = 0.001); (b) failure to adjust the dose properly for cardiac output and peripheral vascular resistance (p < 0.001); and (c) a pregnancy in an earlier year of the investigator's experience (p < 0.001). In the study population, the birth weight increased from the 20th percentile at the beginning of the study period (1991) to the 40th percentile by the end (1999) (p = 0.002) (35).

In a group of pregnant women with symptomatic mitral valve stenosis, 11 were treated with atenolol and 14 with propranolol (36). The mean birth weight of the 25 infants was 2.8 kg (range 2.1–3.5 kg). Atenolol, 25 mg twice daily, was administered from 18 weeks' gestation to term in a normotensive woman who had suffered a myocardial infarction (37). She delivered a 2720-g infant with normal Apgar scores and blood gases.

Intrauterine fetal deaths have been observed in women with severe hypertension treated with atenolol, but this also has occurred with other β -blockers and in hypertensive women not treated with drugs (7,16–18,38). Four cases of fetal death (at 18, 29, and 33 weeks) or neonatal death (at 6.5 days) have been reported when the mothers were treated with atenolol combined with either angiotensin-converting enzyme inhibitors (39–41) or a selective angiotensin II receptor antagonist (42).

In eight women treated with atenolol or pindolol, a decrease in the basal fetal heart rate was noted only in atenolol-exposed fetuses (43). Before and during treatment, fetal heart rates in the atenolol patients were 136 and 120 beats/minute, respectively, whereas the rates for the pindolol group were 128

and 132 beats/minute, respectively. In 60 patients treated with atenolol for pregnancy-induced hypertension, no effect on fetal heart rate pattern in response to uterine contractions was observed (44). Accelerations, variables, and late decelerations all were easily distinguishable.

Persistent β -blockade was observed in a newborn whose mother was treated with atenolol, 100 mg/day, for hypertension (5). At 15 hours of age, the otherwise normal infant developed bradycardia at rest and when crying, and hypotension. The serum atenolol concentration was 0.24 mcg/mL. Urinary excretion of the drug during the first 7 days ranged from 0.085 to 0.196 mcg/mL.

A 1992 case report described a pregnant woman who was diagnosed with a pheochromocytoma at 28 weeks' gestation (45). She was treated with atenolol (100 mg/day) and phenoxybenzamine (30 mg/day) to control her blood pressure. An elective cesarean section was performed at 37 weeks to deliver a normal female infant (birth weight not given).

A woman with a renal transplant was treated with cyclosporine, prednisolone, and atenolol (50 mg/day) throughout a normotensive pregnancy without proteinuria (46). An 820-g (below the 3rd percentile) male infant was delivered at 30 weeks' gestation because of severe IUGR. The authors attributed the growth restriction to cyclosporine, but atenolol and prednisolone probably contributed to the condition.

A review published in 2002 examined the pharmacokinetic and pharmacodynamic issues relevant to the toxic effects of atenolol exposure during pregnancy (47). The authors concluded that (a) maternal hypertension can potentiate the adverse effects of atenolol on placental and fetal circulation, resulting in decreased placental and birth weight; (b) decreased placental weight has been significantly associated with IUGR and lower birth weight independent of gestational age; (c) the effects of atenolol are duration-dependent; and (d) several other agents have a more favorable effect on birth weight, including labetalol, pindolol, acebutolol, and calcium channel blockers (47).

The duration of treatment, rather than the dose used, appears to be a critical factor in causing atenolol-induced fetal growth restriction (48). At one center, adjustment of the dose for maternal cardiac output and peripheral vascular resistance reduced these toxic effects. Infant behavior is apparently not affected by atenolol exposure, as no differences were noted in the development at 1 year of age of offspring from mothers treated during the 3rd trimester for mild-to-moderate pregnancy-induced hypertension with either bed

rest alone or rest combined with atenolol (49). The mean duration of therapy in the atenolol-treated patients was 5 weeks.

BREASTFEEDING SUMMARY

Atenolol is excreted into breast milk (6,8,10,47,50–54). The drug is a weak base, and when used during lactation, accumulation in the milk will occur with concentrations significantly greater than corresponding plasma levels (6,8,47,50–53). Peak milk concentrations after single-dose (50 mg) and continuous-dosing (25–100 mg/day) regimens were 3.6 and 2.9 times greater, respectively, than simultaneous plasma levels (52). Atenolol has been found in the serum and urine of breastfed infants in some studies (6,8,10,50). Other studies have been unable to detect the drug in the infant serum (test limit 10 ng/mL) (51,52).

Symptoms consistent with β -adrenergic blockade were observed in a breastfed, 5-day-old, full-term female infant, including cyanosis, hypothermia (35.5°C rectal), and bradycardia (80 beats/minute) (54). Blood pressure was 80/40 mmHg. Except for these findings, physical examination was normal and bacterial cultures from various sites were negative. The mother had been treated orally with atenolol, 50 mg every 12 hours, for postpartum hypertension. Breastfeeding was stopped 3 days after onset of the symptoms and 6 hours later, the infant's symptoms had resolved. A milk sample, collected 10 days postpartum and 1.5 hours after a 50-mg dose, contained 469 ng/mL of atenolol. Concentrations in the infant's serum, 48 and 72 hours after breastfeeding, were 2010 and 140 ng/mL, respectively. The calculated serum half-life in the infant was 6.4 hours. By extrapolation, the minimum daily dose absorbed by the infant was estimated to be 8.97 mg, approximately 9% of the mother's daily dose (54). (These calculations have been questioned and defended [55,56].)

Except for the single case cited above, adverse reactions in infants have not been reported. However, because milk accumulation occurs with atenolol, nursing infants must be closely monitored for bradycardia and other signs and symptoms of β -blockade. Moreover, one author has recommended that water-soluble, low-protein-bound, renally excreted β -blockers, such as atenolol, should not be used during lactation (57). Because of the availability of safer alternatives, this seems to be good advice. Long-term effects on infants exposed to β -blockers from breast milk have not been studied but warrant evaluation.

The American Academy of Pediatrics classifies atenolol as a drug that has

been associated with significant effects in nursing infants (cyanosis and bradycardia) and should be used by nursing mothers with caution (58).

ATOMOXETINE

Psychotherapeutic (Miscellaneous)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although the animal data suggest risk, the absence of detailed human pregnancy experience prevents an assessment of the embryo–fetal risk. Until such data are available, the safest course is to avoid the drug in pregnancy. If the mother’s condition requires atomoxetine, the lowest effective dose, avoiding the 1st trimester if possible, should be used. However, inadvertent exposure in the 1st trimester does not appear to represent a major risk. Long-term follow-up of exposed offspring may be warranted.

FETAL RISK SUMMARY

Atomoxetine is used for the treatment of attention deficit/hyperactivity disorder (ADHD). Atomoxetine has an equipotent active metabolite, but the plasma concentration is only 1% (in normal metabolizers) of the parent drug. A second active metabolite has much less activity and its plasma levels are 5% (in normal metabolizers) of the parent drug. The plasma elimination half-life in normal (extensive) metabolizers is about 5 hours. In persons who are “poor metabolizers” (7% of whites and 2% of blacks), the drug plasma levels are much higher and the plasma elimination half-life is 24 hours. The plasma protein binding is 98%, primarily to albumin (1).

Reproduction studies have been conducted in rats and rabbits. No effects on rat fertility were observed at doses up to about 6 times the maximum human dose based on BSA (MHD). In one of two studies in which rats were treated in the diet for 2 weeks prior to mating through organogenesis and lactation with doses up to about 6 times the MHD, a decrease in pup weight (female only) and pup survival (also seen at 3 times the MHD) was observed. The no-effect

dose for pup survival was about 2 times the MHD. A diet dose about 5 times the MHD given throughout the period of organogenesis resulted in a decrease in fetal weight and an increase in the incidence of incomplete ossification of the vertebral arch in fetuses. The no-effect dose for these effects was about 2.5 times the MHD. No adverse fetal effects were observed when rats were gavaged with doses up to 17 times the MHD throughout organogenesis (1).

In pregnant rabbits given atomoxetine by gavage, a dose about 23 times the MHD resulted in an increase in early absorptions and a decrease in live fetuses in one of three studies. In addition, slight increases in the incidences of atypical origin of carotid artery and absent subclavian artery were observed, as was slight maternal toxicity. The no-effect dose was about 7 times the MHD. The high dose produced plasma levels (AUC) in rabbits that were about 3.3 times (normal metabolizers) or 0.4 times (poor metabolizers) those in humans receiving the MHD. The no-effect dose for these effects was about 7 times the MHD (1).

It is not known if atomoxetine or its active metabolites cross the human placenta. The molecular weight for the parent drug (about 256 for the free base) combined with elimination half-life suggests that atomoxetine will cross to the embryo and/or fetus. The extensive protein binding, however, will limit the amount available for transfer.

In a brief correspondence, representatives of the manufacturer and others stated that there had been three pregnancies in adult clinical trials with atomoxetine (2). Two resulted in healthy newborns, but the third pregnancy was lost to follow up. No other details were provided.

BREASTFEEDING SUMMARY

No reports describing the use of atomoxetine during human lactation have been located. The molecular weight of the parent drug (about 256 for the free base) and the relatively long elimination half-life (5 hours for normal metabolizers; 24 hours for poor metabolizers) suggest that the drug and/or its metabolites will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown. If a mother chooses to breastfeed while taking atomoxetine, the infant should be monitored for potential toxicity (such as upper abdominal pain, constipation, and dyspepsia).

ATORVASTATIN

Antilipemic Agent

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

The interruption of cholesterol-lowering therapy during pregnancy should have no effect on long-term treatment of hyperlipidemia. Moreover, because cholesterol and products synthesized by cholesterol are important during fetal development, the use of atorvastatin is contraindicated during pregnancy. However, the absolute embryo risk from inadvertent exposure in the 1st trimester appears to be low.

FETAL RISK SUMMARY

Atorvastatin, a lipophilic 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitor (statin), is indicated as an adjunct to diet to reduce total cholesterol, low-density lipoprotein cholesterol, apolipoprotein B, and triglyceride levels in patients with primary hypercholesterolemia and mixed dyslipidemia. It has the same mechanism of action as other available drugs in this class, fluvastatin, lovastatin, pitavastatin, pravastatin, rosuvastatin, and simvastatin (cerivastatin was withdrawn from the market in 2001). Atorvastatin is extensively metabolized and some of the metabolites are as pharmacologically active as the parent compound. Atorvastatin is highly bound ($\geq 98\%$) to plasma proteins and it has a mean plasma elimination of about 14 hours. However, because of the active metabolites, the half-life of inhibitory activity for HMG-CoA reductase is 20–30 hours (1,2).

In reproduction studies with pregnant rats and rabbits, doses that were about 30 and 20 times, respectively, the human exposure (HE) based on BSA, were not teratogenic. With maternal dosing in rats from gestation day 7 through lactation day 21 (weaning), at a dose 22 times the HE based on AUC, there was decreased pup survival at birth, during the neonatal period, at weaning, and at maturity, and decreased pup weight at birth, during nursing, and at maturity. In addition, pup development was inhibited at this dose (1–3). A 1994

report described developmental toxicity of atorvastatin at maternally toxic doses in pregnant rats and rabbits (4). There was no evidence, however, of teratogenicity in either species (4).

It is not known if atorvastatin or its active metabolites cross the human placenta. The relatively high molecular weight (about 1161 for the nonhydrated form) and extensive protein binding suggest that transfer across the placenta will be inhibited. In pregnant rats, however, fetal liver levels of atorvastatin were equivalent to maternal concentrations (1–3).

A 2002 report described the use of atorvastatin in early pregnancy (5). A 35-year-old woman with several diseases (hypertension, diabetes mellitus, hypercholesterolemia, anxiety disorder, epilepsy, and morbid obesity) conceived while being treated with multiple drugs: atorvastatin (40 mg/day), rosiglitazone, gliclazide (a sulfonylurea), acarbose, spironolactone, hydrochlorothiazide, carbamazepine, thioridazine, amitriptyline, chlordiazepoxide, and piperzolate bromide (an antispasmodic). Her pregnancy was diagnosed in the 8th week of gestation and all medications were stopped. She was treated with methyldopa and insulin for the remainder of her pregnancy. At 36 weeks' gestation, a healthy, 3.5-kg female infant was delivered by cesarean section. Apgar scores were 7 and 8 at 1 and 5 minutes, respectively. The infant was developing normally after 4 months (5).

A 2004 report described the outcomes of pregnancy that had been exposed to statins and reported to the FDA (see Lovastatin).

A 2005 abstract reported 19 pregnancies exposed to a statin in the 1st trimester, 7 of which involved atorvastatin (6). The pregnancy outcomes included one healthy newborn, two spontaneous abortions (one with trisomy 18), one elective abortion, one newborn with jaundice, and two infants with congenital defects (VACTERL association, also exposed to trandolapril and insulin) and unilateral dilated renal pelvis (also exposed to enalapril) (6).

A 2008 prospective, observational cohort study compared the pregnancy outcomes of 64 women who had taken a statin in the 1st trimester with 64 matched controls without exposure to known teratogens (7). The statin exposures were atorvastatin (N = 46), simvastatin (N = 9), pravastatin (N = 6), and rosuvastatin (N = 3). Sixty-one women discontinued the drug in the 1st trimester, but three continued taking a statin into the 2nd trimester. Twenty-one (33%) women in the exposed group had other medical conditions, in addition to hyperlipidemia, and seven had more than one chronic condition. The rates of major malformations in the two groups were 2.2% (1/46 live births) and 1.9% (1/52 live births) ($p = 0.93$), respectively. There were also no statistical

differences in the other outcomes: live births (71.9% vs. 81.2%), spontaneous abortions (21.9% vs. 17.2%), elective abortions (4.7% vs. 0%), and stillbirths (1.5% vs. 1.6%). Gestational age at birth (38.4 vs. 39.3 weeks) and birth weight (3.14 vs. 3.45 kg) were significantly lower in the exposed group (7).

BREASTFEEDING SUMMARY

No reports describing the use of atorvastatin in human lactation have been located. The relatively high molecular weight (about 1161 for the nonhydrated form) suggests that excretion into milk would be inhibited, but some excretion should be expected. Because of the potential for adverse effects in a nursing infant, women who are taking atorvastatin should not breastfeed.

ATOVAQUONE

Antiprotozoal

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential
Toxicity

PREGNANCY SUMMARY

The use of atovaquone, usually combined with proguanil (see also Proguanil), during human pregnancy does not appear to increase the risk of major birth defects. The lack of toxicity in animals with doses close to those used in humans is reassuring. Two reviews, one in 2004 (1) and the other in 2011 (2), concluded that the drug could be used in pregnancy. Because the maternal benefit appears to exceed the unknown embryo–fetal risk, the agent should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Atovaquone is an analog of ubiquinone that is indicated for the prevention and treatment of *Pneumocystis carinii* pneumonia in patients intolerant of trimethoprim–sulfamethoxazole (3). The agent, when combined with proguanil, is also indicated for the prevention and treatment of malaria due to *Plasmodium falciparum* (2,4). Unlabeled uses include the treatment of babesiosis (in combination with quinine and/or clindamycin and/or azithromycin) and toxoplasmosis (in combination with pyrimethamine) (5). The drug undergoes little, if any, metabolism and is extensively bound (99.9%) to plasma proteins. The elimination half-life is long, ranging from about 67–78 hours (3).

Reproduction studies have been conducted in rats and rabbits (3,4). In rats, no teratogenicity or reproductive toxicity was observed at plasma concentrations 2–3 times the estimated human exposure (HE) for *P. carinii* (3) or 5–6.5 times the HE for malaria (4). In rabbits, plasma concentrations about 0.5 times the HE for *P. carinii* (3) and 0.6–1.3 times the HE for malaria (4) were maternally toxic. At these exposures, mean fetal body weights and lengths were decreased, and there were higher numbers of early resorption

and post-implantation losses. These effects may have been due to the maternal toxicity (3,4). The combination of atovaquone and proguanil was not teratogenic in rats (1.7 and 0.10 times the HE for malaria, respectively) or rabbits (0.34 and 0.82 times the HE for malaria, respectively). There was also no embryotoxicity in rabbits at these exposures (4).

Atovaquone was not carcinogenic in rats, but hepatocellular adenoma and carcinoma were observed with all doses tested in mice (1.4–3.6 times the average plasma concentrations in humans). In other tests, there was no evidence of atovaquone-induced mutagenicity or genotoxicity (3).

It is not known if atovaquone crosses the human placenta. The molecular weight (about 367), absence of metabolism, and long elimination half-life suggest that atovaquone will cross the human placenta to the embryo–fetus. However, the extensive plasma protein binding might limit the amount that crosses.

In an antenatal clinic in Thailand, 24 pregnant women who had tested positive for malaria were treated with a triple combination of atovaquone (20 mg/kg/day), proguanil (8 mg/kg/day), and artesunate (4 mg/kg/day) for 3 days (5). The study was conducted to determine the pharmacokinetic properties of the drugs in pregnancy. The median estimated gestational age at the start of treatment was 28.5 weeks (range 19.1–35.9 weeks). No adverse effects of the therapy were observed in the fetuses or newborns (5).

Some of the same authors in the above report used the identical regimen to treat 27 pregnant women with multidrug-resistant malaria (6). The treatment occurred at a mean gestational age of 28.2 weeks. They found no evidence of toxicity in the mothers or the fetuses (6).

The 3-day triple anti-infective regimen described above was compared with a 7-day supervised trial of quinine for the treatment of uncomplicated falciparum malaria (7). There were 39 pregnant women in the three-drug group and 42 in the one-drug group. All of the women were in the 2nd or 3rd trimesters. The three-drug regimen was significantly better and had a much lower failure rate. There were no significant differences in pregnancy duration, birth weight, congenital anomalies, or in growth and development of infants monitored for 1 year (7).

A combination tablet containing atovaquone 250 mg and proguanil 100 mg was used to treat 26 women (gestational age 24–34 weeks) with acute uncomplicated *P. falciparum* malaria (8). The study was designed to determine the pharmacokinetics of the two drugs and cycloguanil, the active metabolite of proguanil. No serious toxicities were observed and the newborns had no

physical anomalies (8).

A large nationwide cohort study from Denmark, covering the period 2000–2008, compared the pregnancy outcomes (live births) of women exposed to atovaquone–proguanil during the 1st trimester with those not exposed (9). In weeks 3–8 after conception, 93 were exposed (1 major birth defect, 1.1%) compared with 570,784 unexposed (13,994 major birth defects, 2.5%). The adjusted prevalence odds ratio (POR) was 0.43 and 95% confidence interval (CI) 0.06–3.11. For exposure anytime in the 1st trimester, 149 were exposed (2 major birth defects, 1.3%) compared with 570,728 unexposed (13,993 major birth defects, 2.5%), POR 0.55, and 95% CI 0.14–2.21. The birth defects were those observed in the first year of life (9).

BREASTFEEDING SUMMARY

No reports describing the use of atovaquone during lactation have been located. The molecular weight (about 367), absence of metabolism, and long elimination half-life (about 67–78 hours) suggest that the drug will be excreted into breast milk. However, the extensive plasma protein binding (99.9%) should limit the amount in milk. The effect of this exposure on a nursing infant is unknown. The severity of the mother's illness, such as infection with HIV, may preclude breastfeeding. In addition, the potential for severe adverse effects in a nursing infant, such as gastrointestinal symptoms, rash, fever, headache, hepatic toxicity, and carcinogenicity, suggests that even HIV-negative women should not breastfeed if they are taking this drug.

ATRACURIUM

Skeletal Muscle Relaxant

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No adverse effects in the fetus or newborn attributable to in utero atracurium exposure have been reported. Because of the drug's high molecular weight and ionization at physiologic pH, only small amounts cross the human placenta, thus limiting the exposure of the embryo or fetus. Moreover, direct administration to the fetus in the latter part of pregnancy has not been associated with fetal harm. Human fetal exposures early in pregnancy, however, have not been reported. Animal reproduction studies have only been conducted in rabbits, and although the drug may be a potential teratogen in this species, further studies are required to determine the magnitude of this potential. Based on the data below, the use of atracurium during the latter portion of human pregnancy appears to represent little, if any, risk.

FETAL RISK SUMMARY

The competitive (nondepolarizing) neuromuscular blocking agent, atracurium besylate, provides muscle relaxation during surgery or mechanical ventilation. The drug undergoes rapid, nonenzymatic, spontaneous degradation in the plasma (Hofmann elimination) that is independent of hepatic or renal mechanisms (1,2).

In reproduction studies in rabbits with SC doses of 0.15 mg/kg once daily or 0.10 mg/kg twice daily (human IV bolus doses vary from 0.08 to 0.5 mg/kg), an increased incidence of spontaneously occurring visceral or skeletal anomalies was observed in both treatment groups when compared with nontreated controls (3). Moreover, in comparison to controls, a lower percentage of male fetuses (41% vs. 51%) and a higher percentage of post-implantation losses

(15% vs. 8%) were observed in the 0.15 mg/kg-once-daily group (3).

In a study conducted by the manufacturer published in 1983, SC doses of atracurium, identical to those above, were injected into rabbits on days 6–18 of pregnancy (4). Rabbits, and cats in the perinatal study below, were used because the pharmacokinetics of atracurium in these species are similar to those in humans, whereas the kinetics in rats is markedly different from humans. No teratogenicity or adverse effects were observed in the rabbit fetuses (4).

Theoretically, the relatively high molecular weight (about 1244) of atracurium besylate and its high degree of ionization at physiologic pH should inhibit the placental passage of atracurium. In the perinatal portion of the study cited above, six pregnant cats, 1–3 days before term, were given a single dose of atracurium, 0.6 mg/kg IV (4). No atracurium was detected in fetal blood, leading to the conclusion that the drug did not cross the placenta (4). Moreover, no depression of respiratory activity was observed when a dose of 0.6 mg/kg was injected directly into the fetuses. A brief 1985 report described the failure to detect placental transfer of atracurium during a 60-minute interval after a 0.5-mg/kg IV dose in five pregnant sheep (5). Small amounts of laudanosine, the major metabolite, crossed the placenta and were detected in some of the fetuses. The metabolite, however, is considered to be inactive at the doses of parent drug used clinically (1).

In contrast to the above animal data, human placental transfer of atracurium has been documented (6,7). In five women, from a total group of 26 undergoing cesarean section, average venous concentrations of the drug, following a 0.3-mg/kg IV dose, ranged from 3.34 mcg/mL at 3 minutes to 0.7 mcg/mL at 10 minutes (6). Venous cord blood concentrations of atracurium ranged from undetectable to 0.23 mcg/mL, suggesting that the cord:maternal ratio varied from 5% to 20% (6). In the second report by these authors, 53 women, delivered by cesarean section, received atracurium 0.3 mg/kg IV followed by increments of 0.1–0.2 mg/kg IV as necessary to maintain surgical relaxation (7). Concentrations of the drug in 16 women at delivery ranged from 0.54 to 3.34 mcg/mL. Only one patient received a second IV dose (0.2 mg/kg). Venous cord concentrations in seven newborns were undetectable (<0.1 mcg/mL in two and <0.05 mcg/mL in five), one cord blood sample was contaminated, and in eight newborns, concentrations ranged from 0.05 to 0.23 mcg/mL. The cord:maternal blood ratio varied from 0.03 to 0.33 (mean 0.12). Newborn neuromuscular activity was reported as normal in all newborns. Further, no adverse effects on Apgar scores or on the time to sustained respiration

attributable to atracurium were observed in these two studies (6,7) or in an earlier report by the same authors (8).

A number of reports have described the safe use of atracurium during human pregnancy (9–13). A woman scheduled for a cesarean section had a low plasma concentration of cholinesterase activity. Atracurium, which does not depend on plasma cholinesterase for its metabolism, was successfully used for neuromuscular blockade in a dose of 0.4 mg/kg IV bolus (9). A healthy newborn with Apgar scores of 8 and 10 at 1 and 5 minutes, respectively, was delivered 10 minutes after the IV bolus. In another case, an IV infusion of atracurium was used during a 16-hour interval to maintain maternal muscle paralysis in a patient with pneumococcal pneumonia who required mechanical ventilation (10). In addition to other anesthetic agents, the woman received 520 mg of atracurium over 16 hours or an average of 32.5 mg/hour until vaginal delivery of a 1800-g female infant. No neuromuscular blockade was observed in the newborn that had Apgar scores of 7, 10, and 10 at 1, 5, and 10 minutes, respectively. Neuromuscular blockade with atracurium was used in a pregnant woman at 24 weeks' gestation that underwent resection of a pheochromocytoma (11). She eventually delivered a healthy, 2977-g male infant at 39 weeks' gestation. Normal newborns were also described in two other reports following the use of atracurium prior to cesarean section (12,13). Moreover, a 1986 review on obstetrical anesthesia concluded that atracurium was safe to use in obstetric patients (14).

Three studies have described the direct human fetal administration of atracurium to achieve neuromuscular blockade (15–17). In one study, atracurium (0.4 mg/kg) was used in 11 fetuses during 18 intrauterine transfusions and compared with pancuronium (0.1 mg/kg, 12 fetuses, 19 transfusions) (gestational ages not specified in either group) (15). The two agents were similar in onset of neuromuscular blockade. Atracurium, however, was statistically superior to pancuronium in terms of return of fetal movements (22 vs. 67 minutes), more fetal movements, fetal movements/minute, and more heart accelerations than pancuronium after transfusion (15). The authors concluded that atracurium was the preferred drug if fetal paralysis was required. A 1988 reference also used a 0.4-mg/kg IV fetal dose after determining that a 0.2-mg/kg dose was inadequate to arrest fetal activity during intrauterine transfusions (16). Atracurium was used in 6 women undergoing 12 transfusion procedures for fetal Rh isoimmunization. Onset of paralysis occurred within 1–5 minutes and fetal activity returned between 20 and 130 minutes. One fetus developed bradycardia and died 1 hour after transfusion of

severe erythroblastosis fetalis and rupture of the spleen.

Atracurium, 1.0 mg/kg IM (fetal gluteal muscle), was used in five fetuses for various intrauterine procedures conducted between 32 and 38 weeks' gestation (17). In comparison to five fetuses treated with pancuronium, 0.15 mg/kg IM, neuromuscular blockade was achieved slightly faster (mean 4.7 vs. 5.8 minutes) and fetal movements returned sooner (mean 36 vs. 92 minutes) with atracurium. One fetus with peritonitis given pancuronium was stillborn, one fetus with peritonitis given atracurium was born alive with a gastrointestinal perforation, and one fetus given atracurium for ascites drainage and albumin transfusion died after birth. Although the authors did not discuss these outcomes, they do not appear to be related to the neuromuscular blocking agents. No evidence of soft tissue, nerve, or muscle damage at the sites of injection was observed in the newborns.

BREASTFEEDING SUMMARY

No reports describing the use of atracurium during human lactation have been located. Atracurium undergoes rapid, spontaneous degradation in plasma (Hofmann elimination) with an elimination half-life of approximately 20 minutes. The metabolites are not biologically active. In addition, the drug has a relatively high molecular weight (about 1244) and is highly ionized at physiologic pH, both of which are factors that would markedly reduce transfer into milk. Although usage in a lactating woman is possible, at least several hours (and most likely much more time) would pass after use of atracurium before lactation was resumed. The rapid breakdown of atracurium that occurs in plasma would also be expected in milk, even though the latter medium is slightly more acidic than plasma. Thus, any amounts that were transferred into milk would most likely be rapidly degraded. Based on these data, nursing can probably be safely resumed, especially after single-dose use, following recovery from atracurium-induced neuromuscular blockade. A 1994 review of anesthetic agents also concluded that nursing could be allowed as soon as feasible after surgery (18).

ATROPINE

Parasympatholytic

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Although the human data describing pregnancy outcomes are limited, there is no evidence of embryo or fetal harm.

FETAL RISK SUMMARY

Atropine, an anticholinergic, rapidly crosses the placenta (1–4). Atropine exposure in the 1st, 2nd, and 3rd trimesters was estimated in one study to be 11.3, 6.7, and 6.3/1000 women, respectively (5). The drug has been used to test placental function in high-risk obstetric patients by producing fetal vagal blockade and subsequent tachycardia (6).

IV atropine (0.5 mg) caused a decrease of 10%–100% in fetal breathing in 13 of 15 fetuses, an increase of 300% in 1 fetus, and no effect in another (7). The decrease in fetal breathing occurred approximately 2 minutes after administration of the drug and lasted 5–10 minutes. No fetal hypoxia was observed, nor was there an effect on fetal heart rate or beat-to-beat variability.

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 401 of whom used atropine in the 1st trimester (8, pp. 346–353). For use anytime during pregnancy, 1198 exposures were recorded (8, p. 439). In neither group was evidence found for an association with malformations. However, when the group of parasympatholytics were taken as a whole (2323 exposures), a possible association with minor malformations was found (8, pp. 346–353).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 381 newborns had been exposed to atropine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 18 (4.7%) major birth defects were observed (16 expected). Specific data were available for six defect categories, including (observed/expected) 4/4 cardiovascular defects, 0/0.5 oral clefts, 1/0

spina bifida, 2/0 polydactyly, 1/1 hypospadias, and 2/0 limb reduction defects. Only with the latter defect is there a suggestion of a possible association, but other factors such as the mother's disease, concurrent drug use, and chance may be involved.

Atropine has been used to reduce gastric secretions before cesarean section without producing fetal or neonatal effects (9,10). In a study comparing atropine and glycopyrrolate, 10 women in labor received 0.01 mg/kg of IV atropine (11). No statistically significant changes were noted in fetal heart rate or variability nor was there any effect on uterine activity.

A single case of a female infant born at 36 weeks' gestation with multiple defects, including Ebstein anomaly, was described in a 1989 report (12). In addition to the cardiac defect, other abnormalities noted were hypertelorism, epicanthal folds, low-set posteriorly rotated ears, a cleft uvula, medially rotated hands, deafness, and blindness. The mother had taken Lomotil (diphenoxylate and atropine) for diarrhea during the 10th week of gestation. Because exposure was beyond the susceptible stages of development for these defects, the drug combination was not considered causative. However, a possible viremia in the mother as a cause of the diarrhea could not be excluded as playing a role in the infant's anomalies.

BREASTFEEDING SUMMARY

The passage of atropine into breast milk is controversial (13). It has not been adequately documented whether measurable amounts are excreted or, if excretion does occur, whether it may affect the nursing infant. Although neonates are particularly sensitive to anticholinergic agents, no adverse effects have been reported in nursing infants whose mothers were taking atropine. The American Academy of Pediatrics classifies the agent as compatible with breastfeeding (14).

AURANOFIN

Immunologic Agent (Antirheumatic)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of auranofin in human pregnancy have been located. Although there was evidence of embryo–fetal toxicity and/or teratogenicity in animals, the doses used caused maternal toxicity and the comparisons to the human dose (HD) were based on body weight. Doses that were not maternally toxic did not cause these effects. Based on experience with other gold compounds (see Gold Sodium Thiomalate), gold does not appear to pose a major risk to the fetus. However, long-term follow-up studies of exposed fetuses have not been reported. If auranofin is indicated in a pregnant woman she should be informed of this information.

FETAL RISK SUMMARY

Auranofin is an oral disease-modifying antirheumatic drug (DMARD) containing 29% gold. It is indicated in the management of adults with active classical or definite rheumatoid arthritis who have had an insufficient therapeutic response to, or are intolerant of, an adequate trial of full dose of one or more nonsteroidal anti-inflammatory drugs. Auranofin is rapidly metabolized and intact auranofin is undetectable in blood. Approximately 25% of the gold in auranofin is absorbed. The gold in auranofin is moderately bound (60%) to plasma proteins. The mean terminal plasma half-life of auranofin gold at steady state is 26 days (range 21–31 days), whereas the mean terminal body half-life at steady state is 80 days (range 42–128 days) (1).

Reproduction studies have been conducted in rabbits, rats, and mice. In rabbits, maternal toxic (impaired food intake) doses about 4–50 times the HD resulted in decreased fetal weights, increased incidence or resorptions and abortions, and an increased incidence of congenital abnormalities, mainly

abdominal defects such as gastroschisis and umbilical hernia. No teratogenicity was noted in rats given a maternal toxic dose 42 times the HD, but there was an increase in the incidence of resorptions and a decrease in litter size and weight. A dose 21 times the HD that was not maternally toxic did not cause these effects or teratogenicity. In mice, a dose 42 times the HD was not teratogenic or maternal toxic (1).

In a 24-month carcinogenicity study in rats, doses that were 3–21 times the HD resulted in renal tumors. In a 12-month study in rats, a dose 192 times the HD caused renal tumors, whereas a dose 30 times the HD did not. In an 18-month study in mice, doses that were 8–72 times the HD were not associated with a significant increase in tumors. Auranofin was mutagenic in one assay but not in other assays (1). The effects of the drug animal fertility were apparently not studied.

Intact auranofin is not available to cross to the embryo or fetus because the agent has not been detected in blood. However, gold, released from auranofin, will cross the placenta (see Gold Sodium Thiomalate).

BREASTFEEDING SUMMARY

No reports describing the use of auranofin during human lactation have been located. Intact auranofin has not been detected in blood and, thus, would not be excreted into breast milk. However, gold, released from auranofin, will be excreted into milk (see Gold Sodium Thiomalate). Based solely on that information, breastfeeding when the mother is being treated with auranofin is probably compatible.

AUROTHIOGLUCOSE

[Withdrawn from the market. See 9th edition.]

AVANAFIL

Impotence Agent

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of avanafil in human pregnancy have been located. Animal data suggest low risk, but the absence of human pregnancy experience prevents a more complete assessment of embryo–fetal risk. Such reports are unlikely because of the indication. However, the drug is a vasodilator and could be used for other indications (e.g., see Sildenafil).

FETAL RISK SUMMARY

Avanafil, a vasodilator, is a phosphodiesterase inhibitor that enhances the effect of nitric oxide. It is in the same pharmacologic class as sildenafil and yohimbine. Avanafil is indicated for the treatment of erectile dysfunction. It undergoes partial hepatic metabolism. Plasma protein binding is about 99% and terminal elimination half-life is about 5 hours (1).

Reproduction studies have been conducted in rats and rabbits. In rats given the drug during gestation days 6–17, no evidence of teratogenicity, or embryo or fetal toxicity was observed at exposures up to about 8 times the exposure at the maximum recommended human dose of 200 mg based on AUC for total avanafil (protein bound plus free drug) (MRHD). At the maternally toxic dose producing exposures about 30 times the MRHD, decreased fetal body weight with no signs of structural anomalies was noted. When the drug was given from gestation day 6 through lactation day 20, maternal exposures that were ≥ 17 times the human exposure caused reduced offspring growth and maturation. There was no observed effect on reproductive performance of maternal rats or offspring, or on the behavior of offspring at the highest dose. In rabbits given the drug during gestation days 6–18, no evidence of teratogenicity was

observed at exposures about 6 times the exposure at the MRHD. At a maternally toxic (reduced body weights) dose, increased post-implantation loss was observed consistent with increased late resorptions (1).

Studies for carcinogenicity in mice and rats were negative, as were various assays for mutagenic and clastogenic effects. In fertility impairment studies in male and female rats, a decrease in fertility, altered estrous cycles, no or reduced sperm motility, and an increased percentage of abnormal sperm occurred at exposures that were about 11 times the MRHD (1).

It is not known if avanafil crosses the human placenta. The molecular weight (about 484) and moderately long termination half-life suggest that the drug will cross to the embryo–fetus. However, the high plasma protein binding should limit the amount available to cross.

BREASTFEEDING SUMMARY

No reports describing the use of avanafil during human lactation have been located. Such reports are unlikely given its indication. However, the drug is a vasodilator and could be used for other indications (e.g., see Sildenafil). The molecular weight (about 484) and moderately long termination half-life (about 5 hours) suggest that the drug will be excreted into breast milk. However, the high plasma protein binding (about 99%) should limit the amount excreted. The most common ($\geq 2\%$) adverse effects observed in adults were headache, flushing, nasal congestion, nasopharyngitis, and back pain (1). Although use of the drug during breastfeeding is unlikely, nursing infants of mothers receiving the drug should be monitored for these effects.

AXITINIB

Antineoplastic (Tyrosine Kinase Inhibitor)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of axitinib during human pregnancy have been located. In one animal species, the drug was teratogenic, embryotoxic, and fetotoxic at maternal exposures that were lower than human exposures. Moreover, axitinib impairs fertility in both female and male animals. Although the human risk is unknown, women taking this drug should be informed of the potential risk to their embryo–fetus if they become pregnant.

FETAL RISK SUMMARY

Axitinib, available as oral tablets, is an inhibitor of receptor tyrosine kinases including vascular endothelial growth factor receptors that are implicated in pathologic angiogenesis, tumor growth, and cancer progression. There are several other agents in this subclass (see Appendix). It is indicated for the treatment of advanced renal cell carcinoma after failure of one prior systemic therapy. The drug is metabolized to relatively inactive metabolites and is highly bound (>99%) to plasma proteins with preferential binding to albumin and moderate binding to α_1 -acid glycoprotein. The plasma half-life is 2.5–6.1 hours (1).

Reproduction studies have been conducted in mice. An increase in post-implantation loss was observed when mice were given twice-daily doses up to about 10 times the systemic exposure (AUC) from the recommended human starting dose (RHSD) before mating and through the first week of pregnancy. In mice given twice-daily doses during organogenesis, embryo–fetal toxicities were observed, in the absence of maternal toxicity, that included cleft palate and variation in skeletal ossification at about 0.5 and 0.15 times, respectively, the exposure from the RHSD (1).

Carcinogenicity studies have not been conducted with axitinib. The drug was

not mutagenic or clastogenic in two in vitro assays, but was genotoxic in an in vivo assay. In fertility studies with male mice and dogs, testes/epididymis toxicity was observed that included decreased organ weight, atrophy or degeneration, decreased numbers of germinal cells, hypospermia or abnormal sperm forms, and reduced sperm density and count. Findings in the female reproductive tracts of these species included delayed sexual maturity, reduced or absent corpora lutea, decreased uterine weights, and uterine atrophy (1).

It is not known if axitinib crosses the human placenta. The molecular weight (about 387) and plasma half-life suggest that the agent will cross to the embryo–fetus, but the high plasma protein binding might limit the amount crossing.

BREASTFEEDING SUMMARY

No reports describing the use of axitinib during human lactation have been located. The molecular weight (about 387) and plasma half-life (2.5–6.1 hours) suggest that the agent will be excreted into breast milk, but the high plasma protein binding (>99%) might limit the amount in milk. However, the drug is given orally and, if excreted into milk, it could be absorbed into the systemic circulation by a nursing infant. The effect of this exposure on a nursing infant is unknown, but severe toxicity is a potential concern. Consequently, mothers taking this drug should not breastfeed.

1. Product information. Inlyta. Pfizer Laboratories, 2012.

AZACITIDINE

Antineoplastic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of azacitidine in human pregnancy have been located. The animal reproduction data at a small fraction of the human dose suggest risk, but the absence of human pregnancy experience prevents a more complete assessment. Pregnant women should not be given this drug, especially in the 1st trimester. If an inadvertent pregnancy occurs, the woman should be advised of the potential risk for severe adverse effects in the embryo and fetus. In addition, because of the animal fertility studies, men should be advised not to father a child while receiving azacitidine (1), and for several months after treatment.

FETAL RISK SUMMARY

Azacitidine, a pyrimidine nucleoside analog of cytidine, inhibits methylation of DNA. It is the same antineoplastic subclass as decitabine and nelarabine. Azacitidine is given by injection. It is indicated for the treatment of patients with the following myelodysplastic syndrome (MDS) subtypes: refractory anemia or ringed refractory anemia with ringed sideroblasts (if accompanied by neutropenia or thrombocytopenia or requiring transfusions), refractory anemia with excess blasts, refractory anemia with excess blasts in transformation, and chronic myelomonocytic leukemia (1). The metabolites are apparently inactive. The mean elimination half-lives of azacitidine and its metabolites are about 4 hours (1).

Reproduction studies have been conducted in mice and rats. In pregnant mice, a single intraperitoneal (IP) dose, which was about 8% of the recommended human daily dose based on BSA (RHDD), on gestation day 10 caused a 44% frequency of embryo death (resorption). IP doses that were about 4%–16% of the RHDD given on or before gestation day 15 were

associated with developmental abnormalities in the brain. In pregnant rats, embryotoxicity was evident when an IP dose (about 8% of the RHDD) was given on gestation days 4–8 (post-implantation). No embryotoxicity was observed when the drug was given on gestation days 1–3 (pre-implantation). Fetal deaths were observed when a single IP dose was given on gestation days 9 or 10; on day 9, the average number of live animals per liter was reduced to 9% of controls. In addition, single IP doses on gestation days 9, 10, 11, or 12 were associated with CNS anomalies (exencephaly/encephalocele), limb defects (micromelia, club foot, and syndactyly), micrognathia, gastroschisis, edema, and rib abnormalities (1).

Azacitidine was carcinogenic in long-term studies in mice and rats. Tumors of the hematopoietic system were seen in female mice given IP doses that were about 8% of the RHDD 3 times weekly for 52 weeks. A similar dose given once per week in mice for 50 weeks caused an increased incidence of tumors in the lymphoreticular system, lung, mammary gland, and skin. A study in male rats dosed twice weekly with about 20%–80% of the RHDD revealed an increased incidence of testicular tumors. Azacitidine was mutagenic and clastogenic in multiple tests (1).

In fertility studies, daily doses that were about 9% of the RHDD given to male mice for 3 days before mating with untreated females were associated with reduced fertility and loss of offspring during subsequent embryonic and postnatal development. When male rats were dosed 3 times weekly for 11 or 16 weeks at about 20%–40% of the RHDD, decreased weight of the testes and epididymides and decreased sperm counts accompanied by decreased pregnancy rates and increased loss of embryos in mated females were observed (1).

It is not known if azacitidine crosses the human placenta. The molecular weight (244) and elimination half-life suggest that the drug will cross to the embryo and/or fetus.

BREASTFEEDING SUMMARY

No reports describing the use of azacitidine during human lactation have been located. The molecular weight (244) and the elimination half-life (about 4 hours) suggest that the drug will be excreted into breast milk. The potential effects of this exposure on a nursing infant are unknown, but the effects may be severe. In adults, the most common adverse effects are nausea, anemia, thrombocytopenia, vomiting, pyrexia, leukopenia, diarrhea, fatigue, constipation, neutropenia, and ecchymosis (1).

AZATADINE

[Withdrawn from the market. See 9th edition.]

AZATHIOPRINE

Immunologic Agent (Immunosuppressant)

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 3rd Trimester

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Although teratogenic in two animal species, azathioprine does not appear to cause structural anomalies in humans when used during organogenesis. Exposure in the 3rd trimester has been linked to immunosuppression. In addition, bone marrow suppression of the newborn has been reported, but modification of the dose in the 3rd trimester appears to reduce the risk of this toxicity. Intrauterine growth restriction also has been reported, but this effect may have been a consequence of multiple factors, one of which was azathioprine, working in combination. Taken in sum, however, the evidence suggests that the maternal benefit of treatment outweighs the potential risk to the fetus and newborn. If azathioprine is used in pregnancy for Crohn's disease, health-care professionals are encouraged to call the toll-free number (877-311-8972) for information about patient enrollment in an Organization of Teratology Information Specialists (OTIS) study.

FETAL RISK SUMMARY

Azathioprine is used primarily in patients with organ transplants or in those with inflammatory bowel disease as an immunosuppressant. Prednisone is commonly combined with azathioprine in these patients. The drug readily crosses the placenta, and trace amounts of its metabolite, 6-mercaptopurine (6-MP), have been found in fetal blood (see also Mercaptopurine) (1). 6-MP is converted intracellularly to active nucleotides (2), also called thioguanine nucleotides (TGNs); (see references 45 and 46).

Azathioprine is teratogenic in rabbits, producing limb reduction defects after small doses, but not in mice and rats (3). The manufacturer, however, has reproduction data on file indicating that azathioprine, in doses equivalent to the

human dose (5 mg/kg/day), was teratogenic in both mice and rabbits (4). Malformations included skeletal defects and visceral anomalies.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 7 newborns had been exposed to azathioprine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). One (14.3%) major birth defect was observed (none expected), but information on the type of malformation is not available. No cases were observed in six defect categories, including cardiovascular defects, oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias.

Most investigators have found azathioprine to be relatively safe in pregnancy (5–26). Several references have described the use of azathioprine during pregnancy in women who have received renal transplants (23,26–30), liver transplants (31–33), or a heart transplant (34). The drug has not been associated with congenital defects in these reports.

Sporadic anomalies have been reported, but these are not believed to be related to the drug therapy (23,27). Defects observed include pulmonary valvular stenosis (35); preaxial polydactyly (thumb polydactyly type) (36); hypothyroidism and atrial septal defect (azathioprine therapy started in 2nd trimester) (37); hypospadias (mother also had severe diabetes mellitus) (20); and plagiocephaly with neurologic damage, congenital heart disease (mild mitral regurgitation), bilateral pes equinovarus, cerebral palsy (frontal hemangioma) and cerebral hemorrhage (died at 2 days of age) in twins, hypospadias, and congenital cytomegalovirus infection (14). The latter infection had also been reported in another infant whose mother was taking azathioprine (11). Chromosomal aberrations were noted in three infants after in utero exposure to the drug, but the relationship to azathioprine and the clinical significance of the findings are questionable (14,38).

Immunosuppression of the newborn was observed in one infant whose mother received 150 mg of azathioprine and 30 mg of prednisone daily throughout pregnancy (11). The suppression was characterized by lymphopenia, decreased survival of lymphocytes in culture, absence of immunoglobulin M, and reduced levels of immunoglobulin G. Recovery occurred at about 15 weeks of age. An infant exposed to 125 mg of azathioprine plus 12.5 mg of prednisone daily during pregnancy was born with pancytopenia and severe combined immune deficiency (39). The infant died at 28 days of complications brought on by irreversible bone marrow and lymphoid hypoplasia. To avoid neonatal leukopenia and thrombocytopenia, maternal doses of

azathioprine were reduced during the 3rd trimester in a 1985 study (40). A significant correlation was found between maternal leukocyte counts at 32 weeks' gestation and at delivery and cord blood leukocyte count. If the mother's count was ≤ 1 SD for normal pregnancy, her dose of azathioprine was halved. Before this technique was used, several newborns had leukopenia and thrombocytopenia, but no low levels were measured after institution of the new procedure (40).

Intrauterine growth restriction may be related to the use of azathioprine in pregnancy. Based on animal experiments and analysis of human exposures, one investigator concluded that growth restriction was associated with the drug (41). Reports that are more recent have also supported this association (42). The incidence of small-for-gestational-age infants from women who have undergone renal transplants and who are maintained on azathioprine and corticosteroids is approximately 20% (21,23), but some centers have rates as high as 40% (42). However, the effects of the underlying disease, including hypertension, vascular disease, and renal impairment, as well as the use of multiple medications other than azathioprine, cannot be excluded as major or sole contributors to the growth restriction.

Azathioprine has been reported to interfere with the effectiveness of intrauterine devices (IUDs) (23,43). Two renal transplant patients, maintained on azathioprine and prednisone, received a copper IUD (Cu7) and both became pregnant with the IUD in place (43). At another institution, 6 of 20 renal transplant patients became pregnant with an IUD in place (23). Because of these failures, additional or other methods of contraception should be considered in sexually active women receiving azathioprine and prednisone.

BREASTFEEDING SUMMARY

A study of four women, two with systemic lupus erythematosus (SLE) and two after liver transplant, who were taking azathioprine (50–100 mg/day) while nursing was reported in 2006 (44). Serial milk samples in two of the women with SLE (both taking 100 mg/day) were analyzed for 6-MP, the active metabolite of azathioprine. 6-MP was not detected in any sample (limit of detection 5 ng/mL). The absolute theoretical infant dose was $<0.09\%$ of the mother's weight-adjusted dose. Milk samples were collected from the other two mothers but were not analyzed. No adverse effects were observed in the four infants and all were doing well at follow-up (44). In a letter correspondence (45) and subsequent reply (46), it was pointed out that the active metabolites of azathioprine are actually toxic TGNs that are converted from 6-MP

intracellularly. Six mother–infant pairs were sampled to determine if TGNs were detectable in the serum of lactating women taking azathioprine and their infants (45). Neither TGNs nor other potentially toxic metabolites were detected. These additional data combined with the absence of detectable 6-MP in milk suggested that the nursing infant would not be exposed to the toxic metabolites of azathioprine (45,46).

AZELASTINE

Antihistamine

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of azelastine in human pregnancy have been located. The animal data suggest that the risk to the embryo–fetus is low. Moreover, the systemic bioavailability of the antihistamine after intranasal administration is only 40% and it is much lower after ocular administration. Nevertheless, the complete absence of human pregnancy experience prevents a full assessment of the risk. A 2000 review of the use of newer asthma and allergy medications in pregnancy stated that, based on the animal studies, there were better choices available than azelastine (1).

FETAL RISK SUMMARY

The antihistamine azelastine is formulated for intranasal and ophthalmic administration. It is a phthalazinone derivative that has histamine H₁-receptor antagonist activity. Azelastine nasal spray is indicated for the treatment of the symptoms of seasonal allergic rhinitis such as rhinorrhea, sneezing, and nasal pruritus and for the treatment of the symptoms of vasomotor rhinitis, such as rhinorrhea, nasal congestion, and postnasal drip (2). The ophthalmic preparation is indicated for the treatment of itching of the eye associated with allergic conjunctivitis (3).

The systemic bioavailability, after nasal administration, is 40% with peak plasma concentrations obtained in 2–3 hours (2). In contrast, very small amounts are absorbed after ophthalmic administration (3). The plasma concentrations of the major active metabolite desmethylazelastine range from 20% to 50% of the parent drug concentrations (2). The elimination half-lives of azelastine and the active metabolite are 22 and 54 hours, respectively.

Reproduction studies have been conducted in mice, rats, and rabbits. In

pregnant mice, an oral dose about 280 times the maximum recommended daily intranasal dose in adults based on BSA (MRDID) caused embryo–fetal death, malformations (cleft palate; short or absent tail; fused, absent, or branched ribs), delayed ossification, and decreased fetal weight. However, the dose also was maternally toxic (decreased weight). Neither maternal nor fetal toxicity was noted at a dose 10 times the MRDID (2). In rats, a dose about 240 times the MRDID was not maternally toxic but did cause fetal malformations (oligo- and brachydactylia), and delayed and skeletal variations. A maternal toxic dose (560 times the MRDID) resulted in embryo–fetal death and decreased fetal weight. A dose 25 times the MRDID caused no toxicity in the mother or fetus (2,4). In rabbits, doses greater than 500 times the MRDID caused severe maternal toxicity and resulted in abortions, delayed ossification, and reduced fetal weight. Neither maternal nor fetal adverse effects were observed with a dose 5 times the MRDID (2,4). In peri- and postnatal studies with rats, doses 25–240 times the MRDID were not associated with toxicity in the pups in terms of physical growth, reflexive behavior, activity, motor coordination, and learning and reproductive performance (4).

No carcinogenic effects in mice and rats were observed in 2-year studies at doses 100 and 240 times the MRDID, respectively. In addition, studies with azelastine for genotoxicity were also negative, as were fertility tests in rats at 240 times the MRDID (2).

It is not known if azelastine crosses the human placenta. The molecular weight (about 382 for the free base) and prolonged elimination half-life suggest that the drug could cross to the embryo and fetus. However, the low systemic concentrations of the parent drug and major active metabolite suggest that the amount available at the maternal:fetal interface will be clinically insignificant.

BREASTFEEDING SUMMARY

No reports describing the use of azelastine during human lactation have been located. The relatively low molecular weight (about 382 for the free base) and the prolonged elimination half-lives of the parent drug and major active metabolite suggest that the drugs will be excreted into breast milk. However, the systemic bioavailability after intranasal administration is only 40% and is much lower after ocular administration. Therefore, it is doubtful if clinically significant amounts will be excreted into milk.

AZFICEL-T

Dermatologic Agent

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of azficel-T in human pregnancy have been located.

Because it is an autologous product that is obtained from the patient by skin biopsy, reproduction studies in animals have not been conducted. The risk to an embryo or fetus appears to be nil.

FETAL RISK SUMMARY

Azficel-T is an autologous cellular product composed of dermal fibroblasts suspended in a sterile medium. The fibroblasts are obtained from postauricular skin biopsy tissue and sent to the manufacturer for aseptic expansion using standard tissue culture procedures. The cells are shipped back to the clinic when sufficient cells for three doses have been obtained and when patient administration has been scheduled. The product is given as three intradermal injections at 3- to 6-week intervals. Azficel-T is indicated for improvement of the appearance of moderate-to-severe nasolabial fold wrinkles in adults (1). Information on metabolism, plasma protein binding, and half-life is not relevant.

Studies in animals or by other means have not been conducted for reproduction, carcinogenicity, mutagenicity, and fertility.

Because the cells are injected intradermal they should not be in the systemic circulation. Moreover, intact cells should not cross the placenta.

BREASTFEEDING SUMMARY

No reports describing the use of azficel-T during human lactation have been located. Because the cells are injected intradermal they should not be in the systemic circulation and would not be present in breast milk. Moreover, the

product is made from the patient's own cells and would not be expected to harm a nursing infant.

AZILSARTAN

Antihypertensive

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of azilsartan in human pregnancy have been located. The limited 1st-trimester experience with other agents in this class does not suggest a risk of major anomalies. The antihypertensive mechanisms of action of azilsartan and angiotensin converting enzyme (ACE) inhibitors are very close. That is, the former selectively blocks the binding of angiotensin II to AT₁ receptors, whereas the latter prevents the formation of angiotensin II itself. Therefore, use of this drug during the 2nd and 3rd trimesters may cause teratogenicity and severe fetal and neonatal toxicity identical to that seen with ACE inhibitors (e.g., see Captopril or Enalapril). Fetal toxic effects may include anuria, oligohydramnios, fetal hypocalvaria, intrauterine growth restriction, prematurity, and patent ductus arteriosus. Anuria-associated anhydramnios/oligohydramnios may produce fetal limb contractures, craniofacial deformation, and pulmonary hypoplasia. Severe anuria and hypotension, resistant to both pressor agents and volume expansion, may occur in the newborn following in utero exposure to valsartan. Newborn renal function and blood pressure should be closely monitored.

FETAL RISK SUMMARY

Azilsartan, an angiotensin II receptor blocker (ARB) given orally, is the active form of the commercially available prodrug azilsartan medoxomil. It is indicated, either alone or with other agents, for the treatment of hypertension. Azilsartan is in the same class of angiotensin II receptor blockers as candesartan, eprosartan, irbesartan, losartan, olmesartan, telmisartan, and valsartan. It is metabolized to inactive metabolites. Plasma protein binding, primarily to

albumin, is high (>99%) and the elimination half-life is about 11 hours (1).

Animal reproduction studies have not been conducted with azilsartan. Long-term studies for carcinogenic potential in mice and rats were negative. Assays for mutagenicity have shown both positive and negative effects. The drug had no effect on the fertility of male and female rats (1).

It is not known if azilsartan crosses the human placenta. The molecular weight (about 607) and the elimination half-life suggest that the drug will cross to the embryo–fetus, even though the high plasma protein binding should limit the exposure. However, other agents in this class are known to cross the placenta and the same should be expected for azilsartan.

A 2012 review of the use of ACE inhibitors and ARBs in the 1st trimester concluded that there may be an elevated teratogenic risk, but the risk appeared to be related to other factors (2). The factors that typically coexist with hypertension in pregnancy included diabetes, advanced maternal age, and obesity.

BREASTFEEDING SUMMARY

No reports describing the use of azilsartan during human lactation have been located. The molecular weight (about 607) and the elimination half-life (about 11 hours) suggest that the drug will be excreted into breast milk, but the high plasma protein binding should limit the amount excreted. The effect of this exposure on a nursing infant is unknown. Diarrhea was the most common (2%) adverse reaction in adults (1). The American Academy of Pediatrics classifies ACE inhibitors, a closely related group of antihypertensive agents, as compatible with breastfeeding (see Captopril or Enalapril).

AZITHROMYCIN

Antibiotic

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

The human pregnancy data do not suggest an embryo–fetal risk of developmental toxicity from azithromycin. The antibiotic has not been associated with an increased risk of pyloric stenosis.

FETAL RISK SUMMARY

Azithromycin, an azalide antibiotic, is derived from erythromycin. It is in the macrolide anti-infective class that includes clarithromycin and erythromycin.

Animal studies using rats and mice treated with daily doses up to maternal toxic levels revealed no impairment of fertility or harm to the fetus. These daily doses were about 1 and 0.5 times, respectively, the human dose of 2 g/day based on BSA (HD) (1).

Long-term studies for carcinogenic effects have not been conducted, but tests for mutagenic and clastogenic effects were negative. No evidence of impaired fertility was found in rats given daily doses up to about 0.05 times the HD (1).

Azithromycin crosses the human placenta at term (2,3). In 20 women scheduled for elective cesarean section, a single 1-g oral dose of azithromycin was given 6 (N = 2), 12 (N = 7), 24 (N = 5), 72 (N = 5), or 168 (N = 1) hours before delivery. The mean maternal concentrations at delivery for the five groups were 311, 144, 63, 60, and <10 ng/mL, respectively, whereas the corresponding mean cord serum levels were 19, 26, 27, 19, and <10 ng/mL, respectively. Cerebrospinal fluid levels in the mothers (all had spinal anesthesia) were undetectable (<16 ng/mL) in each group.

In an ex vivo experiment with term human placentas utilizing a single placental cotyledon model, the mean transplacental transfer of three macrolide antibiotics (azithromycin, erythromycin, and roxithromycin) were 2.6%, 3.0%, and 4.3%, respectively (3). The percentages were calculated as the ratio between the

steady-state level in fetal venous and maternal arterial sides (3).

A number of reports (4–22) have described the use of azithromycin in human pregnancy. A 1994 abstract reported that 16 pregnant patients with cervicitis caused by Chlamydia had been treated with a single 1-g oral dose of the antibiotic in a comparison trial with erythromycin (4). Fifteen of the women had negative tests for Chlamydia after treatment. No data were given on gestational age at the time of treatment or on the pregnancy outcomes. In a second, similar report, also comparing efficacy with erythromycin, 15 pregnant women with chlamydial cervicitis were treated with a single 1-g oral dose (5). All of the women had negative cervical swabs for Chlamydia as analyzed by direct DNA assay 14 days after the dose. Three more recent reports have also documented the efficacy of azithromycin in the treatment of pregnant women with Chlamydia (6–8). Of the five reports, only the last study (8) indicated the gestational age at treatment (about 24 weeks), but none provided information on fetal outcome. In contrast to the effectiveness of azithromycin for Chlamydia infections, a single 1-g oral dose of the antibiotic was ineffective in reducing lower genital colonization with ureaplasma in pregnant women between 22 and 34 weeks' gestation with ruptured membranes or preterm labor (9). Two women with scrub typhus (tsutsugamushi disease) in the 2nd trimester were treated successfully with 3-day courses of azithromycin (10). Both delivered healthy infants.

A 1998 noninterventional observational cohort study described the outcomes of pregnancies in women who had been prescribed ≥ 1 of 34 newly marketed drugs by general practitioners in England (11). Data were obtained by questionnaires sent to the prescribing physicians 1 month after the expected or possible date of delivery. In 831 (78%) of the pregnancies, a newly marketed drug was thought to have been taken during the 1st trimester with birth defects noted in 14 (2.5%) singleton births of the 557 newborns (10 sets of twins). In addition, two birth defects were observed in aborted fetuses. However, few of the aborted fetuses were examined. Azithromycin was taken during the 1st trimester in 11 pregnancies. The outcomes of these pregnancies were 1 elective abortion and 10 normal, term babies (11).

In a 2005 abstract, 145 pregnant women were exposed to a new macrolide (38 azithromycin, 53 clarithromycin, and 54 roxithromycin), of which 103 were exposed in the 1st trimester (12). The rates of congenital anomalies compared with 928 exposed to a nonteratogen were similar (4.0% vs. 3.75%, $p = 0.156$). In a 2006 study, comparisons were made between three groups each containing 123 pregnancies: azithromycin (88 exposed in 1st trimester),

nonteratogenic antibiotics, and nonteratogenic agents (13). The rates of congenital anomalies were not significantly different, 3.4%, 2.3%, and 3.4%, respectively. The authors concluded that azithromycin was relatively safe during pregnancy (13).

A retrospective cohort study using data from Tennessee Medicaid included 30,049 infants born in 1985–2000 was published in 2009 (14). Infants with fetal exposures in the 1st trimester to four antibiotics recommended for potential bioterrorism attacks (azithromycin, amoxicillin, ciprofloxacin, and doxycycline) were compared with infants with no fetal exposure to any antibiotic. Erythromycin was included as a positive control. In the 559 infants exposed to azithromycin and no other antibiotics, the number of cases, risk ratios, and 95% CI were as follows: any malformation (23, 1.37, 0.85–2.22), cardiac (7, 1.13, 0.50–2.55), musculoskeletal (8, 1.58, 0.61–4.10), genitourinary (4, 1.34, 0.44–4.03), gastrointestinal (4, 1.57, 0.52–4.75), CNS (1, 0.81–6.27), and orofacial (2, 4.85, 0.88–26.60). The authors concluded that the four antibiotics should not result in a greater incidence of overall major malformations (see also Amoxicillin, Ciprofloxacin, and Doxycycline) (14).

A 2009 case report described the use of azithromycin (500 mg/day for 6 days) for the treatment of Q fever in the 9th week of pregnancy (15). A healthy 3500-g infant was born at 40 weeks'.

A study evaluating the effects of mass treatment (cefixime, azithromycin, and metronidazole) for AIDS prevention in Uganda was published in 1999 (16). Compared with controls, the prevalences of trichomoniasis, bacterial vaginosis, gonorrhea, and Chlamydia infection were significantly lower, but no difference was observed in the incidence of HIV infection. A second study using this same group of patients found, in addition to the lower rates of infection, reduced rates of neonatal death, low birth weight, and preterm delivery (17). However, in a third study involving the same Uganda women as above, children of 94 women with *Trichomonas vaginalis* who had been treated during pregnancy with the three-drug combination had increased low birth weight (<2500 g) and preterm birth rate compared with untreated controls (18). The authors concluded that treatment of the condition during pregnancy was harmful and that it was most likely due to metronidazole.

A prospective multicenter study published in 2008 compared pregnant women exposed to a new macrolide (azithromycin, clarithromycin, or roxithromycin) with two comparison groups (19). Of 161 women exposed to a macrolide, 118 were exposed in the 1st trimester. The rate of major malformations in the study group was 4.1% compared with 2.1% of those

exposed to other antibiotics (OR = 1.41, 95% CI 0.47–4.23). The authors concluded that the use of the new macrolides did not represent an increased risk of congenital defects strong enough for an elective abortion (19).

A prospective, multicenter observational 2012 study was conducted by teratogen information services in Italy, Israel, Czech Republic, the Netherlands, and Germany (20). Of the 608 women exposed to macrolides, 511 were exposed in the 1st trimester. The study group was compared with 773 women exposed to nonteratogens in the 1st trimester. The rate of major congenital defects were similar in the groups (3.4% vs. 2.4%, $p = 0.36$; OR 1.42, 95% CI 0.70–2.88) or in the rate of cardiovascular defects (1.6% vs. 0.9%). The rates for azithromycin (N = 134) were 5.2% vs. 2.4% ($p = 0.09$; OR 2.23, 95% CI 0.91–5.5) and 3% vs. 0.9% ($p = 0.06$; OR 3.59, 95% CI 0.99–12.88) (20).

Two reports, one an abstract, have examined the potential of azithromycin in the prevention of premature birth (21,22). In the abstract, azithromycin combined with metronidazole was compared with placebo in three different periods: <32 weeks', <35 weeks', and <37 weeks' (21). The combination did not decrease the incidence of preterm birth. In the other report, azithromycin was compared with placebo. The results provided no evidence that the use of the antibiotic could prevent preterm birth (22).

In a 2003 Danish study, 188 women received a macrolide (see Breastfeeding Summary) within 30 days of birth and none of their infants had infantile hypertrophic pyloric stenosis (23).

BREASTFEEDING SUMMARY

Azithromycin accumulates in breast milk. A woman, in the 1st week after a term vaginal delivery, was treated with a single 1-g oral dose of azithromycin for a wound infection following a bilateral tubal ligation and then, because of worsening symptoms, was given 48 hours of IV gentamicin and clindamycin (24). She was discharged from the hospital on a 5-day course of azithromycin, 500 mg daily, but only took three doses because she wanted to resume breastfeeding that had been stopped during azithromycin therapy. The patient continued pumping her breasts during this time to maintain milk flow and resumed breastfeeding 24 hours after the third dose of the antibiotic. Drug doses and approximate time from the first dose were 1 g (0 hours), 500 mg (59 hours), 500 mg (83 hours), and 500 mg (107 hours). Milk concentrations of azithromycin and times from the first dose were 0.64 mcg/mL (48 hours), 1.3 mcg/mL (60 hours), and 2.8 mcg/mL (137 hours) (maternal serum concentrations were not determined). The authors attributed the antibiotic's milk

accumulation to its lipid solubility and ion trapping of a weak base (24).

A 2003 study investigated the association between maternal use of macrolides and infantile hypertrophic pyloric stenosis (23). The Danish population-based cohort study comprised 1166 women who had been prescribed a macrolide (azithromycin, clarithromycin, erythromycin, spiramycin, or roxithromycin) from birth to 90 days postnatally compared with up to 41,778 controls. The odds ratios (ORs) for stenosis were 2.3–3.0, depending on the postnatal period of exposure (42, 56, 70, or 90 days), but none were significant. When stratified by gender, the ORs for males were 1.8–3.1 and again were not statistically significant. For females, the ORs at 70 and 90 days post-birth were 10.3 and 7.5, respectively, but only the former was significant (95% CI 1.2–92.3) (23).

Investigators from Israel examined the possible association between macrolide (azithromycin, clarithromycin, erythromycin, or roxithromycin) exposure in milk and infantile hypertrophic pyloric stenosis in a 2009 study (25). They compared 55 infants exposed to a macrolide antibiotic with 36 infants exposed to amoxicillin. In the macrolide group, seven (12.7%) had an adverse reaction (rash, diarrhea, loss of appetite, or somnolence), whereas three infants (8.3%) in the amoxicillin group had an adverse reaction (rashes or somnolence). The rates of adverse reactions were comparable. No cases of infantile hypertrophic pyloric stenosis were observed (25).

AZTREONAM

Antibiotic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No reports describing the therapeutic use of aztreonam in human pregnancy have been located. However, several studies have found that the drug crosses the human placenta and have described the pharmacokinetics in pregnancy. The animal reproduction data suggest low risk, but the absence of therapeutic experience in pregnancy prevents a more complete assessment of the embryo–fetal risk. Nevertheless, if the drug is indicated, it should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Aztreonam is a synthetic, monocyclic β -lactam antibiotic that is structurally different from other β -lactam antibiotics, such as the penicillins and cephalosporins. Administration of high IV doses of the drug to pregnant rats (15 times the maximum recommended human dose [MRHD]) and rabbits (5 times the MRHD) did not produce embryotoxic, fetotoxic, or teratogenic effects (1–5).

Single 1-g IV doses of aztreonam administered 2–8 hours before elective termination produced detectable concentrations of the antibiotic in fetal serum and amniotic fluid (6). In other studies, the drug was rapidly distributed into cord serum and amniotic fluid (7–11). Six studies have described the pharmacokinetics of aztreonam in pregnancy (7–12). No maternal or fetal adverse effects were reported in these studies.

BREASTFEEDING SUMMARY

Aztreonam is excreted into breast milk (7,11,13). In one study, peak milk concentrations 6 hours after a single 1-g IV dose were <0.4–1.0 mcg/mL (7). In an earlier study, 12 lactating women received a single 1-g dose of the

antibiotic either by IM injection (N = 6) or by the IV route (N = 6) (13). Infants were not allowed to breastfeed during the study. Milk and serum samples were collected at scheduled intervals for 8 hours after the dose. In the IM group, the mean peak milk concentration was estimated to be 0.3 mcg/mL, corresponding to a milk:serum ratio of 0.007. Similar calculations for the IV group yielded a peak value of 0.2 mcg/mL and a ratio of 0.002. The low milk concentrations measured in the study were compatible with the acidic nature of the drug and its very low lipid solubility. In another study, the milk concentration was 0.1–0.4 mcg/mL (11).

These data, combined with the poor oral absorption of the antibiotic, indicate that direct systemic effects from the antibiotic in nursing infants are unlikely (13).

The American Academy of Pediatrics classifies aztreonam as compatible with breastfeeding (14).

B

BACAMPICILLIN

[Withdrawn from the market. See 9th edition.]

BACITRACIN

Antibiotic

PREGNANCY RECOMMENDATION: Compatible (Topical)

BREASTFEEDING RECOMMENDATION: Compatible (Topical)

PREGNANCY SUMMARY

The pregnancy information is very limited, but the risk from topical use probably is nil. The IM formulation is not approved for use in adults and should not be used in pregnancy.

FETAL RISK SUMMARY

No reports linking the use of bacitracin with congenital defects have been located. The drug is primarily used topically, although the injectable form is available. One study listed 18 patients exposed to the drug in the 1st trimester (1). The route of administration was not specified. No association with malformations was found.

BREASTFEEDING SUMMARY

No reports describing the use of bacitracin during human lactation have been located. Such reports are unlikely because the drug is not approved for use in adults.

BACLOFEN

Muscle Relaxant

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

The human pregnancy experience with baclofen is limited to 10 cases, 7 of which involved intrathecal administration. This method results in plasma concentrations 100 times less than those achieved with oral administration (1). Late onset neonatal seizures were observed in one case in which the mother was taking 80 mg/day, the maximum recommended daily oral dose. No signs of toxicity were observed in the other two pregnancies in which the mothers were taking lower oral doses. This appears to be consistent with a dose–effect relationship, because the chemical and pharmacokinetic characteristics of baclofen suggest that it will cross the placenta. Although the human data are very limited, there is no evidence of developmental toxicity from other agents in the same pharmacologic class. The animal reproduction data have reduced relevance because, in one study, the teratogenic dose also caused maternal toxicity and, in another, a comparison with the human dose was not made. However, three other studies observed no teratogenicity in mice, rats, and rabbits, so the risk appears to be low. Taken in sum, more human data are required to assess the risk to the embryo and/or fetus adequately. However, the intrathecal route is probably low risk because of the expected very low systemic exposure. If a woman requires oral baclofen, it should not be withheld because of pregnancy, but the lowest dose possible should be used and offspring should be monitored for late-onset seizures.

FETAL RISK SUMMARY

Baclofen, an analog of γ -aminobutyric acid, is a centrally acting skeletal muscle relaxant. Although their specific mechanisms of action may differ, baclofen is in

the same class of centrally acting skeletal muscle relaxants as carisoprodol, chlorzoxazone, cyclobenzaprine, metaxalone, methocarbamol, orphenadrine, and tizanidine. Plasma protein binding is only about 30%, and 70%–80% of the drug is excreted unchanged in the urine. The plasma elimination half-life is 3–4 hours, whereas the elimination half-life in the cerebrospinal fluid is 1–5 hours. The maximum recommended daily oral dose is 80 mg (1,2). Because of its specialized indication to control spasticity secondary to multiple sclerosis and other spinal cord diseases and injuries, its use in pregnancy is anticipated to be limited.

Reproduction studies have been conducted in pregnant rats, mice, and rabbits. In rats, a maternal toxic (decreased food intake and weight gain) dose approximately 3 times the maximum recommended human dose based on BSA was associated with an increased incidence of omphalocele (ventral hernias) in fetuses. This defect was not observed in mice and rabbits (1). Shepard reviewed three studies involving rats, mice, and rabbits in which the drug was administered during organogenesis and all reported negative teratogenic findings (3). In contrast, in a 1995 study of pregnant rats that administered 30- or 60-mg/kg doses, vertebral arch widening was observed on day 10 of gestation at the lower dose, similar to that produced by valproic acid in rats (4). The author concluded that baclofen could produce spina bifida or other neural tube defects in rats. Interestingly, the 60-mg/kg dose did not produce this effect, causing speculation that the dose caused a greater severity of neural tube defects, and thus a greater number of unrecorded early fetal deaths (4).

It is not known if baclofen crosses the human placenta. The molecular weight (about 214), low plasma protein binding and metabolism, and the plasma elimination half-life suggest that the drug will cross to the embryo and fetus.

Six reports involving seven pregnancies have been published in which a continuous intrathecal infusion of baclofen was administered via an implanted pump in six and intrathecal bolus dose in one (5–10). The first case involved a 29-year-old woman with quadriplegia who was treated with 1000 mcg/day for 15 months to control her intractable spasticity (5). Conception occurred after ovulation stimulation with clomiphene. The baclofen dose was gradually increased to 1200 mcg/day to maintain control of her spasticity as the pregnancy progressed. Because of severe symptoms of autonomic dysfunction and loss of spasticity control (even at 1400 mcg/day), a cesarean section was performed under epidural bupivacaine anesthesia during the 35th week of gestation. A 2.04-kg healthy female infant was delivered with Apgar scores of 9 and 10, presumably at 1 and 5 minutes, respectively (5).

The second and third cases, both involving the same woman, were published in 2000 (6). A 38-year-old woman became pregnant after approximately 3.5 years of continuous intrathecal baclofen infusion to control severe spasticity resulting from a complete 5th cervical vertebra (C5)–level medullar injury. Good control of her spasticity was obtained with 140 mcg/day throughout her pregnancy. A healthy, 2.155-kg male infant was delivered by cesarean section at 36 weeks' gestation with Apgar scores of 9 and 10 at 1 and 5 minutes, respectively. The birth weight, length (47 cm), and head circumference (33 cm) were appropriate for gestational age. No major or minor malformations were noted on physical and ultrasonography examinations, and the child was developing normally at 24 months of age (6). Three months after delivery of her first infant, the woman became pregnant a second time while receiving 140 mcg/day throughout gestation. A cesarean section was performed at 34 weeks with delivery of a healthy, 2.24-kg male infant with Apgar scores of 8 and 10 at 1 and 5 minutes, respectively. The weight, length (46 cm), and head circumference (32 cm) were appropriate for gestational age. No abnormalities were noted in the infant, and he was developing normally at 12 months of age (6).

A 17-year-old woman, 27 weeks pregnant, presented with clinical symptoms and signs of severe tetanus (7). She was treated with intrathecal bolus doses of baclofen for 21 days to control her muscular contractures and paroxysms. The mean daily dose was 1350 mcg (range 250–1500 mcg).

She also received a continuous IV infusion of diazepam 20–200 mg/day. Diazepam was stopped at about 32 weeks' gestation, 3 days before the onset of spontaneous labor. A healthy 1.50-kg male infant was delivered with an Apgar score of 10 at 5 minutes. The infant had no muscular weakness or evidence of respiratory or neurologic distress. The infant was discharged home with his mother at 9 days of age (7).

A 23-year-old paraplegic woman at 30 weeks' gestation was started on intrathecal baclofen for increasing spasticity and spasticity-related pain (8). An infusion pump was implanted under general anesthesia with an initial dose of 150 mcg/day. Over the following 6 weeks, the infusion dose required to control her spasms increased to 375 mcg/day. Labor was induced at 37 weeks' gestation, and she gave birth to a healthy 2.81-kg female infant. The child was developing normally at 2 years of age (8).

A 2008 report described a 38-year-old woman with multiple sclerosis complicated by spasticity (9). The spasticity was treated with intrathecal baclofen 202.6 mcg/day throughout gestation. Because of spontaneous rupture

of the membranes and a transverse lie at 36 5/7 weeks, a healthy 2.68-kg male infant was delivered by cesarean section. Apgar scores were 9 and 10, presumably at 1 and 5 minutes, respectively. No follow-up of the infant was reported (9). In a similar case, but in which intrathecal baclofen (dose not reported) was used throughout gestation to control spasticity secondary to cerebral palsy, a 28-year-old woman gave birth at 38 weeks to a healthy 3.30-kg infant (sex not specified) (10). Apgar scores were 9 and 10 at 1 and 5 minutes, respectively. At 1-year follow-up, the infant was doing well.

A 2001 case report described a paraplegic woman who had used baclofen 80 mg/day (the maximum recommended daily oral dose), oxybutynin 9 mg/day, and trimethoprim 100 mg/day throughout an uneventful pregnancy (11). The fetus developed tachycardia at an unspecified gestational age and an apparently healthy female infant was delivered (birth weight not given). Apgar scores were 10 at 1 and 5 minutes. At 7 days of age, the infant was admitted to the hospital for generalized seizures, but the mother had noted abnormal movements 2 days after birth. All diagnostic test results were negative and the seizures did not respond to phenytoin, phenobarbital, clonazepam, lidocaine, or pyridoxine. Because seizures had been reported in adults after abrupt withdrawal of baclofen, a dose of 1 mg/kg divided into four daily doses was started and the seizures stopped 30 minutes after the first dose. Baclofen was slowly tapered and then discontinued after 2 weeks. Magnetic resonance imaging of the infant's brain on day 17 suggested a short hypoxic ischemic insult that was thought to have been secondary to the seizures (11).

A 41-year-old woman with stiff-limb syndrome was treated with oral baclofen and diazepam throughout an uncomplicated pregnancy (12). The dose of baclofen during the 1st trimester was 100 mg/day (i.e., >maximum recommended dose), whereas the diazepam dose was 60 mg/day. She was able to reduce the dose of the two drugs to 25 and 15 mg/day, respectively, from the 2nd trimester onward. Despite a birth complicated by fetal distress requiring assisted forceps delivery, the apparently healthy female infant had no evidence of sedation or withdrawal and remained well during breastfeeding. No other details regarding the infant were provided (12).

A 27-year-old woman was diagnosed about 2 months before pregnancy with stiff person syndrome (Moersche-Woltman syndrome) (13). She was treated with gabapentin (2700 mg/day), diazepam (30 mg/day), and a prednisone taper. When pregnancy was diagnosed, diazepam was discontinued but, without the drug, her muscle spasms increased and baclofen (30 mg/day) was started. The patient was able to wean down her medications in the 2nd and 3rd

trimesters (specific details not provided). Labor commenced at about 40 weeks while still on gabapentin and baclofen. A cesarean section was conducted because of fetal repetitive late decelerations to deliver a 3230-g female infant with Apgar scores of 5 and 8 at 1 and 5 minutes, respectively. The infant, discharged home on day 4, was doing well (age assumed to be 6 weeks) (13).

A 2004 report described the pregnancy outcome of a 38-year-old woman with reflex sympathetic dystrophy who was treated throughout gestation with baclofen 20 mg/day, clonazepam 2 mg/day, and oxycodone 50 mg/day in divided doses (14). A 3.71-kg female infant was delivered by cesarean section at 39 2/7 weeks' gestation because of breech presentation and maternal health considerations. The baclofen concentration in cord blood was below the level of quantitation (0.08 mcg/mL), but the interval between the last dose and birth was not specified. The infant developed transient respiratory distress shortly after birth that was attributed to retained lung fluid. Oral baclofen 0.5 mg/kg/day in four divided doses was started shortly after birth and tapered over 9 days. Although no seizure activity was observed, phenobarbital was started on day 2 because of narcotic withdrawal symptoms. On day 16 of life, the infant was discharged home on low-dose phenobarbital. Neurologic examination results were normal at discharge and at 6 weeks (14).

BREASTFEEDING SUMMARY

In an animal study, the γ -aminobutyric acid agonist, baclofen, was a potent inhibitor of suckling-induced prolactin release from the anterior pituitary (15). The drug had no effect on milk ejection. Because prolactin release is required to maintain lactation, the potential for decreased milk production with chronic use may exist. However, no human studies on this topic have been located.

Small amounts of baclofen are excreted into human milk after oral administration. A 20-year-old woman with spastic paraplegia, who was 14 days postpartum, was given a single 20-mg (94 microM) oral dose of baclofen (16). No mention was made as to whether her infant was nursing. Serum samples were drawn at 1, 3, 6, and 20 hours after the dose, and milk samples were obtained at 2, 4, 8, 14, 20, and 26 hours. The highest serum concentration measured, 1.419 microM/L, occurred at 3 hours, whereas the highest milk level, 0.608 microM/L, was obtained at 4 hours. The total amount of drug recovered from the milk during the 26-hour sampling period was 22 mcg (0.10 microM), or about 0.1% of the mother's dose. The authors speculated that this amount would not lead to toxic levels in a nursing infant (16).

The American Academy of Pediatrics classifies baclofen as compatible with

breastfeeding (17).

BALSALAZIDE

Anti-inflammatory Bowel Disease Agent

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of balsalazide in human pregnancy have been located. Balsalazide is a prodrug that is converted in the bowel to mesalamine (see Mesalamine). A 2002 review concluded that mesalamine is safe to use during pregnancy (1). Therefore, the maternal benefits of balsalazide appear to outweigh the unknown risks to the fetus.

FETAL RISK SUMMARY

The oral prodrug balsalazide is enzymatically cleaved in the colon to produce mesalamine (5-aminosalicylic acid) (see also Mesalamine). It is indicated for the treatment of mildly to moderately active ulcerative colitis. A very small portion of a balsalazide dose is absorbed intact into the systemic circulation where it is extensively ($\geq 99\%$) protein bound (2).

Reproduction studies have been conducted in rats and rabbits. In pregnant rats and rabbits, doses up to 2.4 and 4.7 times the recommended human dose based on BSA, respectively, revealed no evidence of impaired fertility or fetal harm. In addition, studies with mesalamine in these species did not observe fetal toxicity or teratogenicity (see Mesalamine) (2).

It is not known if balsalazide crosses the human placenta. The molecular weight (about 437) is low enough but the very small amounts in the plasma and extensive plasma protein binding suggest that little if any drug crosses to the embryo–fetus. Moreover, only small amounts of mesalamine are absorbed into the systemic circulation and then are rapidly excreted in the urine.

BREASTFEEDING SUMMARY

No reports describing the use of the prodrug balsalazide during human lactation

have been located. Only small amounts of balsalazide and its active metabolite mesalamine are absorbed into the systemic circulation. Moreover, the parent drug is extensively ($\geq 99\%$) bound to plasma proteins. A 2002 review concluded that mesalamine was safe to use by nursing mothers (1). However, a possible allergic reaction (diarrhea) was observed in a nursing infant whose mother was using mesalamine rectal suppositories. Because of this adverse effect, nursing infants should be closely observed for changes in bowel function if the mother is taking balsalazide.

BASILIXIMAB

Immunologic Agent (Immunosuppressant)

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably
Compatible

PREGNANCY SUMMARY

No reports describing the use of basiliximab in human pregnancy have been located. The animal data suggest low risk, but the absence of human pregnancy experience prevents a full assessment of the embryo–fetal risk. A 2004 review concluded that immunosuppressive antibodies, such as basiliximab, have little implication for pregnancy because they are used either for induction immunosuppression or to prevent an acute rejection episode (1). If exposure does occur during pregnancy, the risk for developmental toxicity appears to be low, but long-term studies of exposed offspring for functional abnormalities and other developmental toxicity are warranted. The manufacturer recommends that women of childbearing potential use effective contraception before and during therapy, and for 4 months afterward (2).

FETAL RISK SUMMARY

Basiliximab, an interleukin-2 (IL-2) receptor antagonist, is a chimeric (murine/human) monoclonal antibody (IgG_{1k}) indicated for the prophylaxis of acute organ rejection in patients receiving renal transplantation (2). Basiliximab is classified as a nondepleting (i.e., does not destroy T- or B-lymphocytes) protein immunosuppressant (3). It binds only to IL-2 receptor sites expressed on the surface of activated T-lymphocytes. This binding inhibits IL-2-mediated activation of lymphocytes. Basiliximab is used with immunosuppressive regimens that include cyclosporine and corticosteroids. The elimination half-life is about 7 days (2).

Reproduction studies have been conducted in monkeys. No maternal toxicity, embryotoxicity, or teratogenicity was observed when doses producing blood

concentrations 13 times higher than those observed in humans were given during organogenesis. However, immunologic toxicity studies were not performed in the offspring (2).

It is not known if basiliximab crosses the human placenta. The molecular weight of the glycoprotein (about 144,000) may prevent transfer. However, the prolonged elimination half-life and the fact that immunoglobulin G molecules are known to cross the placenta, at least in the 3rd trimester, suggest that some exposure of the embryo and/or fetus will occur.

IL-2 receptors may have an important role in the development of the immune system, but the potential effect of basiliximab on this development was not evaluated in monkey offspring. Moreover, while in the circulation, basiliximab impairs the response of the immune system to antigenic challenges. It is unknown if the ability to respond to these challenges returns to normal after clearance of basiliximab (2).

BREASTFEEDING SUMMARY

No reports describing the use of basiliximab during human lactation have been located. Because immunoglobulins and other large molecules are excreted into colostrum in the first 2–3 days after birth, basiliximab is also probably excreted during this time. It may not be possible to avoid exposure during this early period of lactation because of the prolonged elimination half-life (about 7 days). Excretion into mature milk also is possible. Although partial digestion of the antibody in the gastrointestinal tract is probable, the effects, if any, on a nursing infant from this exposure are unknown.

BECLOMETHASONE

Respiratory Drug (Corticosteroid)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

In a position statement from a joint committee of the American College of Obstetricians and Gynecologists (ACOG) and the American College of Allergy, Asthma, and Immunology (ACAAI) published in 2000, either beclomethasone or budesonide were considered the inhaled steroids of choice for use during pregnancy (1).

FETAL RISK SUMMARY

Beclomethasone dipropionate is given by inhalation for the chronic treatment of bronchial asthma in patients requiring corticosteroid therapy for the control of symptoms. It is also available for intranasal use and, outside of the United States, for topical application.

Beclomethasone was embryocidal (increased fetal resorption) and teratogenic when administered by SC injection to mice and rabbits at approximately 10 times the human dose (HD) (2,3). Congenital malformations observed included cleft palate, agnathia, microstomia, absence of the tongue, delayed ossification, and agenesis of the thymus. Similar toxic effects in both species were observed with SC injections that were approximately one-half the maximum recommended adult daily inhalation dose based on BSA (4). In the rat, no embryo or fetal harm was found with inhaled (at 10 times the HD) or oral (at 1000 times the HD) beclomethasone (2,3).

No human reports associating the use of beclomethasone with human congenital anomalies have been found. A 1975 report briefly mentioned seven healthy babies born from mothers who had used beclomethasone aerosol for >6 months (5). In another report, beclomethasone was used during 45 pregnancies in 40 women (6). Dosage ranged between 4 and 16 inhalations/day (mean 9.5), with each inhalation delivering 42 mcg of drug.

Three of the 33 prospectively studied pregnancies ended in abortion that was not thought to be caused by the maternal asthma. Forty-three living infants resulted from the remaining 42 pregnancies. Six infants had low birth weights, including two of the three premature newborns (<37 weeks' gestation). There was no evidence of neonatal adrenal insufficiency. One full-term infant had cardiac malformations (double ventricular septal defect, patent ductus arteriosus, and subaortic stenosis). However, the mother's asthma was also treated with prednisone, theophylline, and epinephrine. In addition, she had schizophrenia and diabetes mellitus for which she took fluphenazine and insulin (6). Cardiac malformations are known to occur with diabetes mellitus (see Insulin).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 395 newborns had been exposed to beclomethasone during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 16 (4.1%) major birth defects were observed (16 expected). Specific information was not available on the defects, but no anomalies were observed in six categories (cardiovascular defects, oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias). These data do not support an association between the drug and congenital defects.

A 2004 prospective, double-blind, double placebo-controlled, randomized study compared inhaled beclomethasone (194 women) with theophylline (191 women) for the treatment of moderate asthma during pregnancy (7). The mean gestational age at randomization was about 20 weeks in both groups. There was no significant difference in the rate of asthma exacerbations between the groups, but significantly fewer discontinued beclomethasone because of adverse effects. There also were no differences in maternal or perinatal outcomes (7).

A 2004 study examined the effect of inhaled corticosteroids on low birth weight, preterm births, and congenital malformations in pregnant asthmatic patients (8). The inhaled steroids with the number of patients were beclomethasone (N = 277), fluticasone (N = 132), triamcinolone (N = 81), budesonide (N = 43), and flunisolide (N = 25). Compared with the general population, the study found no increased incidence of small-for-gestational-age infants (<10th percentile for gestational age), low birth weight (<2500 g), preterm births, and congenital malformations (8).

A 2006 meta-analysis on the use of inhaled corticosteroids during pregnancy was published in 2006 (9). The analysis included five agents: beclomethasone,

budesonide, flunisolide, fluticasone, and triamcinolone. The results showed that these agents do not increase the risk of major congenital defects, preterm delivery, low birth weight, and pregnancy-induced hypertension. Thus, they could be used during pregnancy (9).

A 2007 report described the use of inhaled beclomethasone in 29 pregnant women (10). No effects on fetal growth or pregnancy outcomes were observed. Beclomethasone was metabolized by placental enzymes (10).

BREASTFEEDING SUMMARY

It is not known whether beclomethasone is excreted into breast milk. Other corticosteroids are excreted into milk in low concentrations (see Prednisone), and the passage of beclomethasone into milk should be expected. One report mentioned three cases of maternal beclomethasone use during breastfeeding (5). Effects on the nursing infants were not mentioned.

BEDAQUILINE

Antituberculosis

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of bedaquiline in human pregnancy have been located. The animal data suggest low risk but the absence of human pregnancy experience prevents a full assessment of embryo–fetal risk. Nevertheless, tuberculosis is a severe infection and, if indicated, bedaquiline should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Bedaquiline fumarate is an oral diarylquinoline antimycobacterial drug. It is indicated as part of combination therapy in adults (≥ 18 years) with pulmonary multidrug-resistant tuberculosis. It is metabolized to an inactive metabolite (M2). Plasma protein binding of bedaquiline is $>99.9\%$. The mean terminal elimination half-life of both bedaquiline and M2 is about 5.5 months, thought to reflect the slow release from peripheral tissues (1).

Reproduction studies have been conducted in rats and rabbits. In these studies, no evidence of fetal harm was found. The plasma exposure in rats was twofold higher (lower in rabbits) than the human plasma exposure (1).

Bedaquiline was not mutagenic or clastogenic in several assays. The drug had no effects on fertility in male and female rats (1).

It is not known if bedaquiline or M2 cross the human placenta. The molecular weight of bedaquiline (about 556) and the very long elimination half-lives of the parent compound and M2 suggest that both may cross to the embryo–fetus. However, the high plasma protein binding might reduce the amount available to cross the placenta.

BREASTFEEDING SUMMARY

No reports describing the use of bedaquiline during breastfeeding have been located. The molecular weight of bedaquiline (about 556) and the very long elimination half-lives (about 5.5 months) of the parent compound and M2 suggest that both may be excreted into breast milk, but the high plasma protein binding might reduce the amount excreted. However, bedaquiline is concentrated in the milk of rats with concentrations 6–12 times the maximum maternal plasma level. If a mother chooses to nurse while receiving the drug, her infant should be observed for nausea, arthralgia, headache, hemoptysis, and chest pain, the most common ($\geq 10\%$) adverse reactions observed in patients.

BELATACEPT

Immunologic Agent (Immunosuppressant)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk Contraindicated—1st Trimester (If Combined with Mycophenolate)

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible Contraindicated (If Combined with Mycophenolate)

PREGNANCY SUMMARY

No reports describing the use of belatacept in human pregnancy have been located. The animal data suggest low risk but the absence of human pregnancy experience prevents a better assessment. However, belatacept is used in combination with basiliximab induction, mycophenolate, and corticosteroids, and the latter two agents are known human teratogens (see Mycophenolate and Prednisone). Nevertheless, rejection of a transplanted organ has serious consequences for the mother and her pregnancy. Therefore, if indicated, the drug should not be withheld because of pregnancy but the woman should be informed of the potential risk to her embryo–fetus. In addition, physicians are encouraged to register pregnant patients in the National Transplant Pregnancy Registry by calling 1-877-955-6877.

FETAL RISK SUMMARY

Belatacept, a selective T-cell costimulation blocker given as an IV infusion, is a protein that is fused to a portion of human immunoglobulin G1 antibody. The parent molecule, abatacept, differs from belatacept by two amino acids. Belatacept is indicated for prophylaxis of organ rejection in adult patients receiving a kidney transplant and is used in combination with basiliximab induction, mycophenolate mofetil, and corticosteroids. Although information on the metabolism of belatacept was not provided by the manufacturer, the terminal half-life was about 8–10 days depending on the dose (1).

Reproduction studies have been conducted in rats and rabbits. In these species, no teratogenicity was observed at exposures that were 16 and 19

times the maximum recommended human dose during the first month of treatment based on AUC (MRHD). In rats, daily belatacept during gestation and throughout the lactation period was associated with maternal toxicity (infections) in a small percentage of dams at doses that were ≥ 3 times the MRHD. This toxicity resulted in increased pup mortality (up to 100% in some dams), but there were no abnormalities or malformations in surviving pups. The in vitro data indicate that belatacept has lower potency in rodents than in humans, but the in vivo difference in potency is unknown. Thus, the relevance of the rat toxicities to humans and the significance of the magnitude of the relative exposures to humans are unknown (1).

Carcinogenicity studies have not been conducted with belatacept but have been with abatacept, the more active analog in rodents. Weekly SC injections of abatacept in mice were associated with increases in the incidences of malignant lymphomas and mammary gland tumors (in females). The clinical significance of these findings is unknown because the mice were infected with endogenous murine leukemia and mouse mammary tumor viruses which are associated with an increased incidence of lymphomas and mammary gland tumors, respectively. However, cases of posttransplant lymphoproliferative disorder (a premalignant or malignant proliferation of B lymphocytes) have been reported in clinical trials. Genotoxicity studies have not been conducted with belatacept because they are not required for protein therapeutics. No effects on male or female fertility were observed (1).

It is not known if belatacept crosses the human placenta. The protein is known to cross the placenta of animals. The molecular weight (about 90,000) suggests that transfer of the agent across the placenta will be limited, but the elimination half-life will place it at the maternal–fetal interface for a prolonged period. Moreover, the parent molecule, abatacept crosses the placenta. In addition, immunoglobulin G crosses the placenta, especially in the latter portion of pregnancy and belatacept is an immunoglobulin G antibody. Therefore, exposure of the embryo and/or fetus should be expected.

BREASTFEEDING SUMMARY

No reports describing the use of belatacept during human lactation have been located. The molecular weight (about 90,000) suggests that excretion of the agent into breast milk will be limited, but the terminal half-life is very long (8–10 days). Immunoglobulin G is excreted into colostrum and belatacept is an immunoglobulin G antibody. Moreover, belatacept is used in combination with basiliximab induction, mycophenolate mofetil, and corticosteroids. Basiliximab

and corticosteroids appear to be compatible with breastfeeding (see Basiliximab and Prednisone), but mycophenolate is contraindicated (see Mycophenolate). Thus, although belatacept alone is probably compatible, if taken with mycophenolate breastfeeding should be avoided.

BELIMUMAB

Immunologic Agent (Immunomodulator)

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of belimumab in human pregnancy have been located. Teratogenicity was not observed in cynomolgus monkeys. This species was chosen because belimumab binds cynomolgus monkey and human B-lymphocyte stimulator protein with equal affinity. Compared with controls, an increased risk of fetal death was observed at the lowest but not the highest dose. An increased risk of infant death compared with controls also was observed with both doses. A dose relationship was not apparent in either outcome and the rates were consistent with historical control data for macaques. No other forms of developmental toxicity were observed in the offspring. If belimumab is used in pregnancy, patients should be informed of the lack of human pregnancy experience.

FETAL RISK SUMMARY

Belimumab is a human immune globulin G1 lambda (IgG1 λ) monoclonal antibody that is a specific inhibitor of soluble human B-lymphocyte stimulator protein. It is indicated for the treatment of adult patients with active, autoantibody-positive, systemic lupus erythematosus who are receiving standard therapy. The terminal half-life is 19.4 days (1).

Reproduction studies have been conducted in pregnant cynomolgus monkeys with IV infusion doses of 0 (controls), 5, and 150 mg/kg (the highest dose was about 9 times the anticipated maximum human exposure based on AUC) given every 2 weeks from gestation day 20 to 150. The antibody was not associated with direct or indirect teratogenicity. Skeletal and cardiac variations were observed but the rates were within historical control rates. Fetal deaths were observed in 14%, 24%, and 15%, respectively, and infant deaths were

observed in 0%, 8%, and 5%, respectively. The cause of the deaths was not known, but the incidences were considered incidental as they were comparable with historical control data for macaques. After cessation of treatment, B-cell numbers recovered about 1 year postpartum in adult monkeys and by 3 months of age in offspring (1,2).

Neither the carcinogenic potential nor the mutagenic potential has been evaluated. The effects on male and female fertility in animals have not been studied (1).

Although the molecular weight is high (about 147,000), belimumab crossed the placenta late in gestation in cynomolgus monkeys as expected for an immune globulin antibody (2). Because the human and monkey placentas are similar, exposure of the human fetus probably occurs.

BREASTFEEDING SUMMARY

No reports describing the use belimumab during human lactation have been located. Although the molecular weight is high (about 147,000), belimumab was excreted into the milk of cynomolgus monkeys (1). In addition, because maternal antibodies are excreted into breast milk, the presence of belimumab in milk should be expected. The effect of this exposure on a nursing infant is unknown.

BELLADONNA

Parasympatholytic

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The limited pregnancy experience showing teratogenicity requires confirmation. In general, however, anticholinergics appear to be low risk in pregnancy. (See Atropine.)

FETAL RISK SUMMARY

Belladonna is an anticholinergic agent. The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 554 of whom used belladonna in the 1st trimester (1, pp. 346–353). Belladonna was found to be associated with malformations in general and with minor malformations. Specifically, increased risks (standardized relative risk >1.5) were observed for respiratory tract anomalies, hypospadias, and eye and ear malformations. The association between belladonna and eye and ear malformations was statistically significant. Interpretation of these data is difficult, however, because the authors of the study emphasized that even though some agents had elevated risks and significant associations did occur, a cause-and-effect relationship could not be inferred. For use anytime during pregnancy, 1355 exposures were recorded (1, p. 439). No association was found in this group.

A 1994 case report described the use of belladonna alkaloid (4 times daily for 5 days) in two women with hyperemesis and excessive salivation (2). A phenothiazine (specific agent not mentioned) antiemetic also was given. One woman gave birth to a normal female infant at term, whereas the other gave birth to twins at 30 weeks. All three infants had normal examinations (2).

BREASTFEEDING SUMMARY

No reports describing the use of belladonna during lactation have been located.

In general, however, agents in this class are probably compatible with breastfeeding. (See Atropine.)

BENAZEPRIL

Antihypertensive

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The fetal toxicity of benazepril in the 2nd and 3rd trimesters is similar to other angiotensin-converting enzyme (ACE) inhibitors. The use of this drug during the 2nd and 3rd trimesters may cause teratogenicity and severe fetal and neonatal toxicity. Fetal toxic effects may include anuria, oligohydramnios, fetal hypocalvaria, intrauterine growth restriction (IUGR), prematurity, and patent ductus arteriosus. Stillbirth or neonatal death may occur. Anuria-associated oligohydramnios may produce fetal limb contractures, craniofacial deformation, and pulmonary hypoplasia. Severe anuria and hypotension, which is resistant to both pressor agents and volume expansion, may occur in the newborn following in utero exposure. Newborn renal function and blood pressure should be closely monitored.

FETAL RISK SUMMARY

Benazepril is an ACE inhibitor. It is indicated for the treatment of hypertension. It is metabolized to benazeprilat, a more potent active metabolite. The effective half-life of accumulation of benazeprilat is 10–11 hours (1).

Reproduction studies have been conducted in mice, rats, and rabbits. No teratogenic effects were observed at doses that were 9, 60, and >0.8 times, respectively, the maximum recommended human dose based on BSA (assuming a 50-kg woman) (1).

Benazepril crosses the human placenta (1). This is consistent with the molecular weight (about 425 for the free base of the parent drug) and suggests that its active metabolite also will cross.

A 1997 report described the use of benazepril (40 mg/day) in a 35-year-old woman with chronic hypertension (2). Treatment began several years before

conception. Anhydramnios was noted at 27 weeks' gestation and the drug was discontinued. Twelve days later, complete resolution of the severe oligohydramnios was documented and the woman eventually delivered a healthy 2600-g (10th percentile) male infant at 38 weeks' gestation. No signs or symptoms of impaired renal function were observed in the healthy infant (2).

A retrospective study using pharmacy-based data from the Tennessee Medicaid program identified 209 infants born between 1985 and 2000 who had 1st trimester exposure to ACE inhibitors (3). Infants of mothers with evidence of diabetes, either before or during pregnancy, were excluded, as were those exposed to angiotensin-receptor antagonists (ARBs), ACE inhibitors, or other antihypertensives beyond the 1st trimester, and known teratogens. The subject group (N=209) was compared with two groups, other antihypertensives (N=202) and no antihypertensives (N=29,096). The number of major birth defects in each of the three groups was 18 (8.6%), 4 (2%), and 834 (2.9%), respectively. Compared with the no antihypertensives group, exposure to ACE inhibitors was associated with a significantly increased risk of major defects (relative risk [RR] 2.71, 95% confidence interval [CI] 1.72–4.27). When the analysis was conducted by the type of defect, the highest rates were with cardiovascular defects, 9, 2, and 294, respectively, RR 3.72, 95% CI 1.89–7.30, and with CNS defects, 3, 0, and 80, respectively, RR 4.39, 95% CI 1.37–14.02. The major defects observed in the subject group were atrial septal defect (N = 6) (includes three with pulmonic stenosis and/or three with patent ductus arteriosus [PDA]), renal dysplasia (N = 2), PDA alone (N = 2), and one each of ventricular septal defect, spina bifida, microcephaly with eye anomaly, coloboma, hypospadias, intestinal and choanal atresia, Hirschsprung disease, and diaphragmatic hernia (3). In an accompanying editorial, it was noted that neither previous reports of 1st trimester exposure to ACE inhibitors nor the animal studies had observed an increased risk of birth defects (4). It also was noted that no mechanism for ACE inhibitor-induced teratogenicity was known. A subsequent communication raising concerns about the validity of the study in terms of adequate exclusion of diabetes, charting and coding errors in busy medical practices, and the effects of maternal obesity (5) was addressed by the investigators (6).

Benazepril and other ACE inhibitors are human teratogens when used in the 2nd and 3rd trimesters, producing fetal hypocalvaria and renal defects. The cause of the defects and other toxicity is probably related to fetal hypotension and decreased renal blood flow. The compromise of the fetal renal system may result in severe, and at times fatal, anuria, both in the fetus and in the newborn.

Anuria-associated oligohydramnios may produce pulmonary hypoplasia, limb contractures, persistent PDA, craniofacial deformation, and neonatal death (7,8). IUGR, prematurity, and severe neonatal hypotension may also be observed.

Two reviews of fetal and newborn renal function indicated that both renal perfusion and glomerular plasma flow are low during gestation and that high levels of angiotensin II may be physiologically necessary to maintain glomerular filtration at low perfusion pressures (9,10). Benazepril prevents the conversion of angiotensin I to angiotensin II and, thus, may lead to in utero renal failure. Since the primary means of removal of the drug is renal, the impairment of this system in the newborn prevents elimination of the drug resulting in prolonged hypotension. Newborn renal function and blood pressure should be closely monitored. If oligohydramnios occurs, stopping benazepril may resolve the problem but may not improve infant outcome because of irreversible fetal damage (7).

In those cases in which benazepril must be used to treat the mother's disease, the lowest possible dose should be used combined with close monitoring of amniotic fluid levels and fetal well-being. Guidelines for counseling exposed pregnant patients have been published and should be of benefit to health professionals faced with this task (7,11). However, the observation in Tennessee Medicaid data of an increased risk of major congenital defects after 1st trimester exposure to ACE inhibitors raises concerns about teratogenicity that have not been seen in other studies (4). Medicaid data are a valuable tool for identifying early signals of teratogenicity, but are subject to a number of shortcomings and their findings must be considered hypotheses until confirmed by independent studies.

In a 2002 case report, a woman with chronic hypertension presented at about 24 weeks' gestation with severe oligohydramnios (amniotic fluid index <2) (12). Her medications included benazepril, carvedilol, amiodarone, and furosemide. The fetus had a misshapen cranium with overlapping sutures, pericardial effusion, small bladder, echogenic focus in the heart, echogenic bowel, and normal-appearing kidneys. All the drugs except carvedilol were discontinued. An examination 18 days later revealed normal amniotic fluid volume and normal cranial anatomy. At about 37 weeks, she gave birth to a 2060-g (<3rd percentile) female infant with Apgar scores of 7 and 9 at 1 and 5 minutes, respectively. The infant's initial physical examination was normal. Except for bilious vomiting on day 1, that resolved by day 2, the infant's hospital course was normal. At 1 year of age, the infant was healthy and weighed 18 lb

(5th percentile) (12).

A 2012 review of the use of ACE inhibitors and ARBs in the 1st trimester concluded that there may be an elevated teratogenic risk, but the risk appeared to be related to other factors (13). The factors, that typically coexist with hypertension in pregnancy, included diabetes, advanced maternal age, and obesity.

BREASTFEEDING SUMMARY

Benazepril and benazeprilat are excreted into human breast milk (14). Nine women were given benazepril 20 mg/day for 3 days. At 1 hour after a dose, peak milk concentrations of benazepril were 0.9 mcg/L, whereas the peak level of benazeprilat was 2 mcg/L at 1.5 hours postdose. The estimated infant dose as a percentage of the mother's weight-adjusted dose was <0.14% (14). These results are consistent with the data from other ACE inhibitors (see Captopril and Enalapril) that have found low amounts in milk and no adverse effects in nursing infants.

BENDAMUSTINE

Antineoplastic (Alkylating Agent)

PREGNANCY RECOMMENDATION: Contraindicated—1st Trimester

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of the alkylating antineoplastic agent bendamustine in human pregnancy have been located. Other agents in this class (see below) are known to cause human teratogenicity and, combined with the animal data strongly suggest that bendamustine should not be given in the 1st trimester. If a woman is inadvertently exposed to the drug during the 1st trimester, she should be informed of the potential risk.

FETAL RISK SUMMARY

Bendamustine is an alkylating antineoplastic agent that is a bifunctional mechlorethamine derivative given by IV infusion. It is in the same subclass of antineoplastics as busulfan, chlorambucil, cyclophosphamide, carmustine, dacarbazine, ifosfamide, mechlorethamine, melphalan, and streptozocin. Bendamustine is indicated for the treatment of patients with chronic lymphocytic leukemia. It also is indicated for indolent B-cell non-Hodgkin's lymphoma that has progressed during or within 6 months of treatment with rituximab or a rituximab-containing regimen. Bendamustine is metabolized to two minor active metabolites (M3 and M4) that have low plasma concentrations (10% and 1% of the parent compound concentrations, respectively). Plasma protein binding of bendamustine is 94%–96%. The elimination half-lives of the parent compound and the two active metabolites are about 40 minutes, 3 hours, and 30 minutes, respectively (1).

Reproduction studies have been conducted in mice and rats. In mice, an intraperitoneal dose about 2.1 times the recommended human dose based on BSA (RHD) given during organogenesis caused an increase in resorptions, decreased fetal body weights, and skeletal and visceral malformations (exencephaly, cleft palates, accessory rib, and spinal deformities). The dose did not cause apparent maternal toxicity. Repeat intraperitoneal dosing on

gestational days 7–11 resulted in increased resorptions and similar malformations. In rats, intraperitoneal doses about 1.2 times the RHD given 5 times during gestational days 4–13 caused embryo and fetal death. A significant increase also was observed in external (effect on tail, head, and herniation of external organs [exomphalos]) and internal (hydronephrosis and hydrocephalus) malformations (1).

Bendamustine was carcinogenic in mice, producing peritoneal sarcomas in females after 4 days of intraperitoneal injections and mammary carcinomas and pulmonary adenomas after 4 days of oral dosing. The drug also was mutagenic and clastogenic in several assays. In human males, impaired spermatogenesis, azoospermia, and total germinal aplasia have been reported after treatment with other alkylating agents and might occur with bendamustine (1).

Although it is apparent that bendamustine crosses the placenta in animals, it is not known if it or the active metabolites cross the human placenta. The molecular weight of the parent compound (about 359 for the free base) is low enough for passage, but the short elimination half-life combined with high plasma protein binding should reduce the amount transferred to the embryo or fetus. A similar conclusion can be reached for M4, which has a shorter half-life and a serum concentration that is only 1% of the parent compound's concentration. M3 has a longer half-life and its serum concentration is 10% of the parent compound's concentration.

Occupational exposure of the mother to antineoplastic agents during pregnancy may present a risk to the fetus. A position statement from the National Study Commission on Cytotoxic Exposure and a research article involving some antineoplastic agents are presented in the monograph for cyclophosphamide. (See Cyclophosphamide.)

BREASTFEEDING SUMMARY

No reports describing the use of bendamustine during human lactation have been located. The molecular weight of the parent compound (about 359 for the free base) and the presence of two active metabolites suggest that excretion into breast milk will occur. Because of the potential for serious toxicity in a nursing infant, breastfeeding should be discontinued while the mother is receiving therapy. Pumping and discarding the milk for at least 24 hours after a dose should prevent exposure of the nursling.

BENDROFLUMETHIAZIDE

Diuretic

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The available pregnancy experience with bendroflumethiazide is limited. Nevertheless, the published experience with 1st trimester use of thiazides and related diuretics does not indicate these agents are teratogenic. One large study (the Collaborative Perinatal Project) did find an increased risk of defects when diuretics were used during the 1st trimester in women with cardiovascular disorders, but causal relationships cannot be inferred from these data without independent confirmation. (See Chlorothiazide.) Diuretics are not recommended for the treatment of gestational hypertension because of the maternal hypovolemia characteristic of this disease. Other risks to the fetus or newborn include hypoglycemia, thrombocytopenia, hyponatremia, hypokalemia, and death from maternal complications. Moreover, thiazide diuretics may have a direct effect on smooth muscle and inhibit labor.

FETAL RISK SUMMARY

Bendroflumethiazide is a thiazide diuretic. Animal reproduction studies during the period of organogenesis have not been conducted with this agent.

In a study reported in 1964, 1011 women received bendroflumethiazide, 5 mg/day, from 30 weeks' gestation until delivery in an attempt to prevent preeclampsia and eclampsia (1). No fetal adverse effects were noted.

See Chlorothiazide for other reports of the clinical use of thiazide diuretics in pregnancy and the potential fetal and newborn toxicity of these agents.

BREASTFEEDING SUMMARY

Bendroflumethiazide has been used to suppress lactation (see Chlorothiazide)

(2). The American Academy of Pediatrics classifies bendroflumethiazide as compatible with breastfeeding (3).

BENZOCAINE

Local Anesthetic

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Only one source has described the use of benzocaine in human pregnancy and there are no animal reproduction studies. Systemic absorption may occur from mucous membranes or from damaged skin with the amount absorbed dependent on the administered dose. There are about 50 over-the-counter (OTC) products that contain benzocaine, a number suggesting wide use of this anesthetic. There is no evidence that topical use of this drug class is associated with any aspect of developmental toxicity. Nevertheless, the best course is to avoid use of benzocaine on mucous membranes or damaged skin during pregnancy.

FETAL RISK SUMMARY

Benzocaine (ethyl aminobenzoate) is a topical local anesthetic that is indicated for various purposes such as pruritic dermatoses, pruritus, minor burns, insect bites, toothache, and minor sore throat pain. Systemic absorption is poor from intact skin but it is well absorbed from mucous membranes and traumatized skin. It is metabolized, primarily by cholinesterase in plasma, to inactive metabolites. The agent is available OTC in formulations for oral and topical sprays, solutions, lozenges, creams, and gels (1).

Reproduction studies in animals have not been conducted.

It is not known if benzocaine crosses the human placenta. The molecular weight (about 165) is low enough that exposure of the embryo or fetus, if absorption has occurred, should be expected. However, appropriate clinical use should minimize any exposure.

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 47 of whom had exposure to benzocaine during the 1st trimester (2, pp. 357–363).

No evidence of an association with large classes of malformations was found. For use anytime during pregnancy, 238 exposures were recorded (2, p. 440). From these data, no evidence of an association with large categories of major or minor malformations or to individual defects was found. These results were also cited in a 1988 review of anesthetic agents (3).

BREASTFEEDING SUMMARY

No reports describing the use of benzocaine during breastfeeding have been located. Although the molecular weight (about 165) is low enough for excretion into breast milk, systemic absorption is poor from intact skin. However, the anesthetic is well absorbed from mucous membranes and traumatized skin and use of agent on these surfaces should be avoided or kept to minimum during breastfeeding.

BENZPHETAMINE

Anorexiant

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of benzphetamine in human pregnancy have been located. There are no animal reproductive data, but because of its close relationship to amphetamines, the manufacturer classes the drug as contraindicated during pregnancy. Although this drug should not be used in pregnancy, inadvertent exposure to benzphetamine does not appear to represent a significant risk to the embryo or fetus (see Amphetamines).

FETAL RISK SUMMARY

The sympathomimetic amine, benzphetamine, is chemically and pharmacologically related to the amphetamines. The primary pharmacologic actions include CNS stimulation and elevation of blood pressure. The drug is contraindicated in patients with moderate to severe hypertension and several other conditions. Benzphetamine is indicated in the management of obesity in combination with a regimen of weight reduction based on caloric restriction. As with all agents in this class, tolerance and tachyphylaxis may develop. Animal reproduction studies have not been conducted (1).

It is not known if benzphetamine crosses the human placenta to the fetus. The relatively low molecular weight (about 276), however, suggests that exposure of the embryo–fetus will occur.

BREASTFEEDING SUMMARY

No reports describing the use of benzphetamine during lactation have been located. The relatively low molecular weight (about 276) suggests that the drug will be excreted in breast milk. The effects on a nursing infant from exposure via the milk are unknown, but there is potential for severe toxicity. Benzphetamine is chemically and pharmacologically related to the amphetamines. As such, it is contraindicated during nursing. (See

Amphetamines.)

BENZTHIAZIDE

Diuretic

See Chlorothiazide.

BENZTROPINE

Parasympatholytic

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

One surveillance study found a possible association between benztropine and cardiovascular defects, but confirmation is required. Exposure near term has been associated with paralytic ileus in the newborn.

FETAL RISK SUMMARY

Benztrapine is an anticholinergic agent structurally related to atropine (see also Atropine). It also has antihistaminic activity. In a large prospective study, 2323 patients were exposed to this class of drugs during the 1st trimester, 4 of whom took benztropine (1). A possible association was found in the total group with minor, but not major, malformations.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 84 newborns had been exposed to benztropine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Four (4.8%) major birth defects were observed (three expected), three of which were cardiovascular defects (one expected). No anomalies were observed in five other categories of defects (oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available. Based on a small number of exposures, a possible association is suggested with cardiovascular defects.

Paralytic ileus has been observed in two newborns exposed to chlorpromazine and benztropine at term (2). In one of these infants, other anticholinergic drugs may have contributed to the effect (see Doxepin). The small left colon syndrome was characterized by decreased intestinal motility, abdominal distention, vomiting, and failure to pass meconium. The condition cleared rapidly in both infants after a Gastrografin enema.

A 2008 case report described a 25-year-old pregnant woman who was under treatment for bipolar disorder with lithium carbonate (500 mg twice daily), haloperidol (5 mg twice daily), and benzotropine (2 mg twice daily) (3). Her pregnancy was normal until the last 2 weeks when she began to lose weight and developed hypertension. At 39 weeks, a cesarean section delivered a 2.500-kg male infant with Apgar scores of 9 and 10 at 1 and 5 minutes, respectively. Both the infant and placental weights were below the mean for the population. In addition, the maternal plasma concentrations of phosphatidylcholine and free choline were also below the population means in the 3rd trimester. Because these nutrients are important in pregnancy, the authors speculated that one of her drugs, most likely lithium, was the cause of the low birth and placenta weights (3).

BREASTFEEDING SUMMARY

No reports describing the use of benzotropine during human lactation have been located. In general, however, agents in this class are probably compatible with breastfeeding. (See Atropine.)

BENZYL ALCOHOL

Pediculicide/Anti-infective

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible (Topical) Contraindicated (Injectable)

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible (Topical) Contraindicated (Injectable)

PREGNANCY SUMMARY

Benzyl alcohol is used topically for head lice and as a bacteriostatic preservative in injectable solutions and other drug formulations. The animal reproduction data suggest low risk, but there is only one report describing its use as a preservative in a drug during human pregnancy and none as a pediculicide. Although a dose–response relationship has not been established, it is doubtful if sufficient benzyl alcohol would be absorbed from topical application to cause embryo–fetal toxicity. Thus, the embryo–fetal risk from topical use appears to be low, if it exists at all. The embryo–fetal risk from benzyl alcohol-preserved injectable products given to a pregnant woman is unknown. However, the plasma concentrations of the agent will be much higher than that obtained from topical use, so the safest course is to avoid injectable products, especially IV fluids, containing benzyl alcohol during pregnancy.

FETAL RISK SUMMARY

Benzyl alcohol is a pediculicide that is available as a 5% lotion. It is also used as a preservative in some injectable fluids and in multidose vials. As a lotion, it is indicated for the topical treatment of head lice infestation in patients 6 months of age and older. Treatment is repeated in 7 days. Small amounts of the drug were absorbed in 4 of 19 subjects when an exaggerated exposure period (3 times the normal exposure period) was used. Plasma concentrations in three subjects (6 months–3 years age group) at 0.5 hour posttreatment were 1.97–2.99 mcg/mL, whereas one subject in the 4–11 year age group 1 hour after treatment had a concentration of 1.63 mcg/mL (1). Benzyl alcohol is rapidly oxidized to benzoic acid and then conjugated in the liver with glycine to

form hippuric acid (2). No information on the plasma protein binding, pK_a , or elimination half-life has been located.

Comparisons between animal and human exposures could not be conducted because of the low systemic exposures in humans. Consequently, SC injections were given to pregnant rats and rabbits in doses that were 100–500 and 100–400 mg/kg, respectively. No teratogenic effects were noted in either species, but maternal toxicity was observed at the highest doses.

The carcinogenic potential of the lotion in animals has not been evaluated. However, no evidence of carcinogenic activity was observed in oral 2-year high dose studies in rats and mice. Mutagenic studies have revealed positive and negative findings. Fertility studies have not been conducted (1).

It is not known if benzyl alcohol crosses the human placenta. The molecular weight (about 108) is low enough, but the plasma concentrations are very low even after a higher than normal exposure period with the lotion.

A 1977 report described a postpartum woman with severe flaccid paraplegia that was thought to be due to benzyl alcohol. One hour after delivery, normal saline (40 mL) containing 1.5% benzyl alcohol as a preservative had been inadvertently injected into an epidural catheter. The neurologic symptoms gradually improved over the next 16 months (3).

Beginning in pregnancy, a 22-year-old woman who was homozygous for factor V Leiden was treated with dalteparin injections from a multidose vial that contained benzyl alcohol (4). In the fifth month of pregnancy, the physician became aware of the exposure and changed to a dalteparin formulation without the preservative. No toxicity was observed and 4 months later the woman gave birth to a healthy infant (no other details provided) (4).

BREASTFEEDING SUMMARY

No reports describing exposure to benzyl alcohol during lactation have been located. The molecular weight (about 108) is low enough for excretion into milk, but the plasma concentrations after topical use of the lotion are very low, if at all. Higher plasma concentrations should be expected if the mother has an IV catheter requiring flushes with benzyl alcohol preserved fluids or is receiving injections from multidose vials containing the preservative. Premature infants and term neonates typically have immature liver function and may not be able to conjugate benzoic acid, the initial metabolite, to hippuric acid, resulting in metabolic acidosis (2). However, although a dose–response relationship has not been determined, it appears unlikely that a nursing infant’s exposure to benzyl alcohol from breast milk would be high enough to cause toxicity.

BEPOTASTINE

Ophthalmic (Antihistamine)

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of bepotastine in human pregnancy have been located. The animal data suggest low risk. The systemic bioavailability is very low from ocular use; in addition, H₁-receptor antihistamines are considered low risk in pregnancy. Although human pregnancy experience is needed, the drug probably is compatible in pregnancy.

FETAL RISK SUMMARY

Bepotastine is a histamine H₁-receptor antagonist and inhibitor of the release of histamine from mast cells. It is indicated for the treatment of itching associated with allergic conjunctivitis. The product is available as a 1.5% solution with each milliliter containing 15 mg of bepotastine besilate (equivalent to 10.7 mg of bepotastine). The systemic absorption is minimal. In healthy adults, one drop of solution in both eyes 4 times daily for 7 days produced a peak plasma concentration of 7.3 ng/mL 1–2 hours after instillation. The elimination half-life apparently has not been determined, but plasma levels were below the quantifiable limit (2 ng/mL) at 24 hours. Metabolism also is minimal as about 75%–90% is excreted unchanged in the urine. Plasma protein binding is moderate (about 55%) (1).

Reproduction studies have been conducted with oral doses in rats and rabbits. During organogenesis and fetal development in rats, doses up to about 3300 times the systemic concentrations anticipated for topical ocular use in humans (SCH) were not teratogenic. At a dose 5 times higher, there was potential for causing skeletal abnormalities. When this higher dose was given during the perinatal and lactation periods, an increase in stillbirths and

decreased growth and development were observed in rat pups. The no-observed-effect level was about 1650 times the SCH. In rabbits during organogenesis and fetal development, doses >13,000 times the human dose based on body weight were not teratogenic (1).

Bepotastine did not significantly induce neoplasms in mice or rats in long-term studies. There also was no evidence of genotoxicity in multiple assays. There was a slight reduction in fertility index and surviving fetuses when a dose much higher than 3300 times the SCH was given to male and female rats. Infertility was not seen when the dose was lowered to 3300 times the SCH (1).

It is not known if bepotastine crosses the human placenta. The molecular weight (about 389 for free acid) and moderate plasma protein binding suggest that the drug will cross to the embryo–fetus. However, the minimal systemic bioavailability suggests that the exposure will be clinically insignificant.

BREASTFEEDING SUMMARY

No reports describing the use of bepotastine during human lactation have been located. The molecular weight (about 389 for free acid) and moderate plasma protein binding suggest that the drug will be excreted into breast milk. However, the minimal systemic bioavailability suggests that any exposure of a nursing infant will be clinically insignificant.

BEPRIDIL

[Withdrawn from the market. See 9th edition.]

BESIFLOXACIN

Ophthalmic (Anti-infective)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of besifloxacin in human pregnancy have been located. The animal data suggest low risk. Because the systemic bioavailability of the antibiotic is very low, the risk to the embryo or fetus also appears to be low.

FETAL RISK SUMMARY

Besifloxacin ophthalmic suspension is a quinolone antimicrobial that is indicated for the treatment of bacterial conjunctivitis caused by susceptible bacteria. Besifloxacin is in the same subclass of ophthalmic antibiotics as ciprofloxacin, gatifloxacin, levofloxacin, moxifloxacin, norfloxacin, and ofloxacin. Systemic absorption is minimal. Maximum plasma concentrations after bilateral dosing 3 times daily for 16 doses were <1.3 ng/mL (mean 0.43 ng/mL). The average elimination half-life in plasma was about 7 hours (1).

Reproduction studies using oral besifloxacin have been conducted in rats. No skeletal or visceral malformations were observed in fetuses with doses producing maternal plasma concentrations that were >45,000 times the mean plasma concentrations measured in humans (PCH). Increased postimplantation loss, decreased fetal weights, and decreased fetal ossification were noted, but these doses also produced maternal toxicity (reduced body weight gain and food consumption) and mortality. The no-observed-effect level (NOEL) was >11,000 times the PCH. The NOEL also was the same in a prenatal and postnatal development study in rats (1).

Long-term studies in animals for carcinogenicity have not been conducted. The drug was not mutagenic in one test but, similar to other quinolones, was mutagenic in another test. The drug also induced chromosomal aberrations. No

impairment of fertility in male and female rats was observed with oral doses that were >10,000 times the daily human ophthalmic dose (1).

It is not known if besifloxacin crosses the human placenta. The molecular weight (about 394 for the free base) and long plasma elimination half-life suggest that the drug will cross to the embryo–fetus. However, the minimal plasma concentrations suggest that the exposure will not be clinically significant.

BREASTFEEDING SUMMARY

No reports describing the use of besifloxacin during human lactation have been located. The molecular weight (about 394 for the free base) and long plasma elimination half-life (7 hours) suggest the drug will be excreted into breast milk. However, the maximum plasma concentrations (<1.3 ng/mL) suggest that exposure of a nursing infant will be clinically insignificant.

β-CAROTENE

Vitamin

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

There is no known embryo–fetal risk from the use of this vitamin in pregnancy.

FETAL RISK SUMMARY

β-Carotene, a natural precursor to vitamin A found in green and yellow vegetables as well as being commercially available, is partially converted in the small intestine to vitamin A (1). Even with therapeutic doses of the drug, serum levels of vitamin A do not rise above normal. Studies in animals have failed to show a teratogenic effect (see also Vitamin A) (2).

A single case describing the therapeutic use of this vitamin in human pregnancy has been located. A 35-year-old woman at 6.5 weeks' gestation was seen because of her daily intake of 180 mg (300,000 IU) of β-carotene for the past year for the treatment of skin lesions of porphyria (3). She had stopped taking the vitamin at 4.5 weeks' gestation because of the pregnancy, but her skin still had a yellow-orange tinge. Serum levels of β-carotene and retinol (vitamin A) were determined 2 weeks after her last dose. The β-carotene level was markedly elevated (0.403 mg/dL; normal 0.05–0.2 mg/dL) whereas the retinol concentration was low normal (0.069 mg/dL; normal 0.05–0.2 mg/dL) (3). At 18 weeks' gestation, her β-carotene level had fallen to 0.22 mg/dL. She delivered a healthy, normal-appearing, 3910-g male infant without skin discoloration at term. The infant was developing normally at 6 weeks of age.

BREASTFEEDING SUMMARY

Although there are no reports describing the use of β-carotene during human lactation, this vitamin is considered to be compatible with breastfeeding (see also Vitamin A).

BETAMETHASONE

Corticosteroid

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably
Compatible

PREGNANCY SUMMARY

Although no reports linking the use of betamethasone with birth defects have been located, four large epidemiologic studies have associated the use of corticosteroids during the 1st trimester with orofacial clefts. Betamethasone was not specifically identified in these studies, but only one study listed the corticosteroids used (see Hydrocortisone for details).

FETAL RISK SUMMARY

Betamethasone is often used in patients with premature labor at about 26–34 weeks' gestation to stimulate fetal lung maturation (1–15). The benefits of this therapy are as follows:

- Reduction in incidence of respiratory distress syndrome (RDS)
- Decreased severity of RDS if it occurs
- Decreased incidence of, and mortality from, intracranial hemorrhage
- Increased survival of premature infants

Betamethasone crosses the placenta to the fetus (16). The drug is partially metabolized (47%) by the perfused placenta to its inactive 11-ketosteroid derivative but less so than other corticosteroids, although the differences are not statistically significant (17).

In patients with premature rupture of the membranes (PROM), administration of betamethasone to the mother does not always reduce the frequency of RDS or perinatal mortality (18–22). An increased risk of maternal infection has also been observed in patients with PROM treated with corticosteroids (19,20). In a study comparing betamethasone therapy with nonsteroidal management of women with PROM, neonatal sepsis was observed in 23% (5 of 22) of steroid-

exposed newborns vs. only 2% (1 of 46) of the non-steroid-exposed group (21). A 1985 study also found increased neonatal sepsis in exposed newborns who were delivered >48 hours after PROM, 18.6% (14 of 75) vs. 7.4% (4 of 54) of nonexposed controls (22). In addition, moderate to severe respiratory morbidity was increased over that in controls, 21.3% vs. 11.1%, as well as overall mortality, 8% vs. 1.8% (22). Other reports, however, have noted beneficial effects of betamethasone administration to patients with PROM with no increase in infectious morbidity (15,23,24). In women colonized with group B streptococci, the combined use of betamethasone and ampicillin improved the outcome of preterm pregnancies with PROM (25).

Betamethasone therapy is less effective in decreasing the incidence of RDS in male infants than in female infants (23,26,27). The reasons for this difference have not been discovered. Slower lung maturation in male fetuses has been cited as a major contributing factor to the sex differential noted in neonatal mortality (28). Therapy is also less effective in multiple pregnancies (27,29), even when doses have been doubled (27). In twins, only the first-born seems to benefit from antenatal steroid therapy (27).

An increased incidence of hypoglycemia in newborns exposed in utero to betamethasone has been reported (30). Although other investigators have not observed this effect, maternal betamethasone-induced hyperglycemia is a possible explanation if the drug was given shortly before delivery.

In the initial study examining the effect of betamethasone on RDS, investigators reported an increased risk of fetal death in patients with severe preeclampsia (1). They proposed that the corticosteroid had an adverse effect on placentas already damaged by vascular disease. A second study did not confirm these findings (7).

A case of suspected betamethasone-induced leukemoid reaction was observed in an 880-g female infant at 30 weeks' gestation whose mother received 12 mg of betamethasone 4 hours prior to delivery (31). A second case, in a female infant born at 25–26 weeks 71 hours after betamethasone, was published in 1997 (32). Within about 7–10 days, the white blood cell count had returned to normal in both infants. A 1984 study examined the effect of betamethasone on leukocyte counts in mothers with PROM or premature labor (33). No effect, as compared with untreated controls, was found in either group.

A case of acute, life-threatening exacerbation of muscular weakness requiring intubation and mechanical ventilation was reported in a 24-year-old woman who was treated with betamethasone, 12 mg IM, to enhance fetal lung

maturity at 32 weeks' gestation (34). The onset of symptoms occurred 30 minutes after the corticosteroid dose. The authors attributed the crisis to betamethasone (adrenocorticosteroids are known to aggravate myasthenia) after other potential causes were ruled out. The infant was delivered by emergency cesarean section and, except for the typical problems related to prematurity, he had a normal hospital course.

Hypertensive crisis associated with the use of ritodrine and betamethasone has been reported (35). Systolic blood pressure was >300 mmHg with a diastolic pressure of 120 mmHg. Although the hypertension was probably caused by ritodrine, it is not known whether the corticosteroid was a contributing factor.

The effect of betamethasone administration on patent ductus arteriosus (PDA) was investigated in premature infants with a birth weight <2000 g (36). Infants of nontreated mothers had a PDA incidence of 44% vs. 6.5% for infants of treated mothers ($p < 0.01$). This reduction in the incidence of PDA after betamethasone therapy has also been observed in other studies (25). A study published in 1989 indicated that betamethasone caused transient, mild constriction of the ductus arteriosus (37). Eleven women with placenta previa with a mean gestational age of 31.7 weeks (range 27.3–37.3 weeks) were given two 12-mg IM doses of the drug, 24 hours apart, to promote fetal lung maturation. Fetal Doppler echocardiography of the ductus arteriosus was conducted just before the first dose then at 5 and 30 hours after the dose. Two of the fetuses showed mild constriction of the ductus 4–5 hours after the first injection, but the tests were normal when performed at 30 hours. No evidence of tricuspid regurgitation was observed (37). The authors concluded that the changes were probably not clinically significant.

A 1984 article discussed the potential benefits of combining thyroid hormones with corticosteroids to produce an additive or synergistic effect on fetal lung phosphatidylcholine synthesis (38). The therapy may offer advantages over corticosteroid therapy alone, but it is presently not possible because of the lack of commercially available thyroid stimulators that cross the placenta. The thyroid hormones, T4 and T3, are poorly transported across the placenta and thus would not be effective.

Five premature infants (three males and two females), exposed in utero to two 8-mg IM doses of betamethasone administered to the mother 48 and 24 hours before birth, were evaluated to determine the effect of the drug on endogenous progesterone, mineralocorticoid, and glucocorticoid activity (39). Plasma levels of the mineralocorticoids, aldosterone and 11-

deoxycorticosterone, were not significantly decreased in the newborns at birth or during the next few days. Glucocorticoid activity in the newborns, as measured by levels of corticosterone, cortisol, cortisone, and 11-deoxycortisol, was significantly depressed at birth but rebounded above normal values when the subjects were 2 hours of age, then returned to normal ranges shortly after this time. Progesterone and 17-hydroxyprogesterone levels in the fetuses and neonates were not affected by betamethasone.

A 1994 case report described a pregnancy in which seven weekly courses (two 12.5-mg IM doses every 12 hours) of betamethasone were given between 24 weeks' gestation and delivery at 34.5 weeks (40). The 2625-g male infant had a "moon facies" appearance and a "buffalo hump" of apparent excess adipose deposition in the upper back. Tests in the mother and infant shortly after delivery were consistent with hypothalamic–pituitary–adrenal axis suppression with low basal serum cortisol levels (40). At 10 months of age, the infant's motor development and cognitive function were normal for age, length and head circumference were at the 20th percentile, and weight was slightly less than the 5th percentile. The cushingoid features had completely resolved (40). Two more recent reports have also described adrenal suppression in women secondary to multiple antenatal betamethasone courses (41,42), and in newborns exposed to ≥ 3 courses (43). A 1999 study, however, did not observe adrenal suppression in nine infants whose mothers had received a mean of 4.8 treatment courses of betamethasone (44).

Although human studies have usually shown a benefit, the use of corticosteroids in animals has been associated with several toxic effects (45,46):

- Reduced fetal head circumference
- Reduced fetal adrenal weight
- Increased fetal liver weight
- Reduced fetal thymus weight
- Reduced placental weight

None of these effects has been observed in human investigations with single courses of betamethasone. However, multiple courses of betamethasone have been associated with lower birth weights and reduced head circumference at birth (43,47,48).

In children born of mothers treated with betamethasone for premature labor, studies conducted at 4 and 6 years of age have found no differences from controls in cognitive and psychosocial development (49,50). Two studies

published in 1990 evaluated children at 10–12 years of age who had been exposed in utero to betamethasone in a randomized, double-blind, placebo-controlled trial of the effects of the corticosteroid on fetal lung maturity (51,52). No differences were found between the exposed and placebo groups in terms of intellectual and motor development, school achievement, and social-emotional functioning (51). Concerning physical development, no differences between the groups were measured in terms of physical growth, neurologic and ophthalmologic development, and lung function (52). However, during the first few years of life the corticoid-exposed group had significantly more hospital admissions relating to infections than did those in the placebo group (52).

Studies conducted on very-low-birth-weight infants (500–1500 g) at 2 years of age indicated that, compared with nonexposed controls, exposed infants received antenatal betamethasone therapy that was associated with a significant improvement in survival, improved growth, and a decrease in early respiratory morbidity (53). Further study of the children at 5 years of age, but limited to those with birth weights of 500–999 g, found significantly improved survival but without significantly improved growth or decrease in early respiratory morbidity (54).

A study published in 1999 (55), with an accompanying editorial (54), reported a decrease in the incidence of cystic periventricular leukomalacia (PL) with prenatal betamethasone, but not with dexamethasone. Among 883 liveborn infants, with gestational ages ranging from 24 to 31 weeks, the rates of cystic PL in infants of mothers given betamethasone (N = 361), dexamethasone (N = 165), or no prenatal corticosteroids (N = 357) were 4.4%, 11.0%, and 8.4%, respectively. Cystic PL (necrosis of the white matter adjacent to the lateral ventricles resulting in the formation of cysts (56)) is the most frequent cause of cerebral palsy in premature infants (55).

A 1999 study reported a modest reduction in the risk of cerebral white matter damage (echolucency) and intraventricular hemorrhage (IVH) but a significant reduction in ventriculomegaly in premature infants weighing 500 to 1500 g (57). Significant reductions in the risk for echolucency and ventriculomegaly were seen in the gestationally youngest infants and in those with IVH, hypothyroxinemia, or vasculitis of the umbilical cord or chorionic plate of the placenta (57). In addition to this study, three other reports have also shown that the risk of IVH is reduced in preterm infants by the administration of antenatal betamethasone (58–60).

Another study on the reduction of PL with betamethasone appeared in 2001

(61). In 1161 neonates born at gestational ages of 24–34 weeks, 400 were exposed to antenatal betamethasone and 761 were not exposed (controls). The effects of antenatal betamethasone compared with controls were PL or IVH 23% vs. 31%, $p = 0.005$; PL with IVH 5% vs. 11%, $p = 0.001$; and isolated PL 3% vs. 7%, $p = 0.009$. The investigators concluded that antenatal betamethasone therapy was associated with a greater than 50% decrease in PL in preterm infants (61).

Among miscellaneous effects of antenatal betamethasone, decreased fetal heart rate variability has been demonstrated (62,63). In addition, a 1999 report described three newborns who developed various degrees of transient hypertrophic cardiomyopathy after multiple courses of antenatal betamethasone (64).

BREASTFEEDING SUMMARY

No reports describing the use of betamethasone during human lactation have been located. However, the molecular weights (about 435 for the acetate salt and about 517 for the sodium phosphate salt) are low enough that excretion into milk should be expected.

BETAXOLOL

Sympatholytic (Antihypertensive)

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

In one study, betaxolol was started in the 3rd trimester and no fetal harm was observed. Some β -blockers may cause intrauterine growth restriction (IUGR) and reduced placental weight, especially those lacking intrinsic sympathomimetic activity (ISA) (i.e., partial agonist). Treatment beginning early in the 2nd trimester results in the greatest weight reductions, whereas treatment restricted to the 3rd trimester primarily affects only placental weight. Betaxolol does not possess ISA. However, IUGR and reduced placental weight may potentially occur with all agents within this class. Although growth restriction is a serious concern, the benefits of maternal therapy with β -blockers, in some cases, might outweigh the risks to the fetus and must be judged on a case-by-case basis. If used near delivery, the newborn infant should be closely monitored for 24–48 hours for signs and symptoms of β -blockade. Long-term effects of in utero exposure to β -blockers have not been studied but warrant evaluation.

FETAL RISK SUMMARY

Betaxolol is a cardioselective β_1 -adrenergic blocking agent used in the treatment of hypertension and topically in the therapy of glaucoma. Betaxolol is teratogenic in rats producing skeletal and visceral anomalies at maternally toxic doses (600 times the maximum recommended human dose [MRHD]) (1). At this dose, postimplantation loss and reduced litter size and weight were also noted. At doses 6 and 60 times the MRHD, a possible increased incidence of incomplete descent of testes and sternebral reductions were observed (1). No teratogenic effects were observed in rabbits, but an increase in postimplantation loss occurred at the highest dose tested (54 times the MRHD)

(1).

Betaxolol rapidly crosses the human placenta (2–4). The mean fetal:maternal ratio at birth was 0.93. The half-life in newborns was 14.8–38.5 hours compared with that in the mothers of 15.6–22.1 hours (mean 19 hours) (2,3).

A 1990 report from France described the pregnancy outcomes of 22 women treated with betaxolol (10–40 mg/day) for mild to moderate hypertension (4). Treatment was begun at a mean of 30.7 weeks. The mean gestational age at birth was 37.2 weeks and the mean birth weight of the 23 neonates (1 set of twins) was 2.6 kg. One of the newborns was growth restricted (onset before betaxolol therapy) and five were premature. All were doing well at 9 months (4).

BREASTFEEDING SUMMARY

Betaxolol is excreted into human milk in quantities sufficient to produce β -blockade in a nursing infant (1). Although no reports have been located that describe the use of this agent during nursing, one study measured betaxolol concentrations in the milk of three mothers who had been treated with drug during pregnancy in the first 3 postpartum days (3). The last maternal dose had been taken 3–26 hours before delivery. The milk concentrations ranged from 3 to 48 ng/mL and the milk:plasma ratios ranged from 2.0 to 11.6, with the highest ratios occurring in one mother 48 and 72 hours after delivery. No mention was made if the mothers breastfed their infants

If betaxolol is used during nursing, the infant should be closely observed for hypotension, bradycardia, and other signs or symptoms of β -blockade. Long-term effects of exposure to β -blockers from milk have not been studied but warrant evaluation.

BETHANECHOL

Parasympathomimetic (Cholinergic)

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Human pregnancy experience is too limited to assess the embryo–fetal risk.

FETAL RISK SUMMARY

Bethanechol is indicated for the treatment of nonobstructive urinary retention and neurogenic atony of the urinary bladder with retention. Reproduction studies in animals have not been conducted (1).

The use of bethanechol in human pregnancy has been reported, but too little data are available to analyze (2).

BREASTFEEDING SUMMARY

Specific data on the excretion of bethanechol into breast milk are lacking. The molecular weight (about 197) is low enough, however, that excretion into milk should be expected. One author cautioned that mothers receiving regular therapy with this drug should not breastfeed (3). Abdominal pain and diarrhea have been reported in a nursing infant exposed to bethanechol in milk (4).

BEVACIZUMAB

Antineoplastic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Six reports describing the use of bevacizumab in human pregnancy have been located. All of these reports involved intravitreal injections. Three of the exposures involved unknown pregnancies. The outcomes of the pregnancies were two spontaneous abortions and seven healthy, term infants. The animal reproduction data, although involving only one species, suggest risk. Angiogenesis is critical to fetal development (1), so the drug is best avoided in pregnancy (2). Because of the very long elimination half-life, it could take as long as 100 days (range 55–250 days) to eliminate 97% of the drug from the plasma. If a pregnant woman requires treatment with bevacizumab, she should be advised of the potential risks to the embryo–fetus that include growth restriction, structural anomalies, and death.

FETAL RISK SUMMARY

Bevacizumab is a recombinant humanized monoclonal IgG1 antibody. It is indicated, in combination with IV 5-fluorouracil-based chemotherapy, as first- or second-line treatment of patients with metastatic carcinoma of the colon or rectum. Bevacizumab binds and inhibits the histologic activity of human vascular endothelial growth factor (VEGF). This effect prevents the formation of new blood vessels (angiogenesis). The drug is given as an IV infusion every 2 weeks. The estimated elimination half-life is about 20 days (range 11–50 days) (1). No information is available on metabolism.

Reproduction studies have been conducted in rabbits. Doses that approximated the human dose based on body weight were associated with developmental toxicity, including reduced maternal and fetal body weights, an

increased number of fetal resorptions, and an increased incidence of specific gross and fetal skeletal alterations. Adverse fetal outcomes were observed at all doses tested (1).

Carcinogenic and mutagenic studies have not been conducted with bevacizumab. Bevacizumab may impair fertility. Female cynomolgus monkeys were given doses that were equal to or 5 times the human 10 mg/kg dose for 13 or 26 weeks. Following recovery, dose-related decreases in ovarian and uterine weights, endometrial proliferation, number of menstrual cycles, and arrested follicular development or absent corpora lutea were observed (1).

It is not known if bevacizumab crosses the human placenta. Although antibodies are large molecules, the molecular weight of bevacizumab is about 149,000, some immune globulins are transported across the placenta to the embryo–fetus (e.g., see Immune Globulin Intravenous).

A brief 2009 report described the use of bevacizumab and verteporfin in a pregnant woman treated for choroidal neovascularization (CNV) secondary to punctate inner choroidopathy (3). She received photodynamic therapy with IV verteporfin about 1–2 weeks postconception. At 3-months postconception, she underwent intravitreal injection of 1.25 mg bevacizumab. The patient delivered a healthy infant at term with no evidence of congenital anomalies at birth or at 3-months of age (3).

A 2009 report described the use of intravitreal 1.25 mg bevacizumab in two early pregnancies, one at about 4 weeks in a 29-year-old and the other at about 3 weeks in a 25-year-old (4). Both pregnancies were spontaneously aborted 7 and 10 days, respectively, after the intravitreal injection. The authors cited a website stating that a 1.25-mg bevacizumab intravitreal injection achieves high systemic concentrations (100's ng/mL) and that blood levels have been detected for up to a month after injection (5). The authors speculated that the abortions resulted from the VEGF action of the drug (4).

In a 2010 case report, a woman with CNV received bevacizumab 1.25-mg intravitreal injection in both eyes, performed 1 week apart, and 6 weeks later, received a second 1.25-mg dose in the left eye (total dose 3.75 mg) (6). Three weeks later, she was diagnosed with a 5-week pregnancy. After an uneventful pregnancy, she gave birth at term to a healthy 3.17-kg female infant. No developmental abnormalities were observed in the infant who was doing well at 12 months of age (6).

Four pregnant women were treated with bevacizumab for CNV in a 2010 report (7). The women received a mean 2.6 injections (range 1–6) during pregnancy. All delivered healthy full-term infants who remained healthy with

normal growth and development during infancy (7).

A 2012 report described the pregnancy outcome of a 35-year-old woman with CNV who was treated with bevacizumab (dose not specified) in her 7th gestational week (8). She delivered vaginally a healthy 3.75-kg male infant at term with Apgar scores of 10 and 10. The infant had no congenital anomalies and had normal visual behavior. His growth and development were normal in his first 12 months (8).

BREASTFEEDING SUMMARY

No reports describing the use of bevacizumab during human lactation have been located. Although antibodies are large molecules (the molecular weight of bevacizumab is about 149,000), some immune globulins are excreted into breast milk. Of importance, human IgG is excreted into milk (1). Therefore, the excretion into milk of the closely related bevacizumab should be expected. The effects of this exposure on a nursing infant are unknown, but the toxicity could be severe. Thus, the best course is to not breastfeed if the woman is receiving bevacizumab therapy.

BEXAROTENE

Antineoplastic

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Bexarotene is contraindicated in pregnancy. No reports describing its use during human pregnancy have been located. Pregnancy should be excluded and the use of effective contraception (two reliable forms used simultaneously) confirmed before bexarotene therapy is started in women of childbearing age. If these criteria are met, therapy should be initiated on the 2nd or 3rd day of a normal menstrual cycle. The contraceptive methods should be used for 1 month before therapy, during therapy, and for 1 month after stopping therapy. The manufacturer also recommends that pregnancy tests be repeated monthly during treatment (1). In addition, male patients with sexual partners who are pregnant, possibly pregnant, or who could become pregnant, should use condoms during sexual intercourse during therapy and for 1 month after therapy has been stopped (1).

FETAL RISK SUMMARY

Bexarotene is a member of a subclass of retinoids that selectively binds and activates retinoid X receptor subtypes (RXR α , RXR β , and RXR γ). These subtypes then interact with various receptor partners to function as transcription factors that regulate the expression of genes that control cellular differentiation and proliferation. Bexarotene is indicated for the treatment of refractory cutaneous manifestations of cutaneous T-cell lymphoma. Four active metabolites have been identified (1).

In reproduction studies with pregnant rats during organogenesis, an oral dose approximately one-third of the AUC in humans at the recommended dose (RHD) caused incomplete ossification (1). When a dose about 1.33 times the RHD was given, cleft palate, depressed eye bulge/microphthalmia, and small ears were observed. Doses higher than about 0.8 times the RHD caused

embryo and fetal death. The no-effect dose was one-sixth the RHD (1). Studies on fertility and carcinogenicity have not been conducted, but tests for mutagenicity or clastogenicity were negative (1).

It is not known if bexarotene crosses the human placenta. The molecular weight (about 348) is low enough that transfer to the fetus should be expected.

BREASTFEEDING SUMMARY

No reports describing the use of bexarotene in human lactation have been located. The molecular weight (about 348) is low enough that excretion into breast milk should be expected. Because of the unknown amounts present in milk and the potential for serious adverse effects in a nursing infant, women receiving bexarotene should probably not breastfeed.

BIMATOPROST

Ophthalmic (Prostaglandin Agonist)

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of bimatoprost in human pregnancy have been located. The animal data suggest low risk, but the absence of human pregnancy experience prevents a more complete assessment of the embryo–fetal risk. However, clinically significant exposure of the embryo–fetus is unlikely and use of the drug in pregnancy is probably compatible.

FETAL RISK SUMMARY

Bimatoprost is a synthetic structural analog of prostaglandin with ocular hypotensive activity. It is given as one drop in the affected eye(s) once daily. It is in the same class of prostaglandin agonists as latanoprost, tafluprost, and travoprost. Bimatoprost is indicated for the reduction of elevated intraocular pressure in patients with open angle glaucoma or ocular hypertension. In healthy adults given one drop daily in each eye for 2 weeks, blood concentrations peaked (mean 0.08–0.09 ng/mL) at 10 minutes and were below the limit of detection (0.025 ng/mL) in most subjects at 1.5 hours after dosing. The drug is metabolized to apparently inactive metabolites. Plasma protein binding is about 88% and the elimination half-life, after an IV dose, was about 45 minutes (1). A similar elimination half-life appears to reflect the blood levels after ocular administration.

Reproduction studies have been conducted in mice and rats. In these species, abortion occurred at oral doses that were about 33 or 97 times, respectively, the maximum intended human exposure based on blood AUC (MIHE). At doses at least 41 times the MIHE, the gestation length was reduced, and the incidence of dead fetuses, late resorptions, perinatal and postnatal pup mortality was increased. In addition, pup body weights were

decreased (1).

Carcinogenicity studies were negative in mice or rats given oral doses of bimatoprost. The drug was not mutagenic or clastogenic in multiple assays. No impairment of fertility was observed in male and female rats given oral doses up to about 103 times MIHE (1).

It is not known if bimatoprost crosses the human placenta. The molecular weight (about 416) and moderate plasma protein binding suggest that the drug will cross to the embryo–fetus. However, the short elimination half-life and the very low blood concentrations probably indicate that any exposure will not be clinically significant.

Prostaglandin F2a has been used for pregnancy termination in humans via intrauterine extra-amniotic infusion to treat missed abortion or intrauterine death. However, there is no evidence that at doses given to reduce elevated ophthalmic pressure, an increased risk for uterine contractions would be seen (see Latanoprost).

BREASTFEEDING SUMMARY

No reports describing the use of bimatoprost during human lactation have been located. The molecular weight (about 416) and moderate plasma protein binding (about 88%) suggest that the drug will be excreted into breast milk. However, the short elimination half-life (about 45 minutes) and the very low blood concentrations suggest that clinically significant exposure will not occur.

BIPERIDEN

[Withdrawn from the market. See 9th edition.]

BISACODYL

Gastrointestinal Agent (Laxative)

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of bisacodyl in animal or human pregnancy have been located. A 1984 reference found no reports of adverse effects in pregnancy (1). In addition, a 1985 review considered stimulant laxatives, such as bisacodyl, to be safe in pregnancy, but regular or chronic use should be avoided (2). Because only small amounts are in the systemic circulation, the direct embryo–fetal risk probably is nil.

FETAL RISK SUMMARY

Bisacodyl is a diphenylmethane stimulant laxative that is indicated for the treatment of constipation and for the evacuation of the bowel before diagnostic procedures or surgery (3). It is structurally and pharmacologically related to phenolphthalein (4). (See also Phenolphthalein.) Bisacodyl is available as oral tablets and suppositories. Bisacodyl is converted to its active metabolite in the gastrointestinal tract and acts primarily in the large intestine (3). Only minimal amounts (about 5%) are absorbed into the systemic circulation (3,4).

Animal reproduction studies with bisacodyl have not been located.

It is not known if bisacodyl crosses the human placenta. The molecular weight (about 361) is low enough for passive diffusion across the placenta, but the minimal amounts in the circulation suggest that neither the embryo nor fetus will have clinically significant exposure to the drug.

BREASTFEEDING SUMMARY

No reports describing the use of bisacodyl during human lactation have been located. Although the molecular weight (about 361) is low enough for excretion into milk, only minimal amounts (about 5%) are absorbed into the maternal

circulation. The effects of this exposure on a nursing infant are unknown but appear to be negligible. Others have previously arrived at the same conclusion (5,6).

BISMUTH SUBSALICYLATE

Antidiarrheal

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Inorganic bismuth salts, formed from metabolism of bismuth subsalicylate in the gastrointestinal tract, apparently present little or no risk to the fetus from normal therapeutic doses, but the data available for bismuth in pregnancy are poor and the actual fetal risk cannot be determined (1). On the other hand, the potential actions of salicylates on the fetus are complex. Although the risk for toxicity may be small, significant fetal adverse effects have resulted from chronic exposure to salicylates. Because of this, the use of bismuth subsalicylate during gestation should be restricted to the first half of pregnancy, and then only in amounts that do not exceed the recommended doses.

FETAL RISK SUMMARY

Bismuth subsalicylate (bismuth salicylate) is hydrolyzed in the gastrointestinal tract to bismuth salts and sodium salicylate (2,3). Two tablets or 30 mL suspension of the compound yields 204 mg and 258 mg, respectively, of salicylate. Inorganic bismuth salts, in contrast to organic complexes of bismuth, are relatively water-insoluble and poorly absorbed systemically, but significant absorption of salicylate does occur (2,3). A brief 1992 study found minimal absorption of bismuth (exact serum concentrations not specified) from bismuth subsalicylate in 12 healthy subjects as opposed to a peak serum level of 0.050 mcg/mL after a dose of 216 mg of colloidal bismuth subcitrate in a single patient (4). Some bismuth absorption was documented across the normal gastric mucosa, but the primary absorption occurred from the duodenum. Others believe, however, that the design of the study produced the observed results, and that bismuth absorption occurs only in the gastric antrum, not in the gastric body or duodenum (5).

Although absorption of inorganic bismuth salts is negligible, in a study of chronic administration of bismuth tartrate, 5 mg/kg/day, one of four lambs born of treated ewes was stunted, hairless, and exophthalmic, and a second was aborted (6). Moreover, in one case report, the use of an extemporaneously compounded antidiarrheal mixture containing bismuth subsalicylate was associated with bismuth encephalopathy in a 60-year-old man who took an unknown amount of the preparation for a period of 1 month (7). Encephalopathy was diagnosed by an electroencephalogram characteristic of bismuth toxicity and a blood bismuth level of 72 ng/mL (upper limit of normal is 5 ng/mL).

No reports of adverse fetal outcome after the use of commercially available bismuth subsalicylate have been located for humans. The Collaborative Perinatal Project recorded 15 1st trimester exposures to bismuth salts (bismuth subgallate N = 13, bismuth subcarbonate N = 1, and milk of bismuth N = 1), but none to bismuth subsalicylate (8, pp. 384–387). These numbers are small, but no evidence was found to suggest any association with congenital abnormalities. For use anytime during pregnancy, 144 mother–child pairs were exposed to bismuth subgallate and 5 of the in utero–exposed infants had inguinal hernia, a hospital standardized relative risk of 2.6 (8, pp. 442, 497). A causal relationship, however, cannot be determined from these data.

In contrast to bismuth, salicylate is rapidly absorbed with >90% of the dose recovered in the urine. Data on the use of salicylates in human pregnancy, primarily acetylsalicylic acid (aspirin), are extensive. The main concerns from exposure to this drug during pregnancy include congenital defects, increased perinatal mortality from premature closure of the ductus arteriosus in utero, intrauterine growth restriction, and salicylate intoxication (see Aspirin). An increased risk of intracranial hemorrhage in premature or low-birth-weight infants is a potential complication of aspirin exposure near delivery, but other salicylates, including sodium salicylate, probably do not present a risk because the presence of the acetyl moiety seems to be required to suppress platelet function (9–11).

BREASTFEEDING SUMMARY

The excretion of significant amounts of bismuth obtained from bismuth subsalicylate into breast milk is not expected because of the poor absorption of bismuth into the systemic circulation. Salicylates, however, are excreted in milk and are eliminated more slowly from milk than from plasma with milk:plasma ratios rising from 0.03 to 0.08 at 3 hours to 0.34 at 12 hours (12). Because of

the potential for adverse effects in the nursing infant, the American Academy of Pediatrics recommends that salicylates should be used cautiously during breastfeeding (13). A review stated that bismuth subsalicylate should be avoided during lactation because of systemic salicylate absorption (14).

BISOPROLOL

Sympatholytic (Antihypertensive)

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Some β -blockers may cause intrauterine growth restriction (IUGR) and reduced placental weight, especially those lacking intrinsic sympathomimetic activity (ISA) (i.e., partial agonist). Treatment beginning early in the 2nd trimester results in the greatest weight reductions, whereas treatment restricted to the 3rd trimester primarily affects only placental weight. However, IUGR and reduced placental weight may potentially occur with all agents within this class. Although growth restriction is a serious concern, the benefits of maternal therapy with β -blockers, in some cases, might outweigh the risks to the fetus and must be judged on a case-by-case basis.

Newborn infants of mothers consuming the drug near delivery should be closely observed for 24–48 hours for signs and symptoms of β -blockade. Long-term effects of in utero exposure to β -blockers have not been studied but warrant evaluation.

FETAL RISK SUMMARY

Bisoprolol is a cardioselective β_1 -adrenergic blocking agent used in the management of hypertension. In animal reproduction studies, bisoprolol was not teratogenic in rats at doses up to 375 and 77 times the maximum recommended human dose (MRHD) based on weight and BSA, respectively, but fetotoxicity (increased late resorptions) was observed (1). No teratogenic effects were observed in rabbits at doses up to 31 and 12 times the MRHD based on body weight and BSA, respectively (1). Embryo lethality (increased early resorptions) was observed in rabbits.

A 2004 case report described a 24-year-old woman who took bisoprolol (5

mg/day), naproxen (550 mg about twice a week), and sumatriptan (100 mg about once a week) for migraine headaches during the first 5 weeks of pregnancy (2). An elective cesarean section was performed at 37 weeks for breech presentation to deliver a 3125-g male infant. The infant had a wide bilateral cleft lip/palate, marked hypertelorism, a broad nose, and bilateral but asymmetric toe abnormalities (missing and hypoplastic phalanges) (2).

BREASTFEEDING SUMMARY

No reports describing the use of bisoprolol in lactating women have been located. Nursing infants of mothers consuming bisoprolol should be closely observed for hypotension, bradycardia, and other signs or symptoms of β -blockade. Long-term effects of exposure to β -blockers from milk have not been studied but warrant evaluation.

BIVALIRUDIN

Thrombin Inhibitor

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably
Compatible

PREGNANCY SUMMARY

No reports describing the use of bivalirudin in human pregnancy have been located. The animal data suggest low risk. The absence of human data prevents an assessment of the embryo–fetal risk. However, the manufacturer recommends that bivalirudin should always be used with aspirin (300–325 mg/day) and aspirin may cause developmental toxicity (see Aspirin). In addition, maternal bleeding secondary to both agents is a potential complication, especially in the 3rd trimester, and in the newborn if exposure has occurred within a week of delivery. If indicated, however, the maternal benefit appears to outweigh the potential, but unknown embryo–fetal risk.

FETAL RISK SUMMARY

The reversible direct thrombin inhibitor bivalirudin is a synthetic 20-amino acid peptide. It is indicated, in combination with aspirin, for use as an IV anticoagulant in patients undergoing percutaneous transluminal coronary angioplasty. In patients with normal renal function, bivalirudin has a very short half-life (25 minutes) but may be as long as 3.5 hours for dialysis-dependent patients. Bivalirudin is not bound to plasma proteins (other than thrombin) or to red blood cells (1).

Reproduction studies have been conducted in rats and rabbits. In rats, SC doses up to 1.6 times the maximum recommended human dose based on BSA (MRHD) revealed no evidence of impaired fertility or fetal harm. Similar findings were observed in rabbits with SC doses up to 3.2 times the MRHD (1).

It is not known if bivalirudin crosses the human placenta. The molecular weight (about 2180 for the anhydrous free base) and the very short elimination

half-life in patients with normal renal function suggest that little, if any, of the peptide will cross the placenta.

BREASTFEEDING SUMMARY

No reports describing the use of bivalirudin during human lactation have been located. The molecular weight (about 2180 for the anhydrous free base) and short elimination half-life (25 minutes in patients with normal renal function) suggest that little, if any, drug will be excreted into milk. The indication for the drug suggests that women should not breastfeed while receiving bivalirudin. Waiting 3 hours or longer for patients with impaired renal function after the last dose would assure that the exposure of a nursing infant was minimal or nil. In addition, bivalirudin is a peptide that should be digested in the nursing infant's gastrointestinal tract.

BLACK SEED/KALANJI

Herb

PREGNANCY RECOMMENDATION: No Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

There are no animal or human pregnancy data for the seeds of *Nigella sativa* (black seed/kalanji) or its active ingredients. However, one animal study did show a protective effect of thymoquinone in pregnant diabetic mice. Hepatotoxicity has been observed in some animal tests and the oil can cause contact dermatitis. Because of its use since antiquity, it is unlikely that black seed/kalanji causes teratogenicity. However, its use to stimulate menstruation and its potential contraceptive properties suggests that the product should be avoided in pregnancy.

FETAL RISK SUMMARY

The seeds of the annual plant *N. sativa*, commonly known as black seed or kalanji, have been used as a medicine and food or spice for several thousand years in the Middle East, Europe, Africa, and India. The seeds contain a large number of compounds, including fixed oils, proteins, alkaloids, saponin, fatty acids, vitamin C, minerals, and essential oil. The main active constituents are thymoquinone, dithymoquinone, thymohydroquinone, and thymol (1,2).

The seeds and/or their active constituents have been used for numerous diseases and conditions and are thought to have beneficial effects on the respiratory, immune, and gastrointestinal systems. They also are claimed to have anticancer effects and have been used for their antioxidant, antidiabetic, anti-inflammatory, analgesic, antihypertensive, broad-spectrum antimicrobial, and anthelmintic properties. However, there are few clinical studies of these uses, and information on the doses taken is lacking. In women, the seeds have been used to stimulate menstruation and increase milk flow (1,2).

Animal reproduction tests with the seeds or its active compounds have not

been conducted. However, in a study of pregnant mice with streptozotocin-induced diabetes, thymoquinone (10 mg/kg/day) was shown to reduce the rate of malformations (3). Moreover, studies in rats and guinea pigs with the volatile oil of *N. sativa* have shown anti-oxytocic potential by inhibiting spontaneous uterine contractions and to have a potential contraceptive effect (1,2,4).

It is not known if any of the active constituents or other compounds found in the seeds of *N. sativa* cross the placenta.

BREASTFEEDING SUMMARY

No reports describing the use of black seed/kalanji during breastfeeding have been located. The seeds of *N. sativa* have been used for thousands of years and it is unlikely that they cause significant toxicity in a nursing infant. The product has been used to increase milk flow but, apparently, there are no clinical studies to support this claim (1,2).

BLACK WIDOW SPIDER ANTIVENIN

Antidote

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Only three reports describing the use of black widow spider antivenin in pregnancy have been located. In each case, the maternal symptoms did not respond to other therapies but did within 1 hour to the antivenin. No fetal harm was observed in these cases. Although there is a risk of immediate hypersensitivity reaction, the risk can be reduced by sensitivity testing before administration (1). Because the maternal symptoms can be severe and do not always respond to other therapies, the antivenin should not be withheld because of pregnancy if the test for sensitivity is negative (2).

FETAL RISK SUMMARY

Black widow spider antivenin is used to treat patients with symptoms due to bites by the black widow spider (*Latrodectus mactans*). It is a sterile, nonpyrogenic preparation of specific venom-neutralizing globulins obtained from the blood serum of healthy horses immunized against the venom, a neurotoxin, of black widow spiders. It is given either IM or IV. A skin or conjunctival test should be performed before administration of the antivenin to rule out sensitivity to horse serum (3).

Reproduction studies in animals have not been conducted, nor have studies for carcinogenesis, mutagenesis, and impairment of fertility (3).

It is not known if the globulins cross the human placenta. However, globulins are a family of proteins with high molecular weight. As such, it is doubtful if clinically significant amounts will cross to the embryo–fetus, although exposure in the 3rd trimester might occur.

The first published case of a black widow spider bite in pregnancy was in

1979 (4). A 20-year-old woman in her 16th week of pregnancy was bitten below the right breast. She experienced severe pain accompanied by abdominal and generalized muscle cramps. There was no cervical dilation, vaginal bleeding, or evidence of active labor. Fetal heart tones were 144 beats/minute. After skin testing, she was given an IV dose of antivenin and within 20 minutes was almost asymptomatic. She was discharged home the next day. About 18 weeks later, she gave birth by cesarean section to a healthy 3.7-kg male infant (4).

A 1994 case report described the pregnancy outcome of a 36-year-old woman at 22 weeks' gestation who was bitten by a black widow spider (5). There was no vaginal bleeding and her cervix was long and closed. She experienced restlessness, pain, and muscle cramping and was treated with calcium gluconate, diazepam, and morphine. She had some relief but her symptoms soon returned. After a negative skin test, one 2.5-mL vial of the antivenin was administered IV over 15 minutes. Within 1 hour her symptoms resolved and she was discharged home the following day. No further details on her pregnancy were provided (5).

In a 2000 case report, a 27-year-old woman at 38 1/7 weeks was bitten by a black widow spider (6). Her symptoms included anxiety and severe abdominal, chest, and back pain. She had irregular uterine contractions and her cervix was dilated 1 cm, 50% effaced. She was initially treated with calcium gluconate, morphine, diazepam, and midazolam, but these agents were not effective in relieving her symptoms. After a negative conjunctival test, she was given the antivenin (dose and route not specified) and within 1 hour her symptoms had markedly decreased. She still had uterine contractions and her cervix was now 2 cm, 75% effaced. However, she was discharged home the next day after her contractions stopped and with no further changes in her cervix. One week later, she had a spontaneous vaginal birth of a healthy male infant (6).

BREASTFEEDING SUMMARY

No reports describing the use of black widow spider antivenin during breastfeeding have been located. It is doubtful if such reports will appear because the symptoms of the bites can be quite severe and would probably hinder any attempt to breastfeed. In addition, the antivenin is composed of globulins (i.e., proteins). Even if they were excreted into breast milk, they would probably be digested in the nursing infant's gut. Thus, the limited data suggest that administration of the antivenin to the mother is compatible with

breastfeeding.

BLEOMYCIN

Antineoplastic

PREGNANCY RECOMMENDATION: Human and Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Bleomycin caused developmental toxicity (teratogenicity or death) in two animal species, but there are no reports describing the use of the drug during the 1st trimester in humans. When the drug was used later in pregnancy, it was combined with other antineoplastic agents. Although no reports of toxicity in offspring that were attributable to bleomycin were observed, the most frequent adverse effects in adults involve the skin and mucous membranes.

FETAL RISK SUMMARY

Bleomycin is an antineoplastic agent whose mechanism of action is thought to be inhibition of DNA synthesis and lesser inhibition of RNA and protein synthesis. It is in the same antineoplastic subclass of antibiotics as dactinomycin and mitomycin.

The drug is teratogenic in rats. Skeletal malformations, shortened innominate artery, and hydroureter were observed at an intraperitoneal dose about 1.6 times the recommended human dose based on BSA (RHD) given on days 6–15 of gestation. An IV dose about 2.4 times the RHD administered to rabbits on gestational days 6–18 resulted in abortions, but there were no teratogenic effects (1).

No reports linking the use of bleomycin with congenital defects in humans have been located. Chromosomal aberrations in human marrow cells have been reported, but the significance to the fetus is unknown (2). Two separate cases of non-Hodgkin's lymphoma in pregnancy were treated during the 2nd and 3rd trimesters with bleomycin and other antineoplastic agents (3,4). Normal infants without anomalies or chromosomal changes were delivered. In another case, a 21-year-old woman with a Ewing's sarcoma of the pelvis was treated with

bleomycin and four other antineoplastic agents at approximately 25 weeks' gestation (5). Nine weeks later, recurrence of tumor growth necessitated delivery of the normal infant by cesarean section to allow for more definitive treatment of the tumor. The child was reported to be developing normally at 4 years of age.

A 1989 case report described the effect of maternal chemotherapy on a premature newborn delivered at approximately 27 weeks' gestation (6). The mother was treated with bleomycin (30 mg), etoposide (165 mg), and cisplatin (55 mg) (all given daily for 3 days), 1 week before delivery, for an unknown primary cancer with metastases to the eye and liver. The mother developed profound neutropenia just before delivery. On the 3rd day after delivery, the 1190-g female infant also developed a profound leukopenia with neutropenia, 10 days after in utero exposure to the antineoplastic agents. The condition resolved after 10 days. At 10 days of age, the infant began losing her scalp hair and experienced a rapid loss of lanugo. Etoposide was thought to be the most likely cause of the neutropenia and the alopecia. By 12 weeks of age, substantial hair regrowth had occurred, and at 1 year follow-up, the child was developing normally except for moderate bilateral hearing loss. The investigators could not determine whether the sensorineural deafness was caused by the maternal and/or neonatal gentamicin therapy, or by the maternal cisplatin chemotherapy (6).

A 25-year-old woman underwent surgery at 25 weeks' gestation for an endodermal sinus tumor of the ovary (7). A chemotherapy cycle consisting of bleomycin (50 mg), cisplatin (75 mg/m²), and vinblastine (0.25 mg/kg) was started 9 days later. Approximately 3 weeks later she received a second cycle of therapy. A normal, healthy 1900-g male infant was delivered by scheduled cesarean section at 32 weeks' gestation. The infant was alive and growing normally at the time of the report (7).

Combination chemotherapy with bleomycin was used for teratoma of the testis in two men (8). In both cases, recovery of spermatogenesis with apparently successful fertilization occurred but the possibility of alternate paternity could not be excluded.

The long-term effects of combination chemotherapy on menstrual and reproductive function were described in a 1988 report (9). Only 7 of 40 women treated for malignant ovarian germ cell tumors received bleomycin. The results of this study are discussed in the monograph for cyclophosphamide (see Cyclophosphamide).

Occupational exposure of the mother to antineoplastic agents during

pregnancy may present a risk to the fetus. A position statement from the National Study Commission on Cytotoxic Exposure and a research article involving some antineoplastic agents are presented in the monograph for cyclophosphamide (see Cyclophosphamide).

BREASTFEEDING SUMMARY

No reports describing the use of bleomycin during human lactation have been located. It is not known if the drug is excreted into breast milk. Because of the risk of serious toxicity to a nursing infant, the safest course is to not breastfeed if the antineoplastic is being administered.

BLUE COHOSH

Herb

PREGNANCY RECOMMENDATION: Human and Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Blue cohosh is an herbal product that has uterine stimulant properties. Some of its constituents have been shown to be teratogenic and toxic in various animal species. The herb should be avoided in the 1st trimester because of the animal teratogenicity data and its estrogenic effect demonstrated in humans (1). It is used in human pregnancy to induce labor, but the potential fetal and newborn toxicity appears to outweigh any medical benefit (2,3). In addition, preparations of blue cohosh are not standardized as to content or purity.

FETAL RISK SUMMARY

Blue cohosh (*Caulophyllum thalictroides* Michx.; family Berberidaceae [barberries]) is found throughout damp woodlands of the eastern part of North America, especially in the Allegheny Mountains (1,2). It is an early spring, leafy perennial herb with yellowish-green flowers that mature into bitter, bright blue seeds. The medicinal parts, collected in the autumn, are the matted, knotty rootstock (rhizomes) (1,2). *Caulophyllum robustum* Maxim, a species found in Asia, is also used for medicine (2).

Blue cohosh is often used to stimulate labor. In a survey of nurse-midwives, blue cohosh was the most frequently used herbal preparation for this purpose (65% of respondents), usually administered prior to or instead of oxytocin (4). Native Americans used blue cohosh for menstrual cramps and suppression of profuse menstruation (2). It has also been used as an emmenagogue, antispasmodic, antirheumatic, laxative, or for colic, sore throat, hiccups, epilepsy, hysterics, and uterine inflammation (2,3). The roasted seeds have been used as a coffee substitute (3).

The chemical composition of blue cohosh has been investigated since 1863

(5). Because early Native Americans used the herb to facilitate childbirth, researchers in 1954 described a technique to isolate a crystalline glycoside from blue cohosh rhizome and roots that demonstrated marked activity as a smooth muscle stimulant. Increased tone and rate of contraction were observed in rat, rabbit, and guinea pig uteruses, as well as in other smooth muscle preparations (5).

A number of chemical constituents have been isolated from blue cohosh rhizomes. These include anagyrine, baptifoline, 5,6-dehydro- α -isulupanine, α -isolupanine, lupanine, sparteine, and N-methylcytisine (all are quinolizidine alkaloids), magnoflorine and taspine (aporphine alkaloids), caulophyllosaponin (also known as caulosaponin, a triterpene saponin), and caulosapogenin (1,2,6). In addition, a novel alkaloid, thalictroidine, has been recently found (6). N-Methylcytisine (also known as caulophylline) is a nicotinic agonist in animals (1,2).

Citing previously published data, a 1999 study listed the concentrations of the quinolizidine alkaloids found in some blue-cohosh-containing dietary supplements: N-methylcytisine 5–850 ppm, anagyrine 2–390 ppm, and baptifoline 9–900 ppm (the lower concentrations were found in liquid-extract products) (6). In contrast, the level of magnoflorine in the *C. thalictroides* rhizomes was 11,000 ppm (6).

N-Methylcytisine was teratogenic in a rat embryo culture, but thalictroidine, anagyrine, and α -isolupanine were not teratogenic in this system at the concentrations tested (6). Marked embryo toxicity, without evidence of teratogenicity, was shown for taspine (6).

In an animal reproduction test, pregnant rats were administered either a low or high potency of *Caulophyllum* extract (homeopathic concentrations) on days 1–5 of pregnancy (7). The lower potency prevented implantation by disrupting the site of implantation. In contrast, the high-potency preparation caused no adverse effect compared with controls, but did increase the average number of young per litter (8 vs. 5 for controls) (7).

Anagyrine is teratogenic in ruminants, such as cattle, causing “crooked calf syndrome” (8–13). The severity of the malformations has been shown to be dose-related (11,12). Malformations include bowed or twisted limbs, spinal or neck curvature, and cleft palate. The defects may result from decreased normal fetal movements, which are required for normal skeletal development, secondary to the action of the alkaloid on fetal muscarinic and nicotinic receptors.

In an experiment with rats, a low-potency extract of blue cohosh

(homeopathic concentration) administered between estrus cycles, immediately before estrus, and during estrus was shown to be an effective inhibitor of ovulation and also inhibited physiologic changes in the uterus (14). A high-potency extract (also homeopathic concentration) had no effect on ovulation or uterine changes.

No studies describing the placental crossing of any constituent of blue cohosh have been located. Based on the animal studies above, however, some or all of the alkaloids and other chemicals isolated from the herb probably cross the placenta.

A brief 1996 case report described an adverse newborn outcome after a woman with an uneventful pregnancy was given a combination of black and blue cohosh (dosage not specified) for labor induction (15). After a normal labor, a 3840-g female infant was born with Apgar scores of 1, 4, and 5 at 1, 5, and 10 minutes, respectively. No spontaneous breathing was observed, but resuscitation efforts were successful with the onset of breathing noted at 30 minutes. Mechanical ventilation was required during the hospital course, which was complicated by seizures and acute tubular necrosis. Computed tomography revealed basal ganglia and parasagittal hypoxic injury. Lower limb spasticity was apparent at 3 months of age, and the infant required nasogastric tube feeding. Although the cause of the neurologic toxicity in the newborn was unknown, the authors could not rule out a possible role for the herbal preparation. Citing published data, they speculated that black cohosh may have caused peripheral vasodilation and hypotension, whereas blue cohosh may have caused increased uterine activity. The combination of these actions may have led to a reduction of placental perfusion and caused hypoxia in the infant (15). The accuracy of this assessment has been challenged (16), but the case report below lends credibility to the concept that the use of blue cohosh in pregnancy may cause toxicity (17,18).

A 1998 case report described profound neonatal congestive heart failure in a newborn that was thought to have been caused by the mother's use of blue cohosh to promote uterine contractions (19). The 36-year-old woman had hypothyroidism but was euthyroid on replacement therapy. Except for this one condition, she had an uncomplicated pregnancy. One month before term, she was instructed by a midwife to take one tablet prepared from blue cohosh daily. Instead, for the next 5 weeks, the woman took one tablet 3 times daily. During this period, she reported increased uterine contractions and a decrease in fetal movements. A precipitous delivery occurred 1 hour after the onset of spontaneous labor, 15 minutes after spontaneous rupture of membranes. There

was slight meconium-stained amniotic fluid. The 3.66-kg male infant had Apgar scores of 6 and 9 presumably at 1 and 5 minutes, respectively, but cyanosis and poor perfusion developed within minutes of birth that required intubation and mechanical ventilation. At 1 hour of age, on 100% oxygen, umbilical arterial blood pH was 7.07, P_{CO_2} 40 mmHg, and P_{O_2} 38 mmHg. A chest X-ray revealed cardiomegaly and pulmonary edema and an electrocardiogram showed acute myocardial infarction. Hepatomegaly was present in addition to the cardiac abnormalities. The infant's condition gradually improved and he was discharged home after 31 days. At 2 years of age, the child was progressing well with normal growth and development and good exercise tolerance, but continued to receive digoxin therapy. There was persistent cardiomegaly and his left ventricular function remained mildly reduced. The authors attributed the toxicity to blue cohosh because it contains vasoactive glycosides and it is known to cause toxic effects on the heart of animals (19).

A 2004 case report described a stroke in a female, full-term infant (birth weight 3860 g) 26 hours after birth (20). The mother, on advice of her physician, had consumed a tea made from blue cohosh to induce labor. A cesarean section was performed because of a failed attempt at vaginal delivery. Focal motor seizures of the right arm began at 26 hours of age. At 2 days of age, a computed tomographic scan revealed an evolving infarct in the distribution of the left middle cerebral artery. Laboratory tests in the infant for thrombophilia were normal and a family history for clotting disorders was negative. A cocaine metabolite, benzoylecgonine, was detected in the urine, meconium, the mother's bottle of blue cohosh, and the contents of a sealed bottle of a different preparation of the herb. Although cocaine contamination of the products could not be excluded, a blue cohosh preparation (Inca Tea) contains coca leaves and can cause a positive test for cocaine exposure (20). In addition, among the natural constituents of blue cohosh, caulophyllosaponin can cause uterine contraction and coronary-artery constriction in animals (20), and methylcytisine is a nicotine agonist. In subsequent correspondence regarding the presence of benzoylecgonine, a chemical not related to blue cohosh, there was speculation that the mother may have taken cocaine or, more likely, it involved detection of a cross-reacting substance by an insensitive assay (21–23).

BREASTFEEDING SUMMARY

No reports describing the use of blue cohosh during lactation have been located. It is not known if the constituents of the herb are excreted into breast

milk. Depending on the maternal serum concentration of the various chemicals, however, some excretion should be expected. The effects of this exposure on a nursing infant are unknown, but the potential toxicity and estrogenic effects are substantial reasons to avoid blue cohosh ingestion during breastfeeding. At least one source states that its use during this period is likely unsafe (3).

BOCEPREVIR

Antiviral Agent

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk (Contraindicated 3-Drug Combination)

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity (3-Drug Combination)

PREGNANCY SUMMARY

No reports describing the use of boceprevir in human pregnancy have been located. The animal data suggest low risk. However, the indication for boceprevir involves the combined use with ribavirin and peginterferon alfa. Although peginterferon alfa is probably compatible with pregnancy (see Interferon Alfa), ribavirin is contraindicated because it has caused developmental toxicity in all animal species tested (see Ribavirin). The three-drug combination should be avoided in pregnancy.

FETAL RISK SUMMARY

Boceprevir, a mixture of two diastereomers administered orally, is an inhibitor of the hepatitis C virus protein serine protease. It is indicated, in combination with peginterferon alfa and ribavirin, for the treatment of chronic hepatitis C genotype 1 infection in adults with compensated liver disease, including cirrhosis, who are previously untreated or who have failed previous interferon and ribavirin therapy. It is metabolized by the liver to inactive metabolites. Plasma protein binding is about 75% and the mean elimination plasma half-life is about 3.4 hours (1).

Reproduction studies with boceprevir alone have been conducted in rats and rabbits. AUC exposures in these species that were 11.8 and 2.0 times, respectively, the human exposure at the recommended dose of 800 mg 3 times daily produced no effects on fetal development. However, ribavirin causes dose-related teratogenicity or embryoletality in animals (see Ribavirin) and peginterferon alfa causes dose-related abortions in animals (see Interferon Alfa) (1).

Two-year carcinogenicity studies in rats and mice with boceprevir were

negative. Similar studies in these species with ribavirin also were negative. Boceprevir was not genotoxic, but ribavirin was, in multiple assays. Ribavirin induced reversible testicular toxicity in animals and interferon alfa impaired fertility in females. Boceprevir caused reversible effects on fertility and early embryonic development in female rats, as well as dose-related testicular degeneration in male rats. This latter effect was not observed in mice and monkeys, and limited clinical monitoring has revealed no evidence of testicular toxicity in humans (1).

It is not known if boceprevir crosses the human placenta. The molecular weight (about 520), moderate plasma protein binding and elimination half-life suggest that the agent will cross to the embryo–fetus.

BREASTFEEDING SUMMARY

Studies describing the use of boceprevir during human lactation have not been located. The molecular weight (about 520), moderate plasma protein binding (about 75%) and elimination half-life suggest that the agent will be excreted into breast milk. The effects of this exposure on a nursing infant are unknown. However, boceprevir is always combined with ribavirin and peginterferon alfa (see Ribavirin and Interferon Alfa). The latter agent is known to be excreted into breast milk and ribavirin is probably excreted. If a woman taking this therapy is breastfeeding, her nursing infant could be exposed to all three agents. Thus, the best course of action is to not breastfeed.

BORTEZOMIB

Antineoplastic (Proteasome Inhibitor)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of bortezomib in human pregnancy have been located. The drug caused developmental toxicity (growth restriction and death) at a dose one-half of the human clinical dose of 1.3 mg/m² based on body surface area (HCD) in one of two species. Because the recommended dose is given over several weeks, use during pregnancy could result in multiple exposures of the embryo and/or fetus to a cytotoxic agent. The manufacturer recommends that women should be advised to use effective contraceptive measures to prevent pregnancy (1). Until human pregnancy data are available, the best course is to avoid the drug during pregnancy. However, if treatment is required during gestation, the decision to use bortezomib should be made on a case-by-case basis, but the woman should be advised of the potential risk to her embryo–fetus.

FETAL RISK SUMMARY

Bortezomib is a cytotoxic antineoplastic that is given as an IV bolus injection. It is the same class as carfilzomib. Bortezomib is indicated for the treatment of multiple myeloma patients who have received at least one prior therapy. The mean elimination half-life after first dose has ranged 9–15 hours, but has not been fully characterized in multiple myeloma patients. Plasma protein binding is moderate (about 83%). Bortezomib undergoes some metabolism to inactive metabolites, but plasma levels of metabolites at 10 and 30 minutes after a dose were low compared with the parent compound (1).

Reproductive studies have been conducted in rats and rabbits. No teratogenicity was observed at the highest doses tested during organogenesis in rats and rabbits that were about 0.5 times the HCD. However, in rabbits given the highest dose during organogenesis, there was significant postimplantation loss and decreased number of live fetuses, as well as

significant decreases in the weight of live fetuses (1).

Carcinogenic studies have not been conducted with bortezomib. The agent was not genotoxic in various tests, but did demonstrate clastogenic activity in one test. Although fertility studies have not been conducted, 6-month studies conducted for general toxicity in rats revealed degenerative changes in the ovaries and testes at doses that were approximately one-fourth and equivalent, respectively, to the HCD (1).

It is not known if bortezomib crosses the human placenta. The molecular weight (about 384), the long elimination half-life, the moderate plasma protein binding, and lack of rapid metabolism all suggest that the drug will cross to the embryo and/or fetus.

BREASTFEEDING SUMMARY

No reports describing the use of bortezomib during human lactation have been located. It is not known if bortezomib is excreted into breast milk. The molecular weight (about 384), the long elimination half-life, the moderate plasma protein binding, and lack of rapid metabolism all suggest that the drug will be excreted in milk. Bortezomib is given as IV bolus injections over several weeks. The effects of this exposure on a nursing infant are unknown, as is the oral bioavailability. However, because the drug is cytotoxic, the best course is to not breastfeed during treatment.

BOSENTAN

Vasodilator

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Three reports have described the use of bosentan in human pregnancy. No embryo–fetal harm was observed. Based only on the animal data, the manufacturer states that pregnancy must be excluded and that reliable contraceptive methods should be used before the drug is prescribed. It also recommends monthly pregnancy tests during treatment (1). Pregnant women should not take this drug unless the severity of pulmonary arterial hypertension warrants the risk.

FETAL RISK SUMMARY

The endothelin receptor antagonist bosentan is indicated for the treatment of pulmonary arterial hypertension. It is a neurohormone that binds specifically to endothelin receptor types ET_A and ET_B. After oral administration, bosentan has one active (contributes 10%–20% of the total activity) and two inactive metabolites. Bosentan is highly (98%) bound to plasma albumin (1). It has an elimination half-life of about 5 hours (1,2).

Reproduction studies have been conducted in rats and rabbits. In rats, daily doses equal to or greater than 2 times the maximum recommended human daily dose based on BSA (MRHDD) showed dose-related teratogenicity (defects of the head, mouth, face, and large blood vessels). Increased stillbirths and pup mortality were observed at doses 2 times the MRHDD or higher. Birth defects were not observed in rabbits given doses up to 1500 mg/kg/day (relationship to MRHDD not specified), but plasma concentrations were lower than those obtained in rats. The malformations observed in rats were similar to those observed in animals with other endothelin receptor antagonists and were thought to represent a class effect of these drugs (1).

Bosentan showed dose-related carcinogenicity in mice and rats given the agent over a 2-year period but no mutagenic or clastogenic activity. Short-duration studies showed no effect on fertility in male or female rats (1).

In near-term rats, closure of the fetal ductus arteriosus by indomethacin, N-nitro-L-arginine monomethyl ester (L-name), or dexamethasone was prevented by the simultaneous administration of bosentan (3). An investigational selective endothelin receptor (ET_A) blocker (CI-1020) also was effective in preventing ductus closure (3).

The effects of bosentan on uteroplacental and maternal renal blood flow in pregnant rats were described in a 2002 report (4). On gestational day 19 (term 23 days), bosentan increased uteroplacental blood flow significantly higher than the normal physiologic increase but had no effect on renal blood flow. On gestational days 20–21, bosentan had no effect on uteroplacental blood flow but decreased renal blood flow by 20% (4).

It is not known if bosentan or its active metabolite crosses the human placenta. The molecular weight (about 570) and long elimination half-life suggest that the drug, and possibly the active metabolite, will cross the placenta, but the high plasma protein binding should limit the exposure of the embryo–fetus.

A 2005 case report described the use of bosentan throughout pregnancy in a woman with Eisenmenger's syndrome due to pulmonary hypertension (5). Sildenafil was added at 27 weeks' gestation. At 30 weeks, a planned cesarean section gave birth to a 1.41-kg healthy female infant. Postoperatively, the mother was treated with bosentan, sildenafil, and warfarin. Her infant was nursed in the hospital for 11 weeks without problems, but died at 26 weeks of age from a respiratory infection (5).

A second 2005 report described a woman with pulmonary arterial hypertension who received bosentan and warfarin until 8 weeks when her therapy was changed to inhaled iloprost (6). The woman suffered a cardiorespiratory arrest at about 25 weeks but was successful resuscitated after about 1 minute and was converted to IV iloprost for 5 days. At that time, a cesarean section delivered a 0.65-kg male infant with Apgar scores of 8 and 9. No congenital anomalies were observed in the infant. The child was progressing well at 16 months of age (6).

Bosentan (250/day), sildenafil (150 mg/day), hydroxychloroquine (200 mg/day), azathioprine (100 mg/day), and phenprocoumon were used up to 5 weeks' gestation in a 29-year-old woman with systemic lupus erythematosus-associated pulmonary arterial hypertension (7). At that time, bosentan and

phenprocoumon were discontinued and the other three agents were continued along with low-molecular-weight heparin. At 35 weeks, inhaled iloprost was added. At 37 weeks, a planned cesarean section gave birth to a healthy 2.760-kg female infant with Apgar scores of 8, 9, and 10 at 1, 5, and 10 minutes, respectively. Breastfeeding was declined. At the time of the report, the child was doing well (7).

Bosentan is an isoenzymes-inducer and is metabolized by the isoenzymes CYP2C9 and CYP3A4. Because many hormonal contraceptives are metabolized by CYP3A4, treatment with bosentan could cause decreased plasma concentrations and failure of these agents. Therefore, women should not rely on hormonal contraceptives alone (oral, injectable, or implantable) for contraception (1,2).

BREASTFEEDING SUMMARY

One report described the use of bosentan during breastfeeding (see reference 5), but milk concentrations were not determined. The molecular weight (about 570) and long elimination half-life (about 5 hours) suggest that the drug, and possibly the active metabolite, will be excreted into breast milk. However, the high plasma protein binding (98%) should limit the amount of drug in milk. Although the effect of this exposure on a nursing infant is unknown, no adverse effects were mentioned in the above case, but there is a potential for toxicity.

BOSUTINIB

Antineoplastic (Tyrosine Kinase Inhibitor)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of bosutinib in pregnancy have been located. The animal data cannot be interpreted because in one species inadequate doses were used and, in the other, fetal toxicity occurred with maternal toxic doses. Nevertheless, the manufacturer warns that the drug can cause fetal harm based on the drug's mechanism of action (1). Thus, use of bosutinib should be avoided in pregnancy, especially during the 1st trimester.

FETAL RISK SUMMARY

Bosutinib is an oral tyrosine kinase inhibitor. There are several other agents in this subclass (see Appendix). Bosutinib is indicated for the treatment of adult patients with chronic, accelerated, or blast phase Philadelphia chromosome-positive chronic myelogenous leukemia with resistance or intolerance of prior therapy. It is metabolized to inactive metabolites and is highly (96%) bound to plasma protein. The mean terminal phase elimination half-life is 22.5 hours (1).

Reproduction studies have been conducted in rats and rabbits. Rats were given daily oral doses during organogenesis that resulted in exposures that were about <3 times the human exposure at 500 mg/day based on AUC (HE). However, the study did not expose the rats to sufficient drug to fully evaluate adverse outcomes. In rabbits given daily doses during organogenesis, a maternal toxic dose that resulted in exposures that were about 4 times the HE, fetal anomalies (fused sternebrae and various visceral anomalies), and an approximate 6% decrease in fetal body weight were observed (1).

A 2-year carcinogenicity study in male and female rats was negative, as were tests and assays for mutagenic and clastogenic effects. Reduced fertility was observed in male rats given high doses of the drug that resulted in exposures about equal to the HE. Although fertility (number of pregnancies)

was not affected in female rats, doses resulting in exposures less than the HE were associated with increased resorptions and decreased implantations and number of viable embryos (1).

It is not known if bosutinib crosses the human placenta. The molecular weight (about 530 for the anhydrous form) and long elimination half-life suggest that the drug will cross to the embryo–fetus. However, the high plasma protein binding might limit the exposure.

BREASTFEEDING SUMMARY

No reports describing the use of bosutinib during human lactation have been located. The molecular weight (about 530 for the anhydrous form) and long elimination half-life (22.5 hours) suggest that the drug will be excreted into breast milk, but the high plasma protein binding (96%) might limit the amount in milk. The effect on a nursing infant from this exposure is unknown. If a woman receiving the drug chooses to nurse, her infant should be closely monitored for the most common adverse effects observed in adults (diarrhea, nausea, vomiting, thrombocytopenia, abdominal pain, rash, anemia, pyrexia, and fatigue).

BOTULINUM TOXIN TYPE A

Central Nervous System Agent (Physical Adjunct)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of commercially prepared botulinum toxin type A in human pregnancy have been located. The animal data are suggestive of low risk, but the absence of human pregnancy experience prevents a full assessment of the embryo–fetal risk. However, the commercially prepared and wild toxins should be identical. Moreover, the case reports above suggest that the wild toxins do not cross the human placenta in the last half of pregnancy. In addition, the appearance in the systemic circulation of botulinum toxin type A is not expected after IM injections. Therefore, although the safety of use of the commercial toxin in pregnancy is unknown (1,2), the risk of embryo or fetal harm appears to very low or nonexistent.

FETAL RISK SUMMARY

Botulinum toxin type A is produced by fermentation of the anaerobic bacterium *Clostridium botulinum* type A. One unit (U) of the commercial preparation corresponds to the calculated median intraperitoneal lethal dose (LD₅₀) in mice. Botulinum toxin type A causes paralysis by binding to acceptor sites on motor nerve terminals, entering the nerve terminals, and inhibiting the release of acetylcholine (3). The toxin is not expected to enter the systemic circulation following IM injection. Botox is indicated for the treatment of cervical dystonia to decrease the severity of abnormal head position and neck associated with the disorder. It is also indicated for the treatment of strabismus and blepharospasm associated with dystonia, including benign essential blepharospasm or seventh nerve disorders (3). Botox Cosmetic is indicated for the temporary improvement in the appearance of moderate to severe glabellar

lines associated with corrugator or procerus muscle activity (4).

Reproduction studies have been conducted in mice, rats, and rabbits. In mice and rats given IM injections during organogenesis, the developmental no-observed-effect level (NOEL) was 4 U/kg. Doses of 8 or 16 U/kg were associated with decreased fetal body weights and/or delayed ossification. Doses >8 U/kg impaired fertility in female rats by altering the estrous cycle. In rabbits, IM doses of 0.125 U/kg/day (gestational days 6–18) or 2 U/kg/day (gestational days 6 and 13) resulted in severe maternal toxicity, abortions, and fetal malformations. Higher doses caused maternal death (3). Interestingly, a 1965 study provided indirect evidence that botulinum toxin type A crossed the placentas of pregnant mice, even though the toxin has a very high molecular weight (5).

It is not known if botulinum toxin type A crosses the human placenta. It is a large protein with a very high molecular weight. In addition, it is not expected to enter the systemic circulation and, therefore, would not be present at the maternal–fetal interface. Moreover, the case reports below provide indirect evidence that botulinum toxins do not cross to the fetus in clinically significant amounts.

The first reported case of botulism in a pregnant woman appeared in 1975 (6). The case report involved a 32-year-old woman at 34 weeks' gestation who developed botulism and required assisted ventilation. Botulinum toxin type A was detected in her serum and she was treated with trivalent botulism antitoxin, but with limited success. Fetal heart tones were 140–160 beats per minute. On the 5th day of illness, she precipitously delivered a 1538-g male infant who was cyanotic with shallow respirations. No botulinum toxin was detected in the infant's serum obtained within 4 hours of birth. The infant's hospital 42-day course included aspiration pneumonia, anemia, seizures, and a probable intraventricular hemorrhage. The infant developed hydrocephalus several months after discharge but the condition resolved spontaneously. At 20 months of age, he was nearly totally blind (probable optic atrophy) and developmentally slow. The infant's condition was attributed to hypoxia, a precipitous delivery, and intraventricular hemorrhage (6).

A 30-year-old woman at about 27 weeks' gestation was admitted to a hospital with signs and symptoms of botulism (7). She had been "skin popping" black tar heroin and had developed multiple abscesses on her left leg. Because botulism was suspected, she received two vials of antitoxin. The abscesses were excised and culture revealed *C. botulinum* type A. Ten days before she was discharged from the hospital, at 34 weeks' gestation, her baby was

delivered by cesarean section. No details regarding the infant were provided other than the fact that the infant remained in intensive care at 24 days of age (7).

A 1996 case report described a 37-year-old woman at 23 weeks' gestation who developed botulism from home-produced green beans (8). She eventually required assisted ventilation because of near-complete paralysis. At the peak of the disease, fetal movement was the visible motion. Although she was treated with botulism antitoxin, she required tracheotomy and ventilation for 2 months. Throughout the woman's 3-month hospitalization, repeated surveillance revealed normal fetal development. Four months after the onset of the poisoning, a normal infant was delivered spontaneously (sex and other details of the infant not provided) (8).

A second 1996 case report involved a 24-year-old Alaskan native at 16 weeks' gestation that was poisoned by consumption of fermented whitefish (9). Both *C. botulinum* types A and E were cultured from her stool and type E organisms and toxin were detected in the whitefish. Ultrasonography revealed a fetus with normal breathing and movements. The woman was treated with trivalent botulinum antitoxin and rapidly recovered. At 42 weeks' gestation, she spontaneously delivered a healthy 4300-g male infant. The child's growth and development during the 1st year were normal (9).

In an *in vitro* study, botulinum toxin type A has been demonstrated to inhibit or completely arrest myometrial activity (10). The investigators thought that the toxin might eventually have application in the prevention of preterm labor after fetal surgery. Moreover, the effects were potentially reversible (10).

BREASTFEEDING SUMMARY

No reports describing the use of botulinum toxin type A during human lactation have been located. Because the toxin is not expected to appear in the systemic circulation, it would not be available for excretion into breast milk. Therefore, the risk to a nursing infant is probably nil.

BRENTUXIMAB VEDOTIN

Antineoplastic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of brentuximab in human pregnancy have been located. The animal data in the only species studied suggest risk. Moreover, the mechanism of action suggests that the drug can cause fetal harm. If the drug must be used in pregnancy, avoiding the 1st trimester should be considered. In addition, the patient should be informed of the potential risk to her fetus.

FETAL RISK SUMMARY

Brentuximab is an IgG1 antibody specific for human CD30 combined with a microtubule disrupting agent (MMAE) and a protease-cleavable linker. It is given as an IV infusion every 3 weeks. Brentuximab is indicated for the treatment of patients with Hodgkin lymphoma after failure of autologous stem cell transplant (ASCT) or after failure of at least two prior multiagent chemotherapy regimens in patients who are not ASCT candidates. It also is indicated for treatment of patients with systemic anaplastic large cell lymphoma after failure of at least one prior multiagent chemotherapy regimen. The antibody–drug conjugate undergoes minimal metabolism and the terminal half-life is about 4–6 days (1).

Reproduction studies have been conducted in rats. During organogenesis, embryo–fetal toxicities were observed in rats given IV doses of brentuximab that resulted in systemic exposures that were approximately the same as the human exposure. The drug-induced toxicities were increased early resorption ($\geq 99\%$), postimplantation loss ($\geq 99\%$), decreased number of live fetuses, and external malformations (umbilical hernias and malrotated hind limbs) (1).

Carcinogenicity studies with brentuximab have not been conducted.

Consistent with its mechanism of action, MMAE was genotoxic in the rat bone marrow micronucleus study, but it was not mutagenic in two assays. Fertility studies have not been conducted. However, impairment of male reproductive function and fertility was observed in repeat-dose toxicity studies in rats (1).

It is not known if brentuximab crosses the human placenta. The molecular weight (about 153,000) and minimal metabolism suggest that exposure of the embryo–fetus will be limited. However, immune globulin crosses the placenta, especially late in gestation (see Immune Globulin Intravenous) and the animal data (see above) suggest that the agent crosses the placenta in rats.

BREASTFEEDING SUMMARY

No reports describing the use of brentuximab during human lactation have been located. The molecular weight (about 153,000) and minimal metabolism suggest that exposure of a nursing infant will be limited, if it occurs at all. However, immune globulin is excreted into colostrum during the first few days after birth and brentuximab is an IgG1 antibody-drug conjugate. Nevertheless, the amount of the drug in colostrum or breast milk should be low and the potential for harm of a nursing infant appears to be low.

BRETYLIUM

[Withdrawn from the market. See 9th edition.]

BROMFENAC

Ophthalmic

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of bromfenac in human pregnancy have been located. The animal reproduction data suggest low risk. Although the lack of human pregnancy experience does not allow a more complete assessment, the very small amounts, if any, of the drug in the systemic circulation suggest that it represents no risk to the embryo or fetus.

FETAL RISK SUMMARY

Bromfenac is a nonsteroidal anti-inflammatory drug (NSAID) that is used topically as a 0.09% solution on the eye. It is indicated for the treatment of postoperative inflammation and the reduction of ocular pain in patients who have undergone cataract extraction. The maximum recommended dose is one drop (0.09 mg) in each eye 2 times daily. It is not known if the drug is absorbed into the systemic circulation, but based on the dose, the amount in the systemic circulation is estimated to be below the limit of quantification (50 ng/mL) (1).

Reproduction studies have been conducted in rats and rabbits. In pregnant rats and rabbits, oral doses up to 540 and 4500 times, respectively, the recommended human ophthalmic dose revealed no evidence of teratogenicity. However, the highest dose in rats was associated with embryo, fetal, and neonatal death, and reduced postnatal growth. The highest dose in rabbits caused increased postimplantation loss (1).

It is not known if bromfenac crosses the human placenta. The molecular weight (about 254 for the nonhydrated free acid) is low enough, but only very small amounts, if any, are present in the systemic circulation. Thus, clinically significant exposure of the embryo or fetus is unlikely.

BREASTFEEDING SUMMARY

No reports describing the use of bromfenac during human lactation have been located. The molecular weight (about 254 for the nonhydrated free acid) is low enough for excretion into breast milk, but only very small amounts, if any, are present in the systemic circulation. Moreover, other NSAIDs are compatible with breastfeeding, even when given orally (e.g., see Ibuprofen). Therefore, the use bromfenac should also be compatible.

BROMIDES

Anticonvulsant/Sedative

PREGNANCY RECOMMENDATION: Human and Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Chronic ingestion of drugs containing bromides is a risk for development toxicity. Exposure near delivery has been reported to cause neonatal bromism.

FETAL RISK SUMMARY

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 986 of whom had 1st trimester exposure to bromides (1, pp. 402–406). For use anytime during pregnancy, 2610 exposures were recorded (1, p. 444). In neither group was evidence found to suggest a relationship to large categories of major or minor malformations. Four possible associations with individual malformations were found, but independent confirmation is required: polydactyly (14 cases), gastrointestinal anomalies (10 cases), clubfoot (7 cases), and congenital dislocation of hip (use anytime) (92 cases).

Two infants with intrauterine growth restriction from a mother who chronically ingested a proprietary product containing bromides (Bromo-Seltzer) have been described (2). Both male infants were microcephalic (one at the 2nd percentile and one at less than the 2nd percentile) and one had congenital heart disease (atrial septal defect with possible pulmonary insufficiency). The mother did not use the product in three other pregnancies, two before and one after the affected children, and all three of these children were of normal height. In a similar case, a woman chronically ingested tablets containing bromides throughout gestation and eventually gave birth to a female infant who was growth restricted (all parameters below the 10th percentile) (3). Follow-up of the infant at 2.5 years of age indicated persistent developmental delay.

Neonatal bromide intoxication from transplacental accumulation has been described in four infants (4–7). In each case, the mother had either taken

bromide-containing medications (three cases) or was exposed from employment in a photographic laboratory (one case). Bromide concentrations in three of the four infants were 3650, 2000, and 2420 mcg/mL on days 6, 5, and 5, respectively (4–6). In the fourth case, a serum sample, not obtained until 18 days after birth, contained 150 mcg/mL (7). All four infants exhibited symptoms of neonatal bromism consisting of poor suck, weak cry, diminished Moro reflex, lethargy, and hypotonia. One of the infants also had cyanosis and a large head with dysmorphic face (7). Subsequent examinations of three of the above infants revealed normal growth and development after several months (4–6). One infant, however, had mild residual hypotonia of the neck muscles persisting at 6 and 9.5 months (7).

Cord serum bromide levels were determined on 1267 newborn infants born in Rochester, New York, during the first half of 1984 (8). Mean bromide concentrations were 8.6 mcg/mL (range 3.1–28.5 mcg/mL), which is well below the serum bromide level (>720 mcg/mL) that is considered toxic (8). The measured concentrations were not related to Apgar scores, neonatal condition, or congenital abnormalities. None of the mothers was taking bromide-containing drugs (most of which have been removed from the market), and the concentrations in cord blood were thought to have resulted from occupational exposure to photographic chemicals or from the low levels encountered in food and water.

BREASTFEEDING SUMMARY

The excretion of bromides into breast milk has been known since at least 1907 (9). A 1938 report reviewed this topic and demonstrated the presence of bromides in milk in an additional 10 mothers (9). A 1935 report measured milk concentrations of 1666 mcg/mL in two patients treated with 5 g daily for 1 month (10). Rash and sedation of varying degrees in several nursing infants have been reported as a result of maternal consumption of bromides during lactation (9–11). Although bromide-containing medications are no longer available in the United States, these drugs may be available in other countries. In addition, high maternal serum levels may be obtained from close, frequent exposure to chemicals used in photographic developing. Women who are breastfeeding and are exposed to such chemicals should be alert for symptoms of sedation or drowsiness and unexplained rashes in their infants. Monitoring of bromide levels in these women may be beneficial. Nursing is not recommended for women receiving bromide-containing medications, although the American Academy of Pediatrics classifies bromides as compatible with breastfeeding

(12).

BROMOCRIPTINE

Endocrine/Metabolic Agent (Miscellaneous)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Bromocriptine apparently does not pose a significant risk to the fetus. The pattern and incidence of anomalies are similar to those expected in a nonexposed population.

FETAL RISK SUMMARY

Bromocriptine has been used during all stages of pregnancy. In 1982, Turkalj et al. (1) reviewed the results of 1410 pregnancies in 1335 women exposed to bromocriptine during gestation. The drug, used for the treatment of infertility as a result of hyperprolactinemia or pituitary tumors including acromegaly, was usually discontinued as soon as pregnancy was diagnosed. The mean duration of exposure after conception was 21 days. The review included all reported cases from 1973 (the year bromocriptine was introduced) through 1980. Since then, 11 other studies have reported the results of treatment in 121 women with 145 pregnancies (2–12). The results of the pregnancies in the combined studies are as follows:

- Total patients/pregnancies 1456/1555
- Liveborn infants 1369 (88%)
- Stillborn infants 5 (0.3%)
- Multiple pregnancies (30 twins/3 triplets) 33*(2.1%)
- Spontaneous abortions 66 (10.7%)
- Elective abortions 26 (1.7%)
- Extrauterine pregnancies 12 (0.8%)
- Hydatidiform moles (2 patients) 3 (0.2%)
- Pregnant at time of report-outcome unknown 10

A total of 48 (3.5%) of the 1374 liveborn and stillborn infants had detectable anomalies at birth (1–12). This incidence is similar to the expected rate of

congenital defects found in the general population. In the review by Turkalj et al. (1), the mean duration of fetal exposure to bromocriptine was similar between children with congenital abnormalities and normal children. No distinguishable pattern of anomalies was found. The malformations detected at birth are shown below (number of infants indicated in parentheses):

- Down's syndrome (2)
- Hydrocephalus and multiple atresia of esophagus and intestine (1)
- Microcephalus/encephalopathy (1)
- Omphalocele/talipes (1)
- Pulmonary artery atresia (1)
- Reduction deformities (4)
- Renal agenesis (1)
- Pierre Robin syndrome (1)
- Bat ear and plagiocephalous (1)
- Cleft palate (1)
- Ear lobe deformity (1)
- Head posture constrained (1)
- Hip dislocation (aplasia of cup) (9)
- Hydrocele (3)
- Hydrocele/omphalocele (1)
- Hypospadias (1)
- Inguinal hernia (2)
- Skull soft and open fontanella (1)
- Single palmar crease (1)
- Single umbilical artery (1)
- Syndactyly (2)
- Talipes (5)
- Umbilical hernia (1)
- Cutaneous hemangioma (4)
- Testicular ectopia (1) (spontaneous correction at age 7 months)

Long-term studies on 213 children followed up to 6 years of age have shown normal mental and physical development (1,2).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 50 newborns had been exposed to bromocriptine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Three (6%) major birth defects were observed (two expected). Specific information was not available on the malformations,

but no anomalies were observed in six categories of defects (cardiovascular defects, oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias) for which data were available. Based on a small number of exposures, the data do not support an association between the drug and congenital defects.

BREASTFEEDING SUMMARY

Since bromocriptine is indicated for the prevention of physiologic lactation, breastfeeding is not possible during therapy (13,14). However, in one report, a mother taking 5 mg/day for a pituitary tumor was able to breastfeed her infant successfully (3). No effects on the infant were mentioned. Because bromocriptine suppresses lactation, the American Academy of Pediatrics classifies bromocriptine as a drug that should be given to nursing women with caution (15).

*Two women with twins were also treated with clomiphene or gonadotropin.

BROMODIPHENHYDRAMINE

[Withdrawn from the market. See 9th edition.]

BROMPHENIRAMINE

Antihistamine

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

In general, antihistamines are considered low risk in pregnancy. However, exposure near birth of premature infants has been associated with an increased risk of retrolental fibroplasia.

FETAL RISK SUMMARY

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 65 of whom had 1st trimester exposure to brompheniramine (1, pp. 322–325). Based on 10 malformed infants, a statistically significant association ($p < 0.01$) was found between this drug and congenital defects. This relationship was not found with other antihistamines. For use anytime during pregnancy, 412 exposures were recorded (1, p. 437). In this group, no evidence was found for an association with malformations.

The use of antihistamines in general (specific agents and dose not given) during the last 2 weeks of pregnancy has been associated with an increased risk of retrolental fibroplasia in premature infants (2). Infants weighing < 1750 g, who had no detectable congenital anomalies and who survived for at least 24 hours after birth, were enrolled in the multicenter National Collaborative Study on Patent Ductus Arteriosus in Premature Infants conducted between 1979 and 1981 (2). After exclusions, 3026 infants were available for study. Exposures to antihistamines and other drugs were determined by interview and maternal record review. The incidence of retrolental fibroplasia in infants exposed to antihistamines during the last 2 weeks of gestation was 22% (19 of 86) vs. 11% (324 of 2940) in infants not exposed during this interval. Adjustment for severity of disease did not change the estimated rate ratio.

BREASTFEEDING SUMMARY

A single case report has been located describing adverse effects in a 3-month-old nursing infant of a mother consuming a long-acting preparation containing 6 mg of dexbrompheniramine and 120 mg of d-isoephedrine (3). The mother began taking the preparation on a twice-daily schedule about 1 or 2 days before the onset of symptoms in the infant. Symptoms consisted of irritability, excessive crying, and disturbed sleeping patterns, which resolved spontaneously within 12 hours when breastfeeding was stopped. One manufacturer considers the drug to be contraindicated for nursing mothers (4). The American Academy of Pediatrics noted the above adverse effects observed with dexbrompheniramine plus d-isoephedrine, but classified the combination as usually compatible with breastfeeding (5).

BUDESONIDE

Respiratory Drug (Corticosteroid)

PREGNANCY RECOMMENDATION: Compatible (Inhaled/Nasal), No Human Data—Animal Data Suggest Risk (Oral)

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Inhaled budesonide does not appear to represent a significant risk for congenital defects in humans, but a small risk may exist between nasal budesonide and cardiac defects. A small, but statistically significant, increased risk for cleft lip with or without cleft palate has been reported for corticosteroids (see Hydrocortisone). A similar risk for orofacial clefts was observed with inhaled budesonide, but the number of exposed infants was too small for statistical significance. The data from the manufacturer's postmarketing surveillance do not show a clustering of defects and thus, in themselves, cannot be used as evidence of an increased risk for birth defects. Surveillance reports of this type are important for detecting early signals of major teratogens, but they have several difficulties. The primary problems with these voluntary reports are their retrospective nature (reported after the outcome is known), their selection bias (mainly adverse outcomes are reported), and their lack of sufficient details on the mother, her family history, her disease, and her pregnancy. Moreover, these data cannot be used to determine true rates of outcomes.

During pregnancy, the benefits of treating allergic rhinitis with any product, including budesonide, must be carefully weighed against the potential risks of therapy. Consideration should be given to limiting corticosteroid exposure, especially during the 1st trimester. In contrast, poorly controlled asthma may result in adverse maternal, fetal, and neonatal outcomes (1). Maternal complications include an increased risk of preeclampsia, pregnancy-induced hypertension, hyperemesis gravidarum, vaginal hemorrhage, and induced and difficult labors. Fetal and neonatal adverse effects may be an increased risk of perinatal mortality, intrauterine growth restriction (IUGR), prematurity, lower birth weight, and neonatal

hypoxia. Because controlling maternal asthma can ameliorate or prevent all of these complications (1), the benefits of therapy outweigh the potential risks of drug-induced teratogenicity or toxicity. Therefore, pregnant women who require an inhaled corticosteroid, such as budesonide, for control of their asthma should be counseled as to the risks and benefits of therapy, but treatment should not be withheld because of their pregnancy.

FETAL RISK SUMMARY

Budesonide is an anti-inflammatory corticosteroid used in the maintenance treatment of asthma as prophylactic therapy (Pulmicort Turbuhaler) or for the management of symptoms of allergic rhinitis (Rhinocort Nasal Inhaler). Pulmicort Turbuhaler delivers approximately 160 mcg of micronized budesonide per actuation, whereas Rhinocort Nasal Inhaler delivers approximately 32 mcg of micronized budesonide per actuation (2,3). The latter dose is suspended in a mixture of propellants (dichlorodifluoromethane, trichloromonofluoromethane, and dichlorotetrafluoroethane) and sorbitan trioleate.

Budesonide has potent glucocorticoid but weak mineralocorticoid activity. Compared with hydrocortisone (cortisol), budesonide is 40 times more potent when administered SC and 25 times more potent when given orally. Approximately 34% of the delivered dose of Pulmicort and 21% of Rhinocort are absorbed systemically (2,3).

Similar to other glucocorticoid agents, budesonide is administered to pregnant rabbits at a SC dose about 0.33 times the maximum recommended human daily inhalation dose based on BSA (MRHD) produced fetal loss, IUGR, and skeletal anomalies (mostly delayed ossification of the vertebra and skull) (2–4). In pregnant rats, a SC dose about 3 times the MRHD resulted in similar outcomes. No teratogenic or embryocidal effects were observed in pregnant rats administered inhalation doses up to about 2 times the MRHD (2,3).

No reports describing the placental transfer of budesonide have been located. The relatively low molecular weight (about 431 for the butyraldehyde formulation) and high lipid solubility suggest substantial placental transfer. The actual amount of active budesonide reaching the fetus, however, may be small because of the low systemic bioavailability after inhaled or nasal administration (see above).

Data from the Swedish Medical Birth Registry involving 2014 infants whose mothers had inhaled budesonide for asthma during early pregnancy were reported in 1999 (5). Drug exposures were identified prospectively, before the

pregnancy outcomes were known. Among the mothers of the 2014 infants, 1675 also used β_2 -adrenergic agonists, 16 used other inhaled corticosteroids in addition to budesonide, and 316 used no other antiasthmatic drug. A total of 76 infants (3.8%) in the exposed group had a congenital malformation, compared with 3.5% for all infants born in 1995–1997. Major structural defects were observed in 41 of the infants, whereas 35 infants had minor and/or variable conditions. Five of the major defects were chromosomal anomalies. It is unlikely that these were due to drug therapy (4). Four (expected 3.3) of the major anomaly group had an orofacial cleft (median cleft palate [N = 2], unilateral cleft lip [N = 1], and unilateral cleft lip and palate [N = 1]) (relative risk 1.2, 95% confidence interval [CI] 0.3–3.1) (4). Among the major and minor defects, 18 (expected 17–18) involved the heart, including 2 premature infants with patent ductus arteriosus (both categorized as minor defects). The other cardiac malformations were as follows: ventricular septal defects (VSD) with or without other anomalies (N = 11); atrial septal defects with or without other anomalies (N = 4); and unspecified cardiac defect (N = 1). Only two of the cases with VSD, one with transposition of the great vessels and another with tricuspidal atresia (both successfully repaired), were reported to the Swedish Child Cardiology Registry (expected number 5.6). Because the other 16 cases were not reported, the authors concluded that the defects were mild and of little clinical significance (5).

The above Registry was updated in 2003 (6). There were now 2968 mothers who had used inhaled budesonide in early pregnancy and gave birth to infants with normal gestational age, birth weight, and length. There also was no increase in rate of stillbirths. The study was not designed to detect birth defects (6).

Twenty-one pregnancies in which the woman received an active drug were reported to the manufacturer during clinical trials of Pulmicort Turbuhaler (A. Marants, personal communication, Astra Pharmaceuticals, 1999). Two of the pregnancies were terminated voluntarily, 1 woman had a miscarriage, 3 had unknown outcomes, 13 delivered normal infants, and 2 delivered infants with congenital malformations. In one case, the 27-year-old mother was receiving budesonide 1600 mcg/day at conception. She was also taking prednisone 10 mg/day and a combination oral contraceptive (levonorgestrel + ethinyl estradiol). Although the reason for early delivery was not specified, a female infant with coarctation of the aorta was delivered by cesarean section at 30 weeks' gestation. The infant was scheduled for surgical repair of the defect. In the second case, a 41-year-old mother used budesonide inhaler for 22 days

(dosage unknown) before discontinuing it because of her pregnancy. Seven months later, she delivered a female infant with double-sided maxillary clefts, double digits of the left hand, and persistent fetal circulation (i.e., patent ductus arteriosus). The infant died at 8 days of age.

The infant outcomes of five asthmatic women who used budesonide during pregnancy were described in retrospective postmarketing reports to the manufacturer (A. Marants, personal communication, Astra Pharmaceuticals, 1999). Only limited data were available for each pregnancy. The first case involved a 36-year-old woman, treated with an unknown dose of budesonide combined with a β_2 -adrenergic agonist (albuterol), who delivered an anencephalic infant. In the second case, a 32-year-old woman administering budesonide 1600 mcg/day gave birth to a healthy 2.65-kg baby. A 33-year-old woman was treated with four antiasthmatic agents during gestation, including budesonide 1600 mcg/day, an oral corticosteroid (name not specified), a β_2 -adrenergic agonist (not specified), and theophylline. She gave birth to a female infant with agenesis of the left foot who was otherwise healthy. Another 33-year-old woman being treated with budesonide 1600 mcg/day, phenobarbital, and terbutaline (a β_2 -adrenergic agonist) delivered an infant with cleft palate, an unspecified cardiac defect, and hydrocephalus. Finally, IUGR and oligohydramnios were noted in a pregnancy of a 36-year-old woman who was being treated with budesonide 400 mcg/day, salmeterol (an inhaled β_2 -adrenergic agonist), and terfenadine (an antihistamine). She gave birth to a growth-restricted infant (2.0 kg) who had multiple malformations, including a diaphragmatic hernia, renal hypoplasia, and a VSD. The infant died on the day of birth.

A 2003 case–control study, using data from three Swedish health registers, was conducted to identify drug use in early pregnancy that was associated with cardiac defects (7). Cases of cardiovascular defects without known chromosome anomalies (N = 5015) were compared with controls consisting of all infants born in Sweden (1995–2001) (N = 577,730). Associations were identified for several drugs, some of which were probably due to confounding from the underlying disease or complaint or multiple testing, but some were thought to be true drug effects. For all inhaled corticosteroids, there were 66 cases in 7404 exposures (odds ratio [OR] 1.05, 95% CI 0.82–1.34). For inhaled budesonide, there were 16 cases in 6557 exposures (OR 1.12, 95% CI 0.87–1.44). For all nasal corticosteroids, there were 31 cases among 2872 exposures (1.24, 95% CI 0.87–1.78), but 28 of the cases involved nasal budesonide (2230 exposures) (1.45, 95% CI 0.99–2.10). Restricting the

analysis of nasal budesonide to less severe defects increased the probability of an association (OR 1.58, 95% CI 1.02–2.46), as also was seen with unspecified cardiovascular defects (OR 2.39, 95% CI 0.96–4.92). The risk for ventricular and atrial septum defects were 1.67 (95% CI 0.99–2.81) and 2.18 (95% CI 0.71–5.08), respectively (7).

A 2004 study examined the effect of inhaled corticosteroids on low birth weight, preterm births, and congenital malformations in pregnant asthmatic patients (8). The inhaled steroids and the number of patients were beclomethasone (N = 277), fluticasone (N = 132), triamcinolone (N = 81), budesonide (N = 43), and flunisolide (N = 25). Compared with the general population, the study found no increased incidence of small-for-gestational-age infants (<10th percentile for gestational age), low birth weight (<2500 g), preterm births, and congenital malformations (8).

A 2006 meta-analysis on the use of inhaled corticosteroids during pregnancy was published in 2006 (9). The analysis included five agents: beclomethasone, budesonide, flunisolide, fluticasone, and triamcinolone. The results showed that these agents do not increase the risk of major congenital defects, preterm delivery, low birth weight, and pregnancy-induced hypertension. Thus, they could be used during pregnancy (9).

A 2007 report described the use of inhaled budesonide in 42 pregnant women (10). No effects on fetal growth or pregnancy outcomes were observed in these patients. Although most synthetic corticosteroids are partially metabolized by placental enzymes, budesonide was not (10).

BREASTFEEDING SUMMARY

The relatively low molecular weight (about 431 for the butyraldehyde formulation) and the high lipid solubility predict excretion of systemic budesonide into milk. However, the systemic bioavailability of budesonide following inhalation therapy is relatively low (see section above), thus, the actual amount in milk also may be low. The results of the below study are consistent with this assessment.

In a 2007 study, milk and plasma budesonide concentrations were measured in eight mothers receiving maintenance treatment with Pulmicort Turbuhaler (200 or 400 mcg twice daily) (11). Plasma concentrations also were measured in their breastfeeding infants. The mean milk:plasma ratio was 0.46. For both dose levels, the estimated daily infant dose was 0.3% of the daily maternal dose. The average plasma concentrations in nursing infants was estimated to be 1/600th of the maternal concentration (all infant levels were less than the

limit of quantification), assuming 100% bioavailability in the infants. The authors concluded that their data supported continued use of inhaled budesonide during breastfeeding (11).

BUMETANIDE

Diuretic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No published reports on the use of bumetanide in human pregnancy have been located, but the diuretic has been recommended for the treatment of the nephrotic syndrome occurring during pregnancy (1). Diuretics are not recommended for the treatment of gestational hypertension because of the maternal hypovolemia characteristic of this disease.

FETAL RISK SUMMARY

Bumetanide is a potent loop diuretic that is similar in action to furosemide; it shares the same indications and precautions for use during gestation as this latter diuretic (see also Furosemide).

The drug is not teratogenic in rats, mice, hamsters, or rabbits (2,3). In rats, doses 3400 times the maximum therapeutic human dose (MTHD) had a slight embryocidal effect, produced fetal growth restriction, and increased the incidence of delayed ossification of sternebrae (3). In rabbits, which are more sensitive to the effects of bumetanide than other test species, doses 3.4 times the MTHD were slightly embryocidal. At doses 10 times the MTHD, an increased embryocidal effect was observed, as well as an increased incidence of delayed ossification of sternebrae (3).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 44 newborns had been exposed to bumetanide during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Two (4.5%) major birth defects were observed (two expected), both of which were cardiovascular defects (0.4 expected).

BREASTFEEDING SUMMARY

No reports describing the use of bumetanide during human lactation have been located. Bumetanide probably is compatible with breastfeeding but, in general, diuretics should be used cautiously during nursing because they may suppress lactation.

BUPRENORPHINE

Narcotic Agonist-Antagonist Analgesic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Buprenorphine is a potent narcotic agonist and antagonist that has been used during human pregnancy for analgesia immediately prior to delivery in a small number of cases. One pregnancy case has been located in which the drug was given as a narcotic substitute for heroin dependency. Neonatal withdrawal was observed, but the symptoms were less than that expected with methadone. Animal studies have demonstrated dose-related maternal, embryo, and fetal toxicity and dose-related behavioral changes in offspring, but no congenital malformations. Although the lack of congenital anomalies is reassuring, the behavioral changes in animals combined with the absence of published early human pregnancy experience prevent an assessment of the risk that this drug presents to the embryo or fetus. Because there is substantially more published human pregnancy experience for other narcotic analgesics, they are preferred to buprenorphine, especially during early gestation. Buprenorphine may have a role as substitution therapy for maternal heroin addiction, but additional reports are needed to define its pregnancy safety profile before this use can be recommended.

FETAL RISK SUMMARY

Buprenorphine, an analgesic that possesses both narcotic agonist and antagonist activity, is approximately 33 times more potent than morphine (0.3-mg buprenorphine is equivalent to 10-mg morphine in analgesic and respiratory depressant effects). Although a sublingual formulation is available in other countries, only parenteral buprenorphine has been approved for general use in the United States. The human adult dose is 0.3–0.6 mg IM or IV repeated up to

every 6 hours (0.017–0.034 mg/kg/day for a 70-kg person).

Buprenorphine is currently under investigation as an alternative to methadone maintenance treatment of narcotic dependence (1–3). The drug has also been studied as an alternative to cocaine, but it is apparently not effective for this use (2). Although these trials have not yet included pregnant women, the advantages of buprenorphine over methadone during gestation may include less respiratory depression at high doses, less toxicity from overdose, less severe withdrawal after abrupt discontinuance of the drug, and potentially less abuse liability (1,2). Of interest, however, abuse of buprenorphine, often concurrently with opiates, has been reported outside of the United States (4,5). One of these latter citations reported frequent abuse of buprenorphine by pregnant women but provided no outcome data (4).

Reproduction studies in rats and rabbits have been conducted (6–12). No fetal adverse effects were observed in rats and rabbits when their mothers were administered doses up to 5 mg/kg IM during organogenesis (6). Shepard (7) cited a study in which fetal growth restriction, but not congenital defects, was observed in rats exposed to maternal doses of >0.05–5 mg/kg/day (about 3–300 times the recommended human dose [RHD]) given after implantation through delivery. Rat fetuses exposed to 5 mg/kg/day in the last week of pregnancy had a reduced survival rate after delivery (7). As reported by the manufacturer, no major congenital malformations were observed in rats given doses of 10–1000 times (SC or IM) or 160 times (IV) the RHD, but significant increases in postimplantation losses and early fetal deaths were noted with IM doses of 10 and 100 times the RHD (8). A slight increase in postimplantation losses was also observed with IV doses of 40 and 160 times the RHD. In rabbits, IM doses produced a dose-related increase in extra rib formation that was statistically significant at 1000 times the RHD (8). Rats pups exposed in utero throughout gestation to maternal doses of buprenorphine, 1 and 2 mg/kg/day SC, had reduced survival. Minimal effects were observed on the endogenous opioid system, however, as determined by a comparison of the brain enkephalin levels of buprenorphine-exposed pups to those in methadone-exposed pups (9).

In a study involving pregnant rats, buprenorphine was administered by a continuous infusion in doses of 0.3, 1.0, and 3.0 mg/kg/day from day 8 of gestation through parturition (10). At these doses, no evidence of significant maternal toxicity was observed, nor were there any significant effects on the offspring in terms of morbidity and mortality, birth weight, and postnatal growth (up to 60 days) (10). In a second publication by these researchers, using the

same drug-administration technique and animal type described above, no disruption in the rest–activity cycle was observed in the exposed offspring at 22 and 30 days of age (11).

The long-term effects on sexual differentiation in rats exposed in utero to maternal injections of buprenorphine, 0.3 or 0.6 mg/kg every 48 hours from day 6 to day 20 of gestation, were described in a study published in 1997 (12). Compared with controls and the lower-dose group, spontaneous parental behavior (at 23–28 days of age) and the expected sex difference in the consumption of a 0.25% saccharin solution (at 42–55 days of age) were impaired in the 0.6-mg/kg-exposed offspring. The authors concluded that the higher dose of buprenorphine produced long-term adverse effects on behavior (12).

As suggested by the molecular weight of the free base (about 468), buprenorphine crosses the placenta to the fetus. In a 1997 case report, a 24-year-old woman was treated with buprenorphine 4 mg/day for heroin addiction, starting in the 4th month of pregnancy (13). Frequent tests during the remainder of the pregnancy and at delivery confirmed her rapid withdrawal from heroin. Except for buprenorphine, all tests were negative for opiates, cocaine, cannabis, and amphetamines. An apparently normal female infant (birth weight not specified) was delivered at 39 weeks' gestation. Apgar scores were 10 and 10 at 1 and 10 minutes, respectively. High levels of buprenorphine and its metabolite were measured in the newborn approximately 20 hours after birth. Maternal trough serum concentrations of buprenorphine and the metabolite, norbuprenorphine, obtained a few days before delivery were 0.3 and 2.3 ng/mL, respectively. Parent drug and metabolite concentrations in the meconium were 107 and 295 ng/g, respectively. Levels of drug and metabolite were, respectively, 1.9 and 1.7 ng/mL in the newborn's serum and 36.8 and 61.1 ng/mL in the newborn's urine. The estimated cord:maternal serum ratio was 6.3, whereas the ratio for the metabolite was 0.7. A weak withdrawal syndrome was observed at 48 hours of age with an adapted Finnegan score (used to evaluate the intensity of withdrawal syndromes; range 0–40) of 12 (13). Symptoms, which resolved without therapy, consisted of agitation, sleep disturbance, tremor, yawning, noisy breathing, and a slight fever (13). The Finnegan score fell to 8 at 3 days of age and was normal by 6 days of age.

The effect of epidural buprenorphine combined with bupivacaine has been compared with epidural combinations of bupivacaine and morphine, fentanyl, sufentanil, and oxymorphone for analgesia during and after cesarean section (14–17). The analgesic effects of the narcotic agents were similar, but

buprenorphine caused a significant increase in maternal vomiting (14–16). No adverse neonatal effects were observed in the two studies that used buprenorphine before delivery (14,17).

The use of sublingual buprenorphine for labor pain in 34 primigravida women was described in a 1992 report (18). Each patient received a single 6-mcg/kg dose during the first stage of labor. No effects were observed on the progression of labor and none of the women had nausea or vomiting. Similarly, no changes in fetal heart rate (range 138–150 beats/minute) were observed. Buprenorphine produced no neonatal depression as evidenced by the average Apgar scores (range not specified) at 1 and 5 minutes of 9.71 and 9.94, respectively.

BREASTFEEDING SUMMARY

Buprenorphine is excreted into human milk. In a 1997 case report (see above), a 24-year-old former heroin addict on buprenorphine maintenance therapy (4 mg/day) gave birth to an apparently normal female infant at 39 weeks' gestation (13). She continued taking buprenorphine while nursing her infant. At 4 weeks of age, buprenorphine and its metabolite, norbuprenorphine, were determined in her milk at each feeding over a 24-hour period. The volume of milk drunk was estimated by weighing the infant before and after the feedings. Although the specific milk concentrations were not provided, the authors estimated that the total doses of drug and metabolite ingested by the infant over the 24-hour period were 3.28 and 0.33 mcg, respectively. No withdrawal symptoms in the infant were observed when lactation was abruptly interrupted at 8 weeks of age.

A study published in 1997 described the effects of continuous extradural bupivacaine and buprenorphine on analgesia and breastfeeding in 20 healthy women who had undergone a cesarean section at term (19). The study group (N = 10) received a 5-mL bolus of bupivacaine 0.25% with 200 mcg of buprenorphine extradurally at cord clamping, followed by a continuous extradural infusion of bupivacaine (0.25%) and buprenorphine (12 mcg/mL) infused at 0.7 mL/hour for 3 days. The control group (N = 10) received the same bolus and continuous infusion, but without the buprenorphine. There were no significant differences in visual analog pain scores between the groups at 2 hours, 1 day, and 2 days, but the controls received significantly more supplemental diclofenac (a nonsteroidal anti-inflammatory agent) during the 2-day period (mean 25 vs. 5 mg, $p < 0.05$). The weight of breast milk ingested at each feeding was estimated by weighing the infant before and after each

feeding. Compared with the control group, the buprenorphine group ingested significantly less milk each day (starting at day 3), and the infant's daily weight as a percentage of birth weight was significantly less starting at day 7. In both effects, the significant differences continued up to 11 days, near the time of discharge from the hospital. The investigators speculated that the differences between the two groups might be due to CNS depression in the mother and infant. Although one author thought the stress of the prolonged hospital stay may have depressed the breastfeeding (20), the investigators responded that long hospital stays are normal in Japan and, if stress is a factor, would have affected both groups similarly (19).

Because buprenorphine is excreted into milk and because depression of the nursing infant resulting in lower weight gain is a possibility, mothers receiving buprenorphine should probably not breastfeed. If breastfeeding is undertaken, the mother should be advised of the potential risk to her infant.

BUPROPION

Antidepressant

PREGNANCY RECOMMENDATION: Limited Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

The animal and most of the human data suggest low risk. Although increased rates of heart defects were reported in two studies, this outcome has not been confirmed by other studies. One study found a strong association between bupropion use in pregnancy and attention deficit/hyperactivity disorder (ADHD) in offspring, but cigarette smoking was a potential confounder. Additional research is required to clarify this risk. If a woman requires bupropion, she should be informed of the potential risks, but the drug should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Bupropion is a unique antidepressant of the aminoketone class that differs from other antidepressants in that it does not inhibit monoamine oxidase and does not alter the reuptake of norepinephrine or serotonin. Anticholinergic effects are much less frequent and less severe than those observed with other antidepressants. The drug is extensively metabolized with three active metabolites, but the antidepressant activity has not been fully characterized. Plasma protein binding of bupropion and one metabolite is 84%, whereas the binding of a second active metabolite is about half that of bupropion. The elimination half-lives of the three active metabolites range from 20 to 37 hours (1).

Reproduction studies in rats and rabbits at doses up to about 7–11 times the maximum recommended human dose based on BSA (MRHD) revealed no clear evidence of impaired fertility or fetal harm. However, in rabbits, a slight increase in the incidence of fetal malformations and a reduction in fetal weight was observed at doses \geq MRHD (2).

Bupropion caused an increase in nodular proliferative lesions of the liver in rats, but not mice, in lifetime carcinogenicity studies. No increase in malignant tumors of the liver or other organs was observed in either species. Bupropion was mutagenic in one test. In rats, a dose about 11 times the MRHD caused chromosomal aberrations (2).

Consistent with its molecular weight (about 240 for the free base), bupropion crosses the human placenta. In a 2010 report, healthy term placentas were used to determine the transplacental transfer and metabolism of bupropion (3). Following a 4-hour infusion, the amounts of bupropion in the maternal and fetal circulations and in the placenta were 32%, 20%, and 48%, respectively. The amount retained by the placenta was metabolized to threohydrobupropion, one of the active metabolites. The ratio of metabolite to parent compound in the three sites was 0.08, 0.07, and 0.06, respectively (3). In a second report from these investigators, it was found that the placenta metabolized bupropion to all three active metabolites (4). Human placental 11 β -hydroxysteroid dehydrogenase was the primary enzyme involved, but CYP2B6 also had activity. Significantly higher amounts of the three active metabolites were measured in the placentas of women who smoked ≥ 20 cigarettes/day compared with those who smoked ≤ 10 cigarettes/day and nonsmokers (4).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, three newborns had been exposed to bupropion during the 1st trimester (F. Rosa, personal communication, FDA, 1993). No major birth defects were observed (none expected).

A prospective comparative study in 136 women exposed to bupropion (for depression or smoking cessation) was published in 2005 (5). The pregnancy outcomes of 105 live births included no major malformations, mean birth weight of 3450 g, mean gestational age of 40 weeks, 20 spontaneous abortions (SABs), 10 elective abortions (EABs), and 1 stillbirth. There also was one neonatal death after delivery at 22 weeks because of abruptio placenta. Compared with nonteratogen-exposed controls, only the number of SABs (14.7% vs. 4.5%; $p = 0.009$) and EABs (7.4% vs. 0.75%; $p = 0.015$) were significantly increased. In a subanalysis, there were no significant differences when women taking bupropion for depression ($N = 91$) were compared with a group using other antidepressants and a nonteratogen exposed group (5).

A 2005 meta-analysis of seven prospective comparative cohort studies involving 1774 patients was conducted to quantify the relationship between seven newer antidepressants and major malformations (6). The

antidepressants were bupropion, fluoxetine, fluvoxamine, nefazodone, paroxetine, sertraline, and trazodone. There was no statistical increase in the risk of major birth defects above the baseline of 1%–3% in the general population for the individual or combined studies (6).

The final report of the Bupropion Pregnancy Registry, covering the period September 1, 1997, through March 31, 2008, was issued in August 2008 (7). The Registry was closed to new enrollments on November 1, 2007. The Registry prospectively (before the pregnancy outcome was known) enrolled 1597 pregnancies exposed to bupropion. Among these cases, 31 were still pregnant, 572 were lost to follow-up, and there were 1005 known outcomes (includes 9 sets of twins and 1 set of triplets). The number of outcomes involving earliest exposure in the 1st, 2nd, or 3rd trimester were 806, 147, and 52, respectively. The outcomes of those with earliest exposure in the 1st trimester included 651 live births without defects, 96 SABs, 33 EABs, and 2 fetal deaths, and outcomes with defects included 18 live births, 5 EABs, and 1 fetal death. For earliest exposure in the 2nd trimester, outcomes without reported defects were 142 live births, 1 SAB, and 1 EAB, and outcomes with defects 3 live births. Among exposures in the 3rd trimester, there were no defects in 51 live births and 1 fetal death. After excluding EABs and fetal deaths without known defects and all SABs, the proportion of birth defects with earliest exposure in the 1st trimester was 3.6% (95% confidence interval [CI] 2.3–5.3). The proportion of birth defects with earliest exposure in the 2nd trimester was 2.1% (95% CI 0.5–6.4) (7).

There were 28 outcomes, 25 with earliest exposure in the 1st trimester, with birth defects reported retrospectively (after the pregnancy outcome was known) (7). Although retrospective reports are usually biased, reporting adverse outcomes and not normal infants, nine of the defects involved the heart and great vessels. The Registry has noted the increased number of cardiac defects in the prospective and retrospective groups. However, the relatively small sample size, the potential bias from the large percentage of cases lost to follow-up, and the incomplete descriptions of the defects prevented determining if the data reflect a potential drug effect on the developing cardiovascular system (7).

Required statement: Committee consensus. After reviewing the 1005 prospectively reported pregnancy outcomes, the Bupropion Pregnancy Registry Advisory Committee concludes the Registry has successfully met its primary purpose which was to exclude a major teratogenic effect in

pregnancies inadvertently or intentionally exposed to any formulation of bupropion. The Registry was not designed to exclude an increase in the risk of specific defects (5).

A study published in 2007 was conducted to determine if bupropion exposure in the 1st trimester was associated with congenital malformations (8). Using data collected in 1995–2004, the prevalence of structural defects in 1213 infants exposed to bupropion in the 1st trimester was compared with 4743 infants exposed to other antidepressants and to 1049 infants exposed to bupropion after the 1st trimester. For all congenital anomalies, the prevalence in the 1st trimester bupropion group was 23.1/1000 infants, adjusted odds ratio (AOR) 0.95 (95% CI 0.62–1.45) and 1.00 (95% CI 0.57–1.73) in comparison to other antidepressants (prevalence 23.2/1000) and bupropion exposure after the 1st trimester (prevalence 21.9/1000), respectively. For cardiovascular anomalies, the prevalence for 1st trimester bupropion exposure was 10.7/1000, AOR 0.97 (95% CI 0.52–1.80) and 1.07 (95% CI 0.48–2.40) compared with other antidepressants (prevalence 10.8/1000) and bupropion exposure after the 1st trimester (prevalence 9.5/1000), respectively. The results did not support a hypothesis of a teratogenic effect of 1st trimester exposure to bupropion (8).

A prospective cohort study evaluated a large group of pregnancies exposed to antidepressants in the 1st trimester to determine if there was an association with major malformations (9). The patient population came from the Motherisk database and involved 928 cases that met their criteria. The 928 matched (for age, smoking, and alcohol use) controls were pregnancies not exposed to antidepressants or known teratogens. In addition to the 113 bupropion cases, the other cases were 184 citalopram, 21 escitalopram, 61 fluoxetine, 52 fluvoxamine, 68 mirtazapine, 39 nefazodone, 148 paroxetine, 61 sertraline, 17 trazodone, and 154 venlafaxine. In the antidepressant group, there were 24 (2.5%) major defects compared with 25 (2.6%) in controls (odds ratio [OR] 0.9, 95% CI 0.5–1.61). There were no major defects in the pregnancies exposed to bupropion, escitalopram, or trazodone (9).

A National Birth Defects Prevention Study to determine if bupropion was associated with congenital heart defects was published in 2010 (10). The retrospective case–control study compared 6853 infants with major heart defects with 5869 control infants. Bupropion exposure was defined as any reported use between 1 month before and 3 months after conception. Case infants were more likely to have left outflow tract defects than control infants (OR 2.6, 95% CI 1.2–5.7). The authors noted that additional studies were

required to confirm their results (10).

Another study published in 2010 found a significant association between bupropion use in pregnancy and ADHD in offspring (11). A claims-based dataset was used to identify 431 (1.13%) children, from 38,074 families, who had a diagnosis or treatment for ADHD at or before 5 years of age. The average maternal age at delivery was 31 years. Maternal age was not associated with ADHD in offspring, but male children were more likely to have ADHD (OR 2.79, $p < 0.001$). Significant associations were found between the presence of ADHD in children and a diagnosis of ADHD in the mother (OR 4.15, $p < 0.001$) or father (OR 3.54, $p < 0.001$). This finding was consistent with the known strong inheritance of the disorder. Significant associations with ADHD in offspring were also found for the mother, but not the father, for diagnosis of bipolar disorder (OR 5.08, $p < 0.001$), psychotic disorder (OR 4.05, $p = 0.02$), or depression (OR 2.58, $p < 0.001$). Exposure to bupropion, especially in the 2nd trimester (OR 14.66, $p < 0.001$) was associated with ADHD in children, but selective serotonin reuptake inhibitors (SSRIs) were not (OR 0.91, $p = 0.74$). Because cigarette smoking during pregnancy has been related to ADHD (see also Cigarette Smoking) and bupropion is used in smoking cessation programs, the author noted that this was a potential confounder. Women taking bupropion before or after pregnancy did not have a higher risk for having children with ADHD (11).

BREASTFEEDING SUMMARY

Bupropion is excreted into breast milk. A 37-year-old lactating woman was treated with 100 mg of bupropion 3 times daily (12). She was nursing her 14-month-old infant twice daily at times corresponding to 9.5 and 7.5 hours after a dose. Peak milk concentrations of bupropion occurred 2 hours after a 100-mg dose with a value of 0.189 mcg/mL, but the peak plasma level measured, 0.072 mcg/mL, occurred at 1 hour. The milk:plasma (M:P) ratios at 0, 1, 2, 4, and 6 hours after a dose were 7.37, 2.49, 4.31, 8.72, and 6.24, respectively. Two metabolites, hydroxybupropion and threohydrobupropion, were also measured with peak concentrations of both occurring at 2 hours in milk and plasma. The milk concentration ranges for the two metabolites were milk levels 0.093–0.132 and 0.366–0.443 mcg/mL, respectively, whereas the M:P ratios were 0.09–0.11 and 1.23–1.57, respectively. The levels of a third metabolite, erythrohydrobupropion, were too low to be measured in breast milk (test sensitivity 0.02 mcg/mL). No adverse effects were observed in the infant nor was any drug or metabolite found in his plasma, an indication that accumulation

had not occurred (12).

Two breastfeeding mothers, one at 15 weeks after birth and the other at 29 weeks, were being treated with bupropion, 75 mg twice daily and sustained release (SR) 150 mg daily, respectively (13). The drug was at steady state in both mothers. Neither bupropion nor its metabolite (hydroxybupropion) was detectable in the infants. No adverse effects were observed in the infants (13).

A 2004 report described the excretion of bupropion and its three active metabolites into breast milk in 10 mothers an average 12.5 months after birth (14). The average weight of the mothers was 59.4 kg. All had stopped breastfeeding and none had taken bupropion before the study. The dose during the study was SR 150 mg/day for 3 days, then SR 300 mg/day for 4 days, and samples were collected on day 7. Milk samples were collected with an electric breast pump. The calculated average bupropion dose in milk, based on 150 mL/kg/day, was 6.75 mcg/kg/day or 0.14% of the mother's weight-adjusted dose. The average M:P ratios of bupropion and the three active metabolites (hydroxybupropion, erythrohydrobupropion, and threohydrobupropion) were 2.8, 0.1, 0.9, and 1.2, respectively. The estimated daily infant doses of the metabolites were 15.75, 10.80, and 68.85 mcg/kg/day, respectively (14).

Seizures were reported in a 6-month-old breastfeeding infant whose mother had just started SR bupropion 150 mg/day (15). The 31-year-old mother, a pediatrician, had taken the agent for depression before pregnancy but had discontinued it before conception. She continued off the drug throughout pregnancy and while nursing her female infant. At 6 months postpartum, she restarted bupropion because of increasing depression. She had taken two doses, about 36 hours apart, when about 72 hours after the first dose she observed the infant arching her back, rolling her eyes, and smacking her lips for about 10–15 seconds. The mother thought the infant was having a seizure. Following this event, the mother observed a 5–10 minute postictal state that included staring and nonresponsiveness. Later examination of the infant at a specialty pediatric seizure clinic revealed a normal physical examination and laboratory tests, as well as an unremarkable electroencephalogram. Neither infant nor maternal bupropion levels were obtained. The mother stopped the drug and continued to nurse with no further seizure activity noted over the next 6 weeks. Because rare seizures have occurred in adults taking the antidepressant, the seizures were attributed to the drug (15).

A 2009 report described bupropion concentrations, but not of metabolites, in the breast milk, serum, and urine of four nursing mothers taking SR 150–300

mg/day at steady state (16). The samples were collected a mean 13 days after birth. The mean peak and trough milk concentrations were 64.1 and 9.2 ng/mL, respectively, whereas the mean M:P ratio was 1.3. Infant serum levels were not checked. In two infants, urine levels of bupropion were not detected (<10 ng/mL) but, in a third infant, born 5.5 weeks prematurely, the bupropion concentration was 41.0 ng/mL. The mean infant dose as a percentage of the mother's weight-adjusted dose was 5.7% (16).

The elevated (>1) M:P ratios for bupropion in the three studies above are consistent with the accumulation in milk observed with weak bases (i.e., ion-trapping). A 1996 review of antidepressant treatment during breastfeeding found no information that bupropion exposure during nursing resulted in quantifiable amounts in an infant or that the exposure caused adverse effects (17). The case above that observed seizures may or may not have been related to bupropion. The reported experience in breastfeeding mothers taking bupropion is too limited to determine the relationship. Nevertheless, nursing mothers and their caregivers should be aware of this possible complication. The American Academy of Pediatrics classifies bupropion as a drug whose effect on the nursing infant is unknown but may be of concern (18).

BUSPIRONE

Sedative

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although no drug-induced congenital malformations have been observed after 1st trimester exposure to buspirone, the data are too limited to assess the safety of the drug in human pregnancy. The cause of the intrauterine death cited below is unknown. Moreover, that study lacked the sensitivity to identify minor anomalies because of the absence of standardized examinations. Late-appearing major defects, including neurobehavior effects, may also have been missed due to the timing of the questionnaires.

FETAL RISK SUMMARY

Buspirone is an antianxiety agent that is unrelated chemically and pharmacologically to other sedative and anxiolytic drugs. Reproduction studies in rats and rabbits at doses approximately 30 times the maximum recommended human dose revealed no fertility impairment or fetal adverse effects (1).

A 1993 report described the use of buspirone, in combination with four other agents, all started before conception, in a pregnant woman with major depression, a coexisting panic disorder, and migraine headaches (2). The pregnancy was electively terminated after 12 weeks, resulting in the delivery of a male fetus with normal organ formation and a normal placenta. No dysmorphism was observed during the complete macroscopic and microscopic examination, including a normal 46,XY karyotype.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 42 newborns had been exposed to buspirone during the 1st trimester (F. Rosa, personal

communication, FDA, 1993). One (2.4%) major birth defect was observed (two expected). The anomaly was not included in six defect categories for which specific data were available (cardiovascular defects, oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias).

A 1998 non-interventional observational cohort study described the outcomes of pregnancies in women who had been prescribed ≥ 1 of 34 newly marketed drugs by general practitioners in England (3). Data were obtained by questionnaires sent to the prescribing physicians 1 month after the expected or possible date of delivery. In 831 (78%) of the pregnancies, a newly marketed drug was thought to have been taken during the 1st trimester with birth defects noted in 14 (2.5%) singleton births of the 557 newborns (10 sets of twins). In addition, two birth defects were observed in aborted fetuses. However, few of the aborted fetuses were examined. Buspirone was taken during the 1st trimester in 16 pregnancies. The outcomes of these pregnancies included 2 elective abortions, 1 intrauterine death, 12 normal term babies, and 1 newborn with a genetic defect (cystic fibrosis) (3).

In a 1998 case report, a 32-year-old woman with bipolar disorder took buspirone, fluoxetine, and carbamazepine (see Breastfeeding Summary for doses and further details) throughout gestation (4). At 42 weeks' gestation she gave birth to a healthy, normally developed 3940-g female infant. The mother continued her medications for 3 weeks while exclusively breastfeeding the infant. She reported seizure-like activity in her infant at 3 weeks, 4 months, and 5.5 months of age (4).

BREASTFEEDING SUMMARY

One report has investigated the excretion of buspirone into human milk. In this 1998 case report, a 32-year-old woman with bipolar disorder took buspirone (45 mg/day), fluoxetine (20 mg/day), and carbamazepine (600 mg/day) throughout pregnancy and during the first 3 weeks postpartum (4). She reported seizure-like activity in the infant at 3 weeks, 4 months, and 5.5 months of age. Breast milk, maternal serum, and infant serum were evaluated for buspirone on postpartum day 13, but the drug was not detected in any of the samples (test sensitivity not reported). Similar evaluations were conducted for fluoxetine, norfluoxetine, and carbamazepine on days 13 and 21 postpartum (see Fluoxetine and Carbamazepine for results). A neurologic examination of the infant, which included electroencephalography, was within normal limits. The authors were unable to determine the cause of the seizure-like activity, if it had indeed occurred (none of the episodes had been observed by medical

personnel) (4).

Although buspirone was not detected in breast milk or maternal and infant serum in the above case, the timing of the samples in relation to the mother's ingestion of the drug and the test sensitivity were not specified. Therefore, because other agents in this pharmacologic class are excreted into milk (e.g., see Diazepam), the excretion of buspirone, at least to some degree, should still be expected.

Because of the potential for CNS impairment in a nursing infant, maternal use of the drug, especially for prolonged periods, should be undertaken cautiously, if at all. The American Academy of Pediatrics classifies other antianxiety agents as drugs whose effects on the nursing infant are unknown, but may be of concern because effects on the developing brain may not be apparent until later in life (5).

BUSULFAN

Antineoplastic

PREGNANCY RECOMMENDATION: Contraindicated—1st Trimester

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Busulfan is a human teratogen when used during organogenesis.

FETAL RISK SUMMARY

Busulfan is an alkylating antineoplastic agent. Reproductive studies in pregnant rats revealed that the drug produced sterility in both male and female offspring due to the absence of germinal cells in testes and ovaries (1).

The use of busulfan has been reported in at least 49 human pregnancies, of which 31 were treated in the 1st trimester (2–10). One of these references reviewed eight earlier cases that are included in the above totals (9). Malformations in six infants were: unspecified malformations, aborted at 20 weeks; anomalous deviation of left lobe liver, bilobar spleen, pulmonary atelectasis; pyloric stenosis; cleft palate, microphthalmia, cytomegaly, hypoplasia of ovaries and thyroid gland, corneal opacity, intrauterine growth restriction (IUGR); myeloschisis, aborted at 6 weeks; IUGR, left hydronephrosis and hydroureter, absent right kidney and ureter, hepatic subcapsular calcifications (2,4–6).

Data from one review indicated that 40% of the infants exposed to anticancer drugs were of low birth weight (2). This finding was not related to the timing of the exposure. One mother with chronic granulocytic leukemia was treated with busulfan and allopurinol beginning at 20 weeks' gestation (8). A growth-restricted infant was delivered at 39 weeks with absence of the right kidney, hydronephrosis of the left kidney, and hepatic subcapsular calcifications. The kidney and liver defects predated the onset of drug therapy, but their cause was unknown. The growth restriction, however, was thought to be caused by busulfan.

Long-term studies of growth and mental development in offspring exposed to busulfan during the 2nd trimester, the period of neuroblast multiplication, have

not been conducted (11). However, a few infants have been studied for periods of up to 10 years without evidence of adverse outcome (3,9,10). Moreover, a 1994 review concluded that although there were insufficient data to assess the fetal risk from busulfan, use after the 1st trimester would reduce the risk of birth defects (12).

Chromosomal damage has been associated with busulfan therapy, but the clinical significance of this to the fetus is unknown (13). Irregular menses and amenorrhea, with the latter at times permanent, have been reported in women receiving busulfan (14,15). Reversible ovarian failure with delivery of a normal infant has also been reported after busulfan therapy (16).

Occupational exposure of the mother to antineoplastic agents during pregnancy may present a risk to the fetus. A position statement from the National Study Commission on Cytotoxic Exposure and a research article involving some antineoplastic agents are presented in the monograph for cyclophosphamide (see Cyclophosphamide).

BREASTFEEDING SUMMARY

No studies describing the use of busulfan during human lactation or measuring the amount, if any, excreted into milk have been located. Because of the potential for serious toxicity in a nursing infant, the use of the drug during lactation should be considered contraindicated.

BUTALBITAL

Sedative

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

The limited evidence suggests that butalbital is not a major human teratogen. However, similar to all barbiturates, chronic exposure in the second half of gestation or high doses near term can cause neonatal withdrawal.

FETAL RISK SUMMARY

Butalbital is a short-acting barbiturate that is contained in a number of analgesic mixtures. In a large prospective study, 112 patients were exposed to this drug during the 1st trimester (1). No association with malformations was found. Severe neonatal withdrawal was described in a male infant whose mother took 150 mg of butalbital daily during the last 2 months of pregnancy in the form of a proprietary headache mixture (Esgic-butalbital 50 mg, caffeine 40 mg, and acetaminophen 325 mg/dose) (2). The infant was also exposed to oxycodone, pentazocine, and acetaminophen during the 1st trimester, but apparently these had been discontinued before the start of the butalbital product. Onset of withdrawal occurred within 2 days of birth.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 1124 newborns had been exposed to butalbital during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 53 (4.7%) major birth defects were observed (45 expected). Specific data were available for six defect categories, including (observed/expected) 10/11 cardiovascular defects, 1/2 oral clefts, 0/0.5 spina bifida, 1/3 polydactyly, 2/2 limb reduction defects, and 2/3 hypospadias. These data do not support an association between the drug and congenital defects.

BREASTFEEDING SUMMARY

No reports describing the use of butalbital during human lactation have been located. The drug probably is excreted into breast milk and sedation of a nursing infant is a potential effect.

BUTAPERAZINE

[Withdrawn from the market. See 9th edition.]

BUTENAFINE

Antifungal (Topical)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of butenafine in human pregnancy have been located. The animal data suggest low risk, as does the very low systemic concentrations. Although a more complete assessment of the embryo–fetal risk cannot be made, the topical use of this agent appears to low risk in human pregnancy.

FETAL RISK SUMMARY

Butenafine, a synthetic antifungal, is a benzylamine derivative with a mechanism of action similar to the allylamine class of antifungal agents. The agent is available as a cream to be applied to the skin. Butenafine is indicated for the topical treatment of the dermatologic infection, tinea (pityriasis) versicolor due to *Malassezia furfur* (formerly *Pityrosporum orbiculare*). Small amounts of butenafine are absorbed into the systemic circulation. After the application 6 and 20 g/day for 14 days, the mean peak plasma concentrations were 1.4 and 5.0 ng/mL, respectively. The biphasic plasma elimination half-lives were estimated to be 35 and >150 hours, respectively. The antifungal agent is metabolized (1).

Reproduction studies have been conducted in rats and rabbits. In rats during organogenesis, daily SC doses up to 0.5 times the maximum recommended human dose for tinea versicolor based on BSA (MRHD) were not teratogenic. In a peri- and postnatal study with rats, daily oral doses up to 2.5 times the MRHD caused no treatment-related effects on postnatal survival, development of the F1 generation, or their subsequent maturation and fertility. In rabbits during organogenesis, daily oral doses up to 16 times the MRHD revealed no evidence of treatment-related fetal harm (1).

Studies for carcinogenic effects have not been conducted with butenafine, but assays for mutagenic and clastogenic effects were negative. No adverse effects on male and female rat fertility were observed with daily SC doses up to 0.5 times the MRHD (1).

It is not known if butenafine crosses the placenta. The molecular weight (about 318 for the free base) and long plasma elimination half-life suggest that the drug will cross to the embryo and fetus, but the very small amounts in the systemic circulation suggest that the exposure will be clinically insignificant.

BREASTFEEDING SUMMARY

No reports describing the use of butenafine during human lactation have been located. The molecular weight (about 318 for the free base) and long plasma elimination half-life suggest that the drug will be excreted into breast milk, but the very small amounts in the systemic circulation suggest that the effects on a nursing infant from this exposure will be clinically insignificant.

BUTOCONAZOLE

Antifungal

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The limited human pregnancy experience suggests that butoconazole is low risk.

FETAL RISK SUMMARY

Butoconazole is available as a topical cream for the treatment of vaginal fungal infections. It is in the same antifungal class of imidazole derivatives as clotrimazole, econazole, ketoconazole, miconazole, oxiconazole, sertaconazole, sulconazole, and tioconazole.

Butoconazole is teratogenic in some animal species, but only when large oral doses are administered (1).

An average 5.5% of a vaginal dose is absorbed systemically with peak plasma levels appearing at about 24 hours (1). No data are available on the placental transfer of this agent, but the low molecular weight (about 475) indicates that transfer to the fetus probably occurs.

No published reports of butoconazole use in the 1st trimester have been located. However, butoconazole is one of several agents that have been approved for 2nd and 3rd trimester use in the treatment of vulvovaginal mycotic infections (2–4). Therapy for 6 days is recommended if this antifungal is used.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 444 newborns had been exposed to vaginal butoconazole during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 16 (3.6%) major birth defects were observed (17 expected). Specific data were available for six defect categories, including (observed/expected) 4/4 cardiovascular defects, 0/1 oral clefts, 1/0 spina bifida, 0/0.5 polydactyly, 0/1 limb reduction defects, and 0/1

hypospadias. These data do not support an association between the vaginal use of the drug and congenital defects.

BREASTFEEDING SUMMARY

No reports describing the use of butoconazole during human lactation have been located. The low systemic bioavailability from topical application suggests that there is little risk to a nursing infant.

BUTORPHANOL

Narcotic Agonist-Antagonist Analgesic

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 3rd Trimester

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Although the human pregnancy experience is very limited, and there is no data during the 1st trimester, agents in this class appear to be low risk. Use during labor, however, may cause a sinusoidal fetal heart rate pattern and transient neonatal depression.

FETAL RISK SUMMARY

No reports linking the use of butorphanol with congenital defects have been located. Because it has both narcotic agonist and antagonist properties, prolonged use during gestation may result in fetal addiction with subsequent withdrawal in the newborn (see also Pentazocine). The drug is commercially available as injection and nasal spray formulations.

No teratogenic effects were observed in reproduction studies in rats and rabbits administered butorphanol during organogenesis (1). An increased frequency of stillbirth was observed in rats given 1 mg/kg (5.9 mg/m²) SC and in rabbits dosed orally with 30 mg/kg (360 mg/m²) and 60 mg/kg (720 mg/m²).

At term, butorphanol rapidly crosses the placenta, producing cord serum levels averaging 84% of maternal concentrations (2,3). Depressant effects on the newborn from in utero exposure during labor are similar to those seen with meperidine (2–4).

The use of 1 mg of butorphanol combined with 25 mg of promethazine administered IV to a woman in active labor was associated with a sinusoidal fetal heart rate pattern (5). Onset of the pattern occurred 6 minutes after drug injection and persisted for approximately 58 minutes. The newborn infant showed no effects from the abnormal heart pattern. A subsequent study to determine the incidence of sinusoidal fetal heart rate pattern after butorphanol

administration was published in 1986 (6). Fifty-one women in labor who received butorphanol, 1 mg IV, were compared with a control group of 55 women who did not receive narcotic analgesia. A sinusoidal fetal heart rate pattern was observed in 75% (38 of 51) of the treated women vs. 13% (7 of 55) of controls ($p < 0.001$). The mean time of onset of the abnormal tracing was 12.74 minutes after butorphanol with a duration of 31.26 minutes. This duration was significantly longer than that observed in the nontreated controls (13.86 minutes; $p < 0.02$). Because no short-term maternal or neonatal adverse effects were observed, the investigators concluded that, in the absence of other signs, the abnormal heart rate pattern was not indicative of fetal hypoxia (6).

A study comparing the effects of maternal analgesics on neonatal neurobehavior was conducted in 135 patients during their 1st day of life (7). Maternal analgesia consisted of 1 mg of butorphanol ($N = 68$) or 40 mg of meperidine ($N = 67$). No difference between the drugs was observed.

BREASTFEEDING SUMMARY

Butorphanol passes into breast milk in concentrations paralleling levels in maternal serum (3). Milk:plasma ratios after IM (12 mg) or oral (8 mg) doses were 0.7 and 1.9, respectively. Using 2 mg IM or 8 mg orally 4 times per day would result in 4 mcg excreted in the full daily milk output (1000 mL). Although it has not been studied, this amount is probably insignificant. The American Academy of Pediatrics classifies butorphanol as compatible with breastfeeding (8).

BUTRIPTYLINE

[Withdrawn from the market. See 9th edition.]

C

CABAZITAXEL

Antineoplastic (Antimitotic Taxoid)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of cabazitaxel in human pregnancy have been located. Animal data in two species suggest risk at exposures much less than human exposures, but the absence of human pregnancy experience prevents a better assessment of the embryo–fetal risk. Such experience is unlikely because the drug is indicated for the treatment of prostate cancer. However, it might be used off-label for other neoplasms.

FETAL RISK SUMMARY

Cabazitaxel, given as 1-hour IV infusion every 3 weeks, is an antimitotic agent that is in the same subclass of taxoids as docetaxel and paclitaxel. It is indicated in combination with prednisone for treatment of patients with hormone-refractory metastatic prostate cancer previously treated with a docetaxel-containing treatment regimen. Cabazitaxel is prepared by semi-synthesis with a precursor extracted from yew needles. The drug is extensively metabolized to about 20 metabolites, 3 of which are active. Human serum binding is 89%–92%, most of which is to albumin (82%) and lipoproteins. It is equally distributed between blood and plasma. The elimination half-life is 95 hours (1).

Reproduction studies have been conducted in rats and rabbits. In rats, a once-daily dose during organogenesis that was about 0.02–0.06 times the peak concentration in patients with cancer at the recommended human dose

(RHD) caused embryo–fetal toxicity consisting of postimplantation loss, embryo and fetal deaths. Decreased mean fetal birth weight associated with delays in skeletal ossification was observed at about 0.02 times the RHD. Fetal abnormalities were not observed in rats or rabbits at exposure levels significantly lower than the expected human exposures. Although specific details were not provided, similar effects (embryo and fetal toxicity and abortions) were observed in pregnant rabbits (1).

Long-term animal studies for carcinogenic effects have not been conducted. The drug was clastogenic in one assay and both positive and negative in other mutagenicity assays. Although cabazitaxel had no effect on mating behavior or the ability to become pregnant in female rats, the agent did cause an increase in preimplantation loss and early resorptions. Multi-cycle studies caused atrophy of the uterus and necrosis of the corpora lutea in female rats. In male rats, no effect on mating performance or fertility were observed, but, in higher dose multi-cycle studies, degeneration of seminal vesicle and seminiferous tubule atrophy in the testis were observed. In dogs, minimal testicular degeneration (minimal epithelial single cell necrosis in epididymis) was observed (1).

It is not known if cabazitaxel or its active metabolites cross the human placenta. The molecular weight (about 836 for the solvent-free form), moderate serum binding, and long elimination half-life suggest that the drug will cross to the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use of cabazitaxel during human lactation have been located. The molecular weight (about 836 for the solvent-free form), moderate serum binding (89%–92%), and long elimination half-life (95 hours) suggest that the drug will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown. In adults, the agent can cause severe toxicity that affects many body systems. Although cabazitaxel is indicated for the treatment of prostate cancer, it might be used off-label for other neoplasms. Thus, if a woman is given this drug, the safest course is to not breastfeed.

CABERGOLINE

Endocrine/Metabolic Agent (Miscellaneous)

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Cabergoline does not exhibit direct embryo or fetal toxicity or teratogenicity in animals. Because it inhibits prolactin release, the agent can prevent or abort pregnancies in mice and rats, but this has no human relevance because human egg nidation is not regulated by prolactin. A 2002 review stated that cabergoline was the current treatment of choice for most patients with hyperprolactinemia (1). In addition, the review recommended that once ovulatory cycles were established, women should stop treatment 1 month before they intended to conceive. Hyperprolactinemia is a frequent cause of infertility (2). In many of these women, the partial or complete resolution of this condition will result in conception (2). When pregnancy is diagnosed, cabergoline should be discontinued. However, no evidence indicates that exposure to cabergoline in pregnancy is harmful.

FETAL RISK SUMMARY

Cabergoline is a synthetic ergot derivative that is a long-acting dopamine receptor (D_2) agonist with low affinity for other dopamine (D_1), adrenergic (α_1 and α_2), and serotonin (5-HT₁ and 5-HT₂) receptors. The drug has a direct inhibitory effect on prolactin secretion from the anterior pituitary gland. Cabergoline is indicated for the treatment of hyperprolactinemic disorders, either idiopathic or due to pituitary adenomas (3).

Animal reproduction studies have been conducted in mice, rats, and rabbits with daily oral doses (comparisons to human doses are made with the total weekly animal dose and the maximum recommended weekly human dose for a 50-kg human [MRHD], both based on BSA). In mice, doses up to about 55 times the MRHD caused maternal toxicity but no teratogenic effects in the offspring. In rats, a dose about 1/7th the MRHD caused an increase in postimplantation embryo and fetal losses, an effect that was thought to be due

to the prolactin inhibitory effects of cabergoline. Conception in female rats was inhibited at a dose 1/28th the MRHD given 2 weeks before mating and throughout the mating period. A similar dose given to pregnant rats from 6 days before delivery throughout the lactation period caused growth restriction and death in offspring because of decreased milk secretion. In rabbits, a dose approximately 19 times the MRHD during organogenesis caused maternal toxicity (decreased food consumption and weight loss). An increased occurrence of various malformations was observed in one rabbit study using a dose 150 times the MRHD, but no increase in defects was observed in a second study at 300 times the MRHD (3).

A 1996 reproduction study in mice, rats, and rabbits concluded that cabergoline did not impair male rat fertility, was not teratogenic in mice and rabbits, had no effects on the latter phase of gestation or parturition in rats, and caused no toxicity in neonatal rats (4). The study also found that cabergoline could inhibit egg nidation in mice and rats and prevent conception. However, this effect has no relevance to humans because egg nidation in these species, but not in humans, is regulated by prolactin through a luteotropic effect. A 1997 study in rats demonstrated that cabergoline-inhibited prolactin release resulted in the inhibition of ovarian progesterone biosynthesis, thereby preventing implantation and terminating pregnancy (5).

No reports describing the placental crossing of cabergoline in humans have been located. The molecular weight (about 452) is low enough; however, that exposure of the embryo and/or fetus should be expected.

In a group of 56 women with amenorrhea secondary to hyperprolactinemia (serum prolactin levels >20 mcg/L), 17 (81% of pregnancy-seeking women) became pregnant while under treatment with cabergoline (6). Women were instructed to discontinue cabergoline immediately after a positive pregnancy test. Of the 17 pregnancies, there was 1 spontaneous abortion, 10 normal-term outcomes, and 6 outcomes pending. All 10 children have had normal physical and mental development (6).

A 1994 case report described the outcome of a pregnancy exposed to cabergoline (7). A 38-year-old woman with a microadenoma of the pituitary gland was treated for hyperprolactinemia with a stable cabergoline dose of 0.5 mg twice weekly. She had a 17-year history of infertility and was intolerant to bromocriptine therapy. The prolactin level 2 days after a dose was 1133 mU/L (normal range 60–550 mU/L). After return of her menstrual cycles, she became pregnant but had a spontaneous abortion at 17 weeks' gestation (not mentioned if cabergoline was stopped when pregnancy was diagnosed).

Approximately 5 months later (2 months after restarting cabergoline), she again became pregnant and cabergoline was stopped (gestational age not specified). Labor was induced at 38 weeks' gestation for intrauterine growth restriction. A 2.26-kg male infant without malformations was delivered with Apgar scores of 3 and 8 at 1 and 5 minutes, respectively. The placenta weight was 370 g. He was discharged home with his mother at 6 days of age (7).

A multinational French study published in 1996 described the outcomes of 226 pregnancies (all singletons) in 205 women who had been receiving cabergoline treatment (0.125–4.0 mg/week) before gestation (2). The women were from a group of 1650 premenopausal hyperprolactinemic women who had been treated with the drug. In seven cases, pregnancy occurred during the first cycle after discontinuation of cabergoline. The time of exposure could not be determined in 18 other cases. In the remaining 201 pregnancies, embryo–fetal exposure to cabergoline was thought to have ranged between 1 and 144 days. The 226 outcomes included early pregnancy loss (N = 56), live births (N = 148), ongoing pregnancies (N = 16), and lost to follow-up (N = 6). Among the 56 early pregnancy losses, there were 28 elective abortions (EABs), 23 spontaneous abortions (SABs), 1 intrauterine death (a cord accident at 25 weeks), 1 tubal pregnancy, and 3 EABs for major anomalies (dose and time of exposure shown in parentheses): Down's syndrome, maternal age 42 years, woman later conceived on another cycle and gave birth to a normal infant (0.5 mg/week; exposure for 2 weeks after conception); limb-body wall defect—large abdominal wall defect, deformed left leg, and proximal phocomelia of right lower limb (0.5 mg/week; exposure for 2 weeks after conception); and hydrocephalus, cerebral atrophy, and facial dysmorphic (0.5 mg/week; exposure for 7 weeks after conception) (2).

Among the 148 live births, 17 were preterm, and 2 cases had an unknown length of gestation (2). Birth weights ranged from 1600 to 4350 g, with 10 infants below 2500 g (6.8%, 95% confidence intervals [CI] 3%–12%). In addition to the three cases above, seven infants had birth defects, but only two of them were major defects. The major defects were (dose and exposure times not specified) left megaureter as well as craniosynostosis and scaphocephaly. Thus, there were 5 infants with major malformations among 151 outcomes (3.3%, 95% CI 1.0%–7.6%). The postnatal development of 148 infants was known for various periods after birth, of which 107 were followed up for 1 to 72 months. All the infants showed normal physical and mental development (2).

In a 1997 report, 9 women became pregnant (from a group of 47) against medical advice after a mean of 12.4 months (range 1–37 months) of

cabergoline therapy for hyperprolactinemia (8). The doses ranged from 0.25 to 3.5 mg/week. Cabergoline was discontinued as soon as pregnancy was diagnosed. One pregnancy aborted spontaneously, and one woman underwent elective abortion at 8 weeks' gestation. In the remaining cases, all the pregnancies were brought to term without complication. The infants were healthy at birth and all had normal development during long-term follow-up (8 years) that was still ongoing (8).

A 2002 study reported the outcomes of 61 pregnancies in 50 women who had been treated with cabergoline for hyperprolactinemia (9). Pregnancy began during treatment in 60 cases and immediately after stopping treatment in 1 case. The median duration of treatment before pregnancy was 42.5 weeks (range 1–236 weeks) and the mean dose was 1.1 mg/week (range 0.25–7.0 mg/week). The pregnancy outcomes were 5 EABs (1 for a suspected malformation; specific details not available), 6 SABs, 1 hydatidiform mole, and 49 livebirths. Among the livebirths, there was one minor defect and one major defect (trisomy 18) (9).

In a 2005 report, a woman with Parkinson's disease took levodopa/carbidopa 330 mg/day and cabergoline 1 mg/day throughout an uncomplicated pregnancy and gave birth at term to a healthy baby girl (10). A few years later, now at age 34 and receiving levodopa/carbidopa 625 mg/day and cabergoline 4 mg/day, she became pregnant again. At 32 weeks, she underwent a cesarean section because of placenta abruption. The baby girl was doing well (10).

A 2010 review cited evidence from nearly 600 pregnancies that cabergoline exposure during gestation does not cause teratogenic effects (11). The review included three reports published in 2008–2010 that found no increased risk for SABs, stillbirths, low birth weight, or congenital malformations (12–14).

A 2013 case report described a 29-year-old woman with Cushing disease and noncurative transsphenoidal pituitary surgery who was treated with cabergoline throughout pregnancy (15). The woman had received the drug for about 1 year before she conceived. The cumulative dose during pregnancy was 300 mg. Spontaneous labor occurred at 38 weeks and she gave birth to a healthy, 3350-g female infant with Apgar scores of 7 and 9 at 1 and 5 minutes, respectively. The infant had no signs of congenital defects or hypoglycemia and was doing well at 6 weeks of age. Breastfeeding was unsuccessful because the drug (4.5 mg twice weekly) caused poor milk production (15).

BREASTFEEDING SUMMARY

Although it is not an approved indication, cabergoline suppresses lactation because of its inhibition of prolactin release from the anterior pituitary gland. This action is similar to that of bromocriptine, another prolactin-inhibiting agent. A number of studies have examined this effect (16–21). The oral doses ranged from 0.4 mg to 1 mg, usually given as a single dose within 24 hours of delivery, but sometimes given as a divided dose over 2 days. The 1-mg dose appeared to be the most effective for long-term suppression of lactation.

The manufacturer states that cabergoline should not be used to suppress physiologic lactation because of the known toxicities associated with bromocriptine, when used for this purpose (3). These toxicities include hypertension, stroke, and seizures.

CABOZANTINIB

Antineoplastic (Tyrosine Kinase Inhibitor)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of cabozantinib during human pregnancy have been located. The animal data suggest risk, but the absence of human pregnancy experience prevents a more complete assessment of the embryo–fetal risk. However, based on the mechanism of action, embryo–fetal harm may occur. If a woman is pregnant or conceives during treatment, she should be informed of the potential risk to her embryo and/or fetus.

FETAL RISK SUMMARY

Cabozantinib, a substrate of CYP3A4 in vitro, is an oral inhibitor of tyrosine kinase activity. There are several other agents in this subclass (see Appendix). Cabozantinib is indicated for the treatment of patients with progressive, metastatic medullary thyroid cancer. The drug is metabolized to apparently inactive metabolites. Plasma protein binding is high (>99.7%) and the effective half-life is about 55 hours (1).

Reproduction studies have been conducted in rats and rabbits. In rats that were given the drug daily during organogenesis, embryo–fetal death was observed at doses that were <1% of the human exposure by AUC at the recommended dose (HE). The findings included delayed ossifications and skeletal variations at doses that were about $\geq 0.03\%$ of the HE. In rabbits administered the drug daily during organogenesis, visceral malformations and variations including reduced spleen size and missing lung lobe were observed at a dose that was about 11% of the HE (1).

Studies evaluating the carcinogenic potential of cabozantinib have not been conducted. The drug was not mutagenic or clastogenic in various assays. Fertility was impaired in male rats (decrease in sperm counts and reproductive organ weights) and female rats (decrease in live embryos and increase in pre-

and postimplantation losses, and ovarian necrosis). Impairment of fertility also was observed in male (hypospermia) and female (absence of corpora lutea) dogs (1).

It is not known if cabozantinib crosses the human placenta. The molecular weight (about 636 for the malate salt) and the long effective half-life suggest that the drug will cross to the embryo–fetus, but the high plasma protein binding might limit the exposure.

BREASTFEEDING SUMMARY

No reports describing the use of cabozantinib during human lactation have been located. The molecular weight (about 636 for the malate salt) and the long effective half-life (about 55 hours) suggest that the drug will be excreted into breast milk, but the high plasma protein binding ($\geq 99.7\%$) might limit the exposure. The effect of this exposure on a nursing infant is unknown. However, because the drug commonly ($\geq 25\%$) causes toxicity in adults, such as diarrhea, stomatitis, decreased appetite and weight, nausea, fatigue, and oral and abdominal pain, the best course is to not use cabozantinib during breastfeeding.

CAFFEINE

Central Stimulant

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Although the amount of caffeine in commonly used beverages varies widely, caffeine consumption in pregnancy in moderate amounts apparently does not pose a measurable risk to the fetus. When used in moderation, no association with congenital malformations, spontaneous abortions (SABs), preterm birth, and low birth weight has been proved.

FETAL RISK SUMMARY

Caffeine is one of the most popular drugs in the world (1). It is frequently used in combination products containing aspirin, phenacetin, and codeine and is present in a number of commonly consumed beverages, such as coffee, teas, and colas, as well as many food items. The mean caffeine content in the usual servings of some common beverages was reported as caffeinated coffee (66–146 mg), nonherbal tea (20–46 mg), and caffeinated soft drinks (47 mg) (2), but these amounts may vary widely. (For example, see also reference 26 in which it is reported that the average caffeine content in two cups of regular coffee totaled 454 mg, and the average content in a similar amount of decaffeinated coffee totaled 12 mg.)

Caffeine crosses the placenta, and fetal blood and tissue levels similar to maternal concentrations are achieved (1,3–5). Cord blood levels of 1–1.6 mcg/mL have been measured (3). Caffeine has also been found in newborns exposed to theophylline in utero (6).

The mutagenicity and carcinogenicity of caffeine have been evaluated in more than 50 studies involving laboratory animals, human and animal cell tissue cultures, and human lymphocytes in vivo (1,3). The significance of mutagenic and carcinogenic effects found in nonmammalian systems has not been established in man. The drug is an animal teratogen only when doses high enough to cause toxicity in the mother have been given (1).

The Collaborative Perinatal Project (CPP) monitored 50,282 mother–child pairs, 5378 of whom had 1st trimester exposure to caffeine (7, pp. 366–370). No evidence of a relationship to congenital defects was found. For use anytime during pregnancy, 12,696 exposures were recorded (7, pp. 493–494). In this group, slightly increased relative risks were found for musculoskeletal defects, hydronephrosis, adrenal anomalies, and hemangiomas or granulomas, but the results are not interpretable without independent confirmation (7, pp. 493–494). A follow-up analysis by the CPP on 2030 malformed infants and maternal use of caffeine-containing beverages did not support caffeine as a teratogen (8). Other reports have also found no association between the use of caffeine during pregnancy and congenital malformations (9–12).

Several authors have associated high caffeine consumption (six to eight cups of coffee/day) with decreased fertility, increased incidence of SAB, and low birth weights (3,13–17). However, a few of these studies have isolated the effects of caffeine from cigarette or alcohol use, both of which are positively associated with caffeine consumption (3). One German study has observed that high coffee use alone is associated with low birth weights (18). In an American study of more than 12,400 women, low birth weights and short gestations occurred more often among offspring of women who drank four or more cups of coffee/day and who smoked (12). No relationship between low birth weights or short gestation and caffeine was found after controlling for smoking, alcohol intake, and demographic characteristics. However, other investigators have questioned whether this study has accurately assessed the total caffeine intake of the women (19,20). A Canadian study retrospectively investigated 913 newborn infants for the effects of caffeine and cigarette smoking on birth weight and placental weight (21). Significant caffeine–cigarette interactions were found when daily consumption of caffeine was ≥ 300 mg. Compared with nonsmokers, cigarette smoking significantly lowered mean birth weight. When caffeine use was considered, daily consumption of ≥ 300 mg combined with smoking ≥ 15 cigarettes caused an additional significant reduction in weight. Head circumference and body length were not affected by any level of caffeine consumption. Placental weight, which normally increases with cigarette smoking, an effect hypothesized to be due to compensatory hypertrophy induced by chronic fetal hypoxia, was found to decrease significantly in women smoking ≥ 15 cigarettes/day and ingesting ≥ 300 mg of caffeine/day (21).

A prospective cohort study examined the relationship between caffeine intake and the incidence of late SAB in 3135 predominantly white, educated,

professional women (22). A total of 2483 (79%) of this population used caffeine during pregnancy. Caffeine consumption was calculated based on the intake of coffee (107 mg/serving), tea (34 mg/serving), colas (47 mg/serving), and drugs. Moderate-to-heavy consumption, defined as ≥ 151 mg of caffeine/day, occurred in 28% (879) and was associated with a twofold increased risk of late 1st and 2nd trimester SAB (relative risk 1.95, $p = 0.07$). Consumption of >200 mg/day did not increase this risk. In women who had an SAB in their last pregnancy, light use of caffeine (0–150 mg/day) was associated with a fourfold increase in late pregnancy loss (relative risk 4.18, $p = 0.04$). The data were adjusted for factors such as demographic characteristics, obstetric and medical histories, contraceptive use, smoking, and alcohol exposure. The investigators cautioned, however, that other independent epidemiologic studies were required to confirm their findings because SAB is of multifactorial etiology (22,23).

No increased risk for SAB, intrauterine growth restriction, or microcephaly was found in a study that was able to identify all abortions that occurred 21 or more days after conception (24). The mean 1st trimester caffeine consumption was statistically similar in those who aborted compared with those who delivered liveborn infants, 125.9 vs. 111.6 mg. After adjustment for other risk factors, notably smoking, the adjusted odds ratios for growth restriction and microcephaly were 1.11 (95% confidence interval [CI] 0.88–1.40) and 1.09 (95% CI 0.86–1.37), respectively (24).

A publication, evaluating studies published between 1981 and 1986, reviewed the effects of caffeine consumption on human pregnancies in terms of congenital malformations, low birth weight, preterm birth, SABs, and behavior in in utero exposed children (25). Based on this evaluation of the literature, the author concluded that moderate intake of caffeine was not related to any adverse pregnancy outcome. A second article (120 references) reviewed the effect of caffeine on pregnancy outcome in both animals and humans (26). This author also concluded that modest amounts of caffeine present no proven risk to the fetus, but that limitation of daily amounts to <300 mg/day may lessen the possibility of growth restriction.

Research on the effects of caffeine consumption on human fecundability (i.e., the probability of becoming clinically pregnant in a given menstrual cycle) was reported in 1988 (27). Drawing from women they had enrolled in a study of very early pregnancy loss, the investigators chose 104 women who had not become pregnant in the first 3 months. Data were recorded daily by the women on menstrual bleeding, intercourse, and caffeine and other substance

exposures. Caffeine consumption was calculated by assuming that brewed coffee contained 100 mg, instant coffee 65 mg, tea 50 mg, and soft drinks 40 mg. The subjects were primarily white, college educated, and in their late 20s or early 30s. Caffeinated beverages were consumed by 93% (97 of 104) of the women. The women were grouped into lower caffeine consumers (<3150 mg/month, or about one cup of brewed coffee/day) and higher consumers (>3150 mg/month). Based on this division, the higher consumers were consistently less likely to become pregnant than the lower consumers, with a weighted mean of fecundability ratios across 13 menstrual cycles of 0.59. (The fecundability ratio was determined in each cycle by dividing the number of women who became pregnant by the total number of woman cycles at risk and then by dividing the fraction obtained in the higher caffeine consumption group by the fraction obtained for the lower consumption group.) The ratio was less than 1.0 in every cycle. For cycles occurring after 6 months, the ratio was 0.53, indicating a slightly stronger association between higher caffeine consumption and the inability to become pregnant (27). Statistical adjustment of the data for age, frequency of intercourse, age at menarche, cigarette smoking, vitamin and analgesic intake, alcohol and marijuana use, and the mother's weight and height did not significantly change these findings. Moreover, when caffeine consumption was further subdivided, a partial dose–response relationship was observed, with a ratio of 0.26 for women consuming >7000 mg/month (i.e., >70 cups of coffee/month). Unadjusted data on infertility (defined as women who failed to achieve pregnancy after 1 year) indicated that only 6% of the lower consumption group met this definition compared with 28% of the higher consumption group, an estimated relative risk of 4.7 ($p < 0.005$) (27). Evidence was also found to suggest that the effects of caffeine on fertility were short acting because recent consumption was far more important than previous consumption. Although the study attempted to include all related factors, the investigators cautioned that they could not exclude the possibility that some unknown factor or condition might have accounted for these results and that independent confirmation was required (27,28). Partial confirmation of this study was reported in 1989 (29). In a retrospective analysis of data collected from 1959 to 1967 on 6303 pregnancies, a dose–response relationship was found between caffeine consumption and difficulty in becoming pregnant. Using data adjusted for ethnicity (white, black), parity (0,1), and smoking, the relative risk of decreased fertility for <1 cup of coffee/day was 1.00, 1–3 cups/day 1.20, 4–6 cups/day 1.88, and >7 cups/day 1.96 (29).

Some investigators have expressed concern over the altering of

catecholamine levels in the fetus by caffeine (30). Two cups of regular coffee containing a total of 454 mg of caffeine have been shown to increase maternal epinephrine levels significantly but not norepinephrine or dopamine concentrations (31). Decaffeinated coffee (12 mg of caffeine in two cups) did not affect these catecholamine levels.

A 1989 single-blind, crossover study of eight women at 32–36 weeks of gestation investigated the effects of 2 cups of caffeinated (regular) or decaffeinated coffee on fetal breathing movements and heart rate (31). Administration of the test beverages, containing a total of 454 mg and 12 mg of caffeine, respectively, were separated by 1 week, and in each case, were consumed over a 15-minute period. Fetal breathing movements increased significantly during the 3rd hour after regular coffee, rising from 144 breaths/hour to 614 breaths/hour ($p < 0.01$). Fetal heart rate fell 9% ($p < 0.05$) at 1–1.5 hours after the regular coffee and then slowly rose toward control levels at 2 and 4 hours. However, the mean number, amplitude, and duration of fetal heart rate accelerations did not differ statistically from the control period. Decaffeinated coffee also caused a significant increase in fetal breathing movements, rising to 505 breaths/hour during the 2nd hour, but this beverage caused only a slight, nonsignificant lowering of the fetal heart rate. In an earlier study using 200-mg tablets of caffeine, no increase in fetal breathing rates was observed (32). The differences between the two studies may have been related to the lower dose and/or the dosage form of caffeine.

Cardiac arrhythmias and other symptoms in newborn infants were associated with maternal caffeine consumption of >500 mg/day ($N = 16$) in comparison with the offspring of women who used less than 250 mg/day ($N = 56$) of caffeine (33). The percentages of observed symptoms in the infants of the high and low caffeine groups were tachyarrhythmias (supraventricular tachycardia and atrial flutter) 25% vs. 1.7% ($p < 0.01$), premature atrial contraction 12.5% vs. 0 ($p < 0.01$), fine tremors 100% vs. 10.7% ($p < 0.001$), and tachypnea (resting respiratory rate >60 respirations/minute) 25% vs. 3.5% ($p < 0.01$), respectively. The authors attributed the symptoms to caffeine withdrawal after birth (33).

Two reports have described adverse fetal outcomes, including teratogenic effects, in the offspring of two mothers taking migraine preparations consisting of ergotamine and caffeine (34,35). Complete details of these cases are provided under Ergotamine.

A 1993 reference compared the effects of maternal caffeine consumption greater than 500 mg/day with those of less than 200 mg/day on fetal behavior in the 3rd trimester (36). Long-term consumption of high amounts of caffeine

apparently modulated fetal behavior in terms of quiet sleep (infrequent body movements, regular breathing patterns, and little variability in fetal heart rate [FHR]), active sleep (rapid eye movements [REM], increased body activity, irregular breathing, and increased FHR variability), and arousal (REM, frequent body movements, highly irregular FHR baseline, and breathing activity). Fetuses of mothers in the high caffeine group spent less mean time in active sleep, similar mean time in quiet sleep, and much greater mean time in arousal than did low caffeine-exposed fetuses. It could not be determined if the modulation of behavior had any clinical significance to the newborn or in later life (36).

A 2001 review concluded that, in those who do not smoke or drink alcohol, moderate caffeine consumption (<5–6 mg/kg/day spread throughout the day) did not increase any reproductive risks (37). Use of high doses may be associated with SABs, difficulty in becoming pregnant, and infertility. A dose–response relationship may exist for the latter two problems. However, confirmation of these findings is needed before any firm conclusions can be drawn. The consumption of high caffeine doses with cigarette smoking may increase the risk for delivery of infants with lower birth weight than that induced by smoking alone. Moreover, consumption of large amounts of caffeine may be associated with becoming a smoker and excessive alcohol drinking (37).

BREASTFEEDING SUMMARY

Caffeine is excreted into breast milk (38–45). Milk:plasma ratios of 0.5 and 0.76 have been reported (39,40). Following ingestion of coffee or tea containing known amounts of caffeine (36–335 mg), peak milk levels of 2.09–7.17 mcg/mL occurred within 1 hour (41). An infant consuming 90 mL of milk every 3 hours would ingest 0.01–1.64 mg of caffeine over 24 hours after the mother drank a single cup of caffeinated beverage (41). In another study, peak milk levels after a 100-mg dose were 3.0 mcg/mL at 1 hour (40). In this and an earlier study, the authors estimated a nursing infant would receive 1.5–3.1 mg of caffeine after a single cup of coffee (39,40).

Nine breastfeeding mothers consumed a measured amount of caffeine (750 mg/day) added to decaffeinated coffee for 5 days, then abstained from all caffeine ingestion for the next 4 days (44). In six women, 24-hour pooled aliquots of milk samples from each feeding were collected on days 5 and 9. In another mother, pooled aliquots were collected daily for 9 days. The average milk caffeine concentrations from these seven mothers on day 5 were 4.3 mcg/mL (range <0.25–15.7 mcg/mL). Caffeine was not detected (i.e.,

<0.25 mcg/mL) in any of the seven samples on day 9. Serum levels in the infants of these seven mothers on day 5 averaged 1.4 mcg/mL (range 0.8–2.8 mcg/mL in five infants, not detectable in two). On day 9, caffeine was detectable in the sera of only two infants, decreasing from 0.8 mcg/mL on day 5 to 0.6 mcg/mL on day 9 in one, and decreasing from 2.8 to 2.4 mcg/mL in the other. The remaining two mothers collected milk samples with each feeding for the entire 9 days of the study but did not pool the samples. These mothers were breastfeeding infants aged 79 and 127 days, and their mean daily milk caffeine levels on days 1–5 ranged from 4.0 to 28.6 mcg/mL. Caffeine could not be detected in any of the milk samples after 5 days. The two infants' sera contained <0.25 mcg/mL (mother's milk 13.4 mcg/mL) and 3.2 mcg/mL (mother's milk 28.6 mcg/mL) on day 5, and both were <0.25 mcg/mL on day 9. The wide variance in milk concentrations of caffeine was attributed to the mother's ability to metabolize caffeine (44). Based on the average level of 4.3 mcg/mL, and assuming an infant consumed 150–180 mL/kg/day, the author calculated the infant would receive 0.6–0.8 mg/kg/day of caffeine (44).

In an extension of the above study, the effect of 500 mg of caffeine consumption/day on infant heart rate and sleep time was evaluated in 11 mother–infant pairs (45). Mothers consumed decaffeinated coffee daily for 5 days and then decaffeinated coffee with added caffeine for another 5-day period. Milk caffeine levels on the last day of the caffeine period ranged from 1.6 to 6.2 mcg/mL, providing an estimated 0.3–1.0 mg/kg/day of caffeine to the infants. No significant difference in 24-hour heart rate or sleep time was observed between the two phases of the study.

The elimination half-life of caffeine is approximately 80 hours in term newborns and 97.5 hours in premature babies (42). A 1987 study investigated the metabolism of caffeine in breast- and formula-fed infants given oral doses of caffeine citrate (46). The serum half-lives of caffeine were greater than three times as long in the breast-fed infants as compared with the formula-fed infants (76 vs. 21 hours at 47–50 weeks postconceptional age; 54 vs. 16 hours at 51–54 weeks postconceptional age). The investigators attributed the findings to inhibition or suppression of caffeine metabolism by the hepatic cytochrome P450 system by some element of breast milk (46).

The amounts of caffeine in breast milk after maternal ingestion of caffeinated beverages are probably too low to be clinically significant. However, accumulation may occur in infants when mothers consume moderate-to-heavy amounts of caffeinated beverages. Irritability and poor sleeping patterns have been observed in nursing infants during periods of heavy maternal use of

caffeine (43). The American Academy of Pediatrics classifies usual amounts of caffeinated beverages as compatible with breastfeeding (47).

CALCIFEDIOL

Vitamin

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

FETAL RISK SUMMARY

Calcifediol is converted in the kidneys to calcitriol, one of the active forms of vitamin D. See Vitamin D.

BREASTFEEDING SUMMARY

See Vitamin D.

CALCIPOTRIENE

Dermatologic Agent (Anti-Psoriatic)

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of calcipotriene in human pregnancy have been located. The animal data suggest moderate risk, but there is no evidence that vitamin D derivatives cause human developmental toxicity. Only low amounts of the drug are absorbed into the systemic circulation and the embryo–fetal risk is probably similar to calcitriol, a vitamin considered compatible with pregnancy (see Calcitriol). Two reviews discussing the treatment of psoriasis, one in 2002 (1) and the other in 2005 (2), considered the topical use of calcipotriene to be safe in pregnancy. Mild hypercalcemia has been observed in a newborn exposed in utero to calcitriol and is a potential complication with calcipotriene.

FETAL RISK SUMMARY

Calcipotriene, a synthetic derivative of vitamin D₃ (calcitriol), is available in cream, ointment, and solution preparations. It is indicated for the treatment of plaque psoriasis in adults. Clinical studies with the ointment found that about 6% and 5% of the applied dose is absorbed systemically when applied to psoriasis plaques and normal skin, respectively. Much of the absorbed drug is converted to inactive metabolites within 24 hours of application. Metabolism is thought to be similar to calcitriol (3,4). Systemic absorption of the cream or solution has not been studied (3).

Reproduction studies have been conducted in rats and rabbits with oral calcipotriene where the expected bioavailability of the dose was about 40%–60%. The maternal and fetal calculated no-effect exposures in the rat and rabbit studies were about equal to the expected human systemic exposure level from dermal application based on BSA (HSEL). In rats, oral doses about 7.4

times the HSEL resulted in a significantly higher incidence of skeletal abnormalities consisting primarily of enlarged fontanelles (thought to be due to the drug's effect on calcium metabolism) and extra ribs. In rabbits, increased maternal and fetal toxicity was noted at about 7.5 times the HSEL. Doses that were about 17.5 times the HSEL resulted in fetuses with a significant increase in the incidences of pubic bones, forelimb phalanges, and incomplete bone ossification (3,4).

Long-term carcinogenesis studies in mice with topical calcipotriene, without exposure to ultraviolet radiation (UVR), caused no significant changes in tumor incidence. However, when mice also were exposed to UVR, the results suggested that the drug enhanced the effect of UVR to induce skin tumors. Calcipotriene was not mutagenic in multiple assays and, at oral doses up to about 7.5 times the HSEL, did not impair the fertility or reproductive performance in rats (3,4).

It is not known if calcipotriene crosses the human placenta. However, the systemic disposition of calcipotriene is expected to be similar to that of the naturally occurring calcitriol that does enter the fetal circulation (4).

BREASTFEEDING SUMMARY

No reports describing the use of calcipotriene during human lactation have been located. Only small amounts are absorbed into the systemic circulation and probably are excreted into breast milk. However, calcipotriene is a synthetic derivative of calcitriol, an active form of vitamin D. Vitamin D is compatible with breastfeeding (see Vitamin D), and the topical use of calcipotriene probably can be classified similarly.

CALCITONIN-SALMON

Calcium Regulation Hormone

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports linking the use of calcitonin-salmon with congenital defects have been located. Marked increases of calcitonin concentrations in fetal serum greater than maternal levels have been demonstrated at term (1). The significance of this finding is unknown.

FETAL RISK SUMMARY

Calcitonin-salmon is a synthetic polypeptide of 32 amino acids in the same linear sequence that is found in the hormone from salmon. The hormone does not cross the placenta (2).

A decrease in fetal birth weights in rabbits has been observed when calcitonin-salmon was administered in doses 14–56 times the recommended human dose. The fetal weight reduction may have been due to metabolic effects on the mother (2).

In a 1990 case, a 28-year-old woman at 30 weeks with a history of a renal transplant was treated for 3 weeks with an IV infusion of calcitonin-salmon for hypercalcemia (3). A cesarean section was performed at 33 weeks for preeclampsia to deliver a normal 1600 g female infant.

BREASTFEEDING SUMMARY

No reports describing the use of calcitonin-salmon during lactation have been located. Because it is a polypeptide, excretion into milk would not be expected. Moreover, calcitonin-salmon has been shown to inhibit lactation in animals (4). Mothers wishing to breastfeed should be informed of this potential complication (2).

CALCITRIOL

Vitamin

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

The near absence of human pregnancy experience prevents a complete assessment of the risk for the embryo and fetus. However, there is no evidence that recommended doses of vitamin D during pregnancy are harmful.

FETAL RISK SUMMARY

Calcitriol is one of three physiologically active forms of vitamin D (see Vitamin D). Calcitriol is teratogenic in rabbits given daily doses that were about two and six times the maximum recommended human dose based on BSA (MRHD) (1). Defects observed included external and skeletal malformations. The high dose given on gestation days 7–18 also increased maternal mortality, decreased mean fetal body weight, and reduced the number of newborn surviving to 24 hours. No teratogenic effects were observed in rats treated with daily doses up to about five times the MRHD (1). However, hypercalcemia was measured in the offspring of rats given doses that were about one and three times the MRHD (1).

The manufacturer cites a case of mild hypercalcemia during the first 2 days of life in an infant who was exposed to a maternal dose of 17–36 mcg/day (approximately 17–36 times the maximum recommended dose) during pregnancy (1). The hypercalcemia resolved by the third day.

BREASTFEEDING SUMMARY

See Vitamin D.

CALCIUM CARBONATE

Nutrient/Antacid

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Sufficient maternal calcium intake is important to ensure adequate mineralization of the fetal skeleton (1). The recommended dietary allowance (RDA) for calcium during pregnancy is based on age: 1300 mg/day for 14–18 years and 1000 mg/day for 19–50 years (2). The primary source of calcium in pregnancy is diet, but antacids and supplements containing calcium carbonate, and prenatal vitamins, also contribute. Recommended doses of calcium carbonate for heartburn relief are safe in pregnancy, but very high doses have caused milk-alkali syndrome and other toxicity. Calcium supplements, such as 1000–2000 mg/day of calcium carbonate, offer few if any benefits for pregnant women if they have adequate dietary calcium intake. However, there may be some benefits for women with low (<600 mg/day) dietary calcium intake.

FETAL RISK SUMMARY

Calcium carbonate is commonly used as a source of calcium either alone or as a component of vitamins products. It also is used as an antacid, either alone or in combination with other antacids, to neutralize stomach acid.

Calcium crosses the human placenta by active transport. The fetal concentration of calcium is related to fetal weight so that most accumulation of calcium takes place in the 3rd trimester (3).

A number of studies have evaluated calcium supplementation with calcium carbonate to prevent or reduce the risk of hypertensive disorders in pregnancy (gestational hypertension and preeclampsia), preterm birth, maternal hemodynamic dysfunction, and long-term effects on the blood pressure of offspring (4–15). Although many of these studies reported a reduction in hypertensive disorders, a large 1997 study conducted by the National Institutes of Health (NIH) did not find this outcome (16). In this study, 4589 healthy

nulliparous women at 13–21 weeks' gestation were randomized to receive daily treatment throughout their pregnancy with either 2 g of calcium carbonate or placebo. In the calcium group (N = 2295), preeclampsia occurred in 158 (6.9%), whereas in the placebo group (N = 2294), 168 (7.3%) developed preeclampsia (relative risk 0.94, 95% confidence interval 0.76–1.16). There also was no significant difference between the groups for pregnancy-associated hypertension without preeclampsia (15.3% vs. 17.3%) or all hypertensive disorders (22.2% vs. 24.6%). The mean systolic and diastolic blood pressures during pregnancy were similar in the groups. Moreover, calcium supplementation did not reduce the number of preterm births (<37 weeks; 10.8% vs. 10.0%), small-for-gestational-age infants (5.8% vs. 4.9%), or fetal and neonatal deaths (27 vs. 25 cases). In addition, calcium supplementation did not increase urolithiasis (3 vs. 4 cases) (16).

In an editorial accompanying the aforementioned NIH study, the author pointed out that whereas the investigators involved diet in the NIH study, this may not have been done in previous studies and might account for the different outcomes (17). The author also cautioned that although the NIH study clearly demonstrates that supplemental calcium 2 g/day offers no benefit for low-risk women if the desired outcome is reduced preeclampsia or improved fetal or neonatal outcome, it did not indicate that adequate or extra dietary calcium was not important (17).

A 1999 randomized, double-blind, placebo-controlled study examined the effect of calcium carbonate supplementation (≥ 2 g/day) during the 2nd and 3rd trimesters on fetal bone mineralization (18). A total of 256 infants (128 per group) were studied. The supplementation did increase fetal bone mineralization in women with low dietary calcium intake (<600 mg/day) compared with placebo, but in women with adequate dietary calcium intake, supplementation did not result in major improvement in this outcome (18).

The results of a multicenter, randomized, placebo-controlled, double-blind trial of calcium supplementation in low-calcium-intake pregnant women were published in 2006 (19). The trial found that calcium carbonate supplementation (1.5 g/day) did not prevent preeclampsia but did reduce its severity. Also noted was a slight, nonsignificant lowering of preterm (<37 weeks) birth (9.8% vs. 10.8%) and a significant decrease in early (<32 weeks) preterm birth (2.6% vs. 3.2%). Maternal morbidity and mortality and neonatal mortality were reduced by supplementation, but two other outcomes, low birth weight in term pregnancies and admission to intensive care units, were similar between the two groups (19).

Using data collected for the aforementioned trial, a 2010 study in Argentina evaluated the effect of calcium supplements on fetal growth in pregnant women with low calcium intake (average calcium intake <600 mg/day) (20). The women, at about 13 weeks' gestation, were randomized to either calcium carbonate 1500 mg/day (N = 231) or placebo (N = 230). No differences between the two groups were found in serial fetal biometric measurements taken five times from 20 to 36 weeks' gestation. Moreover, neonatal characteristics and anthropometric measurements at birth were comparable in both groups. The investigators concluded that calcium supplementation of 1500 mg/day in pregnant women with low calcium intake did not improve fetal somatic or skeletal growth (20).

Excessive consumption of calcium carbonate throughout pregnancy was suspected to be the cause of neonatal hypocalcemia, resulting in seizures (21). The mother, a healthy 24-year-old, had heartburn, which she treated with 10 to 14 extra-strength Tums daily (750 mg calcium carbonate/tablet) starting midway through the 1st trimester and continuing until the onset of labor at 39 weeks. The normal-appearing infant weighed about 3.5 kg at birth and was sent home on the second day. Generalized seizures developed at 8 days of age. Laboratory tests were normal, except for a total calcium level of 6.3 mg/dL that decreased to 6.1 mg/dL the next day (normal: 8.5–11.0 mg/dL) and a high phosphorus level (8.2 mg/dL; normal 4.0–7.0 mg/dL). The infant was treated with phenobarbital and IV calcium gluconate, and at 12 days of age, the total calcium was within the normal range, but the phosphorus level did not return to a normal range until 29 days of age. One possible mechanism proposed by the author was that the excessive maternal calcium intake had suppressed fetal parathyroid function. At 3 months of age, the infant was healthy and doing well (21).

Ingestion of calcium carbonate has been associated with three published cases of milk-alkali syndrome in pregnancy (22–24). The first case involved a 34-year-old woman in her second pregnancy (22). She had excessive vomiting and took large quantities (amount not specified) of calcium carbonate, milk, and cheese. She was admitted to the hospital at 23 weeks' gestation with dehydration and a 3-day history of abdominal pain, nausea, vomiting, and diarrhea. Laboratory tests revealed hypercalcemia (14.3 mg/dL), and acute renal insufficiency (serum creatinine 2.1 mg/dL; blood urea nitrogen 52 mg/dL). The hypercalcemia was caused by the milk-alkali syndrome and resulted in pancreatitis and azotemia. Aggressive IV hydration, 5 L of isotonic saline over 12 hours, resulted in a normal calcium level and renal function and her

abdominal pain resolved in 4 days. She was discharged home in good health. At 37 weeks, she gave birth to a stillborn fetus. The fetus had short limbs and low-set ears but a normal chromosome analysis. An autopsy revealed no evidence of tissue calcification (22).

A 31-year-old woman at 36 weeks' gestation presented with a 3-day history of disorientation, ataxia, nausea, and vomiting (23). Over the previous 2 weeks she had daily ingested 5 glasses of milk and about 30 antacid tablets, each containing 500 mg calcium carbonate. Her total calcium level was 22.5 mg/mL. Because acute severe hypercalcemia (≥ 15 mg/dL) can be life-threatening and may result in intractable nausea, vomiting, polyuria, dehydration, coma, cardiac arrhythmias, and circulatory arrest, she was aggressively treated with IV therapy and furosemide, followed by hemodialysis. The fetal condition was normal with external monitoring. An ultrasound examination revealed normal amniotic fluid volume but no fetal breathing, body motion, or tone. Four weeks later, the woman gave birth to a 2950-g normal male infant who was doing well at 1 year of age (23).

A third case of the milk-alkali syndrome in pregnancy secondary to excessive ingestion of calcium carbonate was reported in 2004 (24). A 32-year-old woman at 16 weeks' gestation, who had taken an antacid (Tums; 6–10 tablets/day) for gastroesophageal reflux, presented with severe hypercalcemia (total and ionized calcium 22 mg/dL and 12.16 mg/dL, respectively), alkalosis, and acute renal insufficiency. The normal ranges for total and ionized calcium were 8.5–10.5 and 4.65–5.20 mg/dL, respectively. At admission, she was treated with IV isotonic saline, furosemide, and a 600-mg dose of IV etidronate. On day 5, symptoms of bisphosphonate-induced hypocalcemia were noted (tingling of the extremities and a positive Chvostek sign). Her symptoms were relieved with IV calcium gluconate and she was started on calcium carbonate. Her low concentrations of total and ionized calcium (7.4–8.0 and 4.00–4.56 mg/dL, respectively) normalized in about 2 weeks. No information was provided on the eventual pregnancy outcome (24).

BREASTFEEDING SUMMARY

The RDA for calcium during lactation is based on age: 1300 mg/day for 14–18 years and 1000 mg/day for 19–50 years (2).

In a small 1994 study, the calcium needed for milk production appeared to be met by decreased urinary excretion and increased bone resorption and not by increased absorption (25). A 1995 study found that calcium carbonate supplements (1000 mg) 5 days each week in Gambian women consuming a

low-calcium diet had no effect on breast milk calcium concentration or on maternal bone mineral content. The investigators concluded that physiologic mechanisms worked to furnish calcium for breast milk production (26).

In a 2006 study, pregnant women in Gambia were randomized to calcium carbonate supplementation (1500 mg/day) (N = 61) or placebo (N = 62) from 20 weeks' gestation to delivery (27). Breast milk levels of calcium were analyzed at 2, 13, and 52 weeks after delivery. No differences between subjects and controls in the calcium or phosphorus concentrations in breast milk were noted. Moreover, calcium supplementation had no effect on infant birth weight, growth, or bone mineral status (27).

In Mexican lactating women with high lead levels (mean blood lead 8.5 mcg/mL), a 2003 study measured the effect of calcium carbonate supplementation (1200 mg/day) compared with placebo (28). The supplements resulted in a small decline (0.29 mcg/dL) of blood lead levels. A greater reduction (1.16 mcg/dL) was observed in women who were compliant with supplement use and had high bone lead levels (patella bone lead ≥ 5 mcg/g bone) (28).

A 1997 study evaluated the effect of calcium carbonate supplementation (1 g/day) compared with placebo on the bone density of the maternal lumbar spine (29). In lactating women, the lumbar spine bone density decreased by 4.2% in the supplement group compared with a 4.9% decrease in the placebo group. In nonlactating women, calcium supplements increased lumbar spine bone density by 2.2% vs. 0.4% with placebo. There was no effect of lactation or supplementation on bone density in the forearm and supplementation did not increase the calcium concentration in breast milk (29). An accompanying editorial supported the findings of the study. The author noted that nursing mothers provide an average of 200–250 mg/day of calcium to their infants and recommended that they increase their calcium intake by 400–800 mg/day (30).

CAMPHOR

Antipruritic/Local Anesthetic

PREGNANCY RECOMMENDATION: Compatible (Topical)

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Limited data suggest that the topical use of camphor during gestation is of low risk.

FETAL RISK SUMMARY

Camphor is a natural product obtained from the subtropical tree *Cinnamomum camphora* in the form of D-camphor; it is also produced synthetically in the optically inactive racemic form. In reproductive studies in rats and rabbits with oral doses, no evidence of embryotoxicity or teratogenicity was observed even at maternally toxic doses (1).

No reports linking the use of topically applied camphor with congenital defects have been located. Camphor is toxic and potentially a fatal poison if taken orally in sufficient quantities. Four cases of fetal exposure after accidental ingestion, including a case of fetal death and neonatal respiratory failure, have been reported (2–5). The drug crosses the placenta (3). A 1997 case report described a 16-year-old girl at 6 weeks' gestation who ingested 30 g of camphor dissolved in 250 mL of wine in an unsuccessful attempt to induce abortion (6). After successful treatment of the symptoms of camphor poisoning, her pregnancy was electively terminated a few weeks later. An autopsy of the embryo was not done.

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 168 of whom had 1st trimester exposure to topical camphor (7, pp. 410–412). No association was found with congenital malformations. For use anytime during pregnancy, 763 exposures were recorded and, again, no relationship to defects was noted (7, pp. 444, 499).

BREASTFEEDING SUMMARY

Although there are no reports describing the use of topical camphor during lactation, its use probably is harmless for a nursing infant.

CANAKINUMAB

Immunologic Agent (Immunomodulator)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of canakinumab in human pregnancy have been located. The animal data in two species suggest low risk, but a no-observed-effect-level (NOEL) for the incomplete fetal skeletal development observed in the species was not reported. The absence of human pregnancy experience prevents an assessment of this and other risks for the human embryo–fetus. If treatment with this antibody is required in pregnancy, the woman should be informed of the absence of human pregnancy data and potential risk.

FETAL RISK SUMMARY

Canakinumab is a recombinant human antihuman interleukin-1 beta (IL-1 β) monoclonal antibody that belongs to the IgG1/k isotype subclass. Canakinumab is indicated for the treatment of cryopyrin-associated periodic syndrome, in adults and children 4 years of age and older, including familial cold autoinflammatory syndrome and Muckle–Wells syndrome. The immunomodulator binds to serum IL-1 β . The mean terminal half-life is 26 days (1).

Reproduction studies have been conducted in monkeys and mice. In monkeys, SC doses, given twice weekly during gestation days 23–109 that were 23–230 times the human dose based on plasma AUC comparison at the maximum recommended human dose (MRHD-AUC) revealed no evidence of embryotoxicity or fetal malformations. However, increases in the incidence of incomplete fetal skeletal development were observed at all dose levels. Because canakinumab does not cross-react with mouse IL-1, mice were given SC doses of a murine analog of canakinumab on gestation days 6, 11, and 17.

A comparison with the human exposure was not given, but the three doses used were identical on a body-weight basis to those given to monkeys. Incomplete fetal skeletal development was increased in a dose-dependent manner at all dose levels tested (1). The NOEL was not reported in either species.

Studies for carcinogenic or mutagenic potential have not been conducted. Fertility studies, using a murine analog of canakinumab, were conducted in male and female mice. SC doses of the analog, identical on a body-weight basis to those given to monkeys, were given before and after mating and had no effect on male or female fertility parameters (1).

It is not known if canakinumab crosses the human placenta. The molecular weight (145,157) suggests that passive transfer will not occur, but the long circulation half-life will place the protein at the maternal: fetal interface for a prolonged period. Moreover, other proteins (e.g., see Immune Globulin Intravenous) cross the placenta. If the delayed skeletal development observed in the two animal species were direct effects (i.e., effects on the embryo and/or fetus and not caused by maternal effects), this would be evidence that the antibody can cross hemochorial placentas.

BREASTFEEDING SUMMARY

No reports describing the use of canakinumab during human lactation have been located. The high molecular weight of this antibody (145,157) and the long circulation half-life (26 days) suggest that excretion into mature breast milk will be inhibited. Because immunoglobulins and other high-molecular-weight substances are excreted into colostrum, exposure of the nursing infant to canakinumab might occur during the first few days after birth. The effect, if any, of this exposure on a nursing infant is unknown. However, an increase in serious infections is a potential complication due to interference with the immune response. Other adverse effects observed in patients treated with this drug include nasopharyngitis, diarrhea, rhinitis, nausea, headache, bronchitis, and gastroenteritis (1). Nursing infants of women receiving the drug should be closely monitored for these effects.

CANDESARTAN CILEXETIL

Antihypertensive

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The antihypertensive mechanisms of action of candesartan and angiotensin-converting enzyme (ACE) inhibitors are very close. That is, the former selectively blocks the binding of angiotensin II to AT₁ receptors, whereas the latter prevents the formation of angiotensin II itself. Therefore, use of this drug during the 2nd and 3rd trimesters may cause teratogenicity and severe fetal and neonatal toxicity that is identical to that seen with ACE inhibitors (e.g., see Captopril or Enalapril). Fetal toxic effects may include anuria, oligohydramnios, fetal hypocalvaria, intrauterine growth restriction, prematurity, and patent ductus arteriosus. Stillbirth or neonatal death may occur. Anuria-associated oligohydramnios may produce fetal limb contractures, craniofacial deformation, and pulmonary hypoplasia. Severe anuria and hypotension, which is resistant to both pressor agents and volume expansion, may occur in the newborn following in utero exposure to candesartan cilexetil. Newborn renal function and blood pressure should be closely monitored.

FETAL RISK SUMMARY

The prodrug, candesartan cilexetil, is hydrolyzed to the active drug, candesartan, during absorption from the gastrointestinal tract. Candesartan is a selective angiotensin II receptor blocker (ARB) that is used, either alone or in combination with other antihypertensive agents, for the treatment of hypertension. It blocks the vasoconstrictor and aldosterone-secreting effects of angiotensin II by preventing angiotensin II from binding to AT₁ receptors (1).

Reproduction studies have been conducted with candesartan cilexetil in mice, rats, and rabbits at oral doses up to approximately 138, 2.8, and 1.7 times the

maximum recommended human dose of 32 mg based on BSA (MRHD), respectively (1). Rat offspring, exposed to the drug during late gestation and through lactation, had decreased survival and an increased incidence of hydronephrosis, whereas no maternal toxicity or fetal harm was observed in pregnant mice. In pregnant rabbits, maternal toxicity (decreased body weight and death) was noted, but, in the offspring of surviving dams, no adverse effects were seen on fetal survival, fetal weight, or on external, visceral, or skeletal development (1). No effects on fertility or reproductive performance were observed in male and female rats given oral doses up to 83 times the MRHD (1).

It is not known if candesartan crosses the human placenta to the fetus. The molecular weight of candesartan (about 440 after hydrolysis of the prodrug, candesartan cilexetil) is low enough such that passage to the fetus should be expected.

In a 2001 case report, candesartan (7 mg/day) was used for mild hypertension throughout gestation (2). Amniotic fluid was reduced at term. The female infant (birth weight not given) had left-sided facial palsy, plexus paresis, and was anuric. On ultrasound, the kidneys were hyperechogenic with poor corticomedullary differentiation. Urine production started at 5 days of age and the sonographic appearance of the kidneys normalized during the following month. At 8 months of age, the infant was developing normally and only a discrete facial and plexus palsy remained (2).

A 41-year-old woman was treated with candesartan throughout a 32-week gestation (3). Because of anhydramnios, she was delivered of a 1120-g (0.4th percentile) male infant in poor condition. The infant had defective ossification of the roof of the calvarium, joint contractures, mild hypospadias, rocker bottom feet, a large abdominal left kidney and absent right kidney. He developed intractable hypotension, unresponsive to hydration, and remained anuric until he died (3).

In a 2003 report, the outcomes of 42 pregnancies exposed to ARAs were described (4). The outcomes of 37 pregnancies (1 set of twins) exposed in the 1st trimester were 3 spontaneous abortions (drugs not specified), 4 elective abortions (one for exencephaly; candesartan until 4 3/7 weeks, carbimazole, hydrochlorothiazide, maternal obesity), 1 stillbirth (no anomalies; valsartan until week 4, cigarette smoking, other antihypertensives), 1 minor malformation (undescended testicles; drug not specified), and 28 healthy newborns. There was one major malformation (cleft palate, patent ductus arteriosus, modest coarctation of the aorta, growth restriction; valsartan until week 13,

hydrochlorothiazide, metoprolol, cigarette smoking). Five cases involved late exposure to ARAs and their outcomes involved one or more of the following: oligohydramnios/anhydramnios, anuria, hypoplastic skull bones, limb contractions, lung hypoplasia, and neonatal death (4).

A 2005 article reviewed the mechanism of ARA-induced fetal toxicity (5). This toxicity, observed in 15 case reports, was similar to that observed with angiotensin-converting enzyme (ACE) inhibitors. The primary effect is suppression of the fetal renin–angiotensin system that results in disruption of the fetal vascular perfusion and renal dysfunction (5).

A 38-year-old pregnant woman with chronic hypertension was treated with candesartan (16 mg/day) and propranolol (160 mg/day) (6). Oligohydramnios was diagnosed at 23 weeks and candesartan was stopped and methyldopa was started. At 26 weeks, no amniotic fluid was noted, the fetal kidneys were small and the bladder was empty. An elective abortion delivered a 860-g male fetus with deformities of the extremities and face due to oligohydramnios. The kidneys had severe tubular dysgenesis with a reduced number and poor differentiation of proximal tubules (6).

A 2007 review cited 64 published cases of pregnancies exposed to ARAs, 42.2% of which had unfavorable outcomes (7). The duration of ARA exposure was longer in the cases with poor outcomes compared with those with good outcomes, 26.3 ± 10.5 vs. 17.3 ± 11.6 weeks.

A 2010 case report described the outcome of an unplanned pregnancy that was exposed to aspirin 75 mg/day, metoprolol 25 mg/day, and candesartan 4 mg/day in the first 22 weeks (8). At that time, ultrasound revealed edematous fetal kidneys and reduced levels of amniotic fluid, and candesartan was discontinued. Five weeks later, normal amniotic fluid and a visible fetal bladder were noted, but the kidneys remained enlarged. At 31 weeks, she gave birth to a 2200-g male infant with Apgar scores of 9 and 9. Renal function studies in the 1-day-old infant were within normal limits. However, at 1 and 2 weeks, ultrasound of the kidneys showed bilateral marked calices, small cysts, and parenchymal increased echogenety. There was complete sonographic normalization of the kidneys at 6 weeks of age. At 6 months of age, a urine analysis was normal. The infant had a systolic murmur related to a patent ductus arteriosus. Based on experimental evidence, concern was expressed for renal dysfunction and arterial hypertension in adulthood (8).

A 2012 review of the use of ACE inhibitors and ARBs in the 1st trimester concluded that there may be an elevated teratogenic risk, but the risk appeared to be related to other factors (9). The factors that typically coexist with

hypertension in pregnancy, included diabetes, advanced maternal age, and obesity.

BREASTFEEDING SUMMARY

No reports describing the use of candesartan cilexetil during human lactation have been located. Because the molecular weight of the active drug, candesartan, is about 440, excretion into human breast milk should be expected. The effects of this exposure on a nursing infant are unknown. The American Academy of Pediatrics, however, classifies ACE inhibitors, a closely related group of antihypertensive agents, as compatible with breastfeeding (see Captopril or Enalapril).

CAPECITABINE

Antineoplastic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of capecitabine during human pregnancy have been located. Studies have observed developmental toxicity in mice (structural anomalies and death) and rabbits (death) at systemic exposures less than those observed with the maximum recommended dose in humans. The drug is converted intracellularly to the active metabolite 5-FU. Although there are no human pregnancy data, capecitabine should be avoided in pregnancy. If it must be used for the mother's benefit, consideration should be given to avoiding the period of organogenesis.

FETAL RISK SUMMARY

Capecitabine, a fluoropyrimidine carbamate, is an oral prodrug that, upon absorption from the gut, is converted in the liver to a precursor (5'-DFUR) of 5-fluorouracil (5-FU). The final metabolic step to 5-FU, the active agent, occurs in tumor and normal cells. (See also Fluorouracil.) Capecitabine is classified as an antimetabolite in the subclass of pyrimidine analogs. In addition to fluorouracil, other antineoplastic agents in the subclass are cytarabine, floxuridine, and gemcitabine. Capecitabine is indicated for adjuvant treatment in patients with Dukes' C colon cancer who have undergone complete resection of the primary tumor, as first-line treatment of patients with metastatic colorectal carcinoma, and, either alone or in combination (see Ixabepilone) in some cases of breast cancer. Plasma protein binding of capecitabine and its metabolites is low (<60%). The elimination half-life of capecitabine and 5-FU is very short (about 0.75 hours) (1).

Reproduction studies have been conducted in mice and monkeys. During organogenesis in mice, a dose that resulted in systemic exposures of 5'-DFUR AUC that were about 0.2 times the human exposure from the recommended

daily dose (HERDD) produced cleft palate, anophthalmia, microphthalmia, oligodactyly, polydactyly, syndactyly, kinky tail, and dilation of cerebral ventricles. In monkeys, during organogenesis, a dose that resulted in systemic exposures of 5'-DFUR AUC that were about 0.6 times HERDD caused fetal death (1).

The carcinogenic potential of capecitabine has not been evaluated. The drug was not mutagenic in two assays but was clastogenic in one test. However, 5-FU causes mutations in bacteria and yeast and chromosomal abnormalities in mice. In mice, a capecitabine dose resulting in exposures that were about 0.7 times the HERDD caused a reversible decrease in fertility in females and degenerative changes in the testes of males. No fetuses survived this dose in mice that became pregnant (1).

It is not known if capecitabine or the precursor 5'-DFUR crosses the human placenta. The molecular weight of capecitabine (about 359) and the low plasma protein binding suggest that the drug will cross to the embryo–fetus, but the very short elimination half-life should limit the exposure. The molecular weight of 5'-DFUR was not specified, but if it or the parent drug were to cross the placenta, intracellular metabolism in normal tissues could expose the embryo–fetus to 5-FU.

BREASTFEEDING SUMMARY

No reports describing the use of capecitabine during human lactation have been located. The molecular weight of capecitabine (about 359) and the low plasma protein binding (<60%) of capecitabine and 5'-DFUR (molecular weight not specified) suggest that the drugs will be excreted into breast milk, but the very short elimination half-life of capecitabine (about 0.75 hours; unspecified for 5'-DFUR) should limit the exposure. The effects of this exposure on a nursing infant are unknown. However, metabolism of the parent drug and the precursor would expose the infant to 5-FU. The mother should not breastfeed if she is being treated.

CAPREOMYCIN

Antibiotic (Antituberculosis)

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of capreomycin during human pregnancy have been located. A 1992 review of tuberculosis and pregnancy stated that the safety of capreomycin in pregnancy was not established, but cited no references of its use (1). Two other sources, one published in 1995 and the other in 1996, concluded that capreomycin should be avoided, if possible, because of the potential for ototoxicity and deafness (2,3). Neither source cited pregnancy data involving capreomycin.

FETAL RISK SUMMARY

Capreomycin is a polypeptide antibiotic isolated from *Streptomyces capreolus*. The antibiotic is a mixture of four active components consisting of capreomycin IA and IB (a combined total of at least 90% of the product) and capreomycin IIA and IIB. Capreomycin is given by IM injection. Less than 1% is absorbed orally. It is indicated, in combination with other antituberculosis agents, as an alternate drug when the primary agents are ineffective or cannot be used because of toxicity. Because the toxicity of capreomycin is similar to aminoglycosides (e.g., cranial nerve VIII and renal), it should not be used with these agents (4).

Capreomycin caused a low incidence of wavy ribs in rats given doses 3.5 times the human dose (1). No studies have been conducted on the effects of the antibiotic on fertility, carcinogenicity, or mutagenicity (4).

It is not known if capreomycin crosses the human placenta. The molecular weight (about 653–669) suggests that the drug will cross to the embryo–fetus.

A 2003 report described the use of capreomycin in a pregnant woman with multidrug-resistant tuberculosis (5). A 22-year-old woman was diagnosed with

the infection at 23 weeks' gestation and daily treatment was initiated with rifampin (600 mg), isoniazid (300 mg), and ethambutol (700 mg). Because of lack of response, her therapy was changed after 3 weeks to capreomycin (IV 1000 mg 5 days/week), cycloserine (750 mg/day), levofloxacin (1000 mg/day), para-aminosalicylic acid (12 g/day), and pyrazinamide (1500 mg/day). After spontaneous rupture of the membrane, she gave birth at 35 weeks' gestation to a healthy, 2003-g infant. The results of a tuberculin skin test and three nasogastric aspiration cultures were negative, as were a neurologic examination and electrophysiology hearing studies. The infant was kept separated from the mother (5).

A 2003 study reported the outcomes of seven pregnancies treated for multidrug-resistant tuberculosis (6). The seven women received multiple anti-infective agents. Three patients (one throughout, one in 1st trimester, and one postpartum) were treated with IV capreomycin. In 2005, the same group reported the long-term follow-up of six of the offspring; a seventh child, not exposed to capreomycin, was lost to follow-up (7). The average age of the children was 3.7 years and each underwent a comprehensive clinical evaluation. None had hearing loss and all had normal vision and neurologic analysis. Of the three exposed to capreomycin (current age and time of exposure), one had mild speech delay (4.6 years; throughout and postpartum), one was hyperactive (5.1 years; postpartum only), and one had no abnormalities (1.25 years; 1st trimester only). All three were breastfed (7). Neither of the two conditions appears to be related to capreomycin.

BREASTFEEDING SUMMARY

No studies reporting the excretion of capreomycin into breast milk have been located. One report mentioned that two infants whose mothers were receiving IV capreomycin and other antituberculosis agents were breastfed (7). No other details were available, but the long-term follow-up revealed no evidence of capreomycin-induced toxicity (see above).

The molecular weight (about 653–669) suggests that the drug will be excreted into breast milk.

The effect on a nursing infant from this exposure is unknown. Although the systemic absorption of capreomycin in a neonate has not been studied, <1% of an oral dose is absorbed by adults, so the risk, if any, to a nursing infant appears to be minimal.

CAPTOPRIL

Antihypertensive

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

The fetal toxicity of captopril in the 2nd and 3rd trimesters is similar to other angiotensin-converting enzyme (ACE) inhibitors. The use of this drug during the 2nd and 3rd trimesters may cause teratogenicity and severe fetal and neonatal toxicity. Fetal toxic effects may include anuria, oligohydramnios, fetal hypocalvaria, intrauterine growth restriction, prematurity, and patent ductus arteriosus. Stillbirth or neonatal death may occur. Anuria-associated oligohydramnios may produce fetal limb contractures, craniofacial deformation, and pulmonary hypoplasia. Severe anuria and hypotension, which is resistant to both pressor agents and volume expansion, may occur in the newborn following in utero exposure. Newborn renal function and blood pressure should be closely monitored.

FETAL RISK SUMMARY

Captopril, an ACE inhibitor, is used for the treatment of hypertension and in the management of heart failure. The drug is embryocidal in animals and has been shown to cause an increase in stillbirths in some species (1–3). In pregnant sheep and rabbits, the use of captopril was associated with a decrease in placental blood flow and oxygen delivery to the fetus (4,5).

Because of the toxicity identified in early animal studies, a committee of the National Institutes of Health recommended in 1984 that captopril be avoided during pregnancy (6). A 1985 review on the treatment of hypertension in pregnancy also stated that captopril should not be used in pregnancy because of the animal toxicity (7). However, use of captopril limited to the 1st trimester does not appear to present a significant risk to the fetus. Fetal exposure after this time has been associated with teratogenicity and severe toxicity in the fetus and newborn, including death.

A number of reports have described the use of captopril, usually in combination with other antihypertensive agents and often after the failure of other medications, for the treatment of resistant hypertension during human pregnancy (8–28). Included among these is a 1991 review that summarized those cases of captopril-exposed pregnancies published before January 1, 1990 (28). Some of these reports are reviewed below.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 86 newborns had been exposed to captopril during the 1st trimester (Franz Rosa, personal communication, FDA, 1993). Four (4.7%) major birth defects were observed (three expected). Specific data were available for six defect categories, including (observed/expected) 1/1 cardiovascular defects, 0/0 oral clefts, 0/0 spina bifida, 1/0 polydactyly, 1/0 limb reduction defects, and 1/0 hypospadias. These data do not support an association between 1st trimester use of captopril and congenital defects.

One pregnancy treated with captopril was reported in a 1997 study of 19 pregnancies exposed to ACE inhibitors (8). Captopril therapy was stopped at 8 weeks' gestation. No congenital anomalies or renal dysfunction was noted in the newborn (8).

A malformed fetus was discovered after voluntary abortion in a patient with renovascular hypertension (9). The patient had been treated during the 1st trimester with captopril, propranolol, and amiloride. The left leg ended at mid thigh without distal development, and no obvious skull formation was noted above the brain tissue. However, because of the very small size of the fetus (1.5 cm), the pathologist could not be certain that the defects were not a result of the abortion (10).

A mother with a history of renal artery stenosis and malignant hypertension was treated throughout gestation with captopril, minoxidil, and propranolol (11). Three of her four previous pregnancies had ended in midgestation stillbirths. The most recent stillbirth, her fourth pregnancy, involved a 500-g male infant with low-set ears but no gross anomalies. The mother had been treated with the above regimen plus furosemide. In her second pregnancy, she had been treated only with hydrochlorothiazide and she had delivered a normal-term infant. No information was available on the first and third pregnancies, both of which ended in stillbirths. In her latest pregnancy, daily doses of the three drugs were 50 mg, 10 mg, and 160 mg, respectively. The infant, delivered by cesarean section at 38 weeks, had multiple abnormalities, including an omphalocele (repaired on the 2nd day), pronounced hypertrichosis of the back

and extremities, depressed nasal bridge, low-set ears, micrognathia, bilateral fifth finger clinodactyly, undescended testes, a circumferential midphallic constriction, a large ventriculoseptal defect, and a brain defect consisting of slightly prominent sulci, especially the basal cisterns and interhemispheric fissure. Growth restriction was not evident, but the weight (3170 g, 60th percentile), length (46 cm, 15th percentile), and head circumference (32.5 cm, 25th percentile) were disproportionate. Neurologic examinations, as well as examinations of the skeleton and kidneys, were normal. Marked hypotension (30–50 mmHg systolic) was present, which resolved after 24 hours. Heart rate, blood glucose, and renal function were normal. The infant's hospital course was marked by failure to thrive, congestive heart failure, prolonged physiologic jaundice, and eight episodes of hyperthermia ($>38.5^{\circ}\text{C}$ without apparent cause) between 2 and 6 weeks of age. The hypertrichosis, which was much less prominent at 2 months of age, is a known adverse effect of minoxidil therapy in both children and adults, and the condition in this infant was thought to be caused by that drug. The cause of the other defects could not be determined, but a chromosomal abnormality was excluded based on a normal male karyotype (46,XY), determined after a midgestation amniocentesis (11).

One case involved a mother with polyarteritis nodosa treated throughout gestation with captopril, hydralazine, and furosemide (12). The pregnancy was electively terminated at approximately 31 weeks' gestation because of worsening maternal disease. A normal, non-growth-restricted infant was delivered who did well in the neonatal period (12).

Oligohydramnios developed after 3 weeks of therapy with captopril in a woman who was treated at 25 weeks' gestation (13). Cesarean section at 29 weeks' gestation produced a 1040-g infant with dehydration, marked peripheral vasodilation, severe hypotension, respiratory distress, and anuria. Epidermolysis of the trunk and extremities appeared after birth. Diagnostic studies indicated a normal bladder, but neither kidney was perfused. ACE activity was reported as very low. The infant died on day 8 as a result of persistent anuria. At autopsy, hemorrhagic foci were discovered in the renal cortex and medulla, but nephrogenesis was adequate for the gestational age.

A woman was treated at 27 weeks' gestation with daily doses of captopril (200 mg), labetalol (1600 mg), and furosemide (80 mg) (14). Fourteen days after treatment was begun, signs of fetal distress, attributed to the maternal hypertension, appeared and the infant was delivered by cesarean section. No adverse effects of the drug treatment were observed in the infant (14).

Captopril and acebutolol were used throughout pregnancy to treat a woman

with nephrotic syndrome and arterial hypertension (15). Intrauterine growth restriction (IUGR), most probably because of the severe maternal disease (although a contribution from drug therapy could not be excluded), was identified early in the 2nd trimester and became progressively worse. The growth-restricted male infant was delivered prematurely at 34 weeks by cesarean section. Captopril was found in the cord blood, with levels in the mother and fetus less than 100 ng/mL, 4 hours after the last dose. ACE activity was below normal limits in both the mother and the newborn. Neonatal respiratory arrest occurred 15 minutes after delivery with varying degrees of hypotension persisting over the first 10 days. A patent ductus arteriosus was also present (15).

A woman with hypertension secondary to bilateral renal artery stenosis was treated with captopril, 150 mg/day, beginning 6 weeks before conception (16). Daily drug therapy during pregnancy consisted of captopril (600 mg), methyldopa (750 mg), and furosemide (80 mg). Oligohydramnios and IUGR were diagnosed at 35 weeks' gestation, at which time a cesarean section was performed to deliver the 2120-g male infant. Some of the abnormalities in the infant, such as pulmonary hypoplasia, small skull circumference (28.5 cm, <3rd percentile), hypoplastic skull bones with wide sutures, and contractures of the extremities, were probably caused by captopril-induced oligohydramnios and fetal hypotension. The severe neonatal hypotension (27/20 mmHg), which slowly resolved over 5 days despite volume expansion and pressor agents, and the anuria were also most likely caused by captopril. The infant was anuric for 7 days, then oliguric with 7–10 mL/day output for the next 12 days. All diagnostic tests during the first 10 days after birth indicated apparently normal kidneys. Peritoneal dialysis was commenced on the 20th day, but the infant died at 1 month of age (16).

A 1985 case report described a woman with twins treated throughout pregnancy with captopril (75–100 mg/day), hydralazine (75 mg/day), metoprolol (200 mg/day), and chlorthalidone (25 mg/day; stopped after 3 months) (17). Three previous pregnancies complicated by severe hypertension had ended with one term, mentally subnormal infant and two spontaneous abortions, one at 5 months and one at 7 months. Two weeks before term the dose of captopril was reduced to 37.5 mg/day. Other than their small size (weight and length of both were <10th percentile), both infants were normal and had normal mental and physical growth at 10 months (17).

In another case report, a woman who had had a renal transplant was treated throughout gestation with daily doses of captopril (75 mg), cyclosporine (200

mg), atenolol (200 mg), cimetidine, and amoxicillin (18). Oligohydramnios was diagnosed at 18 weeks' gestation and IUGR with gross oligohydramnios was discovered at 26 weeks. Ultrasound scanning at 27 weeks indicated renal dysplasia. Intrauterine fetal death occurred at 29 weeks. No congenital anomalies were found at autopsy. The kidneys appeared normal, but no urine was found in the ureters or bladder. The authors attributed the renal dysgenesis to the captopril therapy (18).

An 18-year-old woman with severe chronic hypertension became pregnant while taking captopril, hydralazine, and propranolol (19). Captopril and hydralazine were discontinued on presentation at 10 weeks' gestation. Because her subsequent blood pressure control was poor, her therapy was changed at 20 weeks' gestation to captopril (37.5–75 mg/day), atenolol (100 mg/day), and nifedipine (40 mg/day). IUGR was identified by serial scanning. A healthy, 1590-g female infant was delivered by cesarean section at 30 weeks' gestation. No other additional information was provided, except that the infant survived (19).

Two abstracts described two pregnancies terminating with newborns exhibiting characteristic patterns of captopril-induced fetotoxicity and malformations (24,25). The fetopathy consisted of fetal hypotension, severe anuria and oligohydramnios, IUGR, hypocalvaria, renal tubular dysplasia, and pulmonary hypoplasia. Both infants died.

The result of a survey on the use of captopril during pregnancy was published in 1988 (26). The outcomes of therapy in the 37 pregnancies (38 fetuses, 1 set of twins) were 3 stillbirths, 11 premature births, 4 small-for-gestational-age infants, 4 cases of patent ductus arteriosus, and 2 neonatal deaths secondary to anuria (26).

A 1992 reference described the effects of ACE inhibitors on pregnancy outcome (27). Among 106,813 women enrolled in the Tennessee Medicaid program who delivered either a liveborn or stillborn infant, 19 had taken either captopril, enalapril, or lisinopril during gestation. One premature newborn, exposed in utero to captopril, had microcephaly, a large occipital encephalocele, and was probably blind (27).

Investigators at the FDA summarized some of the known cases of captopril-induced neonatal anuria in a 1989 report (29). These cases have been described above (13,15,16). The FDA authors cautioned that if captopril was used during pregnancy, then preparations should be made for neonatal hypotension and renal failure (29). Of interest, a 1991 review concluded that fetal and neonatal renal dysfunction was more common after maternal use of

enalapril than with captopril (28).

A 1991 report presented two cases of fetopathy and hypocalvaria in newborns exposed in utero to ACE inhibitors, including one case in which captopril, prednisone, atenolol, and furosemide were used throughout pregnancy (same case as described in reference 24) and one case caused by lisinopril (30). Twelve other cases of hypocalvaria or acalvaria were reviewed, three of which were thought to be caused by captopril (N = 2) or enalapril (N = 1) and nine others with causes that were either not drug-related or unknown. The authors speculated that the underlying pathogenetic mechanism in these cases was fetal hypotension (30).

In a 1991 article examining the teratogenesis of ACE inhibitors, the authors cited evidence linking fetal calvarial hypoplasia with the use of these agents after the 1st trimester (31). They speculated that the mechanism was related to drug-induced oligohydramnios that allowed the uterine musculature to exert direct pressure on the fetal skull. This mechanical insult, combined with drug-induced fetal hypotension, could inhibit peripheral perfusion and ossification of the calvaria (31).

Investigators in a study published in 1992 examined microscopically the kidneys of nine fetuses exposed to ACE inhibitors, one of which was enalapril (32). The researchers concluded that the renal defects associated with ACE inhibitors were caused by decreased renal perfusion and are similar to the defects seen in other conditions related to reduced fetal renal blood flow (32).

In a retrospective 2000 study, the outcomes of 10 pregnant women treated with low-dose captopril (12.5–25 mg/day) for severe, unresponsive vasoconstricted hypertension were reviewed (33). Maternal hemodynamics improved without fetal or neonatal complications. Assuming an expected complication rate of 5%–10%, however, the number of exposed pregnancies may have been too small to identify adverse effects (33).

A retrospective study using pharmacy-based data from the Tennessee Medicaid program identified 209 infants, born between 1985 and 2000, who had 1st trimester exposure to ACE inhibitors (34). Infants of mothers with evidence of diabetes, either before or during pregnancy, were excluded, as were those exposed to angiotensin-receptor antagonists (ARBs), ACE inhibitors, or other antihypertensives beyond the 1st trimester, and exposure to known teratogens. Two comparison groups, other antihypertensives (N = 202) and no antihypertensives (N = 29,096), were formed. The number of major birth defects in each of the three groups was 18 (8.6%), 4 (2%), and 834 (2.9%), respectively. Compared with the no antihypertensives group, exposure to ACE

inhibitors was associated with a significantly increased risk of major defects (relative risk [RR] 2.71, 95% confidence interval [CI] 1.72–4.27). When the analysis was conducted by the type of defect, the highest rates were with cardiovascular defects, 9, 2, and 294, respectively (RR 3.72, 95% CI 1.89–7.30), and with central nervous system defects, 3, 0, and 80, respectively (RR 4.39, 95% CI 1.37–14.02). The major defects observed in the subject group were as follows: atrial septal defect (N = 6) (includes three with pulmonic stenosis and/or three with patent ductus arteriosus (PDA)), renal dysplasia (N = 2), PDA alone (N = 2), and one each of ventricular septal defect, spina bifida, microcephaly with eye anomaly, coloboma, hypospadias, intestinal and choanal atresia, Hirschsprung disease, and diaphragmatic hernia (34). In an accompanying editorial, it was noted that neither previous reports of 1st trimester exposure to ACE inhibitors nor the animal studies had observed an increased risk of birth defects (35). It also was noted that no mechanism for ACE inhibitor–induced teratogenicity was known. A subsequent communication raising concerns about the validity of the study in terms of adequate exclusion of diabetes, charting and coding errors in busy medical practices, and the effects of maternal obesity (36) was addressed by the investigators (37).

Captopril and other ACE inhibitors are human teratogens when used in the 2nd and 3rd trimesters, producing fetal hypocalvaria and renal defects. The cause of the defects and other toxicity is probably related to fetal hypotension and decreased renal blood flow. The compromise of the fetal renal system may result in severe, and at times fatal, anuria, both in the fetus and in the newborn. Anuria-associated oligohydramnios may produce pulmonary hypoplasia, limb contractures, persistent patent ductus arteriosus, craniofacial deformation, and neonatal death (38,39). IUGR, prematurity, and severe neonatal hypotension may also be observed. Two reviews of fetal and newborn renal function indicated that both renal perfusion and glomerular plasma flow are low during gestation and that high levels of angiotensin II may be physiologically necessary to maintain glomerular filtration at low perfusion pressures (40,41). Captopril prevents the conversion of angiotensin I to angiotensin II and, thus, may lead to in utero renal failure. Newborn renal function and blood pressure should be closely monitored. If oligohydramnios occurs, stopping captopril may resolve the problem but may not improve infant outcome because of irreversible fetal damage (38). In those cases in which captopril must be used to treat the mother's disease, the lowest possible dose should be used combined with close monitoring of amniotic fluid levels and fetal well-being. Guidelines for counseling exposed pregnant patients have been published and should be of

benefit to health professionals faced with this task (31,38).

The observation in Tennessee Medicaid data of an increased risk of major congenital defects after 1st trimester exposure to ACE inhibitors raises concerns about teratogenicity that have not been seen in other studies (35). Medicaid data are a valuable tool for identifying early signals of teratogenicity, but are subject to a number of shortcomings, and their findings must be considered hypotheses until confirmed by independent studies.

A 2012 review of the use of ACE inhibitors and ARBs in the 1st trimester concluded that there may be an elevated teratogenic risk, but the risk appeared to be related to other factors (42). The factors, which typically coexist with hypertension in pregnancy, included diabetes, advanced maternal age, and obesity.

BREASTFEEDING SUMMARY

Captopril is excreted into breast milk in low concentrations. In 12 mothers given 100 mg three times/day, average peak milk levels were 4.7 ng/mL at 3.8 hours after their last dose (43,44). This represented an average milk:plasma ratio of 0.012. No differences were found in captopril levels in milk before and after the drug. No effects on the nursing infants were observed. The American Academy of Pediatrics classifies captopril as compatible with breastfeeding (45).

CARBACHOL

Parasympathomimetic (Cholinergic)

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Although there are no human reports, carbachol probably is compatible in pregnancy.

FETAL RISK SUMMARY

Carbachol is used in the eye. No reports of its use in pregnancy have been located. As a quaternary ammonium compound, it is ionized at physiologic pH and transplacental passage in significant amounts would not be expected.

BREASTFEEDING SUMMARY

No reports describing the use of carbachol during human lactation have been located. Because clinically significant concentrations are unlikely, the drug should be compatible with breastfeeding.

CARBAMAZEPINE

Anticonvulsant

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Carbamazepine use in pregnancy is associated with an increased incidence of major and minor malformations, including neural tube defects (NTDs), cardiovascular and urinary tract defects, and cleft palate. A fetal carbamazepine syndrome has been proposed, consisting of minor craniofacial defects, fingernail hypoplasia, and developmental delay. The latter abnormality, however, is controversial; some studies have found mild mental retardation and some have not. Although pregnant women should be advised of these potential adverse outcomes, if the drug is required during pregnancy it should not be withheld because the benefits of preventing seizures outweigh the potential fetal harm.

FETAL RISK SUMMARY

Carbamazepine, a tricyclic anticonvulsant, has been in clinical use since 1962. The drug is teratogenic in rats at doses 10–25 times the maximum human daily dose [MHDD] of 1200 mg/day or 1.5–4 times the MHDD based on BSA (1). Anomalies observed included kinked ribs, cleft palate, talipes, and anophthalmos.

The drug crosses the placenta, with highest concentrations found in fetal liver and kidneys (2–4). Fetal levels are approximately 50%–80% of maternal serum levels (4).

Placental function in women taking carbamazepine has been evaluated (5). No effect was detected from carbamazepine as measured by serum human placental lactogen, 24-hour urinary total estriol excretion, placental weight, and birth weight.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 172 newborns had

been exposed to carbamazepine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 13 (7.6%) major birth defects were observed (7 expected), including 4 cardiovascular defects (2 expected), and 1 spina bifida (none expected). No anomalies were observed in four other categories of defects (oral clefts, polydactyly, limb reduction defects, and hypospadias) for which specific data were available. Although the above data have not yet been analyzed to distinguish between combination and monotherapy (F. Rosa, personal communication, FDA, 1993), the total number of malformations suggests an association between the drug and congenital defects (see also discussion of reference 25 below).

Additional reports to the FDA involved five cases of holoprosencephaly in which carbamazepine was used either alone (two cases) or in combination with valproic acid and phenytoin (one case), phenytoin and primidone (one case), or gabapentin (one case) (6). Because of the lack of family histories, an association with familial holoprosencephaly or maternal neurologic problems could not be excluded (6).

A number of reports have described the use of carbamazepine during the 1st trimester (5,7,23,27,33–40). Multiple anomalies were found in one stillborn infant in whom carbamazepine was the only anticonvulsant used by the mother (15). These included closely set eyes, flat nose with single nasopharynx, polydactyly, atrial septal defect, patent ductus arteriosus, absent gallbladder and thyroid, and collapsed fontanel. Individual defects observed in this and other cases include talipes, meningomyelocele, anal atresia, ambiguous genitalia, congenital heart disease, hypertelorism, hypoplasia of the nose, cleft lip, congenital hip dislocation, inguinal hernia, hypoplasia of the nails, and torticollis (7–18). One infant, also exposed to lithium during the 1st trimester, had hydrocephalus and meningomyelocele (18). Decreased head circumference (7 mm less than controls) has been observed in infants exposed only to carbamazepine during gestation (19). The head size was still small by 18 months of age with no catch-up growth evident. Dysmorphic facial features, combined with physical and mental retardation, were described in an infant girl exposed during gestation to 500–1700 mg/day of carbamazepine monotherapy (23). Maternal carbamazepine serum levels had been monitored frequently during gestation and all were reported to be in the therapeutic range (23).

In a 1982 review, Janz stated that nearly all possible malformations had been observed in epileptic patients (24). Minor malformations, such as those seen in the fetal hydantoin syndrome (FHS) (see Phenytoin), have also been observed with carbamazepine monotherapy, causing Janz to conclude that the term FHS

was misleading (24). Because carbamazepine was thought to present a lower risk to the fetus, the drug has been recommended as the treatment of choice for women who may become pregnant and who require anticonvulsant therapy for the first time (25). However, a 1989 report has indicated that carbamazepine is also probably a human teratogen (22).

Eight children were identified retrospectively after in utero exposure to carbamazepine either alone (N = 4), or in combination with other anticonvulsants (phenobarbital N = 2, primidone N = 1, or phenobarbital and clonazepam N = 1) (22). In six mothers, daily carbamazepine doses ranged from 600 to 1600 mg (dosage unknown in two). The following defects were noted in the children: intrauterine growth restriction (two cases), poor neonatal performance (three cases), postnatal growth deficiency (three cases, not determined in four), developmental delay (three cases, not determined in four), microcephaly (three cases, not determined in four), upslanting palpebral fissures (two cases), short nose with long philtrum (two cases), hypoplastic nails (four cases), and cardiac defect (two cases).

Concurrently with the above evaluations, a prospective study involving 72 women treated with carbamazepine in early pregnancy was conducted (22). Fifty-four liveborn children were evaluated from the 72 mothers, with the remaining 18 excluded for various reasons (seven spontaneous abortions, five therapeutic abortions, and six lost to follow-up before delivery). A control group of 73 pregnant women was prospectively selected for comparison. Anticonvulsant drug therapy in the study group consisted of carbamazepine either alone (N = 50) or in combination with phenobarbital (N = 12), phenobarbital and valproic acid (N = 4), primidone (N = 3), valproic acid (N = 1), ethosuximide (N = 1), and primidone and ethosuximide (N = 1). Carbamazepine dosage varied from 200 to 1200 mg/day. Seizures occurred at least once during pregnancy in 59% of the women, but they did not correlate with either malformations or developmental delay in the offspring (22). Of the 54 liveborn children, 48 were examined by the study investigators. Five (10%) of these children had major anomalies consisting of lumbosacral meningomyelocele (N = 1), multiple ventricular septal defects (N = 1), indirect inguinal hernia (N = 1) (all three exposed to carbamazepine alone), and cleft uvula (N = 2) (exposed to carbamazepine and phenobarbital). Five (7%) of the control infants also had major anomalies. The incidence of children with two minor malformations was statistically similar for the study and control groups, 23% (11 of 48) vs. 13% (9 of 70), respectively. Those presenting with three or more minor anomalies, however, were more frequent in the exposed group

(38%, 18 of 48) than in controls (6%, 4 of 70) ($p = 0.001$). Based on the combined results from the retrospective and prospective studies, the investigators concluded that carbamazepine exposure was associated with a pattern of congenital malformations whose principal features consisted of minor craniofacial defects, fingernail hypoplasia, and developmental delay. Because these defects were similar to those observed with the fetal hydantoin syndrome, and because both carbamazepine and phenytoin are metabolized through the arene oxide pathway, a mechanism was proposed that attributed the teratogenicity to the epoxide intermediates rather than to the specific drugs themselves (22).

In a later correspondence concerning the above study, the investigators cited unofficial data obtained from the FDA involving 1307 pregnancies in which the maternal use of carbamazepine was not confounded by the concomitant use of valproic acid (26). Eight infants with spina bifida were identified in the offspring of these mothers. The incidence of 0.6% (1 in 163) represented a ninefold relative risk for the neural tube defect (26).

A 1991 report cited data accumulated by the FDA on 237 infants with spina bifida born to women taking antiepileptic drugs during gestation (27). Carbamazepine was part of the anticonvulsant regimen in at least 64 of the women, 36 without valproic acid and 28 with valproic acid. The author noted that substantial underreporting was likely in these data, and an accurate assessment of the risk of spina bifida with carbamazepine could not be determined from voluntarily reported cases (27). To overcome these and other biases, the pregnancy outcomes of all Medicaid recipients in Michigan who gave birth in the period from 1980 through 1988, and who took anticonvulsants during the 1st trimester, were examined. Four cases of spina bifida were identified from 1490 women, including 107 who had taken carbamazepine. Three of the infants with spina bifida had been exposed to carbamazepine in utero, one of whom was also exposed to valproic acid, and two of whom were also exposed to phenytoin, barbiturates, or primidone alone or in combination. Combined with other published studies, the author concluded that in utero exposure to carbamazepine during the 1st trimester, without concurrent exposure to valproic acid, results in a 1% risk of spina bifida (27). The relative risk (RR) was estimated to be about 13.7 (95% confidence interval [CI], 5.6–33.7) times the expected rate.

The above study generated several published comments involving the risk of spina bifida after 1st -trimester exposure to carbamazepine (28–32). The last reference described an infant with closed spina bifida resulting from a

pregnancy in which the mother took 600 mg of carbamazepine alone throughout gestation (32). The 3400-g female infant, delivered at 36 weeks' gestation, had a lumbosacral myelomeningocele covered with skin and no sensory loss. The authors of this report commented on four other cases of spina bifida after exposure to carbamazepine, either alone or in combination with valproic acid (32).

The effects of exposure (at any time during the 2nd or 3rd month after the last menstrual period) to folic acid antagonists on embryo–fetal development were evaluated in a large, multicenter, case–control surveillance study published in 2000 (33). The report was based on data collected between 1976 and 1998 from 80 maternity or tertiary care hospitals. Mothers were interviewed within 6 months of delivery about their use of drugs during pregnancy. Folic acid antagonists were categorized into two groups: group 1—dihydrofolate reductase inhibitors (aminopterin, methotrexate, sulfasalazine, pyrimethamine, triamterene, and trimethoprim); group 2—agents that affect other enzymes in folate metabolism, impair the absorption of folate, or increase the metabolic breakdown of folate (carbamazepine, phenytoin, primidone, and phenobarbital). The case subjects were 3870 infants with cardiovascular defects, 1962 with oral clefts, and 1100 with urinary tract malformations. Infants with defects associated with a syndrome were excluded as were infants with coexisting NTDs; known to be reduced by maternal folic acid supplementation. Too few infants with limb-reduction defects were identified to be analyzed. Controls (N = 8387) were infants with malformations other than oral clefts and cardiovascular, urinary tract, limb reduction, and NTDs, but included infants with chromosomal and genetic defects. The risk of malformations in control infants would not have been reduced by vitamin supplementation, and none of the controls used folic acid antagonists. For group 1 cases, the RRs of cardiovascular defects and oral clefts were 3.4 (95% CI 1.8–6.4) and 2.6 (95% CI 1.1–6.1), respectively. For group II cases, the RRs of cardiovascular, urinary tract defects, and oral clefts were 2.2 (95% CI 1.4–3.5), 2.5 (95% CI 1.2–5.0), and 2.5 (95% CI 1.5–4.2), respectively. Maternal use of multivitamin supplements with folic acid (typically 0.4 mg) reduced the risks in group 1 cases, but not in group 2 cases (33).

A 2001 case–control study, using the same database as in the above study, compared 1242 infants with NTDs (spina bifida, anencephaly, and encephalocele) with a control group of 6660 infants with congenital defects not related to vitamin supplements (34). Based on six exposed cases, the adjusted odds ratio (OR) for carbamazepine was 6.9%, 95% CI 1.9–25.7. For all folic

acid antagonists (carbamazepine, phenobarbital, phenytoin, primidone, sulfasalazine, triamterene, and trimethoprim), based on 27 cases, the adjusted OR was 2.9, 95% CI 1.7–4.6 (34).

A 1996 study described typical dysmorphic facial features in 6 of 47 children (aged 6 months to 6 years) who had been exposed to carbamazepine monotherapy during pregnancy (35). Moreover, the average cognitive score for the 47 children was significantly lower than a control group. The authors concluded that the facial features and mild mental retardation were consistent with a carbamazepine syndrome that had been described earlier (see references 22 and 35).

In a 2000 study, a group of 100 Swedish children who had been exposed to antiepileptic drugs (carbamazepine most frequently) in utero was compared with 100 matched controls at 9 months of age (36). Exposed children had a significant increase in the number of minor anomalies, 31 vs. 18, and, after carbamazepine exposure, an increased number of facial anomalies, 11 vs. 6. A blinded assessment of psychomotor development using Griffiths' test (gross motor function, personal and social behavior, hearing and speech, eye and hand coordination, and performance), however, found that antiepileptic drug exposure did not influence the results (36).

The effect of in utero exposure to antiepileptic drugs on fetal growth was described for 977 newborns in another 2000 Swedish study (37). Birth data were collected from 1973 to 1997, during which time the frequency of antiepileptic monotherapy increased from 46% to 88%. As expected, the most marked effects on body weight, length, and head circumference were found with polytherapy. For monotherapy, however, only carbamazepine had a negative influence on these measurements (37).

A 1997 study, using the General Practice Research Database in the United Kingdom, reported an increased prevalence of major malformations in infants of epileptic mothers treated with antiepileptic drugs (3.4%, 10 of 297) compared with matched controls (1.0%, 6 of 594), RR 3.3, 95% CI 1.2–9.2 (38). Eight of the ten congenital anomalies involved carbamazepine (seven with monotherapy): ventricular septal defect; pulmonary stenosis; cleft palate, hare lip; Pierre Robin syndrome with cleft palate (also alcohol abuse); sensorineural deafness; congenital megaureter, hydronephrosis syndrome; vesicoureteric reflux; and Marcus Gunn ptosis (combined with sodium valproate) (38).

A 2000 study, using data from the MADRE (an acronym for MAformation and DRug Exposure) surveillance project, assessed the human teratogenicity of anticonvulsants (39). Among 8005 malformed infants, cases were defined as

infants with a specific malformation, whereas controls were infants with other anomalies. Of the total group, 299 were exposed in the 1st trimester to anticonvulsants. Among these, exposure to monotherapy occurred in the following: phenobarbital (N = 65), methobarbital (N = 10), carbamazepine (N = 46), valproic acid (N = 80), phenytoin (N = 24), and other agents (N = 16). A statistically significant association was found between carbamazepine monotherapy and spina bifida (N = 4). When all 1st trimester exposures (mono- and polytherapy) were evaluated, a significant association was found between carbamazepine and hypertelorism with localized skull defects (N = 3). Although the study confirmed some previously known associations, several new associations with anticonvulsants were discovered and require independent confirmation (see Mephobarbital, Phenobarbital, Phenytoin, and Valproic Acid) (39).

A prospective study published in 1999 described the outcomes of 517 pregnancies of epileptic mothers identified at one Italian center from 1977 (40). Excluding genetic and chromosomal defects, malformations were classified as severe structural defects, mild structural defects, and deformations. Minor anomalies were not considered. Spontaneous (N = 38) and early (N = 20) voluntary abortions were excluded from the analysis, as were seven pregnancies that delivered at other hospitals. Of the remaining 452 outcomes, 427 were exposed to anticonvulsants; of which 313 involved monotherapy: carbamazepine (N = 113), phenobarbital (N = 83), valproate (N = 44), primidone (N = 35), phenytoin (N = 31), clonazepam (N = 6), and other (N = 1). There were no defects in the 25 pregnancies not exposed to anticonvulsants. Of the 42 (9.3%) outcomes with malformations, 24 (5.3%) were severe, 10 (2.2%) were mild, and 8 (1.8%) were deformities. There were 12 malformations with carbamazepine monotherapy: 7 (6.2%) were severe (spina bifida, hydrocephalus, diaphragmatic hernia, esophagus atresia, pyloric stenosis, omphalocele, renal dysplasia, and hydronephrosis), 1 (0.9%) was mild (inguinal hernia and valgus/varus foot), and 4 (3.5%) were deformations (club foot and hip dislocation). The investigators concluded that the anticonvulsants were the primary risk factor for an increased incidence of congenital malformations (see Clonazepam, Phenobarbital, Phenytoin, Primidone, and Valproic Acid) (40).

A 2001 prospective cohort study, conducted from 1986 to 1993 at five maternity hospitals, was designed to determine if anticonvulsant agents or other factors (e.g., genetic) were responsible for the constellation of abnormalities seen in infants of mothers treated with anticonvulsants during

pregnancy (41). A total of 128,049 pregnant women were screened at delivery for exposure to anticonvulsant drugs. Three groups of singleton infants were identified: (a) exposed to anticonvulsant drugs, (b) not exposed to anticonvulsant drugs but with a maternal history of seizures, and (c) not exposed to anticonvulsant drugs and with no maternal history of seizures (control group). After applying exclusion criteria, including exposure to other teratogens, 316, 98, and 508 infants, respectively, were analyzed. Anticonvulsant monotherapy occurred in 223 women: phenytoin (N = 87), phenobarbital (N = 64), carbamazepine (N = 58), and too few cases for analysis with valproic acid, clonazepam, diazepam, and lorazepam. Ninety-three infants were exposed to two or more anticonvulsant drugs. All infants were examined systematically (blinded as to group in 93% of the cases) for embryopathy associated with anticonvulsant exposure (major malformations, hypoplasia of the midface and fingers, microcephaly, and intrauterine growth restriction). Compared with controls, significant associations between anticonvulsants and anticonvulsant embryopathy were phenytoin monotherapy 20.7% (18/87), phenobarbital monotherapy 26.6% (17/64), any monotherapy 20.6% (46/223), exposure to two or more anticonvulsants 28.0% (26/93), and all infants exposed to anticonvulsants (mono- and polytherapy) 22.8% (72/316). Nonsignificant associations were found for carbamazepine monotherapy 13.8% (8/58), nonexposed infants with a maternal history of seizures 6.1% (6/98), and controls 8.5% (43/508). The investigators concluded that the distinctive pattern of physical abnormalities observed in infants exposed to anticonvulsants during gestation was due to the drugs, rather than to epilepsy itself (41).

A study published in 2009 examined the effect of AEDs on the head circumference in newborns (42). Significant reductions in mean birth-weight-adjusted mean head circumference (bw-adj-HC) was noted for monotherapy with carbamazepine and valproic acid. No effect on bw-adj-HC was observed with gabapentin, phenytoin, clonazepam, and lamotrigine. A significant increase in the occurrence of microcephaly (bw-adj-HC smaller than 2 standard deviations below the mean) was noted after any AED polytherapy but not after any monotherapy, including carbamazepine and valproic acid (42).

In a study designed to evaluate the effect of in utero exposure to anticonvulsants on intelligence, 148 Finnish children of epileptic mothers were compared with 105 controls (22). Previous studies had shown intellectual impairment from either this exposure or no effect. Of the 148 children of epileptic mothers, 129 were exposed to anticonvulsant therapy during the first 20 weeks of pregnancy, 2 were only exposed after 20 weeks, and 17 were not

exposed. In those mothers treated during pregnancy, 42 received carbamazepine (monotherapy in 9 cases) during the first 20 weeks, and 1 received the drug after 20 weeks. The children were evaluated at 5.5 years of age for both verbal and nonverbal measures of intelligence. A child was considered mentally deficient if the results of both tests were less than 71. Two of the 148 children of epileptic mothers were diagnosed as mentally deficient and 2 others had borderline intelligence (the mother of one of these latter children had not been treated with anticonvulsant medication). None of the controls was considered mentally deficient. One child with profound mental retardation had been exposed in utero to carbamazepine monotherapy, but the condition was compatible with dominant inheritance and was not thought to be caused by drug exposure. Both verbal and nonverbal intelligence scores were significantly lower in the study group children than in controls. In both groups, intelligence scores were significantly lower when seven or more minor anomalies were present. However, the presence of hypertelorism and digital hypoplasia, two minor anomalies considered typical of exposure to some anticonvulsants (e.g., phenytoin), was not predictive of low intelligence (21).

A prospective, controlled, blinded, observational 1994 study compared the global IQ and language development of children exposed in utero with either carbamazepine (N = 34) or phenytoin (N = 36) monotherapy to their respective matched controls (43). The cognitive tests were administered to the children between the ages of 18 and 36 months. The maternal IQ scores and socioeconomic status in the carbamazepine subjects and their controls were similar, 96.5 vs. 96.0, and 44.7 vs. 46.1, respectively, as they were in the phenytoin subjects and controls, 90.0 vs. 93.9, and 40.8 vs. 40.9, respectively. Compared with controls, no significant differences were measured in either IQ or language development scores between carbamazepine-exposed children and their matched controls. In contrast, phenytoin-exposed children had both lower mean global IQ and language development scores than their matched controls (see Phenytoin). No correlation between the daily dose (mg/kg) of either anticonvulsant and global IQ was found. Major malformations were observed in two carbamazepine-exposed children (missing last joint of right index finger and nail hypoplasia; hypospadias), one carbamazepine control (pulmonary atresia), and two phenytoin-exposed children (42). In subsequent correspondence relating to the above study (44,45), various perceived problems were cited and were addressed in a reply (46).

A 2013 study reported dose-dependent associations with reduced cognitive abilities across a range of domains at 6 years of age after fetal valproate

exposure (47). Analysis showed that IQ was significantly lower for valproate (mean 97, 95% CI 94–101) than to carbamazepine (mean 105, 95% CI 102–108; $p = 0.0015$), lamotrigine (mean 108, 95% CI 105–110; $p = 0.0003$), or phenytoin (mean 108, 95% CI 104–112; $p = 0.0006$). Mean IQs were higher in children whose mother's had taken folic acid (mean 108, 95% CI 106–111) compared with children whose mothers had not taken the vitamin (mean 101, 95% CI 98–104; $p = 0.0009$) (47).

A 2001 prospective study compared the outcomes of 210 pregnancies exposed to carbamazepine in the 1st trimester with controls (48). The rate of major defects in exposed subjects was significantly increased compared with controls, RR 2.24, 95% CI 1.1–4.56. There was no specific pattern of defects (48).

A 2002 meta-analysis evaluated pooled data from 21 prospective studies involving 1255 offspring to determine the teratogenic risk of exposure to carbamazepine (49). Of infants, 85 (6.7%) had major defects compared with 88 (2.34%) of 3756 controls ($p < 0.05$). Among 182 untreated women with epilepsy, 5 (2.75%) had major defects. The defects with the greatest increased rate were NTDs, cardiovascular and urinary tract defects, and cleft palate. The drug also may cause a significant, but very small (0.18 weeks) reduction in the mean gestational age at delivery. Combination therapy was more teratogenic than monotherapy (49).

A possible teratogenic mechanism for carbamazepine in combination with other anticonvulsants was proposed in 1984 to account for the higher than expected adverse pregnancy outcome that is observed with combination therapy (50). Accumulation of the toxic oxidative metabolite, carbamazepine-10,11-epoxide, was shown when the drug was combined with other antiepileptic agents, such as phenobarbital, valproic acid, and phenytoin. These last two agents are also known to produce toxic epoxide metabolites that can bind covalently to macromolecules and may produce mutagenic or teratogenic effects (see Phenytoin) (50). However, a 2002 reference pointed out that carbamazepine-10,11-epoxide, while detected in high concentrations in the serum, is stable and nonreactive and is a potent anticonvulsant itself. Moreover, the metabolite was not embryotoxic in animals (51).

A case of attempted suicide with carbamazepine, possibly resulting in a neural tube defect, has been reported (52). A 44-year-old nonepileptic woman at 3–4 weeks after conception (i.e., during the period of neural tube closure) ingested approximately 4.8 g of the drug as a single dose. Her serum carbamazepine levels for 2 days after the ingestion were more than twice the

recommended maximum therapeutic level. Subsequently, a large thoracolumbar spinal defect was observed on sonographic examination and her pregnancy was terminated at 20 weeks' gestation. Fetal autopsy of the male infant revealed an open myeloschisis and a hypoplastic left cerebral hemisphere, the latter defect thought to be the result of focal necrosis (52).

The Lamotrigine Pregnancy Registry, an ongoing project conducted by the manufacturer, was first published in January 1997 (53). The final report was published in July 2010. The Registry is now closed. Among 183 prospectively enrolled pregnancies exposed to carbamazepine and lamotrigine, with or without other anticonvulsants, 180 were exposed in the 1st trimester resulting in 157 live births without defects, 10 SABs, 9 EABs, 1 fetal death, and 3 birth defects. There were three exposures in the 2nd/3rd trimesters resulting in live births without defects (53).

A case of neuroblastoma was described in a developmentally normal 2.5-year-old male infant who had been exposed throughout gestation to carbamazepine and phenytoin (54). The tumor was attributed to phenytoin exposure.

The effect of carbamazepine on maternal and fetal vitamin D metabolism was examined in a 1984 study (55). In comparison with normal controls, several significant differences were found in the level of various vitamin D compounds and in serum calcium, but the values were still within normal limits. No alterations were found in alkaline phosphatase and phosphate concentrations. The observed differences were not thought to be of major clinical significance (55).

BREASTFEEDING SUMMARY

Carbamazepine is excreted into breast milk, producing milk:plasma ratios of 0.24–0.69 (2,4,9,14,56–58). The amount of carbamazepine measured in infant serum is low, with typical levels around 0.4 mcg/mL, but levels may be as high as 0.5–1.8 mcg/mL (2,57). In one case, infant serum levels were 15% and 20% of the maternal total and free carbamazepine concentrations, respectively (56). Accumulation does not seem to occur.

In a 1998 case report, seizures were reported by the mother in a nursing infant (58). The mother had bipolar disorder that was being treated with fluoxetine (20 mg/day), buspirone (45 mg/day), and carbamazepine (600 mg/day) (see Fluoxetine and Buspirone). Carbamazepine was detected in breast milk and the infant's serum (both 0.5 ng/mL). A neurologic examination of the infant, which included electroencephalography, was within normal limits.

The cause of the seizure-like activity could not be determined, if indeed it had occurred (none of the episodes had been observed by medical personnel) (58).

In a 2010 study, 199 children who had been breastfed while their mothers were taking a single antiepileptic drug (carbamazepine, lamotrigine, phenytoin, or valproate) were evaluated at 3 years of age cognitive outcome (59). Mean adjusted IQ scores for exposed children were 99 (95% CI 96–103), whereas the mean adjusted IQ scores of non-breastfed infants were 98 (95% CI 95–101).

The American Academy of Pediatrics classifies carbamazepine as compatible with breastfeeding (60).

CARBARSONE

[Withdrawn from the market. See 8th edition.]

CARBENICILLIN

Antibiotic (Penicillin)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Although the reported pregnancy experience with carbenicillin is limited, all penicillins are considered low risk in pregnancy.

FETAL RISK SUMMARY

Carbenicillin is a penicillin antibiotic (see also Penicillin G). Reproduction studies conducted in mice (200 mg/kg), rats (500 or 1000 mg/kg), and monkeys (500 mg/kg) observed no fetal harm (1).

The drug crosses the placenta and distributes to most fetal tissues (2,3). After a 4-g IM dose, mean peak concentrations in cord and maternal serums at 2 hours were similar. Amniotic fluid levels averaged 7%–11% of maternal peak concentrations.

No published reports linking the use of carbenicillin with congenital defects have been located. The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 3546 of whom had documented 1st trimester exposure to penicillin derivatives (4, pp. 297–313). For use anytime during pregnancy, 7171 exposures were recorded (4, p. 435). In neither group was evidence found to suggest a relationship to large categories of major or minor malformations or to individual defects.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 31 newborns had been exposed to carbenicillin during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of five (16.1%) major birth defects were observed (one expected), one of which was a cardiovascular defect (0.5 expected). No anomalies were observed in five other categories of defects (oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available. The number of exposures is too small to draw any conclusions.

BREASTFEEDING SUMMARY

No reports describing the use of carbenicillin during lactation have been located. Low amounts of the drug were measured in a 1984 study (5). At 5–7 days postpartum in 70 women, the highest mean concentration after a single 1000-mg IM dose was 0.24 mcg/mL at 4 hours. Although adverse effects from other penicillins in breast milk are rare, three potential problems exist for the nursing infant: modification of bowel flora, direct effects on the infant (e.g., allergic response), and interference with the interpretation of culture results if a fever workup is required.

CARBIDOPA

Antiparkinson Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

As expected, a limited number of reports describe the use of carbidopa (in combination with levodopa) during human pregnancy. The indication for this drug in women of childbearing age is relatively rare. Limited studies have not found teratogenicity in animals with carbidopa, except when combined with levodopa, an outcome that may have been related to the latter drug. However, carbidopa did cause fetal deaths in one animal species. The cause of the two miscarriages described above is unknown, but requires further study. Brown fat hemorrhage observed in newborn rats treated during the 1st week of gestation was dose-related, and the toxicity has not been reported in humans. Moreover, the placental passage of carbidopa in animals and humans is limited. Based on the above data and the fact that lower doses of levodopa can be used if carbidopa is added to the mother's regimen, therapy with carbidopa, if indicated, should not be withheld because of pregnancy.

FETAL RISK SUMMARY

This antiparkinson agent has no pharmacologic effect when given alone and is almost always used in conjunction with levodopa (see also Levodopa). Carbidopa (α -methyldopa hydrazine; MK-486) inhibits decarboxylation of extracerebral levodopa. When used in combination with this latter agent, lower doses of levodopa can be administered, resulting in fewer adverse effects, and more levodopa is available for passage to the brain and eventual conversion in that organ to the active metabolite, dopamine.

Combinations of carbidopa and levodopa, as well as levodopa alone, have caused visceral and skeletal malformations in rabbits (1,2). The carbidopa

doses were 10–20 times the maximum recommended human dose (MRHD) (2). A dose about two times the MRHD caused a decrease in the number of live pups delivered by rats (2). Carbidopa, 10 or 100 mg/kg/day given orally to rats from day 1 through day 21 of gestation, did not have a teratogenic effect but did cause a significant dose-related increase in brown fat (interscapular brown adipose tissue) hemorrhage and vasodilation in the newborn pups (3). The hemorrhage, 4.6% and 12.1%, respectively, for the two doses, was thought to be related to dopamine. Combining carbidopa and levodopa resulted in a lower incidence of hemorrhage. No teratogenic effects were observed in mice given carbidopa doses up to 10 times the MRHD (2).

A study published in 1978 examined the effect of carbidopa (20 mg/kg SC every 12 hours for 7 days) and levodopa plus carbidopa (200/20 mg/kg SC every 12 hours for 7 days) on the length of gestation in pregnant rats (4). Only the combination had a statistically significant effect on pregnancy duration, causing a delay in parturition of 12 hours. The results were thought to be consistent with dopamine inhibition of oxytocin release (4).

In pregnant rats, small amounts of carbidopa cross the placenta and can be detected in amniotic fluid and fetal tissue (5). Carbidopa concentrations were measured at 1, 2, and 4 hours after a 20-mg/kg IV dose administered near the end of gestation (19th day). The highest levels in the maternal plasma, placenta, amniotic fluid, and fetus (time of maximum concentration shown in parentheses) were 9.9 mcg/mL (1 hour), 2.35 mcg/g (1 hour), 0.32 mcg/mL (2 and 4 hours), and 0.65 mcg/g (2 hours), respectively (5).

Human placental transfer of carbidopa, although the amounts were very small, was documented in a study published in 1995 (6). A 34-year-old woman with juvenile Parkinson's disease was treated with carbidopa/levodopa (200/800 mg/day) during two pregnancies (see also Levodopa). Both pregnancies were electively terminated, one at 8 weeks' gestation and the other at 10 weeks. Mean concentrations of carbidopa (expressed as ng/mg protein) in the maternal serum, placental tissue (including umbilical cord), fetal peripheral organs (heart, kidney, muscle), and fetal neural tissue (brain and spinal cord) were 2.05, 8.0, 0.14, and <0.15, respectively. The low concentrations of carbidopa in the fetus, compared with those in the mother and placenta, were interpreted as evidence for an effective placental barrier to the transport of carbidopa (6).

Because Parkinson's disease is relatively uncommon in women of childbearing age, only a few reports have been located that describes the use of carbidopa, always in combination with levodopa, in human pregnancy (7–11).

A woman with at least a 7-year history of parkinsonism conceived while being treated with carbidopa/levodopa (five 25/250-mg tablets/day) and amantadine (100 mg twice/day) (7). She had delivered a normal male infant approximately 6 years earlier, but no medical treatment had been given during that pregnancy. Amantadine was immediately discontinued when the current pregnancy was diagnosed. Other than slight vaginal bleeding in the 1st trimester, there were no maternal or fetal complications. She gave birth to a normal-term infant (sex and weight not specified) who was doing well at 1.5 years of age (7).

A 1987 retrospective report described the use of carbidopa/levodopa, starting before conception in five women during seven pregnancies, one of which was electively terminated during the 1st trimester (8). All of the other pregnancies went to term (newborn weights and sexes not specified). Maternal complications in three pregnancies included slight 1st trimester vaginal bleeding, nausea and vomiting during the 8th and 9th months (only one patient reported nausea and vomiting after the 1st trimester), and depression that resolved postpartum, and preeclampsia. One infant, whose mother took amantadine and carbidopa/levodopa and whose pregnancy was complicated by preeclampsia, had an inguinal hernia. No adverse effects or congenital anomalies were noted in the other five newborns, and all remained healthy at follow-up (approximately 1–5 years of age) (8).

A 27-year-old woman with a history of chemotherapy and radiotherapy for non-Hodgkin's lymphoma occurring approximately 4 years earlier had developed a progressive parkinsonism syndrome that was treated with a proprietary preparation of carbidopa/levodopa (co-careldopa; Sinemet Plus; 375 mg/day) (9). She conceived 5 months after treatment began and eventually delivered a healthy, 3540-g male infant at term. Apgar scores were 9 at both 1 and 10 minutes, respectively. Co-careldopa was continued throughout her pregnancy (9).

A brief case report, published in 1997, described a normal outcome in the third pregnancy of a woman with levodopa-responsive dystonia (Segawa disease) who was treated throughout gestation with 500 mg/day of levodopa alone (10). The male infant weighed 2350 g at birth and was developing normally at the time of the report. Two previous pregnancies had occurred while the woman was being treated with daily doses of levodopa (100 mg) and carbidopa (10 mg). Spontaneous abortions had occurred in both pregnancies: one at 6 weeks and the other at 12 weeks. An investigation failed to find any cause for the miscarriages (10).

A successful pregnancy in a 27-year-old woman with Segawa disease was

reported in 2009 (11). The woman was treated throughout gestation with levodopa (1250 mg/day) and, at 36 weeks' gestation, gave birth to a healthy, 2298-g male infant with an Apgar score of 9 at 5 minutes. The infant was doing well at 6 months of age. The authors cited eight other cases of the disease in five pregnant women. Five of the pregnancies were treated with levodopa monotherapy and ended in healthy newborns. In one of those patients, her first two pregnancies were treated with carbidopa/levodopa and both ended in abortions (see reference 10 above). The ninth pregnancy was not treated with any agent and the severely asphyxiated newborn died after birth (11).

A woman with a 12-year history of Parkinson's disease was treated throughout gestation with levodopa, carbidopa, entacapone, and bromocriptine (12). She gave birth at term to a 3175-g female infant, without deformities, with Apgar scores of 9, 10, and 10. Generalized seizures occurred in the infant 1 hour after birth followed by repeated episodes of shivering throughout the first day that responded to diazepam. Slowly improving hypotonia also was observed during the first week. Pneumonia was diagnosed but an extensive workup for the cause of seizures was negative. The child was developing normally at 1 year of age and has not had any other seizures (12).

BREASTFEEDING SUMMARY

No reports describing the use of carbidopa during human lactation have been located. The molecular weight (about 244) suggests that the drug probably will be excreted into breast milk, but the amounts should be low. In at least two cases, breastfeeding was held because of concerns with other drug therapy (levodopa or amantadine) that the mother was taking with carbidopa (7,9). Small amounts are excreted in the milk of lactating rats (5).

CARBIMAZOLE

Antithyroid

Carbimazole is converted in vivo to methimazole. See Methimazole.

CARBINOXAMINE

Antihistamine

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of carbinoxamine in human pregnancy have been located. The antihistamine is in the same subclass of ethanolamines such as clemastine and diphenhydramine. As such, it is probably compatible in pregnancy. However, these agents have marked sedative effects that should be considered if consumed by a pregnant woman.

FETAL RISK SUMMARY

Carbinoxamine is a first-generation (H_1) antihistamine with anticholinergic and sedative properties. Animal reproduction studies have not been conducted with carbinoxamine. Long-term studies for carcinogenesis, mutagenesis, and fertility also have not been conducted (1).

It is not known if carbinoxamine crosses the human placenta. The molecular weight of carbinoxamine maleate (about 407) suggests that the drug will cross to the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use of carbinoxamine during human lactation have been located. The molecular weight of carbinoxamine maleate (about 407) suggests that the drug will be excreted into breast milk. If the drug is used by a mother while nursing, the infant should be monitored for sedation. Although there are no data, the manufacturer considers the drug contraindicated in nursing mothers (1). The reason given for this is the increased sensitivity of newborn or premature infants to antihistamines.

CARBOPLATIN

Antineoplastic

PREGNANCY RECOMMENDATION: Contraindicated—1st Trimester

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Carboplatin exhibits dose-related embryo toxicity and teratogenicity in one animal species. Treatment during human gestation has been reported in a number of cases, all of which were treated well after organogenesis. Moreover, there also are a large number of women who were treated with carboplatin several years before pregnancy. In both of these time periods, no fetal or neonatal toxicity due to carboplatin was noted. However, the absence of human exposures during organogenesis prevents an assessment of the actual teratogenic risk but, based on the animal data and the pharmacology of the drug, the risk appears to be high. Therefore, pregnant women should not be treated with this agent during the 1st trimester. Moreover, carboplatin is mutagenic and probably carcinogenic in experimental systems, but these effects have not been studied in human pregnancy.

FETAL RISK SUMMARY

The antineoplastic agent, carboplatin, is indicated for the treatment of ovarian cancer. It is closely related to cisplatin, another cancer chemotherapeutic agent. Carboplatin and cisplatin share the same cell-cycle nonspecific mechanism of action, producing inter-strand DNA cross-links. Carboplatin is not protein bound (1).

Carboplatin is mutagenic both in vitro and in vivo. Its carcinogenic potential has not been studied, but drugs with similar mechanisms of action are carcinogenic. Carboplatin is embryotoxic and teratogenic in rats given the drug during organogenesis (dose not specified) (1).

A 1989 study reported dose-related embryoletality and teratogenicity in rats treated in the early phase of organogenesis (2). Previous work by these researchers had found no teratogenicity at a dose of 4 mg/kg/day (relationship

to human dose not stated). In their current study, however, a dose of 6 mg/kg/day produced a significant increase in embryo deaths and multiple malformations (e.g., gastroschisis, dilation of cerebral ventricles, cleft sternum, fused ribs, and malformed thoracic vertebrae) (2).

It is not known if carboplatin crosses the placenta early in pregnancy. The molecular weight (about 371) is low enough that passage to the fetal compartment should be expected. A 2002 review of cancer chemotherapy stated that carboplatin was widely distributed throughout all body tissues, including, presumably, the amniotic fluid (3).

A number of reports have described the use of carboplatin in human pregnancy (4–18). In a 1994 study, a 41-year-old primigravid woman at 14 weeks' gestation had surgery for ovarian cancer (4). Beginning at 22 weeks, she received carboplatin every 4 weeks for three cycles. Nine weeks after the last dose, a cesarean section at 37 weeks gave birth to a normal-appearing 3245-g male infant with Apgar scores of 9 and 9. The neonate had normal renal function and no evidence of myelosuppression. Platinum–DNA adducts were found in maternal and cord blood lymphocytes, indicating that the drug crossed the placenta (4).

A 40-year-old woman was treated for ovarian cancer at 20 weeks' gestation with cisplatin and cyclophosphamide (5). A second course of these agents was given a few weeks later. Further cisplatin doses were discontinued because the woman developed ototoxicity. At 30 weeks' gestation carboplatin and cyclophosphamide were given. A normal-appearing 3600-g male infant was delivered by cesarean section 7 weeks later. Apgar scores were 9 and 9 at 1 and 5 minutes, respectively. The infant was developing normally, including normal audiograms and neurologic findings, at 12 months of age (5).

In a follow-up report to the above case, researchers used a modified cisplatin–DNA enzyme-linked immunosorbent assay (ELISA) test to determine if platinum–DNA adducts could be detected in amniotic fluid obtained at 36 weeks or in cord blood at 37 weeks (6). Platinum–DNA adducts were not detected in either sample, but insufficient DNA was extracted from the samples to assay at the limit of ELISA sensitivity. A less-sensitive assay (atomic absorbance spectrometry [AAS]) also failed to detect platinum drug binding to DNA in amniotic fluid or cord blood. In contrast, DNA from the placenta was positive for platinum–DNA adducts in both the ELISA and AAS assays (6).

A 2003 report described the pregnancy outcome of a 30-year-old woman treated with carboplatin and paclitaxel during the 2nd and 3rd trimesters (7). She was diagnosed with an advanced stage of serous papillary

adenocarcinoma of the ovary in the 1st trimester. The woman underwent an exploratory laparotomy at 7.5 weeks' gestation and then consented to chemotherapy beginning at 16–17 weeks. She received six cycles of carboplatin and paclitaxel, and was delivered by cesarean hysterectomy 3 weeks after the last cycle at 35.5 weeks. The newborn (sex not specified) had Apgar scores of 9, 9, and 9 at 1, 5, and 10 minutes, respectively. Birth weight was 2500 g (44th percentile), and the physical examination and laboratory tests were normal. In addition, the placenta appeared grossly normal. The infant was doing well at 15 months of age with no evidence of neurologic, renal, growth, or hematologic effects from the exposure (7).

A 28-year-old woman delivered a normal 3.88-kg male infant 4 years after treatment of a bilateral ovarian dysgerminoma (8). Treatment consisted of a laparotomy to remove the right tube and ovary and carboplatin (dose 735 mg). A 29-year-old woman conceived with the assistance of a donated ovum that had been fertilized in vitro, followed by embryo transfer (9). Five years earlier, both ovaries had been removed for stage III borderline ovarian adenocarcinoma. Her last course of carboplatin chemotherapy was given approximately 4 years before the pregnancy (9). In a retrospective study, the postsurgical reproductive histories of 50 women with ovarian cancer treated with unilateral oophorectomy from 1965 to 2000 were analyzed (10). Twenty-four women had attempted pregnancy and 17 (71%) had conceived 32 pregnancies. Six of the 17 had received prior chemotherapy (carboplatin or cisplatin plus paclitaxel in three; cisplatin plus cyclophosphamide in two; melphalan in one). The pregnancy outcomes were 1 on-going pregnancy, 5 spontaneous abortions (SABs), and 26 term gestations. There were no congenital anomalies in any of the offspring (10).

A large cohort study published in 2000 compared the pregnancy outcomes in survivors of various childhood cancers based on the type of treatment received (11). Among the total group of women, 340 had 594 pregnancies. The pregnancies were divided into five groups: 165 (nonsterilizing surgery or no treatment), 113 (chemotherapy with various agents, including an unknown number treated with carboplatin and cisplatin), 97 (abdominal–pelvic radiation), 53 (chemotherapy plus abdominal–pelvic radiation), and 166 (other treatments). The incidence of SABs and perinatal deaths did not differ among the groups. The proportion of live births with low birth weight (excluding preterm births) or congenital anomalies was highest in those treated only with radiation (16.0%) and those treated only with surgery only (9.5%), respectively. The rates of low birth weight (excluding preterm births) and congenital defects in the

two chemotherapy groups were 2.3% and 2.3% (chemotherapy only) and 7.1% and 2.4% (chemotherapy plus radiation) (11).

In a novel case report, a 21-year-old woman was diagnosed with metastatic ovarian cancer that was initially treated with surgery that left her uterus, right fallopian tube, and ovary in situ (12). She then was enrolled into a phase I transplant protocol and received three cycles of carboplatin and paclitaxel. Subsequent high-dose chemotherapy was then given (carboplatin, paclitaxel, and/or cyclophosphamide). After her chemotherapy, the woman received a successful transplant of autologous peripheral blood stem cells. Approximately 16 months after the transplant she conceived but had a 1st trimester miscarriage. She conceived again several months later and eventually delivered a healthy full-term, 3000-g female infant. The child was developing normally at 17 months of age (12).

In a 2008 case report, a 34-year-old woman became pregnant after 12 years of infertility (13). Gestational diabetes was diagnosed at 5 weeks' gestation (HbA1c 6.9%) and she was treated with insulin. At 16 weeks, bilateral ovarian cancer was diagnosed and, 2 weeks later, she underwent bilateral salpingo-oophorectomy. Four courses of carboplatin were given from 21 to 33 weeks' gestation. At 33 weeks, a cesarean section was conducted to deliver a 2222-g normal male infant with Apgar scores of 9 and 10 at 1 and 5 minutes, respectively. After birth, the mother received five more courses of carboplatin. One year after the completion of therapy, the mother had no evidence of disease and her infant son was normal (13).

A 2008 review described data on seven patients who had received carboplatin during pregnancy (14). Three patients received carboplatin alone, three in combination with other antineoplastics (paclitaxel or cyclophosphamide) and one had received both carboplatin and cisplatin. All of the exposures occurred in the 2nd and 3rd trimesters. No fetal or neonatal toxicity was observed in the seven fetuses, although one neonate (exposed to both carboplatin and cisplatin) had anemia. The offspring were normal at a median follow-up of 13.5 months (range 9–20 months) (14).

Lung cancer with metastasis to the brain was diagnosed in a 33-year-old nonsmoking woman in the 19th week of pregnancy (15). The patient was treated with weekly paclitaxel and carboplatin every 3 weeks. In the 6th week of therapy, progressive disease in the brain was found with only partial response in the lungs. High-dose corticosteroids were given to induce fetal lung maturation and reduce cerebral edema. At 30 weeks, a cesarean section delivered a healthy baby boy (no other details provided). The mother died 4

weeks later. The infant was developing normally at 5 months of age (15).

A 32-year-old woman at about 29 weeks' was treated with one cycle of carboplatin and paclitaxel for cervical cancer (16). Because she refused further chemotherapy, a cesarean section at about 33 weeks' delivered a 2190-g male neonate with no signs of drug-induced toxicity. At 4 years of age, the child was developing normally (16).

A 38-year-old woman with breast cancer was treated with weekly trastuzumab in addition to carboplatin and docetaxel beginning at 15 weeks' (17). Fetal renal insufficiency with anhydramnios and missing visualization of the fetal bladder occurred at 21 weeks. The condition reversed after trastuzumab was discontinued and three instillations of amniotic fluid. The amount of amniotic fluid stabilized after 24 weeks. Because of fetal growth restriction, a cesarean section was performed at 33 weeks to deliver a male infant with birth weight <3rd percentile. The neonate had normal renal function with normal urinalysis (17).

In a 2013 case report, a 36-year-old primigravid woman at 12 weeks was diagnosed with ovarian cancer (18). She underwent left salpingo-oophorectomy and fertility-sparing staging surgery. At 14 weeks, she was started on intraperitoneal carboplatin given on day 1 and IV paclitaxel given on days 1, 8, and 15 of a 28-day cycle. Mild preeclampsia developed at 32 weeks after four of the planned six cycles had been given. Chemotherapy was held because of persistent thrombocytopenia. At 37 weeks, she underwent a planned cesarean section to give birth to a viable 2126-g male neonate with Apgar scores of 8 and 9 at 1 and 5 minutes, respectively. The infant had congenital bilateral talipes equinovarus (clubfoot), but one parent had a family history of this defect. A complete blood count was normal. The infant was doing well at 7 months of age (18).

BREASTFEEDING SUMMARY

Consistent with its molecular weight (about 371), carboplatin is excreted into breast milk. In a 2012 case report, a 40-year-old woman at about 4 months postpartum was exclusively breastfeeding when she began treatment with 6 weekly doses of IV carboplatin and paclitaxel for recurrent papillary thyroid cancer (19). Her infant was fed donor milk during treatment. After the 6th dose, milk samples were collected at 0, 4, 28, 172, and 316 hours. For carboplatin, the relative infant dose was 2.0%, whereas the relative infant dose for paclitaxel was 16.7%. Carboplatin remained detectable (0.16 mg/L) at 316 hours. For paclitaxel, the level at 172 hours was 0.97 mg/L but was

undetectable at 316 hours. The authors concluded that although these levels were probably too low to cause toxicity, potential toxicity could include myelosuppression (especially neutropenia and thrombocytopenia), severe hypersensitivity reactions, nephrotoxicity, and neurotoxicity (19). Because of the potential toxicity, women receiving these agents should not nurse.

CARBOPROST

Endocrine/Metabolic Agent (Prostaglandin)

PREGNANCY RECOMMENDATION: Contraindicated (Unless for Termination/Evacuation of Pregnancy)

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the outcomes of human pregnancies following the use of carboprost in failed medical abortions have been located. Carboprost exposure in animals has resulted in embryotoxicity, but the doses were based on body weight and not compared to the human dose. However, another prostaglandin analog, misoprostol, when used unsuccessfully in the 1st trimester as an abortifacient, has been associated with cranial nerve defects in the fetus.

FETAL RISK SUMMARY

Carboprost tromethamine is a synthetic prostaglandin F_{2α} analog that is given IM to stimulate myometrial contractions in the gravid uterus, leading to evacuation of the products of conception. Carboprost is approved for induced abortion between 13 and 20 weeks' gestation. It also is indicated for postpartum uterine bleeding. In pregnant women in the 2nd trimester who were administered carboprost by continuous IV infusion, the elimination half-life of the drug was approximately 30–45 minutes, with similar findings when carboprost was given by IM injection (1).

Reproductive studies have been conducted with carboprost in rats and rabbits. Rabbits were given doses ranging between 0.0025 and 0.5/mg/kg on 3 consecutive days during organogenesis. Doses above 0.025 mg/kg interfered with implantation, were embryo-lethal, or induced abortion, but no teratogenic effects were seen. In rats, doses ranging from 0.001 to 1.0 mg/kg were given beginning on gestational day 15. Doses larger than 0.025/mg/kg caused abortions. At doses as low as 0.003 mg/kg, abortions or early deliveries occurred and most pups did not survive. There were no effects on structural

development of the pups noted (1).

Studies for carcinogenicity have not been conducted with carboprost. No evidence of mutagenicity was observed in various assays. There was no effect on fertility in male and female rats treated with SC injections of 0.25–1.0 mg/kg for 3 or 6 days before breeding (1).

It is not known if carboprost crosses the placenta. The molecular weight (about 489) suggests that the drug will cross the placenta, but the relatively short elimination half-life should limit passage (1).

No reports describing the outcomes of human pregnancies following the use of carboprost in failed medical abortions have been located. Although a failed attempted abortion would typically be followed by completion of the procedure by some other means; in rare cases a woman may wish to maintain the pregnancy. Isolated case reports suggest that the failed procedure(s) themselves may result in damage to the placenta and therefore damage to the fetus (2). First-trimester exposure to another prostaglandin, misoprostol, in failed induced abortion, has been associated with an increased risk for 6th and 7th cranial nerve damage, leading to Möbius syndrome (3). However, in the case of carboprost, if used as indicated, exposure to the product would typically occur after the first trimester.

BREASTFEEDING SUMMARY

No reports describing the use of carboprost during human lactation have been located. The molecular weight of carboprost (about 489) suggests that the agent might cross into breast milk. Based on the elimination half-life, the manufacturer suggests that breastfeeding be avoided for a minimum of 6 hours after the last dose of carboprost (1).

CARFILZOMIB

Antineoplastic (Proteasome Inhibitor)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of carfilzomib in human pregnancy have been located. The animal data suggest moderate risk, but the absence of human pregnancy experience prevents a more complete assessment of the embryo–fetal risk. The manufacturer states that the drug can cause fetal harm based on its mechanism of action and findings in animals.

FETAL RISK SUMMARY

Carfilzomib is an antineoplastic agent that is given IV on 2 consecutive days each week for 3 weeks, followed by a 12-day rest period before subsequent cycles are given. It is a proteasome inhibitor in the same class as bortezomib. Carfilzomib is indicated for the treatment of patients with multiple myeloma who have received at least two prior therapies, including bortezomib and an immunomodulatory agent, and have demonstrated disease progression on or within 60 days of completion of the last therapy. The drug is rapidly and extensively metabolized to inactive metabolites. Plasma protein binding averaged 97% and the parent drug is cleared from the systemic circulation with a half-life of ≤ 1 hour (1).

Reproduction studies have been conducted in rats and rabbits. No teratogenicity was observed in rats given doses of 0.5–2 mg/kg/day (comparison to the human dose not specified) during organogenesis. In pregnant rabbits, doses that were $\geq 20\%$ of the recommended human dose of 27 mg/m² based on BSA (RHD) caused an increase in preimplantation loss. At a maternal toxic dose (40% of the RHD), an increase in early resorptions and postimplantation loss and a decrease in fetal weight was observed (1).

Carcinogenicity studies have not been conducted with carfilzomib. The drug was not mutagenic in one assay, but clastogenic effects were observed in one of two assays. Although fertility studies have not been conducted, no effects on

reproductive tissues were noted during 28-day repeat-dose toxicity studies in rats and monkeys or in 6-month rat and 9-month monkey chronic toxicity studies (1).

It is not known if carfilzomib crosses the human placenta. The molecular weight (about 720) suggests that the drug will cross the placenta. However, the rapid metabolism to inactive metabolites, high plasma protein binding, and short half-life in the systemic circulation suggest that exposure of the embryo–fetus will be limited.

BREASTFEEDING SUMMARY

No reports describing the use of carfilzomib during human lactation have been located. The molecular weight (about 720) suggests that the drug will be excreted into breast milk. However, the rapid metabolism to inactive metabolites, high plasma protein binding (97%), and short systemic circulation half-life (≤ 1 hour) in the systemic circulation suggest that exposure of a nursing infant will be limited. The effects of this potential exposure on a nursing infant are unknown. The most common ($\geq 30\%$) adverse reactions in adults are fatigue, anemia, nausea, thrombocytopenia, dyspnea, diarrhea, and pyrexia. If a woman receiving this drug is nursing, her infant should be closely monitored for these effects.

CARGLUMIC ACID

Endocrine/Metabolic Agent (Hyperammonemia)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of carglumic acid in human pregnancy have been located. Although the animal data suggested risk when the drug was used from organogenesis through postpartum day 21, a portion of the risk may have reflected exposure during nursing (see Breastfeeding Summary). Women with N-acetylglutamate synthase (NAGS) deficiency must remain on treatment throughout pregnancy to prevent irreversible neurologic damage and death. If a pregnant woman does require this therapy, she should be informed of the absence of human pregnancy experience.

FETAL RISK SUMMARY

Carglumic acid is a structural analog of N-acetylglutamate available as oral tablets. It is indicated as adjunctive therapy for the treatment of acute and chronic hyperammonemia due to the deficiency of the hepatic co-enzyme NAGS. The agent is partially metabolized in the gut before absorption. Plasma protein binding has not been determined. The median terminal half-life is 5.6 hours (1).

Reproduction studies have been conducted in rats and rabbits. In these species, oral doses up to 1.3 times the maximum recommended human starting dose based on BSA (MRHSD) resulted in maternal toxicity, but no effects on embryo–fetal development were observed. When female rats received doses up to 1.3 times the MRHSD from organogenesis through day 21 postpartum, a reduction in offspring survival was seen at the highest dose and a reduction in offspring growth was seen at all doses (1).

Carcinogenicity studies have not been conducted with carglumic acid, but the drug was not mutagenic in multiple assays. No effects on fertility or

reproductive performance were noted in female rats at doses up to 1.3 times the MRHSD, or mating or fertility in male rats at doses up to 0.6 times the MRHSD (1).

It is not known if carglumic acid crosses the human placenta. The molecular weight (about 190) and moderately long terminal half-life suggest that the drug will cross to the embryo–fetus. However, ionization at physiologic pH could limit the exposure.

BREASTFEEDING SUMMARY

No reports describing the use of carglumic acid during human lactation have been located. The molecular weight (about 190) and moderately long terminal half-life (5.6 hours) suggest that the drug will be excreted into breast milk, but ionization at physiologic pH could limit the exposure. The effect of the exposure on a nursing infant is unknown. However, the drug is excreted into rat milk, resulting in increased mortality and impaired body weight gain (1).

CARISOPRODOL

Muscle Relaxant

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

The limited human pregnancy experience with carisoprodol does not suggest a major risk of embryo or fetal harm. The FDA data do raise a hypothesis of an association with oral clefts, but the risk, if it exists, appears to be low. There have been some reports of congenital defects with meprobamate, the active metabolite of carisoprodol, but two large surveillance studies did not support an association between meprobamate and malformations (see Meprobamate). Although the data do not support a significant risk with carisoprodol, the best course would be to avoid this agent, if possible, during the 1st trimester.

FETAL RISK SUMMARY

Carisoprodol is a centrally acting muscle relaxant. It is metabolized by the liver to meprobamate, the active metabolite. The reproductive effects of this drug in animals have not been studied.

It is not known if carisoprodol crosses the human placenta. The molecular weight (about 260) suggests that it will cross to the embryo and fetus. Moreover, the active metabolite, meprobamate, does cross the placenta (see Meprobamate).

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 14 of whom were exposed in the 1st trimester to carisoprodol (1). No association of the drug with large classes of malformations or to individual defects was found.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 326 newborns had been exposed to carisoprodol during the 1st trimester (F. Rosa, personal

communication, FDA, 1993). Twenty (6.1%) major birth defects were observed (14 expected), including (observed/expected) 3/3 cardiovascular defects, 2/0.5 oral clefts, and 1/1 hypospadias. No anomalies were observed in three other categories of defects (spina bifida, polydactyly, and limb-reduction defects) for which data were available. Only with the two cases of oral clefts is there a suggestion of a possible association, but other factors, including the mother's disease, concurrent drug use, and chance, may be involved.

A 2001 case report described the pregnancy outcome of a 27-year-old woman who had taken carisoprodol (700 mg), propoxyphene (70 mg), and acetaminophen (900 mg) three times daily throughout gestation and during the first 6 months of breastfeeding (2). The 2635-g infant (sex not specified), delivered 2 weeks preterm by cesarean section, showed no signs or symptoms of withdrawal after birth. No mention was made of birth defects, and the infant was developing normally at 6 months of age (2).

A similar case was observed in 2006 (3). The woman took carisoprodol (700 mg) four times daily before and throughout gestation for severe back muscle spasm. A healthy female infant was delivered at term. The mother continued treatment while breastfeeding during the first postpartum month. No signs or symptoms of withdrawal were noted in the newborn or in the infant when breastfeeding was stopped about 1 month after birth (3).

BREASTFEEDING SUMMARY

Carisoprodol and its active metabolite, meprobamate, are excreted into breast milk at concentrations two to four times those in the maternal plasma (4). While unique, the two cases below confirm that the drug and its metabolite are present in milk and that the concentrations of meprobamate exceed those in the maternal plasma.

A 2001 case report described the use of carisoprodol (700 mg), propoxyphene (70 mg), and acetaminophen (900 mg) three times daily throughout gestation and during the first 6 months of breastfeeding (2). Levels of carisoprodol and meprobamate were measured in breast milk on 4 consecutive days. The average milk concentrations of the two agents were 0.9 mcg/mL and 11.6 mcg/mL, respectively. Neither the timing of the samples in relationship to the maternal dose nor the maternal plasma levels were specified. Based on an estimated milk intake of 150 mL/kg/day, the absolute and relative doses of carisoprodol plus meprobamate that would have been ingested by an exclusively breastfed infant were 1.9 mg/kg/day and 4.1%, respectively. No signs or symptoms of withdrawal were noted in the infant who

had normal psychomotor development at 6 months of age. However, the infant was partially fed formula because of insufficient maternal milk production (2).

In a similar case, a woman took carisoprodol (700 mg) four times daily before and throughout gestation, and during the first postpartum month for severe back muscle spasm (3). The healthy female infant was delivered at term and was exclusively breastfed. The mother also took an analgesic combination (hydrocodone plus acetaminophen) for a short period after delivery. Blood and milk samples were obtained from the mother about a week after delivery. Peak carisoprodol and meprobamate blood concentrations, obtained 2 hours post-dose, were 3 and 9 mcg/mL, respectively, whereas the milk concentrations, obtained at the same time, were 1.4 and 10.9 mcg/mL, respectively. The corresponding milk:plasma ratios were 0.3 and 1.4, respectively. Trough blood concentrations, obtained about 4 hours postdose, were <2 and <4 mcg/mL, respectively, whereas the milk values were 0.8 and 17.1 mcg/mL, respectively. The corresponding milk:plasma ratios were ≥ 0.4 and ≥ 4.3 , respectively. A blood sample from the infant, obtained 2 hours after breastfeeding that was started 1.5 hours after a maternal dose, revealed undetectable levels of carisoprodol (<2 mcg/mL) and meprobamate (<4 mcg/mL). Nursing was stopped at about 1 month of age. No signs or symptoms of withdrawal or other adverse effects were noted in the newborn or when breastfeeding was stopped about 1 month later (3).

Although the human data are very limited, both cases involved mothers taking carisoprodol doses that were much higher than the recommended dose of 1050–1400 mg/day. The lack of detectable adverse effects in both infants suggests that the risk of toxicity is low, at least in infants that also were exposed during pregnancy. Starting carisoprodol treatment during breastfeeding may have different results in a nursing infant. The American Academy of Pediatrics classifies another centrally acting skeletal muscle relaxant as compatible with breastfeeding (see Baclofen). However, until additional data are available, women taking this drug and who elect to nurse should closely monitor their infants for sedation and other changes in behavior or functions.

CARMUSTINE

Antineoplastic

PREGNANCY RECOMMENDATION: Human and Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Typical of many chemotherapeutic agents, carmustine is carcinogenic, mutagenic, clastogenic, embryotoxic, and teratogenic in experimental animals. However, only two reports have described the use of carmustine in human pregnancy. In one of these, a woman was treated with carmustine before and during the first two trimesters. She gave birth to a normal infant. In the other case, a woman who was not treated until late in the 2nd trimester was electively delivered prematurely because of her disease. Her infant was growth restricted 17 months after birth but had apparently normal mental and motor development. As with other cancer chemotherapeutic agents, treatment after the 1st trimester does not appear to result in newborn toxicity, although bone marrow suppression has been reported when multiple agents were used close to delivery (e.g., see Cyclophosphamide). Several alkylating agents are thought to be human teratogens (e.g., busulfan, chlorambucil, and cyclophosphamide), but few infants have been exposed to these drugs in the 1st trimester. Until proven otherwise, carmustine should be considered a potential teratogen if used during the period of organogenesis. Therefore, a woman whose condition requires treatment during organogenesis, or who conceives while under treatment, should be informed of the potential risk to her embryo.

FETAL RISK SUMMARY

Carmustine (BCNU) is an alkylating agent that is chemically classified as a nitrosourea. Other antineoplastics in this group include lomustine (CCNU) and streptozocin. Carmustine is indicated for the palliative therapy of certain brain tumors, multiple myeloma, Hodgkin's disease, and non-Hodgkin's lymphoma. The drug alkylates deoxyribonucleic acid (DNA) and ribonucleic acid (RNA), in addition to inhibiting some enzymes by carbamoylation of amino acids in

proteins. Carmustine undergoes rapid degradation in the plasma with a terminal half-life of 22 minutes after an IV dose. The antineoplastic and toxic properties of carmustine are thought to be secondary to metabolites. The most severe toxicities are delayed bone marrow suppression and pulmonary toxicity (1,2).

Carmustine is carcinogenic in mice and rats at doses less than the recommended human dose based on BSA (RHD). The agent was mutagenic in in vitro assays and clastogenic in both in vivo and in vitro tests (2). Reproduction studies have been conducted with carmustine in pregnant rats and rabbits (1,2). A dose about 0.17 times the RHD in rats caused embryotoxicity and fetal malformations (anophthalmia, micrognathia, and omphalocele). In rabbits, increased embryoletality was observed at approximately 1.2 times the RHD (1,2). In another animal study, pregnant rats were given an intraperitoneal dose of 20 mg/kg on embryonic day 15 (3). (Note: This dose is approximately 3.4 times the RHD.) Exposed offspring had histologic alterations suggestive of cortical dysplasia (laminar disorganization, cytomegalic neurons, and neuronal heterotopias). Of interest, cortical dysplasia is associated with epilepsy in children and adults (3).

It is not known if carmustine or its metabolites crosses the placenta. The molecular weight (about 214) is low enough that exposure of the embryo or fetus should be expected. Two characteristics of carmustine, its high lipid solubility and its relatively lack of ionization at physiologic pH, will promote transfer of the drug across the placenta. The very short plasma half-life may lessen the transfer of the parent drug, but the pharmacology and pharmacokinetics of the active metabolites have not been fully elucidated.

A 1984 report described a 21-year-old woman with diffuse histiocytic lymphoma who received carmustine and procarbazine for 5 months before conception and throughout the first 24 weeks of pregnancy (4). A second nitrosourea agent, streptozocin, replaced carmustine and procarbazine in the 2nd trimester. Before pregnancy, the patient had received multiple courses of chemotherapy, including cyclophosphamide, doxorubicin, vincristine, bleomycin, methotrexate, cytarabine, and etoposide, in addition to radiation therapy to the neck. Because of the failure of the previous therapy, she was started on carmustine 110 mg IV on day 1 and procarbazine 100 mg orally for 10 days every 4 weeks. She conceived after five monthly cycles of this latter therapy. The woman refused pregnancy termination and received five more cycles of therapy at 4-week intervals starting at 4 weeks' gestation. Three courses of streptozocin, 800 mg IV for 3 days every 4 weeks, were started at 24 weeks' gestation because of disease progression. She received the last dose of

streptozocin 2 weeks before delivery at 35 weeks' gestation. The woman's normal- appearing male infant weighed 2.34 kg with a head circumference of 32.5 cm and a length of 51.5 cm. The Apgar scores were 7 and 9 at 1 and 5 minutes, respectively. The initial blood test revealed a normal hemoglobin, white blood cell and platelet counts. All other clinical tests were within normal limits, including electrolytes, multiple chemistry, urinalysis, renal ultrasound, and chromosome studies (4).

In a second case report, a 27-year-old woman with a history of malignant melanoma was admitted to the hospital at 14 weeks' gestation for progressive weight loss and persistent headache (5). Approximately 9 months earlier an enlarged nevus had been removed from her left shoulder and the pathology had revealed the melanoma. The work-up for metastatic disease was negative and she was discharged home. Two months later, the woman was readmitted for severe back pain, which was attributed to diffuse metastatic disease of the spine. At 23 weeks' gestation, she was started on chemotherapy consisting of carmustine 150 mg/m² IV on day 1, tamoxifen 80 mg orally twice daily for 7 days, cisplatin 25 mg/m² IV on days 1 to 3, and dacarbazine 220 mg/m² on days 1 to 3. Approximately 3 weeks later, she received a second course of these agents. Corticosteroids were administered for fetal lung maturity and as an antiemetic for chemotherapy. Because the woman continued to deteriorate, a 1520-g female infant was delivered by cesarean section at 30 weeks' gestation. The 325-g placenta had malignant melanoma in the intervillous space and melanin pigment granules in villous Hofbauer cells and syncytial trophoblasts. The mother died 1 month later. At 17 months of age the child's weight was 6.6 kg (5th percentile), length 74.5 cm (<5th percentile), and head circumference 47 cm (10th percentile). Examination revealed age-appropriate evaluations for mental age, motor age, and language scores (5).

A number of reports have described pregnancy outcomes after the use of carmustine before conception (6–11). In four studies, the outcomes of 16 pregnancies (12 women) were 14 normal newborns, one stillbirth (twins), and one elective abortion (6–9). In one case, a man treated earlier with carmustine fathered a normal infant (7). A 2000 study analyzed the pregnancy outcomes of 340 cancer survivors who had one or more pregnancies after treatment with carmustine and 11 other alkylating agents (10). The cases were divided into five mutually exclusive treatment groups: nonsterilizing surgery, chemotherapy with alkylating agents, abdominal–pelvic radiation, alkylating agents plus abdominal–pelvic radiation, and all other treatments. The study found no evidence of an increased risk of birth defects or spontaneous abortions (10). In

a 2002 study, 1915 women had 4029 pregnancies after chemotherapy with or without radiation (11). No statistical differences in pregnancy outcomes (live births and spontaneous abortions) by treatment group were found, including the 126 pregnancies in women treated with carmustine.

BREASTFEEDING SUMMARY

No reports describing the use of carmustine during lactation have been located. The low molecular weight (about 214), high lipid solubility, and relative lack of ionization at physiologic pH suggest that carmustine will be excreted into breast milk. The short elimination half-life in the plasma may limit the amount of parent drug in milk, but the pharmacology and pharmacokinetics of the active metabolites have not been adequately characterized. Because there is substantial risk of harm for a nursing infant, women who are being treated with carmustine should not nurse.

CARPHENAZINE

[Withdrawn from the market. See 8th edition.]

CARTEOLOL

Sympatholytic (Antihypertensive)

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No studies describing the use of carteolol in human pregnancies have been located. If used near delivery, the newborn infant should be closely observed for 24–48 hours for signs and symptoms of β -blockade. Long-term effects of in utero exposure to β -blockers have not been studied but warrant evaluation. Some β -blockers may cause intrauterine growth restriction (IUGR) and reduced placental weight, especially those lacking intrinsic sympathomimetic activity (ISA) (i.e., partial agonist). Treatment beginning early in the 2nd trimester results in the greatest weight reductions, whereas treatment restricted to the 3rd trimester primarily affects only placental weight. Carteolol does possess ISA. However, IUGR and reduced placental weight may potentially occur with all agents within this class. Although growth restriction is a serious concern, the benefits of maternal therapy with β -blockers, in some cases, might outweigh the risks to the fetus and must be judged on a case-by-case basis.

FETAL RISK SUMMARY

Carteolol is a nonselective β_1/β_2 -adrenergic blocking agent used in the treatment of hypertension and topically in the therapy of glaucoma. No teratogenic effects were observed in pregnant mice and rabbits treated with doses much higher than the maximum recommended human dose (1–3). A dose-related increase in the incidence of wavy ribs was noted in fetal rats whose mothers were given doses 212 times the maximum recommended human dose (MRHD) (3). Fetotoxicity (increased resorptions and decreased fetal weight) was observed in rats and rabbits at doses up to 5264 and 1052 times the MRHD (3). These effects were not noted in mice at doses up to 1052

times the MRHD (3).

BREASTFEEDING SUMMARY

No reports describing the use of carteolol during human lactation have been located. If carteolol is used during nursing, the infant should be closely observed for hypotension, bradycardia, and other signs or symptoms of β -blockade. Long-term effects of exposure to β -blockers from milk have not been studied but warrant evaluation.

CARVEDILOL

Sympatholytic (Antihypertensive)

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Only one report describing the use of carvedilol in human pregnancy has been located. The animal data and the experience with other, similar agents, suggest that the risk of teratogenicity is low. Intrauterine growth restriction (IUGR), however, has been reported in the case below and is known to occur with other α/β -blockers (see Labetalol). Moreover, some β -blockers have caused IUGR and reduced placental weight, especially those lacking intrinsic sympathomimetic activity (ISA) (i.e., partial agonist). Treatment beginning early in the 2nd trimester results in the greatest weight reductions, whereas treatment restricted to the 3rd trimester primarily affects only placental weight. Carvedilol does not possess ISA. IUGR and reduced placental weight may potentially occur with all agents within this class. Although growth restriction is a serious concern, the benefits of maternal therapy with carvedilol (or other α/β -blockers), in some cases, might outweigh the risks to the fetus and must be judged on a case-by-case basis.

FETAL RISK SUMMARY

Carvedilol is a combined α/β -adrenergic blocking agent that is used for the treatment of hypertension and mild-to-moderate heart failure. The α_1 -adrenoreceptor blocking activity has been associated with vasodilation and a reduction in peripheral vascular resistance. Carvedilol is extensively metabolized and some of the metabolites are weakly active. Plasma protein binding, primarily to albumin, is >98% and the mean terminal elimination half-life of the parent compound is 7–10 hours (1).

Reproduction studies in rats and rabbits at 50 and 25 times the maximum

recommended human dose based on BSA (MRHD), respectively, revealed postimplantation loss in both species. The dose in rats, which was maternal toxic, was also associated with a decrease in fetal weight and an increase in frequency of fetuses with delayed skeletal development (missing or stunted 13th rib). Increased pup mortality at 1 week postpartum was observed when pregnant rats were treated with carvedilol at ≥ 10 times the MRHD during the last trimester and continued through day 22 of lactation. The no-observed-effect-level (NOEL) for developmental toxicity was 10 times the MRHD for rats and 5 times the MRHD for rabbits. Toxicity (sedation, reduced weight gain) and impaired fertility were observed in adult rats at ≥ 32 times the MRHD, including a reduced number of successful matings, prolonged mating time, fewer implants per dam, and complete resorption of 18% of the litters. The drug and/or its metabolites cross the rat placenta (1).

It is not known if carvedilol crosses the human placenta. The molecular weight (about 407) and long terminal elimination half-life suggest that exposure of the embryo–fetus probably occurs. However, the high plasma protein binding should limit the amount crossing the placenta.

In a 2002 case report, a woman with chronic hypertension presented at about 24 weeks' gestation with severe oligohydramnios (amniotic fluid index < 2) (2). Her medications included benazepril, carvedilol, amiodarone, and furosemide. The fetus had a misshapen cranium with overlapping sutures, pericardial effusion, small bladder, echogenic focus in the heart, echogenic bowel, and normal-appearing kidneys. All the drugs except carvedilol were discontinued. An examination 18 days later revealed normal amniotic fluid volume and normal cranial anatomy. At about 37 weeks' gestation, she gave birth to a 2060 g (< 3 rd percentile) female infant with Apgar scores of 7 and 9 at 1 and 5 minutes, respectively. The infant's initial physical examination was normal. Except for bilious vomiting on day 1, which resolved by day 2, the infant's hospital course was normal. At 1 year of age, the infant was healthy and weighed 18 lbs (5th percentile) (2).

BREASTFEEDING SUMMARY

No reports describing the use of carvedilol during human lactation have been located. The molecular weight (about 407) and long terminal elimination half-life (7–10 hours) suggest that the drug will be excreted into breast milk, but the high plasma protein binding ($> 98\%$) should limit the amount. The potential effects of this exposure on a nursing infant include bradycardia, hypotension, and other symptoms of α/β -blockade. However, a similar agent is classified by

the American Academy of Pediatrics as compatible with breastfeeding (see Labetalol).

CASANTHRANOL

Purgative

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Casanthranol is an anthraquinone purgative. Although the data are limited, there is no evidence that drugs in this class pose a risk to the embryo–fetus.

FETAL RISK SUMMARY

In a large prospective study, 109 patients were exposed to this agent during pregnancy, 21 in the 1st trimester (1). No evidence of an increased risk for malformations was found (see also Cascara Sagrada).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 96 newborns had been exposed to casanthranol during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Four (4.2%) (four expected) major birth defects were observed. Specific data were available for six defect categories, including (observed/expected) 2/1 cardiovascular defects, 1/0 spina bifida, and 1/0.5 polydactyly. No anomalies were observed in the other three categories (oral clefts, limb-reduction defects, and hypospadias). These data do not support an association between the drug and congenital defects.

BREASTFEEDING SUMMARY

No reports describing the use of casanthranol during human lactation have been located. Although diarrhea in a nursing infant is a potential effect, the drug is probably compatible with breastfeeding. (See also Cascara Sagrada.)

CASCARA SAGRADA

Purgative

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Cascara sagrada is an anthraquinone purgative. Although the data are limited, there is no evidence that drugs in this class pose a risk to the embryo–fetus.

FETAL RISK SUMMARY

In a large prospective study, 53 mother–child pairs were exposed to cascara sagrada during the 1st trimester (1, pp. 384–387). Although the numbers are small, no evidence for an increased risk of malformations was found. For anytime use during pregnancy, 188 exposures were recorded (1, pp. 438, 442, 497). The relative risk for benign tumors was higher than expected, but independent confirmation is required (1, pp. 438, 442, 497).

A 1977 study found that more than 50% of the women taking laxatives during pregnancy had taken a laxative of the anthraquinone type (2). Danthron (1:8 dihydroxyanthraquinone) was administered to nine women shortly before induction of labor. Presence of the laxative and/or its metabolite was documented in the amniotic fluid and in the urine of the newborns. No fetal adverse effects were noted (2).

BREASTFEEDING SUMMARY

Most reviewers acknowledge the presence of anthraquinones (e.g., cascara and danthron) in breast milk and warn of the consequences for the nursing infant (3–5). A comprehensive review described the excretion of laxatives into human milk, but little is known about the presence of these agents in breast milk (6). Two reports suggest an increased incidence of diarrhea in infants when nursing mothers are given cascara sagrada or senna for postpartum

constipation (7,8). However, the American Academy of Pediatrics classifies cascara and danthron as compatible with breastfeeding (9).

CASPOFUNGIN

Antifungal

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of caspofungin in human pregnancy have been located. A 2003 review of antifungal agents was also unable to find such reports (1). The animal data are suggestive of human risk, especially if exposure occurs in the 1st trimester. However, the absence of human pregnancy experience prevents an assessment of the embryo–fetal risk. If indicated, maternal treatment should be avoided in the 1st trimester, if possible.

FETAL RISK SUMMARY

Caspofungin inhibits the synthesis of glucan, an integral component of the fungal cell wall, and is the first antifungal agent in this class. It is a semisynthetic lipopeptide (echinocandin) compound that is synthesized from a fermentation product of the fungus *Glarea lozoyensis*. Caspofungin is approved for the treatment of *Candida* infections and for invasive aspergillosis in patients who cannot be treated with other antifungals. Caspofungin is extensively bound to albumin (about 97%). Plasma clearance of caspofungin is primarily from distribution, rather than by excretion or by metabolism. The γ -phase half-life is 40–50 hours (2).

Reproduction studies have been conducted in rats and rabbits. In rats, doses producing exposures similar to those obtained in humans treated with a 70-mg dose (HE) were embryotoxic, resulting in increased resorptions and peri-implantation losses. Other effects included incomplete ossification of the skull and torso and an increased incidence of cervical ribs. The agent was also embryotoxic in rabbits, causing increased resorptions at doses similar to the HE. In addition, incomplete ossifications of the talus/calcaneus were observed

in rabbits (2).

Caspofungin crosses the placenta in rats and rabbits (gestational age not specified) and the drug could be detected in fetal plasma (2). It is not known if the agent crosses the human placenta. The molecular weight (about 1213 for the acetate salt) and extensive plasma protein binding should limit the amount crossing the placenta, but the long β -phase half-life should provide substantial amounts of the drug available for transfer.

BREASTFEEDING SUMMARY

No reports describing the use of caspofungin during human lactation have been located. The high molecular weight (about 1213 for the acetate salt) and extensive plasma protein binding (about 97%) should limit the amount of drug excreted in breast milk, but the long γ -phase half-life may allow for some drug in the milk. The effect of this exposure on a nursing infant is unknown. However, other drugs from different classes of antifungal agents, such as fluconazole and ketoconazole, are classified as compatible with breastfeeding by the American Academy of Pediatrics (see Fluconazole and Ketoconazole). The risk of harm from exposure to caspofungin also appears to be low, and women being treated with caspofungin should be allowed to breastfeed. Their infants should be monitored for signs and symptoms of histamine release (e.g., rash, facial swelling, and pruritus) and gastrointestinal complaints.

CASTOR OIL

Laxative/Oxytocic

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Castor oil has been used since ancient times to induce labor. Nevertheless, neither the efficacy for this indication nor the fetal/newborn safety has been documented. One study found that the drug had no value to labor induction (1). Castor oil can cause severe maternal morbidity and possibly mortality, but this toxicity appears to be rare. However, maternal nausea and diarrhea appear to be very common, although underreported. The mechanism of castor oil's oxytocic effect is unknown, but might be due to systemically absorbed ricinoleic acid stimulating uterine contractions. In recent times, the use of castor oil as an oxytocic agent has declined, probably because of the availability of safer and more physiologic agents, such as oxytocin and the two prostaglandins: dinoprostone and misoprostol. Although the report of multiple congenital defects attributed to castor beans early in gestation requires confirmation, castor beans should be avoided in pregnancy. As for castor oil, the limited human data offer no documented benefits for the mother or fetus. Uterine bleeding and abortion are potential toxicities. Thus, the use of castor oil as a laxative or for other purposes before term pregnancy should be avoided. Use at term should only be on the advice of a healthcare provider.

FETAL RISK SUMMARY

Castor, *Ricinus communis*, is an ornamental plant native to the West Indies, but now grows in the United States and Hawaii (2). Castor oil is cold expressed from castor beans (i.e., seeds) and contains a mixture of triglycerides. The principal compound is ricinoleic acid with smaller amounts of linoleic, oleic, pamic, and stearic acids. The oil also contains toxins, such as ricin and ricinine, that are removed with further processing (2). Upon ingestion, castor oil

is hydrolyzed in the duodenum by pancreatic lipase to release glycerol and the active ingredient, ricinoleic acid (3,4). Castor seeds contain ricin and can cause poisoning (3). Castor oil has been used for the induction of labor, and as a cathartic, contraceptive cream, lubricant, and skin emollient (2,3). It also has been combined with quinine to induce labor at term and topically as a contraceptive and abortifacient (3).

A 1983 report described an infant with growth restriction, convulsions, craniofacial dysmorphism, absent deformity of limbs, and vertebral segmentation defect that was born from a 20-year-old mother (5). The mother had taken a castor oilseed, once per month, as a contraceptive for 3 months before conception and during the first 2 months of gestation. No other drugs were taken during pregnancy. Because ricin is a potent toxin, the authors attributed the defects to the castor oilseeds (4). Of interest, a 2002 review stated (without specific reference) that castor bean had emmenagogue and abortifacient effects (6).

Castor oil has been used since ancient Egypt to induce labor (1,2,7–15). A 1958 study evaluated the efficacy of castor oil for the induction of labor (1). In the first part of the study, the investigator polled obstetric department heads of 50 medical schools. Of the 32 who responded, 16 never used castor oil for labor induction, whereas 16 used it some times. A retrospective review of 114 consecutive inductions (1952–1954) was conducted at the investigator's institution. All of the inductions involved rupture of membranes and oxytocin. The group was divided into four subgroups: rupture of membranes and oxytocin (N = 24), added enema (N = 27), added castor oil (N = 31), and added castor oil and enema (N = 32). The average induction times for the four groups were 4, 2, 4, and 4 hours, respectively. The 18 induction failures were nearly equal in the groups: 5, 5, 3, and 5, respectively. These results convinced the investigator that castor oil had no value in the induction of labor (1).

The uterine activity effect of castor oil, soap enema, hot bath, or a combination of all three was described in 60 women at 38–41 weeks' gestation in a 1959 study (7). Castor oil plus soap enema had the most marked effect, but most of the increased activity was due to castor oil. A hot bath had little effect. The effects on delivery times, induction failure, and pregnancy outcomes were not provided. Nevertheless, based solely on uterine activity, the investigators concluded that labor induction with castor oil, with or without soap enema, was useful (7).

A 1999 survey found that among 90 nurse-midwives who used herbal products for labor induction, castor oil (93%) was most the common (8). The

doses used ranged from 5 to 120 mL. The mechanism of the oxytocic effect is unknown, but various authors have stated that it is secondary to intestinal peristalsis or an increase in the concentrations of prostaglandin E (9,10,12). However, a brief 2002 report stated that the oxytocic effect was due to systemically absorbed ricinoleic acid that caused contractions of the uterine musculature (13). Nausea is a very common adverse effect, as is diarrhea after delivery. The use of castor oil does not appear to directly affect the fetus or the Apgar scores at birth, but most reports fail to mention the condition of the newborn. Two reviews concluded that there is insufficient evidence to support the use of castor oil as an induction agent (14,15).

A 1987 study reported an increase in meconium staining of the amniotic fluid in women given castor oil for labor induction compared with controls (16). Meconium staining occurred in 4 (2.3%) of 174 women given castor oil compared with 0 of the 304 controls ($p < 0.1$). Although the authors deemed the result significant, the difference might not have been if the standard p value of < 0.05 has been used. In another report, 10.4% of women receiving castor oil had meconium-stained amniotic fluid compared with 11.5% of controls (ns) (12).

A case report describing amniotic fluid embolism associated temporally with castor oil was published in 1988 (17). A 33-year-old woman at 40 weeks' gestation with an uncomplicated pregnancy and unremarkable medical history ingested 30 mL castor oil for labor induction. About 60 minutes later, spontaneous rupture of membranes occurred, followed by cardiorespiratory arrest. A dead fetus, with no observable abnormalities, was delivered, along with a normal placenta, in the intensive care unit. Maternal blood contained fetal squamous cells and amniotic fluid debris. The clinical course was complicated by seizures and findings consistent with disseminated intravascular coagulation. EEG findings were consistent with anoxic encephalopathy. At the time of the report, the woman remained in a persistent vegetative state (17).

A 2003 case report described uterine rupture in a 39-year-old woman at 39 weeks' gestation (18). The woman experienced a brief bowel movement, followed by severe abdominal pain and rupture of membranes shortly after ingesting castor oil 5 mL for labor induction. A repeat cesarean section, performed for fetal distress and a closed, long cervix, revealed a portion of the umbilical cord protruding from a 2-cm rupture of the lower transverse scar. A female 2724-g female infant was delivered with Apgar scores of 9 at 1 and 5 minutes (18).

An unusual use of castor oil in pregnancy was briefly reported in 1967 (19).

Castor oil was applied to the cervical os to facilitate vaginal delivery. The author noted that the use of oil to lubricate the vagina and os during labor was common among midwives in his region.

BREASTFEEDING SUMMARY

No reports describing the use of castor oil during lactation have been located. Castor oil has been used orally to promote the flow of breast milk (2). Evidence for this effect has not been located. The principal active ingredient, ricinoleic acid, is absorbed systemically and could be excreted into milk. Diarrhea in the nursing infant is a potential complication. In a rural region of India, newborn infants are sometimes given castor oil for its laxative properties in the belief that it will clean the intestine of meconium (20). However, this practice has been discouraged because it can be dangerous for the infant, at times causing paralytic ileus and aspiration pneumonia (20).

CEFACLOR

Antibiotic (Cephalosporin)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No detectable teratogenic risk with cefaclor and other cephalosporin antibiotics was found in a large 2001 study (see Cephalexin).

FETAL RISK SUMMARY

Cefaclor is an oral, semisynthetic cephalosporin antibiotic. Reproduction studies in mice, rats, and ferrets found no evidence of impaired fertility or fetal harm at doses up to 12, 12, and 3 times, respectively, the human dose (1). Cephalosporins are usually considered safe to use during pregnancy (see other cephalosporins for published human experience).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 1325 newborns had been exposed to the antibiotic during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 75 (5.7%) major birth defects were observed (56 expected). Specific data were available for six defect categories, including (observed/expected) 19/13 cardiovascular defects, 8/2 oral clefts, 1/0.7 spina bifida, 1/4 polydactyly, 2/2 limb reduction defects, and 3/3 hypospadias. The data for all defects, cardiovascular defects, and oral clefts are suggestive of an association between cefaclor and congenital defects, but other factors, such as the mother's disease, may be involved. However, similar findings were measured for another cephalosporin antibiotic with more than a thousand exposures (see Cephalexin). Positive results were also suggested for cephradine (339 exposures) but not for cefadroxil (722 exposures) (see Cephradine and Cefadroxil). In contrast, other anti-infectives with large cohorts (see Ampicillin, Amoxicillin, Penicillin G, Erythromycin, and Tetracycline) were not associated with congenital defects.

BREASTFEEDING SUMMARY

Cefaclor is excreted into breast milk in low concentrations. Following a single 500-mg oral dose, average milk levels ranged from 0.16 to 0.21 mcg/mL during a 5-hour period (2). Only trace amounts of the antibiotic could be measured at 1 and 6 hours. Even though these levels are low, three potential problems exist for the nursing infant: modification of bowel flora, direct effects on the infant, and interference with the interpretation of culture results if a fever workup is required.

In a 1993 cohort study, diarrhea was reported in 32 (19.3%) nursing infants of 166 breastfeeding mothers who were taking antibiotics (3). For the five women taking cefaclor, diarrhea was observed in 1 (20%) infants. The diarrhea was considered minor because it did not require medical attention (3).

Although not specifically listing cefaclor, the American Academy of Pediatrics classifies other cephalosporin antibiotics as compatible with breastfeeding (e.g., see Cefadroxil and Cefazolin).

CEFADROXIL

Antibiotic (Cephalosporin)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No detectable teratogenic risk with cephalosporin antibiotics was found in a large 2001 study (see Cephalexin).

FETAL RISK SUMMARY

Cefadroxil is an oral, semisynthetic cephalosporin antibiotic. Reproduction studies in mice and rats found no evidence of impaired fertility or fetal harm at doses up to 11 times the human dose (1). Cephalosporins are usually considered safe to use during pregnancy (see other cephalosporins for published human experience).

At term, a 500-mg oral dose produced an average peak cord serum level of 4.6 mcg/mL at 2.5 hours (about 40% of maternal serum) (2). Amniotic fluid levels achieved a peak of 4.4 mcg/mL at 10 hours. No infant data were given.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 722 newborns had been exposed to cefadroxil during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 27 (3.7%) major birth defects were observed (30 expected). Specific data were available for six defect categories, including (observed/expected) 1/1 cardiovascular defects, 0/1 oral clefts, 0/0.5 spina bifida, 2/2 polydactyly, 2/1 limb reduction defects, and 1/2 hypospadias. These data do not support an association between the drug and congenital defects (see also Cefaclor, Cephalexin, and Cephadrine for contrasting results).

Cefadroxil, 500 mg twice daily for 10 days following an IV dose of ceftazidime, was used in 12 women for the treatment of asymptomatic bacteriuria during the 1st trimester (see also Ceftazidime) (3). No adverse effects of the treatment were observed.

BREASTFEEDING SUMMARY

Cefadroxil is excreted into breast milk in low concentrations. Following a single 500-mg oral dose, peak milk levels of about 0.6–0.7 mcg/mL occurred at 5–6 hours (2). A 1-g oral dose given to six mothers produced peak milk levels averaging 1.83 mcg/mL (range 1.2–2.4 mcg/mL) at 6–7 hours (4). In this latter group, milk:plasma ratios at 1, 2, and 3 hours were 0.009, 0.011, and 0.019, respectively. Although these levels are low, three potential problems exist for the nursing infant: modification of bowel flora, direct effects on the infant, and interference with the interpretation of culture results if a fever workup is required. The American Academy of Pediatrics classifies cefadroxil as compatible with breastfeeding (5).

CEFATRIZINE

[Withdrawn from the market. See 9th edition.]

CEFAZOLIN

Antibiotic (Cephalosporin)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No detectable teratogenic risk with cephalosporin antibiotics was found in a large 2001 study (see Cephalexin).

FETAL RISK SUMMARY

Cefazolin is a parenteral, semisynthetic cephalosporin antibiotic. Reproduction studies in mice, rats, and rabbits found no evidence of impaired fertility or fetal harm at doses up to 25 times the human dose (1).

Cefazolin crosses the placenta into the cord serum and amniotic fluid (2–6). In early pregnancy, distribution is limited to the body fluids and these concentrations are considerably lower than those found in the 2nd and 3rd trimesters (3). At term, 15–70 minutes after a 500-mg dose, cord serum levels range from 35% to 69% of the maternal serum (4). The maximum concentration in amniotic fluid after 500-mg dose was 8 mcg/mL at 2.5 hours (5). No data on the newborns were given. Following a 2-g IV dose given to seven women between 23 and 32 weeks' gestation, the mean serum concentration of cefazolin in hydropic and nonhydropic fetuses was 18.04 and 21.02 mcg/mL, respectively, providing evidence that the presence of hydrops did not significantly impair the transfer of the antibiotic (6).

Cefazolin, 2 g IV every 8 hours, has been used in the treatment of pyelonephritis occurring in the second half of pregnancy (7). No adverse fetal outcomes attributable to the drug were observed.

BREASTFEEDING SUMMARY

Cefazolin is excreted into breast milk in low concentrations. Following a 2-g IV dose, the average milk levels ranged from 1.2 to 1.5 mcg/mL over 4 hours (milk:plasma ratio 0.02) (8). When cefazolin was given as a 500-mg IM dose, one to three times daily, the drug was not detectable (5). Although these levels

are low, three potential problems exist for the nursing infant: modification of bowel flora, direct effects on the infant, and interference with the interpretation of culture results if a fever workup is required. The American Academy of Pediatrics classifies cefazolin as compatible with breastfeeding (9).

CEFDINIR

Antibiotic (Cephalosporin)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No detectable teratogenic risk with cephalosporin antibiotics was found in a large 2001 study (see Cephalexin).

FETAL RISK SUMMARY

Cefdinir is an oral, semisynthetic, third-generation cephalosporin antibiotic. No reports describing its use in pregnancy have been located. The molecular weight (about 395) is low enough that passage to the fetus should be expected.

Reproduction studies have been conducted in pregnant rats and rabbits (1). In pregnant rats, oral doses up to 11 times the human dose based on BSA (HD) were not teratogenic, but decreased fetal weight occurred at doses ≥ 1.1 times the HD. No effects were seen on maternal reproductive performance or offspring survival, behavior, development, or reproductive function. In rabbits, oral doses up to 0.23 times the HD were not teratogenic, but maternal toxicity (decreased body weight) was noted at the highest dose. No adverse effects on offspring were observed (1).

BREASTFEEDING SUMMARY

No published reports describing the use of cefdinir in human lactation have been located. The molecular weight (about 395) is low enough that excretion into breast milk should be expected. However, the drug was not detected in breast milk after a single, 600-mg oral dose (1). Multiple dosing during lactation has apparently not been studied. If excretion does occur, three potential problems exist for the nursing infant: modification of bowel flora, direct effects on the infant, and interference with the interpretation of culture results if a fever workup is required. The American Academy of Pediatrics classifies other cephalosporins as compatible with breastfeeding (e.g., see Cefadroxil and

Cefazolin).

1. Product information. Omnicef. Abbott Laboratories, 2001.

CEFDITOREN

Antibiotic (Cephalosporin)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No detectable teratogenic risk with cephalosporin antibiotics was found in a large 2001 study (see Cephalexin).

FETAL RISK SUMMARY

No reports describing the use of cefditoren in human pregnancy have been located. Cefditoren pivosil is a prodrug that is hydrolyzed during absorption to the active drug, cefditoren. It is an oral, semisynthetic cephalosporin antibiotic similar to other agents in this class. Cefditoren probably crosses the placenta, similar to other cephalosporins.

Reproduction studies have been conducted with cefditoren pivosil in rats and rabbits. In pregnant rats and rabbits, doses up to about 24 and 4 times, respectively, the human dose of 200 mg twice daily based on BSA (HD) were not teratogenic. In addition, rat fertility and reproduction were not affected by the highest dose. However, in rabbits, the highest dose caused severe maternal toxicity resulting in fetal toxicity and abortions. In a postnatal study in rats, a dose 18 times the HD produced no adverse effects on postnatal survival, physical and behavioral development, learning abilities, and reproductive capability at sexual maturity (1).

BREASTFEEDING SUMMARY

No reports describing the use of cefditoren in human lactation have been located. Small amounts of antibiotic have been found in breast milk for all cephalosporins that have been studied, so the presence of cefditoren in milk should be expected. In most cases, the effects of this exposure will be insignificant. However, three potential problems exist for the nursing infant exposed to cefditoren in milk: modification of bowel flora, direct effects on the infant, and interference with the interpretation of culture results if a fever

workup is required. The American Academy of Pediatrics classifies other cephalosporins as compatible with breastfeeding (for example, see Cefadroxil and Cefazolin).

CEFEPIME

Antibiotic (Cephalosporin)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No detectable teratogenic risk with cephalosporin antibiotics was found in a large 2001 study (see Cephalexin).

FETAL RISK SUMMARY

No reports describing the use of cefepime in human pregnancy have been located. It is a parenteral, semisynthetic cephalosporin antibiotic. Serum protein binding is about 20% (1).

No adverse effects on fertility or reproduction, including embryo toxicity and teratogenicity, were observed in mice, rats, and rabbits dosed at one to four times the recommended maximum human daily dose based on BSA (1).

Consistent with the molecular weight (about 481 for the free base), cefepime crosses the human placenta. In a 2010 study, nine women scheduled for a cesarean section were given IV cefepime 1 g over 60 minutes (2). The transplacental passage rate calculated as a percentage of fetal venous concentration to maternal blood concentration was about 23%, whereas the transfetal passage rate calculated as a percentage of fetal arterial drug concentration to fetal venous concentration was about 79% (2).

BREASTFEEDING SUMMARY

Cefepime is excreted in human milk. The manufacturer reports that a nursing infant consuming about 1000 mL of human milk per day would receive about 0.5 mg of cefepime per day (1). In spite of this low dose, three potential problems exist for the nursing infant exposed to cefepime in milk: modification of bowel flora, direct effects on the infant, and interference with the interpretation of culture results if a fever workup is required. Although not specifically listing cefepime, the American Academy of Pediatrics classifies other cephalosporin antibiotics as compatible with breastfeeding (for example,

see Cefadroxil and Cefazolin).

2. Ozyuncu O, Nemutlu E, Katlan D, Kir S, Beksac MS. Maternal and fetal blood levels of moxifloxacin, levofloxacin, cefepime and cefoperazone. *Int J Antimicrob Agents* 2010;36:175–8.

CEFIXIME

Antibiotic (Cephalosporin)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

The limited human pregnancy data do not suggest embryo–fetal risk. In addition, no detectable teratogenic risk with cephalosporin antibiotics was found in a large 2001 study (see Cephalexin).

FETAL RISK SUMMARY

Cefixime is an oral, semisynthetic cephalosporin antibiotic. Serum protein binding is about 65% and the elimination half-life is about 3.5 hours (1).

Reproduction studies found no evidence in rats of impaired fertility or reproductive performance at doses up to 125 times the adult therapeutic dose or, in mice and rats, of teratogenicity at doses up to 400 times the human dose (1).

Consistent with the molecular weight (about 453), cefixime crosses the human placenta.

A 2010 study measured cefixime amniotic fluid concentrations in six women given a 400 mg oral dose about 2 hours before amniocentesis (2). The study was conducted between the 16th and 20th gestational weeks. The mean concentrations of cefixime in maternal blood and amniotic fluid were 2.59 mcg/mL and 0.85 mcg/mL, respectively, and amniotic fluid passage rate of about 38% (2).

A 1998 noninterventional observational cohort study described the outcomes of pregnancies in women who had been prescribed one or more of 34 newly marketed drugs by general practitioners in England (3). Data were obtained by questionnaires sent to the prescribing physicians one month after the expected or possible date of delivery. In 831 (78%) of the pregnancies, a newly marketed drug was thought to have been taken during the 1st trimester, with birth defects noted in 14 (2.5%) singleton births of the 557 newborns (10 sets of twins). In addition, two birth defects were observed in aborted fetuses.

However, few of the aborted fetuses were examined. Cefixime was taken during the 1st trimester in 11 pregnancies. The outcomes of these pregnancies included two spontaneous abortions, one elective abortion, seven normal newborns (one premature), and one unknown outcome (3).

A 2003 study evaluated 95 pregnant women with gonorrhea who were treated with either cefixime (N = 52) or ceftriaxone (N = 43) (4). Treatment in both groups occurred at about 21 weeks' gestation. Both antibiotics were equally effective, with 91 patients cured of the infection. Hyperbilirubinemia occurred more often in infants from mothers treated with ceftriaxone, but the difference was not significant (4).

A study evaluating the effects of mass treatment (cefixime, azithromycin, metronidazole) for AIDS prevention in Uganda was published in 1999 (5). Compared with controls, the prevalences of trichomoniasis, bacterial vaginosis, gonorrhea, and chlamydia infection were significantly lower, but no difference was observed in the incidence of HIV infection. A second study using this same group of patients found, in addition to the lower rates of infection, reduced rates of neonatal death, low birth weight, and preterm delivery (6). However, in a third study involving the same Uganda women as above, children of 94 women with *Trichomonas vaginalis* who had been treated during pregnancy with the 3-drug combination had increased low birth weight (<2500 g) and preterm birth rate compared with untreated controls (7). The authors concluded that treatment of the condition during pregnancy was harmful and that it was most likely due to metronidazole.

BREASTFEEDING SUMMARY

No reports describing the use of cefixime during human lactation have been located. Low concentrations of other cephalosporins have been measured, however, and the presence of cefixime in milk should be expected. Three potential problems exist for the nursing infant exposed to cefixime in milk: modification of bowel flora, direct effects on the infant, and interference with the interpretation of culture results if a fever workup is required. The American Academy of Pediatrics classifies other cephalosporin antibiotics as compatible with breastfeeding (for example, see Cefadroxil and Cefazolin).

CEFOTAXIME

Antibiotic (Cephalosporin)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No detectable teratogenic risk with cephalosporin antibiotics was found in a large 2001 study (see Cephalexin).

FETAL RISK SUMMARY

Cefotaxime is a parenteral, semisynthetic cephalosporin antibiotic. Reproduction studies in mice and rats have found no evidence of impaired fertility or fetal harm at doses up to 20 times the human dose (1). Cephalosporins are usually considered safe to use during pregnancy.

During the 2nd trimester, the drug readily crosses the placenta (2). The half-life of cefotaxime in fetal serum and in amniotic fluid was 2.3 and 2.8 hours, respectively. Five women with chorioamnionitis and in labor received cefotaxime (dose not specified) (3). The maternal and cord blood concentrations were nearly equivalent at 8.90 and 8.60 mcg/mL, respectively, but the placental tissue:maternal blood ratio was 0.2 (dose to delivery interval not specified).

BREASTFEEDING SUMMARY

Cefotaxime is excreted into breast milk in low concentrations. Following a 1-g IV dose, mean peak milk levels of 0.33 mcg/mL were measured at 2–3 hours (2,4). The half-life in milk ranged from 2.36 to 3.89 hours (mean 2.93 hours). The milk:plasma ratios at 1, 2, and 3 hours were 0.027, 0.09, and 0.16, respectively. Although these levels are low, three potential problems exist for the nursing infant: modification of bowel flora, direct effects on the infant, and interference with the interpretation of culture results if a fever workup is required. The American Academy of Pediatrics classifies cefotaxime as compatible with breastfeeding (5).

CEFOTETAN

Antibiotic (Cephalosporin)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No detectable teratogenic risk with cephalosporin antibiotics was found in a large 2001 study (see Cephalexin).

FETAL RISK SUMMARY

Cefotetan is a parenteral, semisynthetic cephalosporin antibiotic. Reproduction studies in rats and monkeys found no evidence of impaired fertility or fetal harm at doses up to 20 times the human dose (1). Cephalosporins are usually considered safe to use during pregnancy.

A 1985 study measured the placental passage of the drug when administered just prior to cesarean section (2). Twenty women received a single, 1-g IV bolus dose of the antibiotic at intervals of 1–4 hours before surgery. The peak maternal plasma level obtained was 28 mcg/mL. Cord blood concentrations progressively increased depending on the length of time after a mother received a dose and were highest (12.5 mcg/mL) when she received the drug 4 hours prior to surgery. Similarly, a progressive increase in amniotic fluid concentrations was observed with values of 5.1, 7.5, and 8.1 mcg/mL measured at 2, 3, and 4 hours, respectively. The increases in the level of antibiotic in the amniotic fluid paralleled those in the cord blood.

Three Japanese studies reported placental passage of cefotetan (3–5). Cord blood levels almost double those measured above, 24.7 mcg/mL, were reported 1 hour after a 1-g IV dose (3). This value was 15.4% of the peak maternal serum level, indicating that the peak maternal level was about 160 mcg/mL. The amniotic fluid concentration was 12.3% of the mother's level, or approximately 20 mcg/mL. A confirming study also found high cord blood levels after a single 1-g IV dose with the highest value of 29.0 mcg/mL measured 3.6 hours after the maternal dose (4). The highest amniotic fluid level, however, was 8.6 mcg/mL, which was also observed at 3.6 hours. The third study

measured cord serum concentrations of 15, 31.4, and 3.5 mcg/mL at 0.85, 3.75, and 16 hours, respectively, after a 1-g IV dose (5). Amniotic fluid concentrations ranged from 1.18 to 13.6 mcg/mL up to 16 hours after a dose.

BREASTFEEDING SUMMARY

Small amounts of cefotetan are excreted into human breast milk (5,6). A 1982 reference reported milk levels ranging from 0.22 to 0.34 mcg/mL 1–6 hours after a 1-g IV dose (5). In six women treated with cefotetan 1 g IM every 12 hours, mean milk levels 4–10 hours after a dose varied from 0.29 to 0.59 mcg/mL (6). No accumulation in the milk was observed, as evidenced by a steady milk:plasma ratio. The mean ratio 10 hours after the first dose was 0.05 compared with 0.07, 10 hours after the fifth dose.

Even though the amounts of antibiotic are very small, and no reports of adverse effects in a nursing infant have been located, three potential problems exist for the infant exposed to cefotetan in milk: modification of bowel flora, direct effects on the infant, and interference with the interpretation of culture results if a fever workup is required. Although not specifically listing cefotetan, the American Academy of Pediatrics classifies other cephalosporin antibiotics as compatible with breastfeeding (for example, see Cefadroxil and Cefazolin).

CEFOXITIN

Antibiotic (Cephalosporin)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No detectable teratogenic risk with cephalosporin antibiotics was found in a large 2001 study (see Cephalexin).

FETAL RISK SUMMARY

Cefoxitin is a parenteral, semisynthetic cephalosporin antibiotic. Reproduction studies found no evidence in rats of impaired fertility or reproductive performance at doses three times the maximum recommended human dose (MRHD) or, in mice and rats, fetal harm (other than a slight decrease in fetal weight) or teratogenesis at doses up to approximately 7.5 times the MRHD (1).

Multiple reports have described the transplacental passage of cefoxitin (2–14). Two patients were given 1 g IV just prior to therapeutic abortion at 9 and 10 weeks' gestation (10). At 55 minutes, the serum level in one woman was 10.5 mcg/mL while none was found in the fetal tissues. In the second patient, at 4.25 hours the maternal serum was "nil," while the fetal tissue level was 35.7 mcg/mL.

At term, following IM or rapid IV doses of 1 or 2 g, cord serum levels up to 22 mcg/mL (11%–90%) of maternal levels have been measured (7–10). Amniotic fluid concentrations peaked at 2–3 hours in the 3–15 mcg/mL range (7,8,10,11,14). No apparent adverse effects were noted in any of the newborns.

BREASTFEEDING SUMMARY

Cefoxitin is excreted into breast milk in low concentrations (6,10,12,13,15). Up to 2 mcg/mL has been detected in the milk of women receiving therapeutic doses (J.J. Whalen, personal communication, Merck, Sharpe & Dohme, May 13, 1981). No data on the infants were given. Following prophylactic administration of 2–4 g of cefoxitin to 18 women during and following cesarean

section, milk samples were collected a mean 25 hours (range 9–56 hours) after the last dose of antibiotic (15). Only one sample, collected 19 hours after the last dose, contained measurable concentrations of cefoxitin (0.9 mcg/mL). Although these levels are low, three potential problems exist for the nursing infant: modification of bowel flora, direct effects on the infant, and interference with the interpretation of culture results if a fever workup is required. The American Academy of Pediatrics classifies cefoxitin as compatible with breastfeeding (16).

CEFPODOXIME

Antibiotic (Cephalosporin)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No detectable teratogenic risk with cephalosporin antibiotics was found in a large 2001 study (see Cephalexin).

FETAL RISK SUMMARY

No reports describing the use of cefpodoxime in human pregnancy have been located. It is an oral, semisynthetic cephalosporin antibiotic. Reproduction studies found no evidence in rats of impaired fertility or reproductive performance or, in rats and rabbits, of embryo toxicity or teratogenicity, at doses up to two times the human dose based on BSA (1).

BREASTFEEDING SUMMARY

According to the manufacturer, low concentrations of cefpodoxime are excreted into human milk (1). Following 200-mg oral doses administered to three women, milk concentrations, as a percentage of concomitant serum levels, 4 hours after the dose were 0%, 2%, and 6%, respectively, and at 6 hours, 0%, 9%, and 16%, respectively. Although not specifically stated for these three women, mean serum concentrations in fasted adults after a 200-mg dose were 2.2 mcg/mL at 2 and 3 hours (peak levels), 1.8 mcg/mL at 4 hours, and 1.2 mcg/mL at 6 hours (1).

In spite of these low levels, three potential problems exist for the nursing infant exposed to cefpodoxime in milk: modification of bowel flora, direct effects on the infant, and interference with the interpretation of culture results if a fever workup is required. Although not specifically listing cefpodoxime, the American Academy of Pediatrics classifies other cephalosporin antibiotics as compatible with breastfeeding (for example, see Cefadroxil and Cefazolin).

CEFPROZIL

Antibiotic (Cephalosporin)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No detectable teratogenic risk with cephalosporin antibiotics was found in a large 2001 study (see Cephalexin).

FETAL RISK SUMMARY

No reports describing the use of cefprozil in human pregnancy have been located. It is an oral, semisynthetic cephalosporin antibiotic. Reproduction studies found no evidence in animals of impaired fertility or, in mice, rats, and rabbits, of fetal harm at doses of 8.5, 18.5, and 0.8 times, respectively, the maximum human daily dose based on BSA (1).

BREASTFEEDING SUMMARY

Low concentrations of cefprozil are excreted in human milk. In a study published in 1992, nine healthy, lactating women were given a single 1000-mg oral dose of cefprozil consisting of cis and trans isomers in an approximately 90:10 ratio (2). The mean peak plasma concentrations of the cis and trans isomers were 14.8 and 1.9 mcg/mL, respectively. For the cis isomer, the mean milk concentration over a 24-hour period ranged from 0.25 to 3.36 mcg/mL, whereas the average maximum concentration in milk of the trans isomer was <0.26 mcg/mL. Less than 0.3% of the maternal dose was excreted into milk for the two isomers. The investigators estimated that an infant receiving 800 mL/day of milk would ingest a maximum of 3 mg of cefprozil, an amount they assessed as clinically insignificant.

Three potential problems exist for the nursing infant exposed to cefprozil in milk: modification of bowel flora, direct effects on the infant, and interference with the interpretation of culture results if a fever workup is required. The American Academy of Pediatrics classifies cefprozil as compatible with breastfeeding (3).

CEFTAROLINE FOSAMIL

Antibiotic (Cephalosporin)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No reports describing the use of ceftaroline fosamil in human pregnancy have been located. Animal data suggest low risk. Although there is no human pregnancy experience, in general, cephalosporins are considered compatible in pregnancy.

FETAL RISK SUMMARY

Ceftaroline fosamil is a cephalosporin antibiotic that is converted to the bioactive ceftaroline after IV administration. It is indicated for the treatment of acute bacterial skin and skin structure infections and community-acquired bacterial pneumonia. Plasma protein binding is about 20% and the elimination half-life after multiple doses is about 2.7 hours (1).

Reproduction studies have been conducted in rats and rabbits. In rats, doses that produced exposures that were about 8 times the human exposure from 600 mg every 12 hours based on AUC (HE) did not cause maternal toxicity or fetal harm. Moreover, a higher dose in rats revealed no evidence of an effect on postnatal development or reproductive performance in offspring. In rabbits, doses that were about 0.8 times the HE or higher were maternal toxic but did not cause malformations (1).

Ceftaroline fosamil was not mutagenic in multiple assays but was clastogenic in an in vitro assay. The latter effect was not observed after metabolic activation. No evidence of impaired fertility was observed in male and female rats at doses up to about 4 times the maximum recommended human dose based on BSA (1).

It is not known if ceftaroline fosamil or ceftaroline crosses the human placenta. The molecular weight of the prodrug (about 685) and lower molecular weight of the active agent, and the elimination half-life and low plasma protein binding, suggest that ceftaroline will cross to the embryo–fetus.

BREASTFEEDING SUMMARY

No reports describing the use of ceftaroline fosamil during human lactation have been located. The molecular weight of the prodrug (about 685) and lower molecular weight of the active agent, and the elimination half-life (about 2.7 hours) and low plasma protein binding (about 20%), suggest that both the prodrug and active agent will be excreted into breast milk. Moreover, low concentrations of other cephalosporins are excreted into milk and the presence in milk of this antibiotic should be expected. Three potential problems exist for the nursing infant: modification of bowel flora, direct effects on the infant, and interference with the interpretation of culture results if a fever workup is required. The American Academy of Pediatrics classifies other cephalosporin antibiotics as compatible with breastfeeding (for example, see Cefadroxil and Cefazolin).

CEFTAZIDIME

Antibiotic (Cephalosporin)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No detectable teratogenic risk with cephalosporin antibiotics was found in a large 2001 study (see Cephalexin).

FETAL RISK SUMMARY

Ceftazidime is a parenteral, semisynthetic cephalosporin antibiotic. Reproduction studies in mice and rats found no evidence of impaired fertility or fetal harm at doses up to 40 times the human dose (1). Cephalosporins are usually considered safe to use during pregnancy.

Ceftazidime administered at various stages of gestation, including the 1st trimester, crosses the placenta to the fetus and appears in the amniotic fluid (2–4). A brief English abstract of a 1983 Japanese report stated that levels in the cord blood and amniotic fluid following a 1-g IV dose exceeded the minimum inhibitory concentrations for most causative organisms but did not give specific values (2).

Nine women, undergoing abortion for fetuses affected by β -thalassemia major between 19 and 21 weeks' gestation, were given ceftazidime 1 g IM three times a day (3). At least three doses of the antibiotic were administered prior to abortion. The average concentrations of the drug in maternal serum at 2 and 4 hours after the last dose were 19.5 mcg/mL (range 14–25 mcg/mL) and 1.5 mcg/mL (range 1.4–1.6 mcg/mL), respectively. The simultaneous levels in amniotic fluid were 2.7 mcg/mL (range 1.3–4 mcg/mL) and 3.1 mcg/mL (range 2.2–3.9 mcg/mL), respectively, corresponding to approximately 14% and 207% of the maternal concentrations, respectively.

In a 1987 report, 30 women received a single 2-g IV bolus dose over 3 minutes of ceftazidime between 1 and 4 hours prior to undergoing abortion of a fetus at a mean gestational age of 10 weeks (range 7–12 weeks) (4). Antibiotic concentrations were determined in maternal plasma, placental tissue, and

amniotic fluid. In maternal plasma, mean levels ranged from 76 mcg/mL at 1 hour to 16.5 mcg/mL at 4 hours. Placental tissue concentrations were constant over this time interval, 12 mg/kg at 1 hour and 13 mg/kg at 4 hours, whereas the amniotic fluid concentration increased from 0.5 to 2.8 mcg/mL, respectively.

Increased renal elimination of ceftazidime was found in 12 women with asymptomatic bacteriuria treated with a 400-mg bolus dose, followed by a continuous infusion of 1 g for 4 hours (5). The initial treatment occurred during the 1st trimester, followed by treatments approximately 2 weeks before delivery at term and after cessation of breastfeeding. The mean renal clearances of the antibiotic during the three administrations were 143, 170, and 103 mL/minute, respectively.

BREASTFEEDING SUMMARY

Low concentrations of ceftazidime are excreted into breast milk (6). Eleven women were treated with 2 g of ceftazidime IV every 8 hours for endometritis following cesarean section. No mention was made as to whether the women were breastfeeding during treatment. Plasma and milk samples were collected between 2 and 4 days of therapy (total number of doses received averaged 12.6). The mean maternal plasma levels of the antibiotic just prior to a dose and 1 hour after a dose were 7.6 and 71.8 mcg/mL, respectively. The mean concentrations in breast milk before a dose and at 1 and 3 hours after a dose were 3.8, 5.2, and 4.5 mcg/mL, respectively. No accumulation of the antibiotic in milk was observed.

Three potential problems exist for the nursing infant exposed to ceftazidime in milk: modification of bowel flora, direct effects on the infant, and interference with the interpretation of culture results if a fever workup is required. The American Academy of Pediatrics classifies ceftazidime as compatible with breastfeeding (7).

CEFTIBUTEN

Antibiotic (Cephalosporin)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No detectable teratogenic risk with cephalosporin antibiotics was found in a large 2001 study (see Cephalexin).

FETAL RISK SUMMARY

No reports describing the use of ceftibuten in human pregnancy have been located. It is an oral, semisynthetic cephalosporin antibiotic. Reproduction studies in rats found no evidence of impaired fertility at doses up to approximately 43 times the human dose based on BSA (HD). No teratogenesis or fetal harm was found in studies with rats and rabbits at doses up to approximately 8.6 and 1.5 times, respectively, the HD (1).

BREASTFEEDING SUMMARY

No reports describing the use of ceftibuten during human lactation have been located. Low concentrations of other cephalosporins are excreted into milk, however, and the presence of ceftibuten in milk should be expected. Three potential problems exist for the nursing infant exposed to ceftibuten in milk: modification of bowel flora, direct effects on the infant, and interference with the interpretation of culture results if a fever workup is required. The American Academy of Pediatrics classifies other cephalosporin antibiotics as compatible with breastfeeding (for example, see Cefadroxil and Cefazolin).

CEFTIZOXIME

Antibiotic (Cephalosporin)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No fetal or newborn adverse effects following exposure to ceftizoxime during pregnancy have been reported. In addition, no detectable teratogenic risk with cephalosporin antibiotics was found in a large 2001 study (see Cephalexin).

FETAL RISK SUMMARY

Ceftizoxime is a parenteral, semisynthetic cephalosporin antibiotic. Reproduction studies in rats found no evidence of impaired fertility at doses up to approximately two times the maximum human daily dose based on BSA or, in rats and rabbits, of fetal harm (1).

The placental transfer of ceftizoxime and cefoperazone were studied in an in vitro perfused human placental system (2). The mean clearance indices for the two antibiotics were 0.126 and 0.037, respectively. The steady-state fetal concentrations of the two agents were 4–5 and 4 mcg/mL, respectively.

Following 1- or 2-g IV doses administered to women at term, peak cord blood levels occurred at 1–2 hours with concentrations ranging between 12 and 30 mcg/mL (3–7). Amniotic fluid concentrations were lower with peak levels of 10–20 mcg/mL at 2–3 hours. The mean fetal:maternal ratio reported in one group of patients after a 2-g IV dose was 0.28 (7). In a different study, maternal, fetal, and amniotic concentrations were measured in women who had received at least three doses of ceftizoxime 2 g at 8-hour intervals (8). Mean levels at delivery in the various compartments were 11.96, 24.54, and 43.45 mcg/mL, respectively. Cord blood levels averaged 1.6 times higher than maternal levels with average amniotic fluid concentrations 2.9 times those in the maternal serum (8). No adverse fetal or newborn effects were noted in any of the trials.

A 1993 report found that protein binding of ceftizoxime was significantly less

in fetal blood than in maternal blood (9). The mean binding to fetal proteins was 21.9% compared with maternal protein binding of 57.8%.

An abstract of a multicenter, double-blind, randomized study published in 1993 found no difference between ceftizoxime (2 g IV every 8 hours) (N =154) and placebo (N = 152) in the percentage of women with preterm premature rupture of the membranes who were undelivered at 7 days (10). Only noninfected women who were not in labor were enrolled in the study. A prospective, double-blind, placebo-controlled study published in 1995 found that ceftizoxime (2 g IV every 8 hours) had no effect on the interval to delivery or duration of pregnancy in women, with intact membranes and without chorioamnionitis, who were in preterm (<37 weeks' gestation) labor (11).

BREASTFEEDING SUMMARY

Ceftizoxime is excreted into breast milk in low concentrations (7,12). Mean levels following single doses of 1 and 2 g were less than 0.5 mcg/mL. Even though these levels are low, three potential problems exist for the nursing infant: modification of bowel flora, direct effects on the infant, and interference with the interpretation of culture results if a fever workup is required. Although not specifically listing ceftizoxime, the American Academy of Pediatrics classifies other cephalosporin antibiotics as compatible with breastfeeding (for example, see Cefadroxil and Cefazolin).

CEFTRIAZONE

Antibiotic (Cephalosporin)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No detectable teratogenic risk with cephalosporin antibiotics was found in a large 2001 study (see Cephalexin).

FETAL RISK SUMMARY

Ceftriaxone is a parenteral, semisynthetic cephalosporin antibiotic. Reproduction studies in rats found no evidence of impaired fertility or reproduction performance at a dose approximately 20 times the recommended human dose or, in mice, rats, and nonhuman primates, of embryotoxicity, fetotoxicity, or teratogenicity at doses approximately 20, 20, and 3 times, respectively, the recommended human dose (1).

A 1993 report described the pharmacokinetics of ceftriaxone, 2 g IV once daily for about 10 days, in nine women at 28 to 40 weeks' gestation who were being treated for chorioamnionitis or pyelonephritis (2). No accumulation of the antibiotic was noted and the pharmacokinetic profile was similar to healthy, nonpregnant adults. No adverse effects in fetuses or newborns were observed.

Peak levels in cord blood following 1- or 2-g IV doses occurred at 4 hours, with concentrations varying between 19.6 and 40.6 mcg/mL (1–8 hours) (3–5). Amniotic fluid levels over 24 hours ranged from 2.2 to 23.4 mcg/mL with peak levels occurring at 6 hours (3–5). Ceftriaxone concentrations in the first voided newborn urine were highly variable, ranging from 6 to 92 mcg/mL. Elimination half-lives from cord blood (7 hours), amniotic fluid (6.8 hours), and placenta (5.4 hours) were nearly identical to maternal serum (3,4,6). No adverse effects in the newborns were mentioned.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 60 newborns had been exposed to ceftriaxone during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Four (6.7%) major birth defects were observed

(three expected), including three cardiovascular defects (one expected). No anomalies were observed in five other categories of defects (oral clefts, spina bifida, polydactyly, limb reduction defects, and hypospadias) for which specific data were available. A possible association between ceftriaxone and cardiovascular defects is suggested, but other factors, such as the mother's disease, concurrent drug use, and chance, may be involved. However, other cephalosporin antibiotics from this study have shown possible associations with congenital malformations (see also Cefaclor, Cephalexin, and Cephadrine).

Ceftriaxone, 1 g IV daily, has been used in the treatment of pyelonephritis occurring in the second half of pregnancy (7). No adverse fetal outcomes attributable to the drug were observed.

Ceftriaxone 1 g IV has been used for preoperative prophylaxis prior to emergency cesarean section (8). Amniotic fluid and fetal serum levels ranged from 0.016 to 0.25 mcg/mL (mean 0.085 mcg/mL) and from 0.66 to 18.4 mcg/mL (mean 4.6 mcg/mL), respectively.

Gonorrhea infecting 114 pregnant women in the 2nd trimester was treated with a single, 250-mg IM dose of ceftriaxone in a study published in 1993 (9). The treatment was compared with approximately similar numbers of pregnant women treated with spectinomycin or amoxicillin with probenecid. Ceftriaxone and spectinomycin were similar in efficacy and both were superior to the amoxicillin/probenecid regimen. A 20-year-old woman with endocarditis due to *Neisseria sicca* was treated for 4 weeks with ceftriaxone, 2 g IV every 12 hours, late in the 3rd trimester (10). She eventually delivered a term, small-for-gestational-age female infant, whose low weight was attributed to the mother's chronic disease state.

BREASTFEEDING SUMMARY

Ceftriaxone is excreted into breast milk in low concentrations. Following either 1- or 2-g IV or IM doses, peak levels of 0.5–0.7 mcg/mL occurred at 5 hours, approximately 3%–4% of maternal serum (3,4). High protein binding in maternal serum probably limited transfer to the milk (3,4). The antibiotic was still detectable in milk at 24 hours (3). Elimination half-lives after IV and IM doses were 12.8 and 17.3 hours, respectively (3). Chronic dosing would eventually produce calculated steady-state levels in 1.5–3 days in the 3–4 mcg/mL range (4). Although these levels are low, three potential problems exist for the nursing infant: modification of bowel flora, direct effects on the infant, and interference with the interpretation of culture results if a fever workup is required. The American Academy of Pediatrics classifies ceftriaxone as compatible with

breastfeeding (11).

CEFUROXIME

Antibiotic (Cephalosporin)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No detectable teratogenic risk with cefuroxime or other cephalosporin antibiotics was found in a large 2001 study (see Cephalexin).

FETAL RISK SUMMARY

Cefuroxime is an oral and parenteral, semisynthetic cephalosporin antibiotic. Reproduction studies in rats have found no evidence of impaired fertility at doses up to 9 times the maximum recommended human dose based on BSA (MRHD) or, mice and rats, of fetal harm at doses up to 23 times the MRHD (1).

Cefuroxime readily crosses the placenta in late pregnancy and labor, achieving therapeutic concentrations in fetal serum and amniotic fluid (2–7). Therapeutic antibiotic levels in infants can be demonstrated up to 6 hours after birth with measurable concentrations persisting for 26 hours. The pharmacokinetics of cefuroxime in pregnancy have been reported (8). The antibiotic has been used for the treatment of pyelonephritis in pregnancy (9). Adverse effects in the newborn after in utero exposure have not been observed.

In women at 15–35 weeks' gestation, a single 750-mg IV dose produced mean serum concentrations in mothers, hydropic fetuses, and fetuses with oligohydramnios of 7.4, 6.2, and 4.9 mcg/mL, respectively (10). The concentrations did not correlate with gestational age. Nine women with premature rupture of the membranes at 27–33 weeks' gestation received 1.5 g IV of cefuroxime three times daily (11). The mean concentrations of the antibiotic in the mothers (1 hour after a dose), umbilical cord plasma, placenta, and membranes were 35.0 mcg/mL, 3.0 mcg/mL, 11.2 mcg/g, and 35.6 mcg/g, respectively.

In a surveillance study of Michigan Medicaid recipients involving 229,101

completed pregnancies conducted between 1985 and 1992, 143 newborns had been exposed to cefuroxime during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Three (2.1%) major birth defects were observed (six expected), but no anomalies were observed in six categories of defects for which specific data were available (cardiovascular defects, oral clefts, spina bifida, polydactyly, limb-reduction defects, and hypospadias). These data do not support an association between the drug and congenital defects (see also Cefaclor, Cephalexin, and Cephadrine for contrasting results).

The pregnancy outcomes of 106 women exposed in the 1st trimester to cefuroxime were described in a 2000 study (12). Compared with 106 matched controls, there was no difference in pregnancy outcomes in terms of live births, spontaneous abortions, gestational age at birth, prematurity, birth weight, fetal distress, method of delivery, and major or minor malformations. Induced abortions, however, occurred in significantly more cefuroxime-exposed women than in controls, possibly due to misinformation and misperception of the risk the antibiotic posed to a pregnancy (12).

BREASTFEEDING SUMMARY

Cefuroxime is excreted into breast milk in low concentrations (1). Even though the levels are low, three potential problems exist for the nursing infant exposed to cefuroxime in milk: modification of bowel flora, direct effects on the infant, and interference with the interpretation of culture results if a fever workup is required. Although not specifically listing cefuroxime, the American Academy of Pediatrics classifies other cephalosporin antibiotics as compatible with breastfeeding (for example, see Cefadroxil and Cefazolin).

CELECOXIB

Nonsteroidal Anti-inflammatory

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 1st and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Celecoxib has been used in human pregnancy as a tocolytic. The animal data are suggestive of a low risk for congenital malformations. Moreover, a brief 2003 editorial on the potential for nonsteroidal anti-inflammatory drug (NSAID)-induced developmental toxicity concluded that NSAIDs, and specifically those with greater COX-2 affinity, had a lower risk of this toxicity in humans than aspirin (1). The use of first-generation NSAIDs during the latter half of pregnancy has been associated with oligohydramnios and premature closure of the ductus arteriosus (e.g., see Indomethacin) (2). Persistent pulmonary hypertension of the newborn may occur if NSAIDs are used in the 3rd trimester close to delivery (2,3). These drugs also have been shown to inhibit labor and prolong pregnancy, both in humans (4) and in animals (5). Similar effects should be expected if celecoxib is used during the 3rd trimester or close to delivery. Women attempting to conceive should not use any prostaglandin synthesis inhibitor, including celecoxib, because of the findings in a variety of animal models that indicate these agents block blastocyst implantation (6,7). Moreover, as noted above, NSAIDs have been associated with spontaneous abortions (SABs) and congenital malformations. The absolute risk for these defects, however, appears to be low. If celecoxib is used in pregnancy for the treatment of rheumatoid arthritis, healthcare professionals are encouraged to call the toll-free number (877-311-8972) for information about patient enrollment in the OTIS Rheumatoid Arthritis study.

FETAL RISK SUMMARY

Celecoxib is a second-generation NSAID that inhibits prostaglandin synthesis

via the inhibition of cyclooxygenase-2 (COX-2). It is in the same NSAID subclass (COX-2 inhibitors) as rofecoxib and valdecoxib. In therapeutic concentrations, it does not inhibit, as do first-generation NSAIDs, the cyclooxygenase-1 (COX-1) isoenzyme. Celecoxib is indicated for the relief of the signs and symptoms of osteoarthritis and rheumatoid arthritis (8).

Celecoxib was not mutagenic or clastogenic in Chinese hamster ovary cells or clastogenic in an in vivo micronucleus test in rat bone marrow. Administration to female rats of oral doses that were about six times the maximum recommended human dose based on AUC at 200 mg twice a day (MRHD) resulted in preimplantation and postimplantation losses and reduced embryo–fetal survival, a natural consequence of its inhibition of prostaglandin synthesis (8).

Reproduction studies have been conducted in rats and rabbits. In pregnant rats, a dose-related increase in diaphragmatic hernias was observed in one of two studies at doses about six times the MRHD. No teratogenic effects occurred in pregnant rabbits at doses equal to the MRHD, but at doses about two times the MRHD, an increased incidence of fetal alterations (fused ribs and fused, misshapen sternbrae) was observed. No evidence of delayed labor or parturition at doses up to about seven times the MRHD was observed in rats (8).

Two studies in pregnant rabbits were designed to test the hypothesis that celecoxib was effective in preventing preterm delivery and did not adversely affect fetal ductus arteriosus patency (9,10). In the first study, the rabbits received a daily dose that was about 0.5 times the MRHD for differing periods starting at day 13 of gestation (9). Concentrations of prostanoids, cytokines, and nitric oxide were altered by the treatment, resulting in decrease in the incidence compared with controls of preterm parturition. In the second study, no adverse effect on the fetal ductus arteriosus was observed (10).

No reports describing the placental transfer of celecoxib have been located. The molecular weight (about 381) is low enough that passage to the fetus should be expected. Celecoxib metabolism is mediated by the cytochrome P450 2C9 enzyme, resulting in at least three inactive metabolites (8). Women, in whom metabolism by this enzyme is known or suspected to be deficient, may have abnormally high plasma levels of celecoxib and, thus, more of the drug will be available for placental transfer.

A combined 2001 population-based observational cohort study and a case–control study estimated the risk of adverse pregnancy outcome from the use of NSAIDs (11). The use of NSAIDs during pregnancy was not associated with

congenital malformations, preterm delivery, or low birth weight, but a positive association was discovered with SABs. A similar study, also published in 2001, failed to find a relationship, in general, between NSAIDs and congenital malformations, but did find a significant association with cardiac defects and orofacial clefts (12). In addition, a 2003 study found a significant association between exposure to NSAIDs in early pregnancy and SABs (13). (See Ibuprofen for details on these three studies.)

A 2006 case–control study found a significant association between congenital anomalies, specifically cardiac septal defects, and the use of NSAIDs in the 1st trimester (14). A population-based pregnancy registry (N = 36,387) was developed by linking three databases in Quebec. (See Naprosyn for other study details.) Case infants were those with any congenital anomaly diagnosed in the first year of life and were compared with matched controls. There were 93 infants (8.8%) with congenital defects from 1056 mothers who had filled prescriptions for NSAIDs in the 1st trimester. In controls, there were 2478 infants (7%) with anomalies from 35,331 mothers who had not filled such a prescription. The adjusted odds ratio (OR) was 2.21 (95% CI 1.72–2.85). The adjusted OR for cardiac septal closure was 3.34 (95% CI 1.87–5.98). There also was a significant association with anomalies of the respiratory system 9.55 (95% CI 3.08–29.63), but this association disappeared when cases coded as “unspecified anomaly of the respiratory system” were excluded. For the cases involving septal closure, 61% were atrial septal defects and 31% were ventricular septal defects. There were no significant associations for oral clefts or defects involving other major organ systems. The five most common NSAIDs were naproxen (35%), ibuprofen (26%), rofecoxib (15%), diclofenac (9%), and celecoxib (9%). Among these agents, the only significant association was for ibuprofen prescriptions in the 1st trimester and congenital defects (p <0.01) (14).

An in vitro study demonstrated that celecoxib had significant uterine relaxant effects (15). Celecoxib was more potent, in this regard, than nimesulide or meloxicam. A 2002 randomized, double-blind, placebo-controlled study compared the tocolytic effects of celecoxib (100 mg orally every 12 hours for 4 doses) and indomethacin (100 mg rectally, then 50 mg orally every 6 hours for 7 doses) (16). The subjects, 12 in each group, were in preterm labor at 24 to 34 weeks’ gestation. Partial premature constriction of the fetal ductus arteriosus occurred in the indomethacin group, but not in the celecoxib group. A transient decrease in amniotic fluid volume was observed in both groups, but more so with indomethacin. Both drugs were equally effective in the

maintenance of tocolysis, but the authors concluded that the safety of celecoxib was superior to that of indomethacin (16).

A randomized trial in 2007 compared the tocolytic effects of celecoxib (200 mg/day) and IV magnesium sulfate, each given for 48 hours (17). Gestational ages were 24–34 weeks and each group had 52 women. No statistical difference (81% vs. 87%) in the arrest of labor was found and there were no severe maternal or neonatal complications (17).

BREASTFEEDING SUMMARY

Celecoxib is excreted into human breastmilk (18–20). A 40-year-old woman who was breastfeeding her 5-month-old daughter was admitted to the hospital for surgery. In the postoperative period, she received four doses of celecoxib (100 mg twice/day) in addition to other medications. Starting about 5 hours after her last dose, four milk samples were obtained by hand expression over a 24-hour interval. The elimination half-life range was 4.0–6.5 hours. These data suggest that celecoxib would be eliminated from breast milk about 24 hours after the last dose. Although maternal plasma was not obtained, the estimated milk:plasma ratios (based on reported adult plasma levels) were 0.27–0.59. The infant did not resume breastfeeding until 48 hours after the last dose. If she had nursed, the estimated maximum infant dose would have been about 40 mcg/kg/day (18).

A 2004 study of five breastfeeding women taking celecoxib, three at steady state (200 mg once daily) and two after a single 200-mg dose, measured a mean milk concentration of 66 mcg/L and a mean milk:plasma ratio of 0.23 (19). The mean absolute infant dose was 9.8 mcg/kg/day and the relative infant dose was 0.30% of the mother's weight-adjusted dose. Plasma concentrations in two infants at 17 and 22 months of age, who were nursing every 3–4 hours during the day and once at night, were below the limit of detection (10 mcg/L) (19).

Six lactating women, who stopped nursing after taking celecoxib, were included in a 2005 report (20). After a single 200-mg dose, the median absolute infant dose was 13 mcg/kg/day and the relative infant dose was 0.23% of the mother's weight-adjusted dose.

Several first-generation NSAIDs are considered low risk during nursing (e.g., see Diclofenac, Fenoprofen, Flurbiprofen, Ibuprofen, Ketoprofen, Ketorolac, and Tolmetin) and, based on the available data, celecoxib, at the doses studied, can be similarly classified. Although only 3 of the 12 patients studied were breastfeeding when taking celecoxib, the authors of the studies concluded

that celecoxib was unlikely to pose a risk to a nursing infant.

CELIPROLOL

[Withdrawn from the market. See 9th edition.]

CENTRUROIDES (SCORPION) IMMUNE F(ab')₂ (EQUINE)

Antidote

PREGNANCY RECOMMENDATION: Maternal Benefit >> Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of Centruroides antivenom in pregnancy have been located. Animal reproduction studies have not been conducted, and the absence of human pregnancy experience prevents any assessment of the embryo–fetal risk. It appears, however, that the maternal benefit outweighs the unknown embryo–fetal risk. Therefore, if indicated, the antivenom should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Centruroides antivenom is prepared from horse plasma immunized to venom from five different species of scorpions. It is given IV to bind and neutralize venom toxins, facilitating redistribution away from target tissues and elimination from the body. The antivenom is indicated for the treatment of clinical signs of scorpion envenomation. The half-life is 159 ± 57 hours (1).

Reproduction studies in animals have not been conducted. Moreover, studies for carcinogenic and mutagenic potential have not been conducted, nor have been fertility impairment studies (1).

It is not known if the antivenom crosses the human placenta. The molecular weight of the antivenom was not given by the manufacturer. The molecular weight is probably very high, because the product is a polyvalent preparation of equine immune globulin F(ab')₂ fragments. Exposure of the fetus, at least in early pregnancy, might be clinically insignificant. However, the long elimination half-life will allow the antivenom to be at the maternal–fetal interface for a several days.

BREASTFEEDING SUMMARY

No reports describing the use of Centruroides antivenom during human lactation have been located. The molecular weight of the antivenom was not given by the manufacturer. The molecular weight probably is very high, because the product is a polyvalent preparation of equine immune globulin F(ab')₂ fragments. Moreover, the antivenom has a long elimination half-life (159 ± 57 hours) and, if it was given shortly before birth, this might allow excretion of small amounts during the colostrum phase. Although the effect of any exposure on nursing is unknown, the antivenom would most likely be digested in the infant's gut.

CEPHALEXIN

Antibiotic (Cephalosporin)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Although some data suggest an association with congenital malformations, most studies have found that cephalosporin antibiotics, in general, are safe to use in pregnancy.

FETAL RISK SUMMARY

Cephalexin is an oral, semisynthetic cephalosporin antibiotic. Reproduction studies found no evidence in rats, at doses up to 500 mg/kg, of impaired fertility or reproductive performance or, in mice and rats, of fetal harm (1).

Several published reports have described the administration of cephalexin to pregnant patients in various stages of gestation (2–12). None of these has linked the use of cephalexin with congenital defects or toxicity in the newborn. However, even though cephalosporins are usually considered safe to use during pregnancy, a surveillance study described below found results contrasting to the published data.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 3613 newborns had been exposed to cephalexin during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 176 (4.9%) major birth defects were observed (154 expected). Specific data were available for six defect categories, including (observed/expected) 44/36 cardiovascular defects, 11/5 oral clefts, 3/2 spina bifida, 3/10 polydactyly, 1/6 limb reduction defects, and 8/9 hypospadias. The data for total defects, cardiovascular defects, and oral clefts are suggestive of an association between cephalexin and congenital defects, but other factors, such as the mother's disease, concurrent drug use, and chance, may be involved. However, similar findings were measured for another cephalosporin antibiotic with more than a thousand exposures (see Cefaclor). Positive results were also suggested for cephradine (339 exposures)

but not for cefadroxil (722 exposures) (see Cephadrine and Cefadroxil). In contrast, other anti-infectives with large cohorts (see Ampicillin, Amoxicillin, Penicillin G, Erythromycin, and Tetracycline) had negative findings.

Transplacental passage of cephalexin has been demonstrated only near term (2,3). Following a 1-g oral dose, peak concentrations for maternal serum, cord serum, and amniotic fluid were about 34 (1 hour), 11 (4 hours), and 13 mcg/mL (6 hours), respectively (3). Patients in whom labor was induced were observed to have falling concentrations of cephalexin in all samples when labor was prolonged beyond 18 hours (4). In one report, all fetal blood samples gave a negative Coombs' reaction (2).

The effect of postcoital prophylaxis with a single oral dose of either cephalexin (250 mg) or nitrofurantoin macrocrystals (50 mg) starting before or during pregnancy in 33 women (39 pregnancies) with a history of recurrent urinary tract infections was described in a 1992 reference (11). A significant decrease in the number of infections was documented without fetal toxicity.

The manufacturer has unpublished information on 46 patients treated with cephalexin during pregnancy (C.L. Lynch, personal communication, Dista Products, 1981). Two of these patients received the drug from 1 to 2 months prior to conception to term. No effects on the fetus attributable to the antibiotic were observed. Follow-up examination on one infant at 2 months was normal.

A 2001 study used the Hungarian Case-Control Surveillance of Congenital Abnormalities (1980–1996) database to examine the association between cephalosporins (cephalexin, cefaclor, cefamandole, cefoperazone, cefotaxime, ceftibuten, and cefuroxime) and birth defects (12). Cases were drawn from 22,865 pregnant women who had fetuses or newborn infants with congenital abnormalities. Matched controls were obtained from pregnant women who had infants without defects. Most of the 308 case women were treated with cephalexin. No detectable teratogenic risk was found.

BREASTFEEDING SUMMARY

Cephalexin is excreted into breast milk in low concentrations (13,14). A 1-g oral dose given to six mothers produced peak milk levels at 4–5 hours averaging 0.51 mcg/mL (range 0.24–0.85 mcg/mL) (13). Mean milk:plasma ratios at 1, 2, and 3 hours were 0.008, 0.021, and 0.14, respectively.

A 30-year-old, penicillin-allergic, breastfeeding woman developed erysipelas/cellulitis in her breasts 9 days after a cesarean section (14). She was treated with IV cephalothin, 1 g every 6 hours for 3 days, then oral cephalexin and probenecid (both 500 mg four times daily). Severe diarrhea,

discomfort, and crying were observed in the nursing infant during IV therapy and continued with oral therapy, but at a decreased level. The symptoms had nearly resolved after partial replacement of breast milk with goat's milk for 7 days. Sixteen days after initiation of oral therapy, the woman collected 12 milk samples (6 pairs of fore- and hind-milk) by manual expression over a 16-hour interval. The average concentrations of cephalexin and probenecid and cephalexin were 0.745 and 0.964 mcg/mL, respectively. The concentrations of the two substances in fore- and hind-milk were not significantly different. The infant doses, based on the milk AUC and an estimated intake of 150 mL/kg/day, of cephalexin and probenecid were 0.5% and 0.7%, respectively, of the mother's weight-adjusted dose. Although these doses were thought to be low enough to exclude systemic effects, it was concluded that cephalexin was the most likely cause of the diarrhea (14).

The above two studies are not comparable because of the dosage and duration. However, they do suggest that probenecid markedly increases the milk concentration of cephalexin. In the absence of any data, it is not known if a lower milk concentration would also have caused the diarrhea observed in the infant. Nevertheless, three potential problems exist for a nursing infant exposed to antibiotics in milk: modification of bowel flora, direct effects on the infant, and interference with the interpretation of culture results if a fever workup is required. Although not specifically listing cephalexin, the American Academy of Pediatrics classifies other cephalosporin antibiotics as compatible with breastfeeding (for example, see Cefadroxil and Cefazolin).

CERTOLIZUMAB PEGOL

Immunologic Agent (Immunomodulator)

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

The limited human pregnancy experience suggests that certolizumab pegol is low risk for embryo–fetal harm. In 2011, the World Congress of Gastroenterology stated, “Certolizumab pegol in pregnancy is considered to be low risk and compatible with use during conception and pregnancy in women” (1). Animal reproduction studies could not be conducted because the antibody is human specific. However, studies in rats with a rodent-specific antibody similar to certolizumab pegol found no evidence of fetal harm. There is some similarity between the action of immunomodulators with anti-TNF α activity and the human teratogen thalidomide, a drug that also decreases the activity of TNF α . (See Infliximab and Thalidomide.) However, decreased production of TNF α may not be a primary cause of the teratogenicity of thalidomide. Theoretically, TNF α antagonists could interfere with implantation and ovulation, but this has not been shown clinically (2).

FETAL RISK SUMMARY

Certolizumab pegol is a recombinant, humanized antibody Fab' fragment that blocks human tumor necrosis factor alpha (TNF α). TNF α is a pro-inflammatory cytokine with a central role in inflammatory processes. Certolizumab is in the same subclass of immunomodulators (blockers of TNF α activity) as adalimumab, golimumab, and infliximab. It is conjugated with polyethylene glycol (PEG) to decrease the renal clearance and metabolism of the antibody. The agent is given by SC injection. Certolizumab pegol is indicated for reducing the signs and symptoms of Crohn's disease and maintaining clinical response in adult patients with moderately to severely active disease that have had an

inadequate response to conventional therapy. The terminal elimination half-life is about 14 days (3).

Reproduction studies in animals have not been conducted with certolizumab pegol because it does not cross-react with mouse or rat TNF α . However, studies were conducted in rats using a rodent anti-murine TNF α pegylated Fab' fragment similar to certolizumab pegol. Doses up to 100 mg/kg revealed no evidence of impaired fertility or fetal harm (3). Although a comparison to the human dose was not specified, the maximum dose was about 17 times the human dose of 5.7 mg/kg from a 400-mg dose given to a 70-kg patient.

Long-term studies to evaluate the carcinogenic potential of certolizumab pegol have not been conducted, but the agent was not genotoxic in multiple assays. The rodent anti-murine TNF α pegylated Fab' fragment had no effect on the fertility and reproductive performance of male or female rats (3).

Although the molecular weight is very high (about 91,000), certolizumab (but not PEG) crosses the human placenta to the fetus in late gestation (4). In 12 newborns (2 sets of twins) at a mean gestational age of 37.8 weeks (range 36–40 weeks), the median (range) of certolizumab concentrations in cord blood as a percentage of maternal concentration was 3.9% (1.5%–24%). The concentrations in cord blood and in the infant were all \leq 1.65 mcg/mL and were undetectable in four cord blood samples and three infants (lower limit of quantification <0.41 mcg/mL). PEG was not detected in any cord blood or infant. No birth defects or neonatal intensive care unit stays occurred in any infant (4).

BREASTFEEDING SUMMARY

Certolizumab was not detected in several milk samples from a mother who was breastfeeding her infant (4). The mother was receiving 400 mg every 4 weeks and had received a dose 1 week before delivery and 3 weeks after delivery. At birth, the levels in the cord blood level and infant were 0.94 mcg/mL and 1.02 mcg/mL, respectively. At 4 weeks post-birth, the levels in the mother and infant were 22.93 mcg/mL and 0.84 mcg/mL (3.7%), respectively. Breast milk samples were obtained at 1 and 2 weeks post-birth and at 4 hours, 3 days, and 6 days after the dose at 3 weeks. Concentrations in each of the five milk samples were undetectable. PEG was not detected in the infant (4).

CETIRIZINE

Antihistamine

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Cetirizine is not an animal teratogen, and there is no evidence in human pregnancy that the antihistamine presents a significant risk to the fetus. However, the number of human pregnancy exposures is too few to adequately assess the potential risk. Although cetirizine appears unlikely to be a major human teratogen, an oral first-generation agent, such as chlorpheniramine or tripeleminamine, should be considered if antihistamine therapy during pregnancy (especially in the 1st trimester) is required. Cetirizine and loratadine were considered acceptable alternatives, except during the 1st trimester, if a first-generation agent was not tolerated (1–3). The use of cetirizine as an antiemetic needs further study.

FETAL RISK SUMMARY

The antihistamine, cetirizine, is a second-generation, orally active, selective peripheral H₁-receptor antagonist. It is indicated for the relief of seasonal and perennial allergic rhinitis and for the treatment of chronic urticaria. The agent is a human metabolite of hydroxyzine.

Reproduction studies in mice, rats, and rabbits at oral doses up to 40, 180, and 220 times the maximum recommended human daily dose based on BSA (MRHD), respectively, revealed no teratogenic effects (4).

It is not known if cetirizine crosses the human placenta to the fetus. The molecular weight (about 462 for the dihydrochloride salt) is low enough that transfer to the fetus should be expected.

A prospective controlled study published in 1997 evaluated the teratogenic risk of cetirizine and hydroxyzine (see also Hydroxyzine) in human pregnancy (5). A total of 120 pregnancies (2 sets of twins) exposed to either cetirizine (N

= 39) or hydroxyzine (N = 81) during pregnancy were identified and compared with 110 controls. The control group was matched for maternal age, smoking, and alcohol use. The drugs were taken during the 1st trimester in 37 (95%) of the cetirizine exposures and in 53 (65%) of the hydroxyzine cases for a variety of indications (e.g., rhinitis, urticaria, pruritic urticarial papules and plaques of pregnancy, sedation, and other nonspecified reasons). Fourteen spontaneous abortions (cetirizine 6, hydroxyzine 3, controls 5) and 11 induced abortions (hydroxyzine 6, controls 5) occurred in the three groups. Among the live births, there were no statistical differences among the groups in birth weight, gestational age at delivery, rate of cesarean section, or neonatal distress. Two minor anomalies were observed in liveborn infants exposed to cetirizine during organogenesis; one had an ectopic kidney and one had undescended testes. No major abnormalities were seen in this group. In the hydroxyzine group, two of the live births had major malformations; one had a ventricular septal defect and one a complex congenital heart defect (also exposed to carbamazepine). A third infant, exposed after organogenesis, also had a ventricular septal defect. Minor abnormalities were observed in four hydroxyzine-exposed infants: one case each of hydrocele, inguinal hernia, hypothyroidism (mother also taking propylthiouracil), and strabismus. In the control group, no major malformations were observed, but five infants had minor defects (dislocated hip, growth hormone deficiency, short lingual frenulum, and two unspecified defects). Statistically, there were no differences between the groups in outcome (5).

A recent review compared the published pregnancy outcomes in terms of congenital malformations of various first- and second-generation antihistamines (6). Based on the one study above, the authors calculated a relative risk for cetirizine of 1.2 (95% confidence interval 0.1–11.7). They concluded that in pregnancy, chlorpheniramine is the oral antihistamine of choice and that diphenhydramine should be used if a parenteral antihistamine is required (6).

A 1998 noninterventional observational cohort study described the outcomes of pregnancies in women who had been prescribed one or more of 34 newly marketed drugs by general practitioners in England (7). Data were obtained by questionnaires sent to the prescribing physicians one month after the expected or possible date of delivery. In 831 (78%) of the pregnancies, a newly marketed drug was thought to have been taken during the 1st trimester with birth defects noted in 14 (2.5%) singleton births of the 557 newborns (10 sets of twins). In addition, two birth defects were observed in aborted fetuses. However, few of the aborted fetuses were examined. Cetirizine was taken during the 1st trimester in 20 pregnancies. The outcomes of these pregnancies

included 4 spontaneous abortions, 1 elective abortion, and 16 normal-term infants (1 set of twins) (7). Although this study found no major birth defects, it lacked the sensitivity to identify minor anomalies because of the absence of standardized examinations. Further, late-appearing major defects may also have been missed because of the timing of the questionnaires.

A 2000 publication reported the antiemetic effects of cetirizine in 60 women who were using the antihistamine (10 mg/day) for the treatment of allergies during pregnancy (8). A control group of pregnant women, matched for the use of pyridoxine (vitamin B6) but who were not taking an antihistamine, was used for comparison. The cetirizine group had a significantly lower rate of nausea and vomiting (7% vs. 37%, $p = 0.0001$) (8). No pregnancy outcome data were provided.

The safety of cetirizine during pregnancy was evaluated in a 2008 prospective observational cohort study (9). A total of 196 pregnant women who were exposed to cetirizine in the 1st trimester were compared with 1686 control women not exposed to the antihistamine. No significant differences were observed in four outcomes (odds ratio; confidence interval): major birth defects (1.07; 0.21–3.59), spontaneous abortions (0.97; 0.54–1.65), preterm births (0.76; 0.35–1.5), and mean birth weight of term infants ($p = 0.13$) (9).

BREASTFEEDING SUMMARY

No published reports describing the use of cetirizine during human lactation have been located, but the manufacturer states that the antihistamine is excreted into human milk. This would be consistent with the relatively low molecular weight (about 462 for the dihydrochloride salt). The effect of this exposure on a nursing infant is unknown, but sedation is a possibility.

CETUXIMAB

Antineoplastic

PREGNANCY RECOMMENDATION: No Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of cetuximab in human or animal pregnancies have been located. It also is not known if the antibody crosses the placenta, but if it does it could disrupt normal embryo–fetal development. Cetuximab binds to epidermal growth factor receptor (EGFR) that is involved in the control of prenatal development and may be essential for normal organogenesis, proliferation, and differentiation in the embryo (1). Because of the potential for embryo and fetal harm, the antibody should not be used in pregnancy. In addition, based on the very long half-life, a woman should not conceive for about 60 days after the last dose. However, head and neck and colorectal cancers can be fatal, so if a woman requires cetuximab and informed consent is obtained, treatment should not be withheld because of pregnancy. If an inadvertent pregnancy occurs, the woman should be advised of the potential risk for severe adverse effects in the embryo and fetus.

FETAL RISK SUMMARY

Cetuximab is a recombinant, human/mouse chimeric monoclonal antibody that is given as a once-weekly IV infusion. It specifically binds to EGFR and competitively inhibits the binding of EGF and other ligands. Cetuximab, in combination with radiation therapy, is indicated for the treatment of locally or regionally advanced squamous cell carcinoma of the head and neck. As a single agent, it is indicated for the treatment of patients with recurrent or metastatic squamous cell carcinoma of the head and neck for which prior platinum-based therapy has failed. It also is indicated, either alone or in combination with irinotecan, for the treatment of EGFR-expressing, metastatic

colorectal carcinoma in patients who are refractory or intolerant of irinotecan-based chemotherapy. The mean half-life is about 112 hours (range 63–230 hours).

Cetuximab may cause severe, infusion-related toxicity, including hypotension and other adverse effects. Premedication with an antihistamine (e.g., 50 mg diphenhydramine IV) is recommended (1). Hypotension in a pregnant woman could have deleterious effects on placental perfusion, resulting in embryo and fetal harm.

Animal reproduction studies have not been conducted with cetuximab. Neither have long-term studies for carcinogenicity. However, no mutagenic or clastogenic effects were noted in tests. In a 39-week toxicity study in female cynomolgus monkeys receiving 0.4–4 times the human dose based on BSA, a tendency for impairment of menstrual cycling was observed, as revealed by increased incidences of irregular or absence of cycles compared with controls. These effects began at week 25 and were continued through the 6-week recovery period. No effects on fertility were noted in male monkeys (1).

It is not known if cetuximab crosses the human placenta. The high molecular weight (about 152,000) suggests that it will not cross. However, human immunoglobulin (IgG) does cross and, therefore, cetuximab may also cross (1).

BREASTFEEDING SUMMARY

No reports describing the use of cetuximab during lactation have been located. The very high molecular weight (about 152,000) suggests that it will not be excreted into breast milk. However, human immunoglobulin (IgG) is excreted into milk and, therefore, cetuximab may also be excreted (1). The effect of this potential exposure on a nursing infant is unknown, but immunosuppression and other severe adverse effects are potential complications.

CEVIMELINE

Parasympathomimetic (Cholinergic)

PREGNANCY RECOMMENDATION: No Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No studies describing the use of cevimeline during human pregnancy have been located. The very limited animal data that did not include exposure during organogenesis, and the lack of any reported human pregnancy experience, prevents an assessment of the risk that this drug presents to a fetus.

FETAL RISK SUMMARY

Cevimeline is an oral cholinergic agonist indicated for the treatment of dry mouth in patients with Sjögren's syndrome.

In reproduction studies with rats, a dose, approximately five times the recommended human dose for a 60-kg person based on BSA, given from 14 days before mating through day 7 of gestation caused a reduction in the mean number of implantations. This effect may have been due to maternal toxicity (1).

No studies examining the placental transfer of cevimeline have been located. The molecular weight (about 245 for the hydrated salt form) is low enough, however, that passage to the fetus should be expected.

BREASTFEEDING SUMMARY

No reports describing the use of cevimeline in human lactation have been located. The molecular weight (about 245 for the hydrated salt form) suggests that excretion into breast milk should be expected. Because the effect of this exposure on a nursing infant is unknown, combined with the lack of data on the amount of drug that may be in milk, women who are taking cevimeline should probably not breastfeed.

CHAMOMILE

Herb

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The only reports describing the use of chamomile in human pregnancy involve its use for morning sickness. Some sources recommend avoiding excessive use of oral chamomile in pregnancy because the herb is thought to have uterine stimulant, emmenagogue, and abortifacient properties (1–4). Neither the period of pregnancy when these effects occurred nor the doses producing them have been stated or quantified. There is no information describing these effects after external use of chamomile. Because of the very limited reporting of human pregnancy experience and the absence of relevant animal reproduction data, the best course is to avoid oral chamomile during pregnancy. However, the risk from consumption of the herb, especially from occasional use, must be very rare because chamomile has been used for thousands of years.

FETAL RISK SUMMARY

Chamomile may refer to the German (*Matricaria chamomilla* or *M. recutita*) or Roman (*Anthemis nobilis* or *Chamaemelum nobile*) chamomiles. Both plants have been called “true chamomile” (1,5). The fragrant flower heads of the plants are dried and used as teas and extracts. Although the plants are different, the main chemicals in the flower heads are the same: chamazulene, apigenin, bisabolol, and angelic acid (1). Regardless of the source, chamomile and its teas have been used for thousands of years for their astringent, antispasmodic, sedative, anxiolytic, and antibacterial properties (1–3,5,6). There are numerous indications based on the properties, but few have been studied or have proven efficacy (7,8).

Animal reproduction studies have not been conducted with chamomile.

However, a study in pregnant rats and rabbits using bisabolol found no evidence of teratogenicity or developmental toxicity after chronic administration of 1 mL/kg (1,4,6). However, in mice, high doses (3 mg/kg) of bisabolol were associated with resorptions of fetuses and reduced birth weight (4,6).

Nurse-midwives frequently prescribe chamomile teas for the treatment of morning sickness (9,10). However, many of these healthcare professionals thought that the use of chamomile teas were unsafe in pregnancy (10).

Both plant sources of chamomile contain coumarin compounds: umbelliferone (in German chamomile) and scopoletin-7-glucoside (in Roman chamomile) (6). Because of the presence of the coumarins, one review cautioned that the use of both chamomiles was a concern for pregnant women with coagulation disorders (11).

BREASTFEEDING SUMMARY

No reports describing the use of chamomile during lactation have been located. However, chamomile-containing teas have been used to treat colic in very young infants and children (6,12,13). Both German and Roman chamomiles have been used for thousands of years. The absence of reported exposures suggests that there is little or no risk from consumption of chamomile during breastfeeding.

CHENODIOL

Gastrointestinal Agent (Gallstone Solubilizing Agent)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Based on the observed hepatotoxicity of this agent, the use of chenodiol is contraindicated during pregnancy.

FETAL RISK SUMMARY

Chenodiol (chenodeoxycholic acid) is a naturally occurring bile acid used orally to dissolve gallstones. No reports on the use of this drug during human pregnancy have been located.

Chenodiol is not teratogenic in animals, but fetotoxicity has occurred in some species. Studies with pregnant rats, mice, and baboons did not observe congenital malformations after in utero exposure to the agent during organogenesis (1–3). In one study using three dosage levels, dose-related hepatotoxicity was observed in dams but not in newborn rats (4). No fetal hepatotoxicity was observed in a study of rats in which the drug composed 0.25% of the maternal diet during pregnancy (5). Hepatotoxicity was observed, however, in newborn baboons and rhesus monkeys exposed to chenodiol during gestation (3,6). Extensive hemorrhagic necrosis of the adrenal glands and interstitial hemorrhage of the kidneys were also noted in the newborn rhesus monkeys (6). Theoretically, the main hepatotoxic property of chenodiol in animals is due to its principal bacterial metabolite, lithocholic acid (7). In contrast to humans who readily metabolize lithocholic acid to poorly absorbed, nontoxic compounds, animals such as rabbits, rhesus monkeys, and baboons are unable to fully form sulfate conjugates to detoxify the metabolite, and thus are susceptible to liver damage (7).

One study concluded that dihydroxy bile acids, such as chenodiol, are transferred, at least in rats, from the mother to the fetus (5).

BREASTFEEDING SUMMARY

No reports describing the use of chenodiol during lactation have been located.

CHLORAL HYDRATE

Sedative/Hypnotic

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

The limited human pregnancy experience and the absence of relevant animal data prevent a complete assessment of the embryo–fetal risk.

FETAL RISK SUMMARY

No reports linking the use of chloral hydrate with congenital defects have been located. The drug has been given in labor and demonstrated to be in cord blood at concentrations similar to maternal levels (1). Sedative effects on the neonate have not been studied.

The Collaborative Perinatal Project recorded 71 1st trimester exposures to chloral hydrate (2, pp. 336–44). From this group, 8 infants with congenital defects were observed (standardized relative risk [SRR] 1.68). When only malformations with uniform rates by hospital were examined, the SRR was 2.19. Neither of these relative risks reached statistical significance. Moreover, when chloral hydrate was combined with all tranquilizers and nonbarbiturate sedatives, no association with congenital malformations was found (SRR 1.13; 95% confidence interval [CI] 0.88–1.44). For use anytime during pregnancy, 358 exposures to chloral hydrate were discovered (2, p. 438). The nine infants with anomalies yielded an SRR of 0.98 (95% CI 0.45–1.84).

BREASTFEEDING SUMMARY

Chloral hydrate and its active metabolite are excreted into breast milk. Peak concentrations of about 8 mcg/mL were obtained about 45 minutes after a 1.3-g rectal dose (3). Only trace amounts are detectable after 10 hours.

Mild drowsiness was observed in the nursing infant of a mother taking 1300 mg of dichloralphenazone every evening (4). The mother was also consuming

chlorpromazine 100 mg three times daily. Dichloralphenazone is metabolized to trichloroethanol, the same active metabolite of chloral hydrate. Milk levels of trichloroethanol were 60%–80% of the maternal serum. Infant growth and development remained normal during the exposure and at follow-up 3 months after the drug was stopped. The American Academy of Pediatrics classifies the drug as compatible with breastfeeding (5).

CHLORAMBUCIL

Antineoplastic

PREGNANCY RECOMMENDATION: Contraindicated—1st Trimester

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

The limited data suggest that chlorambucil is a human teratogen.

FETAL RISK SUMMARY

The use of the alkylating agent, chlorambucil, during pregnancy has resulted in both normal and deformed infants (1–7). Two reports observed unilateral agenesis of the left kidney and ureter in male fetuses following 1st trimester exposure to chlorambucil (3,4). Similar defects have been found in animals exposed to the drug (8). In a third case, a pregnant patient was treated with chlorambucil at the 10th week of gestation (5). A full-term infant was delivered, but died 3 days later of multiple cardiovascular anomalies. The fourth case involved a woman treated with 24 mg/day during weeks 3–4 (6). She aborted in the 1st trimester a fetus with a retinal defect. In a 2012 report, a woman with chronic lymphocytic leukemia was treated with chlorambucil 2 mg/day 3 times per week during the first 20 weeks of pregnancy (7). Because of preeclampsia, she had a cesarean section at 36 weeks' gestation to give birth to a healthy 2235-g male infant who had normal growth and development at 3 months of age.

Chlorambucil is mutagenic as well as carcinogenic (9–13). These effects have not been reported in newborns following in utero exposure. Data from one review indicated that 40% of the infants exposed to anticancer drugs were of low birth weight (14). Long-term studies of growth and mental development in offspring exposed to chlorambucil during the 2nd trimester, the period of neuroblast multiplication, have not been conducted (15).

Amenorrhea and reversible azoospermia with high doses have been reported (16–20). Long-term follow-up of menstrual and reproductive function in women treated with various antineoplastic agents was reported in 1988 (20). Only two of the 40 women studied, however, may have been exposed to chlorambucil

(see Cyclophosphamide).

Occupational exposure of the mother to antineoplastic agents during pregnancy may present a risk to the fetus. A position statement from the National Study Commission on Cytotoxic Exposure and a research article involving some antineoplastic agents are presented in the monograph for cyclophosphamide (see Cyclophosphamide).

BREASTFEEDING SUMMARY

No reports describing the use of chlorambucil during lactation have been located. Because of the potential for severe adverse effects in a nursing infant, women receiving this alkylating agent should not breastfeed.

CHLORAMPHENICOL

Antibiotic

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although apparently nontoxic to the fetus, chloramphenicol should be used with caution at term. Specific details were not provided, but one report claimed that cardiovascular collapse (gray syndrome) developed in babies delivered from mothers treated with chloramphenicol during the final stage of pregnancy (1). Additional reports of this severe adverse effect have not been located. It is well known that newborns exposed directly to high doses of chloramphenicol may develop the gray syndrome (2,3). Because of this risk, some authors consider the drug to be contraindicated during pregnancy (4).

FETAL RISK SUMMARY

No reports linking the use of chloramphenicol with congenital defects have been located. The drug crosses the placenta at term producing cord serum concentrations 30%–106% of maternal levels (5,6).

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 98 of whom had 1st trimester exposure to chloramphenicol (7, pp. 297–301). For use anytime in pregnancy, 348 exposures were recorded (7, p. 435). In neither group was evidence found to suggest a relationship to large categories of major or minor malformations or to individual defects. A 1977 case report described a 14-day course of IV chloramphenicol, 2 g daily, given to a patient with typhoid fever in the 2nd trimester (8). A normal infant was delivered at term. Twenty-two patients, in various stages of gestation, were treated with chloramphenicol for acute pyelonephritis (9). No difficulties in the newborn could be associated with the antibiotic. In a controlled study, 110 patients received one to three antibiotics during the 1st trimester for a total of 589 weeks (10). Chloramphenicol was given for a total of 205 weeks. The incidence of birth

defects was similar to that in controls.

A 1998 report described the use of chloramphenicol for the treatment of Rocky Mountain spotted fever in a woman at 28 weeks' gestation (11). She was treated with IV chloramphenicol (3 g/day) and ceftriaxone (2 g/day) for 1 week and then for 3 weeks with oral amoxicillin. She eventually delivered a full-term, healthy 3916-g infant.

BREASTFEEDING SUMMARY

Chloramphenicol is excreted into breast milk. Two milk samples, separated by 24 hours in the same patient, were reported as 16 and 25 mcg/mL, representing milk:plasma ratios of 0.51 and 0.61, respectively (12). Both active drug and inactive metabolite were measured. No effect on the infant was mentioned. No infant toxicity was mentioned in a 1964 report that found peak levels occurring in milk 1–3 hours after a single 1-g oral dose (13). In a similar study, continuous excretion of chloramphenicol into breast milk was established after the 1st day of therapy (14). Minimum and maximum milk concentrations were determined for five patients receiving 250 mg orally every 6 hours (0.54 and 2.84 mcg/mL) and for five patients receiving 500 mg orally every 6 hours (1.75 and 6.10 mcg/mL). No infant data were given.

The safety of maternal chloramphenicol consumption and breastfeeding is unknown. The American Academy of Pediatrics classifies the antibiotic as an agent whose effect on the nursing infant is unknown but may be of concern because of the potential for idiosyncratic bone marrow suppression (15). Another publication recommended that chloramphenicol not be used in the lactating patient (16). Milk levels of this antibiotic are too low to precipitate the gray syndrome, but a theoretical risk does exist for bone marrow depression. Two other potential problems of lesser concern involve the modification of bowel flora and possible interference with the interpretation of culture results if a fever workup is required. Several adverse effects were reported in 50 breastfed infants whose mothers were being treated with chloramphenicol, including refusal of the breast, falling asleep during feeding, intestinal gas, and heavy vomiting after feeding (17).

CHLORCYCLIZINE

Antihistamine

No data are available. See Meclizine for representative agent in this class.

CHLORDIAZEPOXIDE

Sedative

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 1st and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

The effects of benzodiazepines, including chlordiazepoxide, on the human embryo and fetus are controversial. Although some studies have reported an association with various types of congenital defects, other studies have not found such associations. Maternal denial of exposure and concurrent exposure to other toxic drugs and substances (e.g., alcohol and smoking) may be confounding factors. If the drug does cause birth defects, the risk appears to be low. Continuous use during gestation has resulted in neonatal withdrawal, and depression of the newborn may occur if chlordiazepoxide is used close to birth. Consequently, if the maternal condition requires the use of the drug during pregnancy, the lowest possible dose should be taken. Moreover, abrupt discontinuance of chlordiazepoxide should be avoided. Severe withdrawal symptoms (physical and psychological) may occur in the mother and could result in the substitution of other substances (e.g., alcohol) to treat the symptoms. Fetal withdrawal, such as that observed with narcotics, has not been reported, but should be considered.

FETAL RISK SUMMARY

Chlordiazepoxide is a benzodiazepine (see also Diazepam). The drug has antianxiety, sedative, appetite-stimulating, and weak analgesic actions (1).

No teratogenic effects were observed in rats given doses of 10–80 mg/kg/day through one or two matings (1). At 100 mg/kg/day, maternal toxicity (decreased interest in mating and nursing) and marked decreases in offspring viability and body weight were attributed to sedative effects of the drug (1). Moreover, at this dose, one newborn in each of two matings had major skeletal

abnormalities.

In a study evaluating 19,044 live births, the use of chlordiazepoxide was associated with a greater than fourfold increase in severe congenital anomalies (2). In 172 patients exposed to the drug during the first 42 days of gestation, the following defects were observed: mental deficiency, spastic diplegia and deafness, microcephaly and retardation, duodenal atresia, and Meckel's diverticulum (2). Although not statistically significant, an increased fetal death rate was also found with maternal chlordiazepoxide ingestion (2). A survey of 390 infants with congenital heart disease matched with 1254 normal infants found a higher rate of exposure to several drugs, including chlordiazepoxide, in the offspring with defects (3).

In contrast, other studies have not confirmed a relationship with increased defects or mortality (4–8). The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 257 of whom were exposed in the 1st trimester to chlordiazepoxide (5,8). No association with large classes of malformations or to individual defects was found.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 788 newborns had been exposed to chlordiazepoxide during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 44 (5.6%) major birth defects were observed (34 expected). Specific data were available for six defect categories, including (observed/expected) 10/7 cardiovascular defects, 2/1 oral clefts, 0/0.5 spina bifida, 3/2 polydactyly, 1/1 limb-reduction defects, and 2/2 hypospadias. These data do not support an association between the drug and congenital defects.

A 1992 study reported on heavy benzodiazepine exposure during pregnancy from Michigan Medicaid data collected during 1980 to 1983 (9). Of the 2048 women, from a total sample of 104,339, who had received benzodiazepines, 80 had received 10 or more prescriptions for these agents. The records of these 80 women indicated frequent alcohol and substance abuse. Their pregnancy outcomes were 3 intrauterine deaths, 2 neonatal deaths in infants with congenital malformations, and 64 survivors. The outcome for 11 infants was unknown. Six of the surviving infants had diagnoses consistent with congenital defects (9). The investigators concluded that the high rate of congenital anomalies was suggestive of multiple alcohol and substance abuse and may not have been related to benzodiazepine exposure (9).

Neonatal withdrawal consisting of severe tremulousness and irritability has been attributed to maternal use of chlordiazepoxide (10). The onset of

withdrawal symptoms occurred on the 26th day of life. Chlordiazepoxide readily crosses the placenta at term in an approximate 1:1 ratio (11–13). The drug has been used to reduce pain during labor, but the maternal benefit was not significant (14,15). Marked depression was observed in three infants whose mothers received chlordiazepoxide within a few hours of delivery (13). The infants were unresponsive, hypotonic, hypothermic, and fed poorly. Hypotonicity persisted for up to a week. Other studies have not seen depression (11,12).

BREASTFEEDING SUMMARY

No reports describing the use of chlordiazepoxide during human lactation have been located. The molecular weight (about 300) is low enough, however, that passage into milk should be expected. Moreover, other benzodiazepines are excreted into milk and have produced adverse effects in nursing infants (see Diazepam). Because of the potential for drug accumulation and toxicity in nursing infants, chlordiazepoxide should be avoided during breastfeeding.

CHLORHEXIDINE

Anti-infective

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports of adverse effects in newborns have been reported even though chlorhexidine is used commonly during labor and in the neonate. Moreover, only very small amounts of disinfectant reach the maternal circulation and, presumably, the fetus. Although the agent is an effective disinfectant, single vaginal applications of chlorhexidine solutions do not appear to offer any advantage over sterile water or saline in the prevention of maternal infections during labor or in the postpartum period.

FETAL RISK SUMMARY

Chlorhexidine, a bisbiguanide antiseptic and disinfectant, is effective against most bacteria, and some fungi and viruses (including HIV). In addition to its topical use on the skin and intravaginally, it has been used for gingivitis and the prevention of dental plaque. Chlorhexidine has also been used as a spermicide (1). No adverse fetal effects were observed in pregnant rats administered chlorhexidine by gastric intubation on days 6 through 15 of gestation (2).

A number of studies have documented the safety and possible effectiveness of vaginal disinfection with chlorhexidine prior to delivery, primarily to prevent colonization of newborns with group B streptococci (3–15). Application to the groin and perineum, to the abdomen prior to cesarean section, and whole body washing has also been effective in preventing fetal and maternal infection (3,16–19). However, two double-blinded, placebo-controlled, randomized studies published in 1997, one utilizing a single intravaginal wash with 20 mL of a 0.4% chlorhexidine solution (20) and the other a 200-mL vaginal irrigation with a 0.2% solution (21), both groups in active labor, did not find a significant reduction in maternal infection rates compared with sterile water or saline. No adverse effects in the newborns were observed.

One author, hypothesizing an etiological connection between sudden infant death syndrome (SIDS) and toxigenic *Escherichia coli* or *Chlamydia* species, has suggested that decontamination of the birth canal with chlorhexidine during labor might reduce infant mortality from this disease (22), but a temporal relationship is speculative. In contrast to the real and theoretical benefits realized by the newborn from maternal chlorhexidine use, a single vaginal washing with a 0.4% chlorhexidine solution was not effective in decreasing the incidence of intra-amniotic infection or endometritis (23).

In one study involving nonpregnant women, swabbing of the entire vagina for 1 minute with gauze sponges soaked in 4% chlorhexidine gluconate did not result in detectable blood concentrations (sensitivity 0.1 mcg/mL) of the agent (24). A second study, utilizing a method ten times more sensitive (sensitivity 0.01 mcg/mL), was able to detect chlorhexidine in maternal blood from 34 of 96 women following vaginal washing with a 0.2% solution (25). Mean blood chlorhexidine concentrations obtained using two different methods of washing were 0.0146 and 0.0104 mcg/mL, respectively (range 0.01–0.083 mcg/mL). No accumulation of chlorhexidine in maternal blood was observed after a second vaginal washing at 6 hours in 14 patients or after a third washing, 6 hours later, in 3. The disinfectant was not detected in 62 of the women.

One writer has cautioned that the potential long-term effects (not specified) in the newborn from exposure to respiratory and other epithelial surfaces following vaginal use of chlorhexidine during labor have not been investigated (26).

BREASTFEEDING SUMMARY

No reports describing the excretion of chlorhexidine into milk have been located. The presence of the drug in breast milk is probably clinically insignificant because of the very small amounts absorbed into the maternal circulation following vaginal washing. As a general precaution, the mother's nipples should be rinsed thoroughly with water if chlorhexidine is used on them as a disinfectant, even though absorption of the agent from the gastrointestinal tract is poor.

CHLOROQUINE

Antimalarial/Amebicide

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Although some studies have suggested a low risk of congenital malformations, the lack of a pattern in the defects suggests that a causative association is unlikely. In any event, the maternal and fetal benefit of preventing and treating malaria far outweighs the risk, if any, to the embryo–fetus.

FETAL RISK SUMMARY

Chloroquine is the drug of choice for the prophylaxis and treatment of sensitive malaria species during pregnancy (1–4). The drug is also indicated for the treatment of extraintestinal invasion by the protozoan parasite, *Entamoeba histolytica* (5). Chloroquine is generally considered safe for these purposes by most authorities (1–7). However, the antimalarial is embryotoxic and teratogenic in rats given a 1000-mg/kg dose, causing embryonic death in 27% and producing anophthalmia and microphthalmia in 47% of the surviving fetuses (8).

Chloroquine crosses the placenta to the fetus, with fetal concentrations approximating those in the mother (9). In seven mothers at term in the second stage of labor, chloroquine, 5 mg/kg IM, produced mean levels in maternal blood, cord venous blood, and cord arterial blood that were all about 0.7 mcg/mL. The time interval from administration to sampling averaged 5.3 hours (range 2.4–10.5 hours). In a pregnant monkey, an ¹²⁵I-labeled chloroquine analog crossed the placenta and concentrated in the fetal adrenal cortex and retina (10). Chloroquine rapidly crosses the placenta in pregnant mice and selectively accumulates in the melanin structures of the fetal eyes (11). The drug was retained in the ocular structures for 5 months after elimination from the rest of the body.

The risks of complications from malarial infection occurring during pregnancy are increased, especially in women not living in endemic areas (i.e., nonimmune women) (12–14). Infection is associated with a number of severe maternal and fetal outcomes: anemia, abortion, stillbirths, prematurity, low birth weight, fetal distress, and congenital malaria (12–14). However, it is not yet clear if all of these are related to malarial infection (13). For example, prevention of low birth weight and the resulting risk of infant mortality by antimalarial chemoprophylaxis has not yet been proven (13). Increased maternal morbidity and mortality includes adult respiratory distress syndrome, massive hemolysis, disseminated intravascular coagulation, acute renal failure, and hypoglycemia, with the latter symptom occurring in up to 50% of women in whom quinine is used (14). Severe *Plasmodium falciparum* malaria in pregnant nonimmune women has a poor prognosis and may be associated with asymptomatic uterine contractions, intrauterine growth restriction, fetal tachycardia, fetal distress, hypoglycemia, and placental insufficiency because of intense parasitization (13). Because of the severity of this disease in pregnancy, chemoprophylaxis is recommended for women of childbearing age traveling in areas where malaria is present (12–14).

Congenital malaria may occur in up to 10% of infants born to mothers not living in endemic areas (14). In most cases, clinical malaria manifests 3–8 weeks after birth, probably as a result of exchange of infected maternal erythrocytes at birth, and is characterized by fever, hepatosplenomegaly, jaundice, and thrombocytopenia (14). In areas of hyperendemicity, transplacental passage of maternal IgG may protect the newborn against development of clinical malaria (14).

Congenital defects have been reported in three infants delivered from one mother who was treated during pregnancy with 250–500 mg/day of chloroquine for discoid lupus erythematosus (15). In addition, this woman also had two normal infants, who had not been exposed to chloroquine during gestation, and one normal infant who had been exposed. Anomalies in the three infants were Wilms' tumor at age 4 years, left-sided hemihypertrophy (one infant), and cochleovestibular paresis (two infants).

A 1985 report summarized the results of 169 infants exposed in utero to 300 mg of chloroquine base once weekly throughout pregnancy (16). The control group consisted of 454 nonexposed infants. Two infants (1.2%) in the study group had anomalies (tetralogy of Fallot and congenital hypothyroidism) compared with four control infants who had defects (0.9%). Based on these data, the authors concluded that chloroquine is not a major teratogen, but a

small increase in birth defects could not be excluded (16).

BREASTFEEDING SUMMARY

Chloroquine is excreted into breast milk (9,17). When chloroquine, 5 mg/kg IM, was administered to six nursing mothers 17 days postpartum, mean milk and serum concentrations 2 hours later were 0.227 mcg/mL (range 0.163–0.319 mcg/mL) and 0.648 mcg/mL (range 0.46–0.95 mcg/mL), respectively. The mean milk:blood ratio was 0.358 (range 0.268–0.462). Based on an average consumption of 500 mL of milk/day, an infant would have received about 114 mcg/day of chloroquine, an amount considered safe by the investigators (9). In an earlier study, three women were given a single dose of 600 mg of chloroquine 2–5 days postpartum (17). Serum and milk samples were collected up to 227 hours after administration. The milk:plasma ratios (AUC) for chloroquine and the principal metabolite, desethylchloroquine, ranged from 1.96 to 4.26 and from 0.54 to 3.89, respectively. Based on a daily milk intake of 1000 mL, the nursing infants would have ingested between 2.2% and 4.2% of the maternal doses over a 9-day period (17).

Although the amounts of chloroquine excreted into milk are not considered to be harmful to a nursing infant, they are insufficient to provide adequate protection against malaria (12). The American Academy of Pediatrics classifies chloroquine as compatible with breastfeeding (18).

CHLOROTHIAZIDE

Diuretic

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

The published experience with 1st trimester use of thiazides and related diuretics does not indicate these agents are teratogenic. One large study (the Collaborative Perinatal Project) did find an increased risk of defects when diuretics were used during the 1st trimester in women with cardiovascular disorders, but causal relationships cannot be inferred from these data without independent confirmation. Diuretics are not recommended for the treatment of gestational hypertension or preeclampsia because of the maternal hypovolemia characteristic of this disease. Other risks to the fetus or newborn include hypoglycemia, thrombocytopenia, hyponatremia, hypokalemia, and death from maternal complications. Moreover, thiazide diuretics may have a direct effect on smooth muscle and may inhibit labor.

FETAL RISK SUMMARY

Chlorothiazide is a member of the thiazide group of diuretics. The information in this monograph applies to all members of the group, including the pharmacologically and structurally related diuretics, chlorthalidone, indapamide, metolazone, and quinethazone.

Reproduction studies in mice (500 mg/kg/day), rats (60 mg/kg/day), and rabbits (50 mg/kg/day) revealed no external malformations or growth impairment, and no effect on fetal survival (1). However, these studies did not include a thorough examination for visceral anomalies and skeletal defects (1).

Data from published reports indicate that thiazide and related diuretics are infrequently administered during the 1st trimester. In the past, when these drugs were routinely given to prevent or treat toxemia, therapy was usually begun in the 2nd or 3rd trimester and adverse effects in the fetus were rare (2–11). No increases in the incidence of congenital defects were discovered,

and thiazides were considered nonteratogenic (12–15).

In contrast, the Collaborative Perinatal Project monitored 50,282 mother–child pairs, 233 of whom were exposed in the 1st trimester to thiazide or related diuretics (16, pp. 371–373). All of the mothers had cardiovascular disorders, which makes interpretation of the data difficult. However, an increased risk for malformations was found for chlorthalidone (20 patients) and miscellaneous thiazide diuretics (35 patients, excluding chlorothiazide and hydrochlorothiazide). For use anytime during pregnancy, 17,492 exposures were recorded and only polythiazide showed a slight increase in risk (16, p. 441). The statistical significance of these findings is unknown and independent confirmation is required.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, a number of newborns had been exposed to this class of diuretics during the 1st trimester: 20 (chlorothiazide), 48 (chlorthalidone), and 567 (hydrochlorothiazide) (F. Rosa, personal communication, FDA, 1993). The number of major birth defects observed, the number expected, and the incidence for each drug were: 2/1/10.0%, 2/2/4.2%, and 24/22/4.2%, respectively. Specific data were available for six defect categories (observed/expected): cardiovascular defects 0/0, 1/0.5, and 7/6; oral clefts 0/0, 0/0, and 0/1; spina bifida, 0/0, 0/0, and 0/0.5; polydactyly, 0/0, 0/0, and 1/2; limb-reduction defects 0/0, 0/0, and 0/1; and hypospadias 1/0, 0/0, and 1/1, respectively. Although the number of exposures is small for two of the diuretics, these data do not support an association between the drug and congenital defects.

Many investigators consider diuretics contraindicated in pregnancy, except for patients with heart disease or chronic hypertension, because they do not prevent or alter the course of toxemia and they may decrease placental perfusion (8,17–21). A 1984 study determined that the use of diuretics for hypertension in pregnancy prevented normal plasma volume expansion and did not change perinatal outcome (22). In 4035 patients treated for edema in the last half of the 3rd trimester (hypertensive patients were excluded), higher rates were found for induction of labor, stimulation of labor, uterine inertia, meconium staining, and perinatal mortality (20). All except perinatal mortality were statistically significant compared with 13,103 controls. In another study, a decrease in the endocrine function of the placenta, as measured by placental clearance of estradiol, was found in three patients treated with hydrochlorothiazide (23).

Chlorothiazide readily crosses the placenta at term, and fetal serum levels

may equal those of the mother (24). In 10 women, following 2 weeks of hydrochlorothiazide, 50 mg/day, the cord:maternal plasma ratio determined 2–13 hours after the last dose ranged from 0.10 to 0.80 (25). Chlorthalidone also crosses the placenta (26). Other diuretics probably cross to the fetus in similar amounts, although specific data are lacking.

Thiazides are considered mildly diabetogenic because they can induce hyperglycemia (18). Several investigators have noted this effect in pregnant patients treated with thiazides (27–30). Other studies have failed to show maternal hyperglycemia (31,32). Although apparently a low risk, newborns exposed to thiazide diuretics near term should be observed closely for symptoms of hypoglycemia resulting from maternal hyperglycemia (30).

Neonatal thrombocytopenia has been reported following the use near term of chlorothiazide, hydrochlorothiazide, and methyclothiazide (15,27,33–38). Other studies have not found a relationship between thiazide diuretics and platelet counts (39,40). The positive reports involve only 11 patients; however, although the numbers are small, 2 of the affected infants died (27,34). The mechanism of the thrombocytopenia is unknown, but the transfer of antiplatelet antibody from the mother to the fetus has been demonstrated (38). Thiazide-induced hemolytic anemia in 2 newborns was described in 1964 following the use of chlorothiazide and bendroflumethiazide at term (33). Thiazide diuretics may induce severe electrolyte imbalances in the mother's serum, in amniotic fluid, and in the newborn (41–43). In one case, a stillborn fetus was attributed to electrolyte imbalance and/or maternal hypotension (41). Two hypotonic newborns were discovered to be hyponatremic, a condition believed to have resulted from maternal diuretic therapy (42). Fetal bradycardia, 65–70 beats/minute, was shown to be secondary to chlorothiazide-induced maternal hypokalemia (43). In a 1963 study, no relationship was found between neonatal jaundice and chlorothiazide (44). Maternal and fetal deaths in two cases of acute hemorrhagic pancreatitis were attributed to the use of chlorothiazide in the 2nd and 3rd trimesters (45).

BREASTFEEDING SUMMARY

Chlorothiazide is excreted into breast milk in low concentrations (46). Following a single 500-mg oral dose, milk levels were <1 mcg/mL at 1, 2, and 3 hours. The authors speculated that the risks of pharmacologic effects in nursing infants would be remote. However, it has been stated that thrombocytopenia can occur in the nursing infant if the mother is taking chlorothiazide (47). Documentation of this is needed (48). Chlorthalidone has a very low

milk:plasma ratio of 0.05 (26).

In one mother taking 50 mg of hydrochlorothiazide (HCTZ) daily, peak milk levels of the drug occurred 5–10 hours after a dose and were about 25% of maternal blood concentrations (49). The mean milk concentration of HCTZ was about 80 ng/mL. An infant consuming 600 mL of milk/day would thus ingest about 50 mcg of the drug, probably an insignificant amount (49). The diuretic could not be detected in the serum of the nursing 1-month-old infant, and the measurements of serum electrolytes, blood glucose, and blood urea nitrogen were all normal.

Thiazide diuretics have been used to suppress lactation (50,51). However, the American Academy of Pediatrics classifies bendroflumethiazide, chlorothiazide, chlorthalidone, and hydrochlorothiazide as compatible with breastfeeding (52).

CHLOROTRIANISENE

[Withdrawn from the market. See 9th edition.]

CHLORPHENIRAMINE

Antihistamine

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Use of antihistamines, including chlorpheniramine, is low risk in gestation. However, a possible association with retrolental fibroplasia in premature infants has been reported.

FETAL RISK SUMMARY

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 1070 of whom had 1st trimester exposure to chlorpheniramine (1, pp. 322–34). For use anytime during pregnancy, 3931 exposures were recorded (1, pp. 437, 488). In neither group was evidence found to suggest a relationship to large categories of major or minor malformations. Several possible associations with individual malformations were found, but independent confirmation is required to determine the actual risk.

Polydactyly in blacks (7 cases in 272 blacks)

Gastrointestinal defects (13 cases)

Eye and ear defects (7 cases)

Inguinal hernia (22 cases)

Hydrocephaly (8 cases)

Congenital dislocation of the hip (16 cases)

Malformations of the female genitalia (6 cases)

A 1971 study found that significantly fewer infants with malformations were exposed to antihistamines in the 1st trimester as compared with controls (2). Chlorpheniramine was the sixth most commonly used antihistamine.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 61 newborns had been exposed to chlorpheniramine during the 1st trimester (F. Rosa, personal

communication, FDA, 1993). Most of the exposures involved decongestant combinations including adrenergics. Two (3.3%) major birth defects were observed (three expected), including one case of polydactyly (none expected). No anomalies were observed in five other categories of defects (cardiovascular defects, oral clefts, spina bifida, limb-reduction defects, and hypospadias) for which specific data were available. These data do not support an association between the drug and congenital defects.

A case of infantile malignant osteopetrosis was described in a 4-month-old boy exposed in utero on several occasions to Contac (chlorpheniramine, phenylpropanolamine, and belladonna alkaloids) but this is a known genetic defect (3). The boy also had a continual “stuffy” nose.

An association between exposure during the last 2 weeks of pregnancy to antihistamines in general and retrolental fibroplasia in premature infants has been reported. (See Brompheniramine for details.)

BREASTFEEDING SUMMARY

No reports describing the use of chlorpheniramine during human lactation have been reported. As with other antihistamines, the drug probably is compatible with breastfeeding.

CHLORPROMAZINE

Antipsychotic

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although one survey found an increased incidence of defects and a report of ectromelia exists, most studies have found chlorpromazine to be safe for both mother and embryo–fetus if used occasionally in low doses. However, use near term should be avoided due to the danger of maternal hypotension and adverse effects in the newborn.

FETAL RISK SUMMARY

Chlorpromazine is a propylamino phenothiazine. The drug readily crosses the placenta (1–4). Reproductive studies in rodents have shown a potential for embryotoxicity, increased neonatal mortality, and decreased offspring performance (5). In animals, selective accumulation and retention occur in the fetal pigment epithelium (6). Although delayed ocular damage from high prolonged doses in pregnancy has not been reported in humans, concern has been expressed for this potential toxicity (6,7).

Chlorpromazine has been used for the treatment of nausea and vomiting of pregnancy during all stages of gestation, including labor, since the mid-1950s (8–10). The drug seems to be safe and effective for this indication. Its use in labor to promote analgesia and amnesia is usually safe, but some patients, up to 18% in one series, have a marked unpredictable fall in blood pressure that could be dangerous to the mother and the fetus (11–15). Use of chlorpromazine during labor should be discouraged because of this adverse effect.

One psychiatric patient, who consumed 8000 mg of chlorpromazine in the last 10 days of pregnancy, delivered a hypotonic, lethargic infant with depressed reflexes and jaundice (4). The adverse effects resolved within 3 weeks.

An extrapyramidal syndrome, which may persist for months, has been observed in some infants whose mothers received chlorpromazine near term (16–20). This reaction is characterized by tremors, increased muscle tone with spasticity, and hyperactive deep tendon reflexes. Hypotonicity has been observed in one newborn and paralytic ileus in two after exposure at term to chlorpromazine (4,21). However, most reports describing the use of chlorpromazine in pregnancy have concluded that it does not adversely affect the fetus or the newborn (22–27).

The Collaborative Perinatal Project (CPP) monitored 50,282 mother–child pairs, 142 of whom had 1st trimester exposure to chlorpromazine (28). For use anytime during pregnancy, 284 exposures were recorded. No evidence was found in either group to suggest a relationship to malformations or an effect on perinatal mortality rate, birth weight, or intelligence quotient scores at 4 years of age. Opposite results were found in a prospective French study that compared 315 mothers exposed to phenothiazines during the 1st trimester with 11,099 nonexposed controls (29). Malformations were observed in 11 exposed infants (3.5%) and in 178 controls (1.6%) ($p < 0.01$). In the phenothiazine group, 57 women took chlorpromazine and four infants had malformations: syndactyly; microcephaly, clubfoot/hand, muscular abdominal aplasia (also exposed to acetylpromazine); endocardial fibroelastosis, brachymesophalangy, clinodactyly (also exposed to pipamazine); and microcephaly (also exposed to promethazine).

The case of microcephaly, although listed as a possible drug-induced malformation, was considered by the authors to be more likely a genetic defect since the mother had already delivered two previous children with microcephaly (29). However, even after exclusion of this case, the association between phenothiazines and malformations remained significant (29). In another report, a stillborn fetus delivered at 28 weeks with ectromelia and omphalocele was attributed to the combined use of chlorpromazine and meclizine in the 1st trimester (30).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 36 newborns had been exposed to chlorpromazine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). No major birth defects were observed (two expected).

In an in vitro study, chlorpromazine was shown to be a potent inhibitor of sperm motility (31). A concentration of 53 $\mu\text{mol/L}$ produced a 50% reduction in motility.

Using data from the CPP, researchers discovered that offspring of psychotic/neurotic mothers who had consumed chlorpromazine or other neuroleptics for more than 2 months during gestation, whether or not they were breastfed, were significantly taller than nonexposed controls at 4 months, 1 year, and 7 years of age (32). At 7 years of age, the difference between the exposed and nonexposed groups was approximately 3 cm. The mechanisms behind these effects were not clear, but may have been related to the dopamine receptor-blocking action of the drugs.

Reviewers have concluded that the phenothiazines are not teratogenic (26,33,34) and, because of its extensive clinical experience, chlorpromazine should be included among the treatments of choice if antipsychotic therapy was required during pregnancy (34).

BREASTFEEDING SUMMARY

Chlorpromazine is excreted into breast milk in very small concentrations. Following a 1200 mg oral dose (20 mg/kg), peak milk levels of 0.29 mcg/mL were measured at 2 hours (35). This represented a milk:plasma ratio of less than 0.5. The drug could not be detected following a 600-mg oral dose. In a study of four lactating mothers consuming unspecified amounts of the neuroleptic, milk concentrations of chlorpromazine ranged from 7 to 98 ng/mL, with maternal serum levels ranging from 16 to 52 ng/mL (36). In two mothers, more of the drug was found in the milk than in the plasma. Only two of the mothers breastfed their infants. One infant, consuming milk with a level of 7 ng/mL, showed no ill effects, but the second took milk containing 92 ng/mL and became drowsy and lethargic.

With the one exception described above, there have been no reported adverse effects in breastfed babies whose mothers were ingesting chlorpromazine (26). Based on this report, however, nursing infants exposed to the agent in milk should be observed for sedation. The American Academy of Pediatrics classifies chlorpromazine as an agent whose effect on the nursing infant is unknown but may be of concern because of the drowsiness and lethargy observed in the infant described above, and because of the galactorrhea induced in adults (37).

CHLORPROPAMIDE

Antidiabetic Agent

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 3rd Trimester

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Although the use of chlorpropamide during human gestation does not appear to be related to structural anomalies, insulin is still the treatment of choice for this disease. Oral hypoglycemics might not be indicated for the pregnant diabetic. Moreover, insulin, unlike chlorpropamide, does not cross the placenta and, thus, eliminates the additional concern that the drug therapy itself is adversely affecting the fetus. Carefully prescribed insulin therapy will provide better control of the mother's blood glucose, thereby preventing the fetal and neonatal complications that occur with this disease. High maternal glucose levels, as may occur in diabetes mellitus, are closely associated with a number of maternal and fetal adverse effects, including fetal structural anomalies if the hyperglycemia occurs early in gestation. To prevent this toxicity, the American College of Obstetricians and Gynecologists recommends that insulin be used for types I and II diabetes occurring during pregnancy and, if diet therapy alone is not successful, for gestational diabetes (1,2). If chlorpropamide is used during pregnancy, therapy should be changed to insulin and chlorpropamide discontinued before delivery (the exact time before delivery is unknown) to lessen the possibility of prolonged hypoglycemia in the newborn.

FETAL RISK SUMMARY

Chlorpropamide is a sulfonylurea used for the treatment of adult-onset diabetes mellitus. It is not the treatment of choice for the pregnant diabetic patient.

In a study using neurulating mouse embryos in whole embryo culture, chlorpropamide produced malformations and growth restriction at concentrations similar to therapeutic levels in humans (3). The defects were not

a result of hypoglycemia or of chlorpropamide metabolites.

When administered near term, chlorpropamide crosses the placenta and may persist in the neonatal serum for several days (4–6). One mother, who took 500 mg/day throughout pregnancy, delivered an infant whose serum level was 15.4 mg/dL at 77 hours of life (4). Infants of three other mothers, who were consuming 100–250 mg/day at term, had serum levels varying between 1.8 and 2.8 mg/dL 8–35 hours after delivery (5). All four infants had prolonged symptomatic hypoglycemia secondary to hyperinsulinism lasting for 4–6 days. Another newborn, whose mother had been taking chlorpropamide, had severe, prolonged hypoglycemia and seizures (6). In other reports, totaling 69 pregnancies, chlorpropamide in doses of 100–200 mg or more/day either gave no evidence of neonatal hypoglycemia and hyperinsulinism or no constant relationship between daily maternal dosage and neonatal complications (7,8).

In an abstract (9), and later in a full report (10), the *in vitro* placental transfer, using a single-cotyledon human placenta, of four oral hypoglycemics agents was described. As expected, molecular weight was the most significant factor for drug transfer, with dissociation constant (pKa) and lipid solubility providing significant additive effects. The cumulative percent placental transfer at 3 hours of the four agents and their approximate molecular weights (shown in parenthesis) were tolbutamide (270) 21.5%, chlorpropamide (277) 11.0%, glipizide (446) 6.6%, and glyburide (494) 3.9% (10).

Although teratogenic in animals, an increased incidence of congenital defects, other than that expected in diabetes mellitus, was not found with chlorpropamide in several studies (11–20). Four malformed infants have been attributed to chlorpropamide but the relationship is unclear: hand and finger anomalies (11); stricture of lower ileum, death (11); preauricular sinus (11); and microcephaly and spastic quadriplegia (14).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 18 newborns had been exposed to chlorpropamide during the 1st trimester (F. Rosa, personal communication, FDA, 1993). No major birth defects were observed (one expected).

A 1991 report described the outcomes of pregnancies in 21 non-insulin-dependent diabetic women who were treated with oral hypoglycemic agents (17 sulfonylureas, 3 biguanides, and 1 unknown type) during the 1st trimester (21). The duration of exposure ranged from 3 to 28 weeks, but all patients were changed to insulin therapy at the first prenatal visit. Forty non-insulin-dependent diabetic women matched for age, race, parity, and glycemic control

served as a control group. Eleven (52%) of the exposed infants had major or minor congenital malformations compared with six (15%) of the controls. Moreover, ear defects, a malformation that is observed, but uncommonly, in diabetic embryopathy, occurred in six of the exposed infants and in none of the controls. Six of the 11 infants with defects had been exposed in utero to chlorpropamide (length of exposure during pregnancy in weeks): severe microtia right ear, multiple tags left ear (22 weeks); bilateral auricular tags (8 weeks); single umbilical artery (14 weeks); ear tag (10 weeks); facial, auricular, and vertebral defects, deafness, ventricular septal defect (15 weeks); and multiple vertebral anomalies, ventricular septal defect, severe aortic coarctation; bilateral ear tags and posterior rotated ears (14 weeks) (21).

Sixteen livebirths occurred in the exposed group compared with 36 in controls (21). The groups did not differ in the incidence of hypoglycemia at birth (53% vs. 53%), but three of the exposed newborns had severe hypoglycemia lasting 2, 4, and 7 days, even though the mothers had not used oral hypoglycemics (two women had used chlorpropamide) close to delivery. The authors attributed this to irreversible β -cell hyperplasia that may have been increased by exposure to oral hypoglycemics. Hyperbilirubinemia was noted in 10 (67%) of 15 exposed newborns compared with 13 (36%) of controls ($p < 0.04$), and polycythemia and hyperviscosity requiring partial exchange transfusions were observed in 4 (27%) of 15 exposed vs. 1 (3.0%) control ($p < 0.03$) (one exposed infant not included in these data because presented after completion of study) (21).

A study published in 1995 assessed the risk of congenital malformations in infants of mothers with non-insulin-dependent diabetes during a 6-year period (22). Women were included in the study if, during the first 8 weeks of pregnancy, they had not participated in a preconception care program and then had been treated either with diet alone (group 1), diet and oral hypoglycemic agents (predominantly chlorpropamide, glyburide, or glipizide) (group 2), or diet and exogenous insulin (group 3). The 302 women eligible for analysis gave birth to 332 infants (five sets of twins and 16 with two or three separate singleton pregnancies during the study period). A total of 56 (16.9%) of the infants had one or more congenital malformations, 39 (11.7%) of which were classified as major anomalies (defined as those that were either lethal, caused significant morbidity, or required surgical repair). The major anomalies were divided among those involving the central nervous system, face, heart and great vessels, gastrointestinal, genitourinary, and skeletal (includes caudal regression syndrome) systems. Minor anomalies included all of these, except those of the

central nervous system, and a miscellaneous group composed of sacral skin tags, cutis aplasia of the scalp, and hydroceles. The number of infants in each group and the number of major and minor anomalies observed were group 1—125 infants, 18 (14.4%) major, 6 (4.8%) minor; group 2—147 infants, 14 (9.5%) major, 9 (6.1%) minor; group 3—60 infants, 7 (11.7%) major, 2 (3.3%) minor. There were no statistical differences among the groups. Six (4.1%) of the infants exposed in utero to oral hypoglycemic agents and four other infants in the other two groups had ear anomalies (included among those with face defects). Other than the incidence of major anomalies, two other important findings of this study were the independent associations between the risk of major anomalies (but not minor defects) and poor glycemic control in early pregnancy, and a younger maternal age at the onset of diabetes. Moreover, the study did not find an association between the use of oral hypoglycemics during organogenesis and congenital malformations because the observed anomalies appeared to be related to poor maternal glycemic control (22).

BREASTFEEDING SUMMARY

Chlorpropamide is excreted into breast milk. Following a 500-mg oral dose, the milk concentration in a composite of two samples obtained at 5 hours was 5 mcg/mL (G.G. D'Ambrosio, personal communication, Pfizer Laboratories, 1982). The effects on a nursing infant from this amount of drug are unknown, but hypoglycemia is a potential toxicity.

CHLORPROTHIXENE

[Withdrawn from the market. See 9th edition.]

CHLORTETRACYCLINE

Antibiotic (Tetracycline)

PREGNANCY RECOMMENDATION: Contraindicated in 2nd and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Tetracyclines are known human teratogens. See Tetracycline.

BREASTFEEDING SUMMARY

Chlortetracycline is excreted into breast milk. Eight patients were given 2–3 g orally/day for 3–4 days (1). Average maternal and milk concentrations were 4.1 and 1.25 mcg/mL, respectively, producing a milk:plasma ratio of 0.4. Infant data were not given.

Theoretically, dental staining and inhibition of bone growth could occur in breastfed infants whose mothers were consuming chlortetracycline. However, this theoretical possibility seems remote because in infants exposed to a closely related antibiotic, tetracycline, serum levels were undetectable (<0.05 mcg/mL) (2). The American Academy of Pediatrics classifies tetracycline as compatible with breastfeeding (3). Three potential problems may exist for the nursing infant, even though there are no reports in this regard: modification of bowel flora, direct effects on the infant, and interference with the interpretation of culture results if a fever workup is required.

CHLORTHALIDONE

Diuretic

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Chlorthalidone is structurally related to the thiazide diuretics (see Chlorothiazide). In general, diuretics are not recommended for the treatment of gestational hypertension because of the maternal hypovolemia characteristic of this disease.

FETAL RISK SUMMARY

Reproduction studies in rats and rabbits at doses up to 420 times the human dose have observed no evidence of fetal harm (1).

BREASTFEEDING SUMMARY

See Chlorothiazide.

Reference

1. Product information. Thalitone. Monarch Pharmaceuticals, 2000.

CHLORZOXAZONE

Muscle Relaxant

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The available human pregnancy experience does not suggest a risk of teratogenicity.

FETAL RISK SUMMARY

The reproductive effects of the centrally acting muscle relaxant, chlorzoxazone, have not been studied in animals. Moreover, no published reports of its use in human pregnancy have been located. The relatively low molecular weight (about 170) suggests that the drug will cross the placenta.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 42 newborns had been exposed to chlorzoxazone during the 1st trimester (F. Rosa, personal communication, FDA, 1993). One (2.4%) major birth defect was observed (two expected), a cardiovascular defect (0.5 expected). Earlier data, obtained from the same source between 1980 and 1983, totaled 264 1st trimester exposures with 17 defects observed (17 expected). These combined data do not support an association between the drug and congenital defects.

BREASTFEEDING SUMMARY

No reports describing the use of chlorzoxazone during lactation have been located. The molecular weight (about 170) is low enough that excretion into breast milk should be expected. The effect of this potential exposure on a nursing infant is unknown. However, other muscle relaxants are excreted in milk and do not appear to harm a nursing infant (e.g., see Baclofen and Carisoprodol).

CHOLECALCIFEROL

Vitamin

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

Cholecalciferol (vitamin D₃) is converted in the liver to calcifediol, which in turn is converted in the kidneys to calcitriol, one of the active forms of vitamin D (see Calcitriol and Vitamin D).

BREASTFEEDING SUMMARY

See Vitamin D.

CHOLESTYRAMINE

Antilipemic

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Except for a single case involving maternal and fetal vitamin K deficiency, the use of this drug in pregnancy appears to be low risk.

FETAL RISK SUMMARY

Cholestyramine is a resin used to bind bile acids in a nonabsorbable complex. In a reproductive study involving rats and rabbits, the resin was given in doses up to 2 g/kg/day without evidence of fertility impairment or adverse fetal effects (1). In a comparison between pregnant and nonpregnant rats, administration of cholestyramine failed to lower the plasma cholesterol concentration or to increase bile acid synthesis (2). The drug therapy had no effect, in comparison to control animals, on maternal weight gain, number of fetuses, and fetal weight.

Cholestyramine has been used for the treatment of cholestasis of pregnancy (3–7). Except for the case described below, no adverse fetal effects were observed in these studies. One review recommended the resin as first-line therapy for the pruritus that accompanies intrahepatic cholestasis of pregnancy (6). Cholestyramine also binds fat-soluble vitamins, and long-term use could result in deficiencies of these agents in either the mother or the fetus (8). In one study, treatment with 9 g daily up to a maximum duration of 12 weeks was not associated with fetal or maternal complications (3).

A 31-year-old woman in her third pregnancy was treated with cholestyramine (8 g/day) beginning at 19 weeks' gestation for intrahepatic cholestasis of pregnancy (7). At 22 weeks' gestation, the dose was increased to 16 g/day. Four weeks later, she was clinically jaundiced and at 29 weeks' gestation, she was admitted to the hospital for reduced fetal movements. Fetal ultrasound scans over the next week revealed expanding bilateral subdural hematomas

with hydrocephalus, an enlarged liver, and bilateral pleural effusions (7). The mother's prothrombin ratio was markedly elevated but responded to two doses of IV vitamin K. One week later, following labor induction for fetal distress, a 1660-g infant was delivered who died at 15 minutes of age. It was thought that the fetal subdural hematomas were the result of vitamin K deficiency caused by the cholestyramine, cholestasis, or both (7).

A 1989 report described the use of cholestyramine and other agents in the treatment of inflammatory bowel disease during pregnancy (9). Seven patients were treated during gestation with the resin. One of the seven delivered prematurely (<37 weeks' gestation) and one of the newborns was small for gestational age (<10th percentile for gestational age). Both of these outcomes were probably related to the mother's disease, rather than to the therapy.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 4 newborns had been exposed to cholestyramine during the 1st trimester (10). Thirty-three other newborns were exposed after the 1st trimester. None of the infants had congenital malformations.

BREASTFEEDING SUMMARY

Cholestyramine is a nonabsorbable resin. No reports describing its use during lactation have been located. Because it binds fat-soluble vitamins, prolonged use may result in deficiencies of these vitamins in the mother and her nursing infant.

CHONDROITIN

Dietary Supplement

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of chondroitin in human pregnancy have been located. The animal data suggest low risk, but the absence of reported human pregnancy experience prevents an assessment of the risk to the embryo–fetus. Moreover, the lack of standardization prevents knowledge of the exact dose taken. The oral bioavailability depends on the molecular weight of the product used, and this may not be known from the product’s package insert or label. However, chondroitin is an endogenous substance widely found in human tissues, so the embryo–fetus must synthesize it during development. Therefore, the planned or inadvertent use of chondroitin during gestation does not appear to represent a clinically significant risk of embryo–fetal harm.

FETAL RISK SUMMARY

Chondroitin is a mucopolysaccharide that belongs to a class of very large molecules called glycosaminoglycans (1,2). It is isolated from natural sources, such as shark and bovine cartilage. There are no official standards to regulate its production in the United States, so the actual dose taken cannot be accurately determined. Endogenous chondroitin acts as the flexible connecting matrix (substrate) between protein filaments in cartilage that is found in most mammals. The substance can be found in human cartilage, bone, cornea, skin, and the arterial wall (3). Oral chondroitin, frequently in combination with glucosamine or manganese, is used in the treatment of osteoarthritis, ischemic heart disease, osteoporosis, hyperlipidemia, and other conditions. An IM formulation (not available in the United States) is used for osteoarthritis and topical chondroitin is used for dry eyes and as an adjunct to ocular surgery.

With the possible exceptions of its use for osteoarthritis and dry eyes, studies are needed to confirm the efficacy of chondroitin. The oral bioavailability of oral chondroitin has been reported to be minimal, in the range of 0%–13% (1), but is thought to depend on the molecular weight of the chondroitin product studied (3).

Animal reproduction studies have been conducted in mice and rats, but the doses used were not related to the human daily dose in terms of BSA or AUC. Injection of 1 mL (20 mg) of a 2% solution of chondroitin sulfate into mice during organogenesis resulted in cleft palates or kinky tails (4). No adverse effects were observed with oral doses up to 5000 mg/kg of chondroitin polysulfate given to rats and mice during organogenesis (5).

It is not known if chondroitin crosses the animal or human placenta. The molecular weight (5000–50,000) and probable very low blood concentrations suggest that minimal amounts, if any, will cross to the embryo or fetus.

BREASTFEEDING SUMMARY

No reports describing the use of chondroitin during lactation have been located. Depending on the source, the molecular weight (5000–50,000) and probable very low blood concentrations suggest that little, if any, of the drug will be excreted into breast milk. Therefore, the use of chondroitin during lactation is probably compatible.

CICLESONIDE

Respiratory Drug (Corticosteroid)

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >> Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of ciclesonide in human pregnancy have been located. Poorly controlled asthma may result in adverse maternal, fetal, and neonatal outcomes (4,5). Maternal complications include an increased risk of preeclampsia, gestational hypertension, hyperemesis gravidarum, vaginal hemorrhage, and induced and difficult labor. Fetal and neonatal adverse effects may be an increased risk of perinatal mortality, intrauterine growth restriction (IUGR), prematurity, lower birth weight, and neonatal hypoxia (1). Moreover, a recent study reported that asthma exacerbations during the 1st trimester significantly increased the risk of congenital malformations (2). Because controlling maternal asthma can ameliorate or prevent all of these complications, the benefits of therapy outweigh the potential risks of drug-induced teratogenicity or toxicity. Pregnant women who require an inhaled corticosteroid, such as ciclesonide, for control of their asthma should be counseled as to the risks and benefits of therapy, but treatment should not be withheld because of their pregnancy.

FETAL RISK SUMMARY

Ciclesonide is a nonhalogenated glucocorticoid that is available as an inhaled aerosol and intranasal spray. It is a prodrug that is enzymatically hydrolyzed to the active drug des-ciclesonide (RM1). The oral bioavailability of ciclesonide and RM1 is negligible. RM1 has anti-inflammatory activity with an affinity for glucocorticoid receptors that is 120 times greater than that of ciclesonide and 12 times greater than that of dexamethasone. The inhaled aerosol is indicated for the maintenance treatment of asthma as a prophylactic therapy, whereas the intranasal spray is indicated for the treatment of nasal symptoms

associated with perennial or seasonal allergic rhinitis (3,4). Compared with an IV 800-mcg dose, the absolute bioavailability of ciclesonide after an oral inhalation 1280-mcg dose (four times the recommended dose) was 22% and the relative systemic exposure of RM1 was 63%. Plasma protein binding for ciclesonide and RM1 was $\geq 99\%$. Following IV administration, the mean half-lives of ciclesonide and RM1 were 0.71 and 6–7 hours, respectively (1), but a review cited mean values of 0.38 and 3.5 hours, respectively (5). Only RM1 was detected in the serum after use of the intranasal spray, and then only with daily doses ≥ 400 mcg (4).

Reproduction studies have been conducted in rats and rabbits. There was no teratogenicity or other fetal effects in rats given oral doses that were about 10 times the maximum human daily inhalation dose based on BSA (MHDID) (3). Similarly, no adverse fetal effects were observed when rats were given doses up to about 35 times the maximum human daily intranasal dose based on BSA (MHDND) (4). When rabbits were given a SC dose that was less than either maximum human dose, fetal toxicity consisting of death, reduced weight, cleft palate, skeletal abnormalities including incomplete ossifications, and skin effects were observed (3,4). No adverse effects were observed with a dose that was one-fifth of the toxic dose.

No carcinogenicity was observed in 2-year studies in mice and rats. Ciclesonide was not mutagenic in two assays, but was clastogenic in one of three tests. Similar findings were observed with dexamethasone, the concurrent reference corticosteroid. In addition, there was no evidence of impaired fertility in male and female rats given oral doses up to about 10 times the MHDID or about 35 times the MHDND (3,4).

It is not known if ciclesonide or RM1 crosses the human placenta. The molecular weight of ciclesonide (about 541) is low enough, but the high plasma protein binding and very short half-life suggests that minimal amounts will cross the placenta. In contrast, the half-life of RM1 suggests that exposure of the embryo–fetus to amounts greater than that from ciclesonide is likely.

BREASTFEEDING SUMMARY

No reports describing the use of ciclesonide during human lactation have been located. The molecular weight of the prodrug ciclesonide (about 541) is low enough, but the high plasma protein binding and very short half-life suggests that minimal amounts will be excreted into breast milk. In contrast, the half-life of the active drug des-ciclesonide (RM1; molecular weight not specified) suggests that exposure of the nursing infant will be greater than that from

ciclesonide. Although the prodrug and its active metabolite have negligible oral bioavailability (both <1%), the relatively anti-inflammatory activity of RM1 is 12 times that of dexamethasone. The effects of this exposure on a nursing infant are unknown, but, like all corticosteroids, suppression of the hypothalamic–pituitary–adrenal function is a potential complication.

CICLOPIROX

Antifungal

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Although there is no published human pregnancy data, the low systemic bioavailability and the absence of developmental toxicity in four animal species suggest that the use of ciclopirox is low risk for the embryo–fetus.

FETAL RISK SUMMARY

Ciclopirox is a synthetic anti-infective agent used topically for its antifungal properties. Very small amounts (1.3% of the dose with occlusive dressings) are absorbed systemically from the skin (1).

There was no evidence of teratogenic effects or other fetal harm in animals (mice, rats, rabbits, and monkeys) given doses of 10 times or more the topical human dose by various routes of administration (1).

No reports of its use in human pregnancy have been located. The manufacturer has no reports of congenital abnormalities occurring after use of ciclopirox (C.K. Whitmore, personal communication, Hoechst-Roussel Pharmaceuticals, Inc., 1987).

BREASTFEEDING SUMMARY

No reports describing the use of ciclopirox during lactation have been located. The very small amounts (1.3%) absorbed systemically with occlusive dressings probably indicates that infant exposure via the milk is negligible, if it occurs at all.

CIDOFOVIR

Antiviral

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo—Fetal Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of cidofovir during human pregnancy have been located. It is not known whether the drug crosses the placenta to the fetus, but because of its relatively low molecular weight (approximately 315) passage to the fetus should be expected. Because of the lack of human data, the risk to the human embryo and fetus cannot be assessed. Some risk may exist because of the adverse effects observed at very low doses in the limited animal studies. Despite this risk, the use of cidofovir after the 1st trimester in a pregnant HIV-positive woman with sight-threatening cytomegalovirus (CMV) retinitis may be a rational decision.

FETAL RISK SUMMARY

Cidofovir (HPMPC) is used in the treatment of CMV retinitis in patients with AIDS. The antiviral agent is converted to the active metabolite, cidofovir diphosphate, by intracellular enzymes. In animals, cidofovir is carcinogenic, embryotoxic, and teratogenic.

Cidofovir was carcinogenic in female rats, producing mammary adenocarcinoma at doses as low as about 0.04 times the recommended human dose based on AUC (RHD). Reproductive studies with cidofovir have been conducted with rats and rabbits (1). Both maternal toxicity and embryotoxicity (reduced fetal body weights) were observed at daily IV doses in rats and rabbits that were about 0.12 and 0.24 times the RHD, respectively, administered during organogenesis. The no-observable-effect doses for embryotoxicity in rats and rabbits were about 0.04 and 0.05 times the RHD, respectively. Teratogenic effects, consisting of external, soft tissue, and skeletal malformations (meningocele, short snout, and short maxillary bones), were observed in the fetuses of rabbits given a dose that was about 0.24 times

the RHD during organogenesis.

Pregnant mice inoculated intranasally with equine herpesvirus 1 in the 2nd or 3rd week of gestation were treated with a single dose of cidofovir 50 mg/kg SC 1 day prior to inoculation (2). A noninfected, control group of pregnant mice was also treated at a similar gestational time with the same dose of cidofovir. In the infected group, cidofovir significantly reduced the incidence of virus transfer to the fetus and subsequent abortion, a predictable effect of the virus. No obvious toxic effects were observed in either group.

BREASTFEEDING SUMMARY

No reports describing the use of cidofovir during lactation have been located. This antiviral agent should not be used during breastfeeding because of the potential severe toxicity in a nursing infant. Moreover, although no studies have been reported in lactating humans, cidofovir has induced mammary cancer with very low doses in female rats.

In addition, the mother's clinical status will usually preclude the use of cidofovir during breastfeeding. The only approved indication for this drug is for the treatment of CMV retinitis in patients infected with HIV type 1 (HIV-1). Because HIV-1 is transmitted in milk, breastfeeding is not recommended in developed countries where there are available affordable milk substitutes (3–5).

CIGARETTE SMOKING

Stimulant

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Maternal and paternal cigarette smoking before pregnancy is associated with reduced fertility and ectopic tubal pregnancies. During pregnancy, maternal smoking is related to increased risks for spontaneous abortions (SABs), premature delivery, placental abruption, placenta previa, and premature rupture of membranes (PROM). Symmetric and asymmetric fetal growth restriction that involves weight, length, and head, chest, and shoulder circumference is a consistent finding of numerous studies. Up to 30% of low-birth-weight infants may be due to maternal smoking. A major consequence of smoking-induced toxicity is a significantly increased perinatal mortality rate, in addition to the losses from SABs. Maternal smoking is also a risk for increased neonatal, infant, and adolescent complications. These include increased admissions to a neonatal intensive care unit (NICU), abnormal neurobehavior development, sudden infant death syndrome (SIDS), and childhood diseases such as asthma, respiratory infections, and obesity. Vascular retinal abnormalities in infants are another complication. Although reversible, the abnormalities might be a harbinger of later vascular disease.

Cigarette smoking appears to be associated with small increases (usually less than twofold) in major birth defects and possible deformations. The defects with positive associations involve the heart and great vessels, limbs, skull, genitourinary system, feet, abdominal wall, small bowel, and muscles. Dose-dependent relationships, gene–smoking interactions, and synergistic combinations with some medications have been noted. However, the prevalence and frequency of maternal cigarette smoking are based on self-reports that typically underestimate the actual amount of smoking. This and the failure to adjust for other confounders may have biased the results of some studies. Biochemical validation should be, but rarely is, a component of studies on the effects of smoking during

pregnancy.

FETAL RISK SUMMARY

Cigarette smoking during pregnancy is a significant health hazard to the mother, embryo, fetus, infant, and adolescent. Cigarette smoke contains more than 3000 different compounds, including nicotine, carbon monoxide, ammonia, polycyclic aromatic hydrocarbons, hydrogen cyanide, and vinyl chloride (1–5). Although these and other chemical constituents of cigarette smoke represent a risk to the pregnancy, the principal concerns relate to nicotine and carbon monoxide. Nicotine has a plasma half-life of about 40 minutes, whereas its primary inactive metabolite, cotinine, has a half-life of 15–30 hours (4). Nicotine releases epinephrine that results in a marked reduction in uterine blood flow and an increase in uterine vascular resistance (1–4).

Although the frequency of cigarette smoking during pregnancy is declining, the self-reported overall prevalence ranges from about 13% to 20% (3,4,6,7). The prevalence is dependent on a number of factors, primarily ethnic group, age, and education. The highest frequency is among American Indian or Alaskan Native women (20.2%) and white women (16.2%), whereas it is lower in Black (9.6%), Hispanic (4%) and Asian or Pacific Islander women (3.1%) (5). The highest prevalence of smoking during pregnancy is among women age 18–24 years (5,7) and more women with 12 years of education or less (11.7% to 25.5%) smoke than do women with 13–15 years (9.6%) or ≥16 years (2.2%) of education (5). However, these self-reported rates, whether based on questionnaires, interviews, or birth certificate data, probably underestimate the actual frequency of smoking (5,6,8). The high rates of nondisclosure have led some to recommend that biochemical validation of smoking status should be a part of all studies involving pregnant women (6).

Nicotine and carbon monoxide rapidly cross the placenta (1–5). Nicotine and carboxyhemoglobin fetal concentrations are about 10%–15% higher than those in the mother.

Cigarette smoking before and during pregnancy is associated with a number of adverse reproductive effects. These toxic effects can be classified as follows:

- Subfertility and ectopic pregnancy
- Pregnancy Complications
 - Spontaneous abortions
 - Premature delivery

- Placental abruption/placenta previa
- Placental previa
- Premature rupture of membranes
- Embryo–Fetal Complications
 - Growth restriction
 - Perinatal mortality
 - Congenital malformations
- Neonatal Complications
 - Neonatal Intensive Care Unit admissions
 - Retinal abnormalities
- Adolescent Complications
 - Neurodevelopment
 - Sudden infant death syndrome
 - Childhood morbidity

Subfertility and Ectopic Pregnancy

Cigarette smoking adversely affects female fertility (4,9,10–12). A 1986 review explored this topic in depth and concluded that cigarette smoking adversely affects the ability to conceive during a given menstrual cycle (i.e., reduced fecundity) (11). One of the mechanisms of smoking-induced reduced fecundity might be related to altered uterine tubal function (increased utero-tubal amplitude and tonus). This could also explain the higher incidence of ectopic tubal pregnancies in women who smoke (11). Other potential contributing mechanisms are effects on the preimplantation embryo, implantation, gamete maturation and function, and adverse effects on sperm density, motility, and morphology induced by paternal smoking (11).

Pregnancy Complications

SPONTANEOUS ABORTIONS Cigarette smoking is associated with an increased risk of SABs of fetuses with normal karyotype (1–5,8–11,13,14). Compared with nonsmokers, the risk of abortion may be increased by as much as 20%–80% (2–4,9). An estimated 19,000–141,000 SABs annually may be caused by tobacco (5). However, adjustment for confounding factors, such as a previous history of SAB and alcohol consumption, may reduce the association (9). The mechanism of smoking-induced SAB is unknown but may be due to interference with placentation or implantation (11).

PREMATURE DELIVERY Preterm delivery is increased in women who smoke (1,4,5,7,9,10,14,15). Smoking may be responsible for 14%–15% of all

premature births (5,10). The effect of smoking is most pronounced in infants born at less than 33 weeks' gestation (7). The risk increases with the number of cigarettes smoked (9).

PLACENTAL ABRUPTION/PLACENTA PREVIA An increased risk of vaginal bleeding secondary to placental abruption or previa has been shown with smoking (2–4,6,9,10,12–14,16). There is a dose-dependent association with these complications (2,3,10,13). The risk of abruption and previa in those smoking less than one-pack/day was 23% and 25%, respectively, greater than that of nonsmokers, whereas the risk in those smoking one pack/day or more was increased 86% and 92%, respectively (3). Moreover, a smoking history of more than 6 years was associated with an increased incidence of placenta previa of 14.3% and of placental abruption of 72% (4). The estimated annual number of infant deaths from these two complications is 1900–4800 (5).

PREMATURE RUPTURE OF MEMBRANES PROM is an adverse effect of maternal smoking (1,2,4,5,9). Similar to other complications, a dose-dependent relationship has been found (2,4). One cited study found that the incidence of PROM was 1.4% in women smoking 20 or more cigarettes/day, 0.6% in those smoking 1–5 cigarettes/day, and 0.3% in nonsmokers (4).

Embryo–Fetal Complications

GROWTH RESTRICTION IUGR at any gestational age is a well-known complication of cigarette smoking during pregnancy (1–7,10–16). Growth restriction is typically symmetrical IUGR, but aspects of asymmetrical IUGR may be present in the last trimester (7). The negative effects of smoking on fetal growth include weight, length, and head, chest, and shoulder circumference, and involve a dose-dependent relationship. In comparison to infants of women who do not smoke, the infants of smokers, on average, weigh 200 g less (2–4). Moreover, compared with nonsmokers, the risk of having an infant weighing less than 2500 g was 52% greater in those smoking less than one pack/day and 130% greater in those smoking one-pack/day or more (3). Overall, the relative risk (smokers vs. nonsmokers) of giving birth to an infant weighing less than 2500 g is approximately 2.0 (13). In 1993, it was estimated that smoking was responsible for 40,000 low-birth-weight (LBW) infants (4). Smoking during pregnancy may account for 20%–30% of LBW infants (5). Quitting smoking before or during pregnancy decreases the risk of delivering an LBW infant to that of nonsmokers (5,7,13). The primary cause of the growth restriction is thought to be chronic fetal hypoxia secondary to nicotine and carbon monoxide (1,5,10,12). Nicotine-induced vasoconstriction causes

reduced placental blood flow. Carbon monoxide binds to hemoglobin, both maternal and fetal, with an affinity that is more than 200 times that of oxygen (5).

PERINATAL MORTALITY An increase in perinatal deaths (fetal deaths after 20 weeks' gestation and infant deaths within 28 days of birth) has been frequently associated with cigarette smoking during pregnancy (1–3,5,8–11,13,14,16). Increased rates of perinatal death have been reported, with the highest risk found in smoking women who had had multiple pregnancies, were of low socioeconomic class, and were anemic (2,3). A dose-dependent relationship between maternal smoking and perinatal mortality is evident. The increased perinatal mortality is secondary to stillbirths, prematurity, respiratory distress syndrome, pneumonia, placental abruption, and placenta previa. The risk of perinatal mortality from cigarette smoking is about 10% and most deaths occur in infants with IUGR (9). Of interest, heavy tobacco chewing has been associated with decreased birth weight (100–200 g; primarily due to prematurity) and a threefold increase in the stillbirth rate (2,17).

CONGENITAL MALFORMATIONS The relationship between cigarette smoking during pregnancy and structural malformations is controversial (2–5,9,11,14,15). Several reports have found low associations between smoking and various birth defects, but the studies relied on self-reported smoking prevalence. A 2003 statement from the Teratology Society on the benefits of smoking cessation during pregnancy concluded that smoking was not associated with major congenital malformations (5).

CARDIOVASCULAR DEFECTS (In addition to the references cited in this section, see reference 24.)

In a brief 1971 correspondence using data from the 1958 British Perinatal Mortality Survey, a statistically significant association was found for congenital heart disease between smokers (at least one cigarette/day after the fourth month of pregnancy) and nonsmokers (18). Congenital heart disease was determined by medical examination or autopsy. The incidence of congenital heart disease per 1000 births in smokers and nonsmokers was 7.3 and 4.7, respectively. After adjustment, the smoking effect was independent of maternal age, parity, and social class (18).

A 1978 case–control study found a significant increase in congenital defects in women that smoked 21 or more cigarettes/day (19). There were 1370 cases (41% smoked) and 2968 controls (39% smoked). There was a significant increase in the estimated relative risk (RR) for congenital defects in smokers compared with nonsmokers, 1.6 vs. 1.0, respectively. Defects with RR

estimates of 2.0 or higher were heart valves (2.0), inguinal hernia (2.8), pyloric stenosis (3.3), and defects of the digestive system (2.9) (19). A 1978 study, using data from a previous study on the effects of exposure to trace anesthetic agents on the health of healthcare professionals, discovered a significant association between smoking and an increase in the risk of SABs and congenital defects (20). Compared with nonsmokers, there was an increase for cardiovascular, gastrointestinal, and urogenital malformations. For all defects, smokers had a risk as high as 2.3 times that of nonsmokers (20).

A case–control study conducted in California involved 207 cases with conotruncal heart defects, 246 with neural tube defects (NTDs), 178 with limb deficiencies, and 481 controls delivered during 1987–1988 (21). The confirmed heart defects in infants included tetralogy of Fallot, d-transposition of the great arteries, truncus arteriosus communis, double-outlet right ventricle, pulmonary valve atresia with ventricular septal defect (VSD), subaortic VSD type 1, and aortico-pulmonary window (21). Confirmed cases of NTDs and limb deficiencies in infants and fetuses (spontaneous and elective abortions) included anencephaly, spina bifida cystica, craniorrhachischisis, and iniencephaly, and longitudinal, transverse, or amniotic band limb-deficiency defects of the upper and/or lower limbs (21). Moderately elevated associations, but only when both parents smoked, were found for conotruncal heart defects odds ratio (OR) 1.9 (95% CI 1.2–3.1) and limb deficiencies OR 1.7 (95% CI 0.96–2.9), but parenteral smoking was not associated with increased risks for NTDs (21).

Data relating to risk factors for l-transposition of the great arteries obtained from the Baltimore-Washington Infant Study (1981–1989), a population-based case–control study, were published in 2003 (22). L-transposition of the great arteries is an uncommon congenital cardiovascular malformation. Among 3377 cases of congenital cardiovascular malformations, 36 (1.1%) had the targeted defect. The majority of the cases had multiple cardiovascular anomalies and 47% had a single ventricle. Seventy-five percent of the cases came from two regions (clusters) within the study’s boundaries that were characterized by the release of toxic chemicals into the air and hazardous waste sites (22). For the two clusters, the case–control OR of the targeted defect was 13.4, 95% CI 4.7–37.8. Three other possible associations with l-transposition of the great arteries were identified: maternal smoking (OR 1.6, 95% CI 1.1–2.4), maternal use of hair dye (OR 3.0, 95% CI 0.9–9.7), and paternal exposure to laboratory chemicals (OR 8.2, 95% CI 1.7–40.1) (22).

NEURAL TUBE DEFECTS (NTDs) (In addition to the references cited in this section, see references 21 and 37.)

A 1979 case–control study examined the effects of cigarette smoking on closure defects of the central nervous system (CNS) (anencephaly, myelomeningocele, and encephalocele) (66 cases) and oral clefts (cleft lip or cleft palate) (66 cases) (23). Smoking frequency was determined from hospital records. Although significantly more case women smoked than did control women (83% vs. 39%), there was no association between smoking and CNS closure defects (33% vs. 39%) (23). Another 1979 study found no association, compared with nonsmokers, between smoking and congenital malformations (2.8% vs. 2.8%) (24). Similarly, no associations with specific defects (cardiovascular, gastrointestinal, genitourinary, musculoskeletal, or oral clefts) were found. After adjustment for socioeconomic class, a possible dose-dependent association with NTDs (anencephaly and spina bifida) was found. However, even if smoking was causal, it was thought to have only modest importance in the etiology of NTDs (24). In addition, women might have understated the number of cigarettes smoked because they were aware of medical opposition to smoking, especially during pregnancy. Information was more likely to be accurate for nonsmokers and heavy smokers (24).

A 1998 Swedish study found a protective effect of maternal smoking on the incidence of NTDs: total NTDs OR 0.75 (95% CI 0.61–0.91); anencephaly OR 0.49 (95% CI 0.28–0.85); and spina bifida OR 0.76 (95% CI 0.61–0.95) (25). Although the exact cause for this unexpected finding was unknown, one logical reason could have been an excess in early losses of embryos with NTDs (25).

LIMB DEFECTS (In addition to the references cited in this section, see reference 21.)

A 1994 case–control study used the Hungarian Congenital Abnormality Registry (1975–1984) and three other sources of ascertainment (1,575,904 births) to examine the association between smoking and isolated congenital limb deficiencies (six types) (26). After adjustment, the relative odds (RO) 1.48 (95% CI 0.98–2.23) were higher among smoking mothers of cases of terminal transverse limb deficiencies (but not five other types of limb deficiencies). A causal relationship could not be proven because of unadjusted potential confounders. However, the data did support the hypothesis of vascular disruption as a cause of the defects (26). A 1997 study used data from Swedish Health registries to identify 610 cases of limb reduction defects among 1,109,299 infants born between 1983 and 1993 (27). The OR for an association between any maternal smoking and all cases of limb reductions was 1.2, 95% CI 1.06–1.50. Of the various types of defects, only transverse limb reductions had an OR and 95% CI above unity (27).

CRANIOSYNOSTOSIS An increased risk of craniosynostosis (premature ossification of the skull and obliteration of the sutures resulting in a misshapen head) in mothers who smoked was reported in 1994 (28). In the Colorado Craniosynostosis Registry (1986–1989), 212 cases confirmed by an independent radiologist were identified and participated in the study. Cases and controls were interviewed between 1989 and 1991. The types of craniosynostosis were lambdoid (N = 86), sagittal (N = 69), coronal (N = 25), metopic (N = 18), and multiple suture synostosis (N = 14). Smoking was associated with craniosynostosis OR 1.7 (95% CI 1.2–2.6). For mothers who smoked more than one pack/day, the association for all types of craniosynostosis combined was OR 3.5 (95% CI 1.5–8.4) and for coronal synostosis OR 5.6 (95% CI 2.1–15.3). No significant association was noted for drinking alcohol (28). A 1999 study found a significant association between isolated craniosynostosis and smoking (29). For any smoking, the adjusted OR was 1.67 (95% CI 1.27–2.19), but a dose-dependent association also was found: OR 1.45 (95% CI 1.04–2.02) for <10 cigarettes/day and OR 2.12 (95% CI 1.50–2.99) for ≥10 cigarettes/day. Among the different types of craniosynostosis, only premature closure of the sagittal suture OR 1.48 (95% CI 1.02–2.14) reached statistical significance. Male gender had the strongest association with the defects (29). A 2000 study reported evidence that supported the conclusion of the above studies that smoking was associated with craniosynostosis (30). Using data gathered by the Centers for Disease Control and Prevention’s (CDC) population-based surveillance system (1968–1980), 61 mothers of infants with craniosynostosis and 3029 mothers of normal infants were interviewed. After exclusions, 44 cases of isolated craniosynostosis remained, 27 of which were sagittal synostosis. The association between maternal smoking and isolated craniosynostosis was OR 1.92 (95% CI 1.01–3.66) and for sagittal craniosynostosis OR 1.71 (95% CI 0.75–3.89). As with previous studies, male infants were predominantly affected. A limitation of this study was that smoking exposure was only identified for the first 3 months of pregnancy. Smoking frequency may have changed in the last part of pregnancy, which is the most critical period for the development of craniosynostosis (30).

ORAL CLEFTS (In addition to the references cited in this section, see references 23 and 24.)

Several studies and one review have examined the relationship between smoking and isolated oral clefts. In a 1983 Finish study that appeared to be well controlled for many potential confounders, no significant associations

between smoking (≥ 5 cigarettes/day) and oral clefts, CNS defects, or musculoskeletal anomalies were found (31). Using data from the Atlanta Birth Defects Case-Control Study (1968–1980), 238 cases of cleft lip and/or cleft palate and 107 cases of cleft palate were compared with 2809 match controls (32). Smoking was ascertained by structured questionnaire and exposure was defined as maternal smoking during the period 3 months before conception to 3 months after pregnancy began. After adjustment, significant associations were found between smoking and offspring with isolated cleft lip and/or palate OR 1.55 (95% CI 1.10–2.18), and isolated cleft palate OR 1.96 (95% CI 1.10–3.50) (32).

A 1999 case–control study used data from the Slone Epidemiology Unit Births Defect Study (1976–1992) to examine the relationship between smoking in the first 13 weeks of pregnancy and isolated cleft lip and palate (33). Four control groups, all with other malformations, were selected from the database. The OR and 95% CI was nearly identical in the four groups: 1.5–1.6 (95% CI 1.1–1.3, 1.8–2.7). The investigators concluded that infants with malformations other than the defect of interest were suitable controls (33). Using the same database, the investigators examined the relationship between smoking and oral clefts (34). Cases were isolated oral clefts (cleft lip alone [N = 334], cleft lip and palate [N = 494], or cleft palate [N = 244]), and oral clefts with other malformations (cleft lip [N = 58], cleft lip and palate [N = 140], or cleft palate [N = 209]). Controls had other malformations, but not oral clefts or defects possibly associated with smoking. There were no associations between smoking and any oral cleft group. However, a positive dose response was found in infants with cleft lip and palate and other malformations: 1–14 cigarettes/day OR 1.09 (95% CI 0.6–1.9), 15–24 cigarettes/day OR 1.84 (95% CI 1.2–2.9), and >24 cigarettes/day OR 1.85 (95% CI 1.0–3.5). This finding might have been related to the presence of malformations associated with smoking (34). The authors also reviewed 16 other published studies on the association between smoking and oral clefts.

A 1999 study was conducted in Denmark to determine the relationship between smoking and infant transforming growth factor alpha (TGFA) locus mutations and isolated cleft lip and/or palate (35). A second objective was to determine if there was a synergistic effect of these two risk factors. Smoking was associated with a slightly increased risk of cleft lip and/or palate, OR 1.40 (95% CI 0.88–2.00), but not with isolated cleft palate. The TGFA allele is elevated in the Danish population, occurring in 25% of both cases and controls. It was not associated with either type of oral cleft and no synergistic effect with

smoking was observed (35).

The 1996 U.S. Natality database involving 3,891,494 live births was used in a 2000 case–control study (36). Four states were excluded because they did not collect smoking data. A total of 2207 live births with cleft lip and palate were compared with 4414 normal controls. After adjustment for maternal age, race, education levels, and maternal conditions (diabetes and gestational hypertension), a significant association was found between smoking and the defect, OR 1.34 (95% CI 1.16–1.54). Moreover, compared with no smoking, a dose response was found as follows: 1–10 cigarettes/day OR 1.50 (95% CI 1.28–1.76), 11–20 cigarettes/day OR 1.55 (95% CI 1.23–1.95), and 21 or more cigarettes/day OR 1.78 (95% CI 1.22–2.59) (36).

A 2002 case–control study examined the status of a biotransformation enzyme N-acetyltransferase 2 (NAT2) in 45 cases of mothers who had had a child with an oral cleft, 39 case mothers who had had a child with spina bifida, and 73 control mothers (37). NAT2 is involved in the inactivation of toxic compounds in cigarette smoke and a few drugs. The maternal phenotype, either slow or fast NAT2 acetylators, was determined for case and control mothers. Compared with fast NAT2 acetylators, slow acetylators had no increased risk for oral clefts OR 1.0 (95% CI 0.4–2.3) or spina bifida OR 0.7 (95% CI 0.3–1.7). In the oral cleft group, significantly more mothers smoked and used medications than did controls (36% vs. 18% and 38% vs. 19%, respectively). In the spina bifida group, case mothers were similar to controls for smoking, but significantly more used medications during pregnancy (23% vs. 18% and 44% vs. 19%) (37).

A 1996 review examined the relationship between potentially teratogenic environmental exposures and nonsyndromic oral clefts (38). The origin of oral clefts is multifactorial and involves both genetic and environmental factors, one of which is believed to be cigarette smoking. Several studies, some of which are discussed above, were reviewed, which found negative and positive associations between smoking and oral clefts. Although not arriving at any conclusions as to the specific causes of isolated oral clefts (none were possible), the review did identify common misclassifications and confounding bias that could distort a study's findings (38).

GENITOURINARY DEFECTS (In addition to the references cited in this section, see references 20 and 24.)

A 1996 case–control study assessed the association between smoking and urinary tract anomalies (39). There were 112 cases and 354 controls. After adjustment, a significant association between smoking and urinary tract defects

was found, OR 2.3 (95% CI 1.2–4.5). Significant associations also were found for mothers who smoked 1–1000 cigarettes (light smoking) during the entire pregnancy, OR 3.7 (95% CI 1.7–8.6) or during the 1st trimester OR 2.9 (95% CI 1.4–6.7). When analyzed by infant sex, the associations were significant for females OR 6.1 (95% CI 2.0–18.4) and OR 5.7 (95% CI 2.0–16.5), respectively, but not for males OR 2.5 (95% CI 0.8–7.6) and OR 1.7 (95% CI 0.7–4.5), respectively. No significant associations were found for heavy smoking (>1000 cigarettes) either in the entire pregnancy or in the 1st trimester. The authors hypothesized that the lack of a dose response might have been due to a greater prevalence of fetal loss from SAB or stillbirth and that these fetuses may have had major congenital defects that involved the urinary tract (39). A 1997 study used Swedish health registries to identify 483 infants with kidney malformations and 719 infants with other urinary organ malformations with no involvement of the kidneys from 1,117,021 infants born in 1983–1993 with known smoking exposure in early pregnancy (40). A moderate significant association with kidney malformations (agenesis/hypoplasia, dysplasia, or unspecified cystic disease) was found OR 1.22 (95% CI 1.00–1.48), but there was no dose response (<10 cigarettes/day vs. ≥10 cigarettes/day). No association with other urinary organ malformations was observed (40).

A negative association was found between cigarette smoking and hypospadias in a 2002 case–control study (41). Data from the Swedish health registries provided 3262 cases among 1,413,811 infants born in 1983–1996. The association between any smoking (N = 715) and the defect was OR 0.83 (95% CI 0.76–0.90). The results were similar for those <10 cigarettes/day (N = 450) or ≥10/day (N = 265). Because the negative association was only found in those cases where the mother's parity was 1 or >4, confounding was suspected (41).

FOOT DEFECTS Several studies have discovered positive associations between maternal smoking and foot deformities. A brief 1998 report described an association between maternal smoking and foot defects, adjusted OR 1.21 (95% CI 1.14–1.29) (42). The authors also cited six other studies examining the relationship between foot defects and smoking, four of which had OR ranging from 1.0 to 2.6 with 95% CI above 1.0 (42). In a 2000 study, 346 infants with isolated clubfoot were identified from the Atlanta Birth Defects Case–Control (1968–1980) database (43). Case infants and normal controls (N = 3029) were born in 1968–1980 and the mothers were interviewed in 1982–1983. The adjusted OR and 95% CI were smoking only 1.34 (1.04–1.72), family history

only 6.52 (2.95–14.41), and smoking and family history 20.30 (7.90–52.17). The findings suggested a potentially important gene–environmental factor interaction (43). A 2002 report compared 239 cases of congenital idiopathic clubfoot (talipes equinovarus) to 365 unmatched controls in a population-based study of the relationship between maternal smoking and the foot anomaly (44). The OR for smoking and talipes equinovarus was 2.2 (95% CI 1.5–3.3). A dose-dependent response was seen and, in addition, female infants had a higher risk than males, OR 2.8 vs. 1.8. For isolated clubfoot, the OR for smoking was 2.4 (95% CI 1.6–3.6) (44).

POLAND SYNDROME A 1999 case–control study examined data from the Hungarian Congenital Abnormality Registry (HCAR) (population-based) and the Spanish Collaborative Study of Congenital Malformations (ECEMC) (hospital-based, case–control) to determine if there was an association between maternal cigarette smoking and isolated Poland sequence (45). Poland syndrome or sequence is thought to be caused by interruption of the early embryonic blood supply in the subclavian arteries and is characterized by pectoral muscle defect and ipsilateral hand deficiencies of various types and severity (45). In the HCAR database, 20 cases were identified from 1,575,904 births (prevalence 0.13 per 10,000 births), whereas in the ECEMC database, there were 32 cases among 1,405,392 births (prevalence 0.23 per 10,000 births). Logistic regression analyses (after controlling for maternal age, birth weight, gestational age, and pregnancy order) revealed that maternal smoking was associated with an increased risk of Poland sequence in both databases: HCAR (OR 2.72) and ECEMC (OR 2.61). When combined, the OR was 1.83. The investigators concluded that the results suggested a twofold increase in the risk of Poland sequence from in utero exposure to cigarette smoking. Although the number of cases were small, the results were similar in the two programs with different methodologies and possibly different uncontrolled confounding factors. However, confirmation of the findings is required (45).

GASTROSCHISIS The cause of gastroschisis is unknown, but vascular disruption during early embryonic development has been suggested. No association between cigarette smoking and the abdominal wall defect was found in two studies published in the 1990s (46,47). A 2000 review cited 10 case–control studies that reported various associations with gastroschisis, two of which associated the defect with cigarette smoking, in addition to other factors (48). In one of the studies, smoking ascertainment was obtained from birth certificates, a source known to underestimate maternal smoking, so the significant OR 4.1 (95% CI 1.4–12) is suspect. In the second study, the source

was a 2nd trimester interview and the result was OR 2.1 (95% CI 0.9–4.8) (48).

A 2002 abstract examined gastroschisis and small intestine atresia, two defects believed to arise from vascular disruption (49). Maternal smoking and use of vasoconstrictive drugs (pseudoephedrine, phenylpropanolamine, ephedrine, and ecstasy [methylenedioxymethamphetamine]) was ascertained by retrospective interview. The number of cases and controls were 205 gastroschisis, 127 small intestine atresia, 381 malformed controls, and 416 normal controls. In the four groups, the reported use of a vasoconstrictive drug in the first 2 months of pregnancy was 20%, 21%, 13%, and 12%, respectively, whereas maternal smoking was present in 48%, 24%, 34%, and 34%, respectively. The OR for vasoconstrictive drug use or smoking were gastroschisis, 1.7 (95% CI 1.0–2.8) and 1.5 (95% CI 1.1–2.2); small intestine atresia, 2.0 (95% CI 1.0–3.7) and 1.0 (95% CI 0.6–1.7). Combined exposure to the drugs and smoking increased the gastroschisis risk 2.1-fold and the small intestine atresia risk 2.8-fold. Vasoconstrictive drug use and smoking 20 or more cigarettes/day increased the risks 3.6-fold and 4.2-fold, respectively (49).

Neonatal Complications

NEONATAL INTENSIVE CARE UNIT ADMISSIONS Infants of smoking mothers have an increased risk of admission to an NICU (5). Approximately 14,000 to 26,000 admissions annually may be attributable to smoking.

RETINAL ABNORMALITIES A 2000 study investigated the relationship between maternal cigarette smoking and retinal abnormalities in neonates (50). The infants, both cases and controls (162 each), were grouped by birth weight: small for gestational age (SGA), appropriate for gestational age (AGA), and large for gestational age (LGA). All infants were delivered at term, had clear amniotic fluid, Apgar scores of 7 or higher, and were healthy with no signs of fetal distress either at birth or during the first 3 days after birth. Smoking was determined by maternal interview. Infants of mothers who had stopped smoking during pregnancy were excluded. Eye examinations were conducted on the 2nd or 3rd day of life by one ophthalmologist who was blinded to the maternal smoking history. Compared with infants of nonsmoking mothers, a highly significant increase in the incidence of retinal arterial narrowing and straightening (RANS) was observed in the eyes of infants of smoking mothers, 52 vs. 10 eyes, respectively. Significant increases in the incidences of RANS also were observed when the results were analyzed by birth weight: SGA 22

vs. 2, AGA 26 vs. 8, and LGA 4 vs. 0 eyes, respectively. In addition, eyes of infants in the smoking exposure group had a significant increase in the incidence of retinal venous dilatation and tortuosity (RVDT), 100 vs. 36, respectively. The results for RVDT were significant in SGA (38 vs. 10 eyes) and AGA (56 vs. 24 eyes) infants, but not in LGA infants (6 vs. 2 eyes). The hematocrit of the infants was significantly higher in the total smoking group and in each birth weight subgroup. Intraretinal hemorrhage (IH), in association with elevated hematocrit and RVDT, was found in the total smoking group, 61 vs. 31 eyes, respectively. When analyzed by birth weight, only the incidence in AGA infants was significantly increased, 39 vs. 18 eyes, respectively. No IH was observed when RANS was present. The IH resolved within 3 months and the other retinal abnormalities (RANS, RVDT) resolved by 6 months of age. The rapid resolution of the IH and other considerations suggested that it would not lead to amblyopia. However, concern was expressed that the vascular retinal abnormalities could be a sign that the exposed infants were predisposed to vascular disease early in adult life (50).

Infant/Adolescent Complications

NEURODEVELOPMENT Smoking during pregnancy may have long-term effects on the cognitive performance, emotional development, perceptual motor abilities, and behavior of offspring (1–3,5,8,10–13,14,16,51–53). Similar findings have been found in experimental animal studies (5,14). Negative effects on learning, such as reading, mathematics, and general ability, have been detected in children as old as 11 years (2,11,13,51). In addition, behavior problems and attention deficit hyperactivity disorder (ADHD) have been observed (3,8,13,51,52). Mean decreases in IQ of 5 points for each 100-g weight decrement have been reported (3). A 1996 study of 10-year-olds with idiopathic mental retardation (most had mild retardation with an IQ between 50 and 70) found, after adjustment for multiple factors including LBW and alcohol, that maternal smoking was associated with a 44% increase in the prevalence of mental retardation (52). When mothers smoked at least 1 pack/day, the increase was 70% after adjustment. Some of the adverse neurodevelopment outcomes cannot be completely separated from potential confounding factors such as the actual amount of smoking, socioeconomic status, education, and passive smoking (11), but the experimental animal studies support the findings. Moreover, more recent studies have controlled for social and family history factors and have found consistent patterns of deficits (15). For example, a 1996 study and subsequent correspondence found, after adjustment for

socioeconomic status, parental IQ and ADHD status, and alcohol, a significant association between maternal smoking and ADHD as well as a nearly significant association with decreased IQ (53–55).

SUDDEN INFANT DEATH SYNDROME An increased risk of SIDS has been associated with maternal cigarette smoking (3–5,7–9,12,13,14,16). Approximately 24% (1200 to 2200 cases) of SIDS/year may be due to smoking (5). Prenatal and postnatal smoking doubles the risk of SIDS from a baseline of 2.3 per 1000 births in nonsmokers to 4.6 per 1000 births in smokers (4). The greatest risk appears to be for infants exposed both prenatally and postnatally (9). The risk is also dose-dependent, increasing with the number of cigarettes smoked per day (4,13).

CHILDHOOD MORBIDITY An increased risk of other diseases and complications has been associated with prenatal and postnatal exposure to cigarette smoke. Separating the effects of these exposure periods on childhood morbidity is very difficult because most infants exposed during gestation will also be exposed postnatally. For example, data from 1988 estimated that only 1.2% of children in the United States exposed to cigarette smoking in utero were not exposed after birth (9). Exposed infants have increased incidences of pneumonia and bronchitis (2,5), childhood asthma (5,12), other respiratory illnesses (7,12), childhood obesity (5), and otitis media (7). Not surprisingly, they also have more hospital admissions for pneumonia and bronchitis (5,12).

Smoking Cessation

See Nicotine Replacement Products.

BREASTFEEDING SUMMARY

Nicotine is excreted into breast milk. Nursing infants of mothers who smoke will be exposed to nicotine by inhalation and orally (13,56). Cigarette smoking may also decrease the volume of milk (56). In addition, smoking decreases the duration of breastfeeding. A 1998 review cited data from an earlier survey that found that the duration of breastfeeding was significantly decreased in women who smoked compared with those who did not smoke (57). In nonsmokers, the duration was 145.0 days, whereas the duration of breastfeeding in those who smoked ≤ 1 pack/day or > 1 pack/day was 99.5 and 77.9 days, respectively. Women who are breastfeeding should be urged to quit because cigarette smoking is a significant risk to their health and to their infant's health (see the above sections on Neonatal Complications and Infant/Adolescent Complications). If a woman cannot stop smoking, at least she should try not to

smoke in the same room with the infant or during nursing. The American Academy of Pediatrics encourages smoking cessation during lactation, but makes no recommendation for or against nicotine replacement products because of insufficient data (58).

CIGUATOXIN

Toxin

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Of the cases described, none of the liveborn infants appeared to have had lasting sequelae from exposure to the toxin. However, long-term adverse effects could not be completely excluded in the one infant exposed shortly before birth. The timing of the exposure in relation to delivery may have been a factor in this case. The association between the toxin and the abortion cannot be determined from the available data. Transplacental passage of the toxin has not been studied, but its high molecular weight (1112) presumably limits its crossing the placenta.

FETAL RISK SUMMARY

Ciguatoxin is a marine toxin produced by the blue-green algae, *Gambierdiscus toxicus*, that is concentrated in the fish food chain (1). The toxin is stable to cooking, freezing, drying, or salting and results in ciguatera poisoning when infected tropical fish are ingested (1). Other toxins that may be present with ciguatoxin include scaritoxin and maitotoxin (2,3).

Eight cases of ciguatera poisoning during pregnancy have been published (1–4). An Australian woman at term developed symptoms of poisoning within 4 hours of ingesting the toxin from a reef fish (1). Fetal symptoms of poisoning, beginning simultaneously with the mother's symptoms, consisted of "tumultuous fetal movements, and an intermittent peculiar fetal shivering" (1). The unusual fetal movements continued for 18 hours, then gradually subsided over the next 24 hours. A cesarean section performed 2 days later delivered a 3800-g male infant with meconium aspiration and left-sided facial palsy. At 1 day of age, possible myotonia of the muscles of the hands was noted. Pulmonary signs and symptoms of the meconium aspiration resolved with time. At 6 weeks of age, the baby had not yet smiled, but he was otherwise normal (1). The mother was unable to breast feed due to excruciating hyperesthesia of the nipples.

Six cases of ciguatera poisoning during pregnancy (gestational ages not provided) were described by researchers from the San Francisco Bay area in an abstract published in 1991 (2). The women had neurologic, neuromuscular, and cardiovascular signs and symptoms of poisoning, and all experienced increased fetal activity in conjunction with their symptoms. One fetus was aborted during the acute phase of the poisoning (2). The other five women were delivered, at or near term, of apparently normal infants without sequelae from the exposure. The exposure–delivery intervals for the latter five cases were not specified.

In another case from California, a woman in her 16th week of gestation developed ciguatera poisoning 4 hours after eating a meal of cooked barracuda (4). This case may have been briefly mentioned in another reference (3). Increased fetal movements persisted only for a few hours. A cesarean section, performed 19 days past term, delivered a normal, 3630-g male infant who was developing normally at 10 months of age.

BREASTFEEDING SUMMARY

Ciguatoxin is apparently excreted in breast milk. A 4-month-old infant was breastfed 1 hour and 3 hours after his mother consumed a portion of a presumed ciguatera-infected fish (5). The mother's symptoms of poisoning developed within a few hours of ingesting the fish meal and resolved by 3 weeks. She continued to nurse her infant throughout the entire course of her illness. Approximately 10 hours after the first nursing following the mother's fish meal, the baby became colicky, irritable, and developed diarrhea lasting 48 hours, followed by a fine maculopapular rash. The signs and symptoms in the infant, which were considered compatible with ciguatera toxicity by the authors, completely resolved within 2 weeks (5).

Ciguatoxin was thought to be the cause of green stools in a nursing 3-month-old infant who was breastfed 12 hours after the mother had developed symptoms of ciguatera poisoning (6). The infant was changed to formula and then rechallenged with breast milk a few days later, resulting in the reappearance of the green stools. Prompt cessation of breastfeeding again resolved the problem. No other symptoms were observed in the infant.

CILOSTAZOL

Hematological Agent (Antiplatelet)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of cilostazol during human pregnancy have been located. The drug is teratogenic and toxic in two animal species, but the complete lack of human data prevents any assessment of the risk that cilostazol presents to a human fetus.

FETAL RISK SUMMARY

Cilostazol, an antiplatelet agent, is an inhibitor of cellular phosphodiesterase III. It is indicated for the reduction of symptoms of intermittent claudication. The drug undergoes extensive hepatic metabolism. Two of the metabolites are active.

Reproduction studies have been conducted with cilostazol in rats and rabbits (1). No effects on fertility or mating performance were observed in male and female rats at oral doses up to 1000 mg/kg/day. The highest dose produced systemic exposures less than 1.5 times in males, and about 5 times in females, the human systemic exposure based on AUC of unbound cilostazol at the maximum recommended human dose. In pregnant rats, the 1000-mg/kg/day dose resulted in decreased fetal weights and an increased incidence of congenital malformations in the cardiovascular (ventricular septal, aortic arch, and subclavian artery defects), renal (renal pelvic dilation), and skeletal (14th rib; retarded ossification) systems. Increased incidences of ventricular septal defects and retarded ossification were also observed at 150 mg/kg/day. This same dose administered to rats in late pregnancy was associated with stillbirths and decreased birth weight. In pregnant rabbits, a dose of 150 mg/kg/day was associated with an increased incidence of retarded ossification of the sternum (1).

It is not known if cilostazol crosses the human placenta to the fetus. The molecular weight (about 369) is low enough that transfer to the fetus should be expected. Moreover, transfer of the two active metabolites may also occur.

BREASTFEEDING SUMMARY

No reports describing the use of cilostazol during human lactation have been located. The molecular weight (about 369) suggests that the drug will be excreted into breast milk. The effect on a nursing infant from exposure to cilostazol in milk is unknown. Because of the potential for severe adverse effects, breastfeeding is not recommended.

CIMETIDINE

Gastrointestinal Agent (Antisecretory)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No increased risk of congenital malformations attributable to cimetidine in humans has been reported. Feminization of the fetus has not been reported, but warrants study.

FETAL RISK SUMMARY

Cimetidine is a histamine 2-receptor antagonist (H₂ blocker) that inhibits gastric acid secretion. In pregnancy, the antihistamine is primarily used for the treatment of peptic ulcer disease and for the prevention of gastric acid aspiration (Mendelson's syndrome) prior to delivery.

In studies with multiple animal species, no evidence of impaired fertility or teratogenesis was observed with doses up to 40 times higher than the usual human dose (1). Cimetidine does have weak antiandrogenic effects in animals, as evidenced by a reduction in the size of testes, prostatic glands, and seminal vesicles (2,3), and in humans, by reports of decreased libido and impotence (4). Conflicting reports on the antiandrogenic activity in animals exposed in utero to cimetidine have been published (5–9).

Three references, all from the same research group, described the effects on male rats of exposure to cimetidine from gestation up to the time of weaning (5–7). The rats had decreased weights of testicles, prostate gland, and seminal vesicles at 55 and 110 days of age as compared with nonexposed controls. Exposed animals also had reduced testosterone serum levels, lack of sexual motivation, and decreased sexual performance, but normal luteinizing hormone levels. The observed demasculinization effects were still present 35 days after discontinuation of the drug, indicating that exposure may have modified both central and end-organ androgen receptor activity or responsiveness (5–7). In contrast, researchers from the manufacturer treated rats similarly to the rats in the above reports and found no effect on any of the

parameters described previously (8). Another group found no effect of cimetidine exposure during gestation and lactation on masculine sexual development, except for an insensitivity of the pituitary gland to androgen regulation, and no effect at all on female pups (9). These authors concluded that cimetidine was not an animal teratogen.

Cimetidine crosses the placenta to the fetus by simple diffusion (10–14). In an in vitro study, the placental transfer of cimetidine across human and baboon placentas was similar (10). Cimetidine is not metabolized by the placenta (11). At term, cimetidine crosses the placenta, resulting in a peak mean fetal:maternal ratio of 0.84 at 1.5–2 hours (12). In an earlier study, 20 women were administered a single, 200-mg bolus injection of cimetidine prior to delivery (19 vaginal, 1 cesarean section) (13). The drug was detected in all but two cord blood samples with levels of 0.05–1.22 mcg/mL. The injection-to-delivery intervals in the two patients with no cimetidine in cord blood were prolonged, 435 and 780 minutes. A 1983 study measured a peak mean fetal:maternal ratio of about 0.5 at 2.5 hours (14).

The manufacturer has received a number of reports of women who took the drug during pregnancy, including throughout gestation (B. Dickson, personal communication, Smith Kline & French Laboratories, 1986). They were aware of three isolated incidences of congenital defects, apparently unrelated to cimetidine therapy, including congenital heart disease, mental retardation detected later in life, and clubfoot.

Cimetidine was used throughout pregnancy in a case ending in intrauterine fetal death, but the adverse outcome was believed to be due to severe maternal disease and captopril therapy (see Captopril) (15). Three pregnant women with gastric hemorrhage secondary to peptic ulcer disease were described in a 1982 report (16). The women, at 16, 12, and 31 weeks' gestation, were treated for various lengths of time with cimetidine and other standard therapy and all delivered healthy newborns without congenital defects or metabolic disturbances. In another report, transient liver impairment was described in a newborn exposed to cimetidine at term (17). However, other reports have not confirmed this toxicity (13,18–35).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 460 newborns had been exposed to cimetidine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 20 (4.3%) major birth defects were observed (20 expected). Specific data were available for six defect categories, including (observed/expected) 8/5 cardiovascular defects, 0/1 oral clefts, 0/0

spina bifida, 1/1 polydactyly, 0/1 limb reduction defects, and 1/1 hypospadias. These data do not support an association between the drug and congenital defects.

Cimetidine has been used at term either with or without other antacids to prevent maternal gastric acid aspiration pneumonitis (Mendelson's syndrome) (13,14,19–35). No neonatal adverse effects were noted in these studies.

In a 1991 report, 23 women were exposed in the 1st trimester to cimetidine (N = 9), ranitidine (N = 13), or both (N = 1) (36). The pregnancy outcomes were spontaneous abortions (SABs) 2, elective abortions (EABs) 2, normal births 18, and 1 infant with a large hemangioma of the upper eye lid (removed without incidence). The outcomes suggested that the agents were not teratogenic (36).

A 1996 prospective cohort study compared the pregnancy outcomes of 178 women who were exposed during pregnancy to H₂ blockers with 178 controls matched for maternal age, smoking, and heavy alcohol consumption (37). All of the women had contacted a teratology information service concerning gestational exposure to H₂ blockers (subjects) or nonteratogenic or nonfetotoxic agents (controls). Among subjects (mean daily dose in parentheses), 71% took ranitidine (258 mg), 16% cimetidine (487 mg), 8% famotidine (32 mg), and 5% nizatidine (283 mg). There were no significant differences between the outcomes of subjects and controls in terms of live births, SABs and EABs, gestational age at birth, delivery method, birth weight, infants small for gestational age, or major malformations. Among subjects, there were 3 birth defects (2.1%) among the 142 exposed to H₂ blockers in the 1st trimester: one each of atrial septal defect, ventricular septal defect, and tetralogy of Fallot. There were 5 birth defects (3.0%) among the 165 exposed anytime during pregnancy. For controls, the rates of defects were 3.5% (1st trimester) and 3.1% (anytime). There were also no differences between the groups in neonatal health problems and developmental milestones, but two children (one subject and one control) were diagnosed as developmentally delayed. The investigators concluded that 1st trimester exposure to histamine H₂ blockers did not represent a major teratogenic risk (37).

Data from the Swedish Medical Birth Registry were presented in 1998 (38). A total of 553 infants (6 sets of twins) were delivered from 547 women who had used acid-suppressing drugs early in pregnancy. The odds ratio (OR) for malformations after H₂ blockers was 0.86, 95% confidence interval (CI) 0.33–2.23. Of the 19 infants with birth defects, 9 had been exposed to H₂ blockers, 1 of whom was also exposed to omeprazole. Cimetidine was the only acid-

suppressing drug exposure in 35 infants. Three other offspring were exposed in utero to cimetidine combined either with famotidine (one infant) or with omeprazole (two infants). Two infants with birth defects were exposed to cimetidine: an encephalocele and an unstable hip (see Omeprazole for additional details of this study) (38).

Two databases, one from England and the other from Italy, were combined for a study published in 1999 that was designed to assess the incidence of congenital malformations in women who had received a prescription during the 1st trimester for an acid-suppressing drug (cimetidine, ranitidine, and omeprazole) (39). Nonexposed women were selected from the same databases to form a control group. SABs and EABs (except two cases for anomalies that were grouped with stillbirths) were excluded from the analysis. Stillbirths were defined as any pregnancy loss occurring at 28 weeks' gestation or later. Cimetidine was taken in 233 pregnancies, resulting in 234 live births (14 [6.0%] premature), 3 stillbirths, and 1 neonatal death. Eleven (4.7%) of the newborns had a congenital malformation (shown by system): craniofacial (cleft lip and palate), musculoskeletal (dysplastic hip/dislocation/clicking hip N = 3; polydactyly), genital and urinary (hypospadias N = 2; congenital hydrocele/inguinal hernia, ovarian cyst, renal defects/hydronephrosis), and gastrointestinal (pyloric stenosis). In addition, two newborns had a small head circumference for gestational age. In comparison, the outcomes of 1547 nonexposed pregnancies included 1560 live births (115 [7.4%] premature), 15 stillbirths (includes 2 elective abortions for anomalies), and 10 neonatal deaths. Of the newborns, 64 (4.1%) had malformations involving the following: CNS (N = 2), head/face (N = 13), eye (N = 2), heart (N = 7), muscle/skeletal (N = 13), genital/urinary (N = 18), gastrointestinal (N = 2), and those of polyformation (N = 3) or known genetic defects (N = 4). There were 21 newborns that were small for gestational age and 78 had a small head circumference for gestational age. The relative risk of malformation (adjusted for mother's age and prematurity) associated with cimetidine was 1.3 (95% CI 0.7–2.6), with omeprazole 0.9 (95% CI 0.4–2.4), and with ranitidine 1.5 (95% CI 0.9–2.6) (39).

A population-based observational cohort study formed by linking data from three Swedish national healthcare registers over a 10-year period (1995–2004) was reported in 2009 (40). The main outcome measures were a diagnosis of allergic disease or a prescription for asthma or allergy medications. The drug types included in the study were gastric acid suppressors, including H2 blockers, prostaglandins, proton pump inhibitors, combinations for eradication

of *Helicobacter pylori*, and drugs for peptic ulcer and gastro-esophageal reflux disease. Of 585,716 children, 29,490 (5.0%) met the diagnosis and 5645 (1%) had been exposed to gastric acid suppression therapy in pregnancy. Of these children, 405 (0.07%) were treated for allergic disease. For developing allergy, the odds ratio (OR) was 1.43, 98% CI 1.29–1.59, irrespective of the drug, time of exposure during pregnancy, and maternal history of allergy. For developing childhood asthma, but not other allergic diseases, the OR was 1.51, 95% CI 1.35–1.69, irrespective of the type of acid-suppressive drug and the time of exposure in pregnancy. The authors proposed three possible mechanisms for their findings: (a) exposure to increased amounts of allergens could cause sensitization to digestion labile antigens in the fetus; (b) maternal Th2 cytokine pattern could promote an allergy-prone phenotype in the fetus; and (c) maternal allergen-specific IgE could cross the placenta and sensitize fetal immune cells to food and airborne allergens. Several limitations of the study that might have affected their findings were identified, including a general increase in childhood asthma but not necessarily an increase in allergic asthma (40). The study requires confirmation.

A 2005 study evaluated the outcomes of 553 pregnancies after exposure to H2 blockers, 501 (91%) in the 1st trimester (41). The data were collected by the European Network of Teratology Information Services (ENTIS), The agents and number of cases were cimetidine 113, famotidine 75, nizatidine 15, ranitidine 335, and roxatidine 15. No increase in the number of major malformations were noted (41).

One group of reviewers has recommended that cimetidine not be used during pregnancy because of the possibility for feminization, as observed in some animals and in nonpregnant humans. This effect from in utero exposure to cimetidine has not been studied (42). However, as additional human pregnancy data accumulated, more reviews on the treatment of GERD have concluded that H2 blockers, with the possible exception of nizatidine, could be used in pregnancy with relative safety (43–46).

A 2009 meta-analysis of published studies was conducted to assess the safety of H2 blockers that were used in 2398 pregnancies (47). Compared with 119,892 nonexposed pregnancies, the OR for congenital malformations was 1.14 (95% CI 0.89–1.45), whereas the ORs and 95% CIs for SABs, preterm birth, and small for gestational age were 0.62 [0.36–1.05], 1.17 [0.94–1.147], and 0.28 [0.06–1.22], respectively. The authors concluded that H2 blockers could be used safely in pregnancy (47).

A 2010 study from Israel identified 1148 infants exposed in the 1st trimester

to H₂ blockers (48). No association with congenital malformations was found (OR 1.03, 95% CI 0.80–1.32). Moreover, no association was found with EABs, perinatal mortality, premature delivery, low birth weight, or low Apgar scores (48).

BREASTFEEDING SUMMARY

Cimetidine is excreted into breast milk and may accumulate in concentrations greater than that found in maternal plasma (49). Following a single 400-mg oral dose, theoretical milk:plasma ratio of 1.6 has been calculated. Multiple oral doses of 200 and 400 mg result in milk:plasma ratios of 4.6 to 7.44, respectively. An estimated 6 mg of cimetidine per liter of milk could be ingested by the nursing infant. The results of a study published in 1995 suggested that cimetidine was actively transported into milk (50). Using single oral doses of 100, 600, or 1200 mg in healthy lactating volunteers, the average of the mean milk:serum ratios for the three doses was 5.77 (range 5.65–5.84), much higher than that predicted by diffusion.

The clinical significance of an infant ingesting cimetidine from milk is unknown. Theoretically, the drug could adversely affect the nursing infant's gastric acidity, inhibit drug metabolism, and produce central nervous system stimulation, but these effects have not been reported. The American Academy of Pediatrics classifies cimetidine as compatible with breastfeeding (51).

CINACALCET

Calcium Receptor Agonist

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Two reports described the use of cinacalcet late in the 3rd trimester, but information on the newborn condition was provided only in one case. Cinacalcet is the first member of a new drug class, so there are no other comparable agents. Moreover, therapy in most patients will be prolonged (months). Animal data do show developmental toxicity (growth restriction) but maternal toxicity also was evident. The near absence of human pregnancy experience prevents a more complete assessment of the embryo–fetal risk. Nevertheless, if a woman’s condition requires cinacalcet, it should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Cinacalcet increases the sensitivity of the calcium-sensing receptor to activation by extracellular calcium. It is indicated for the treatment of secondary hyperparathyroidism in patients with chronic kidney disease on dialysis. It also is indicated for the treatment of hypercalcemia in patients with parathyroid carcinoma. Cinacalcet is rapidly and extensively metabolized to inactive metabolites. The terminal half-life is 30–40 hours and plasma protein binding is 93%–97% (1).

Reproduction studies have been conducted in rats and rabbits. In pregnant rats, no teratogenicity was observed with daily oral doses that produced exposures up to four times those resulting with a human dose of 180 mg/day based on AUC (HE). Decreased fetal weights were observed with daily doses producing exposures that were less than one to four times the HE, but maternal toxicity (decreased food consumption and body weight gain) also was noted. Daily doses that produced exposures less than the HE given during gestation

through lactation revealed no evidence of adverse fetal or pup (postweaning) effects. When higher doses were given (two to three times the HE), maternal signs of hypocalcemia (periparturient mortality and early postnatal pup death) and reductions in postnatal maternal and pup weight were noted. In pregnant rabbits, daily oral doses that produced exposures less than the HE revealed no evidence of fetal harm, but maternal toxicity (reduced food consumption and body weight gain) was observed (1).

No evidence of carcinogenic effects was observed in long-term studies in mice and rats.

Assays for mutagenicity were negative. In fertility studies in male and female rats, only daily doses producing exposures greater than four times the HE were associated with slight toxicity (decreases in food consumption and body weight) (1).

It is not known if cinacalcet crosses the human placenta. The drug crosses the rabbit placenta (1). The molecular weight (about 358 for the free base) and long terminal half-life suggest that the drug will cross to the embryo and fetus. However, the extensive metabolism and high plasma protein binding should decrease the exposure to the parent drug.

A 2009 case report described a pregnant 40-year-old woman with severe primary hyperparathyroidism (2). She presented at 32 weeks' gestation with hypertension and hypercalcemia. Treatment with cinacalcet (240 mg/day) and calcitonin (100 mcg SC every other day) decreased the serum calcium. A planned cesarean section delivery was conducted at 34 weeks. No information on the newborn was provided, except that the cord blood had elevated calcium as compared to the mother's blood, indicating that the physiological calcium gradient between the mother and the child had not been disrupted by cinacalcet (2).

In a 2013 report, a 21-year-old woman with primary hyperparathyroidism attributable to parathyromatosis presented with markedly elevated total calcium and ionized calcium levels at 14 weeks' gestation (3). She underwent surgery at 22 weeks to remove hypercellular parathyroid tissue. Because of persistent hypercalcemia that was increasing, cinacalcet (30 mg/day) was started at 33 weeks' gestation and was successful in decreasing the calcium levels. At 38 weeks, a cesarean section delivered a healthy male infant. Other than that he was doing well at 6 weeks of age; no other details about the infant were provided (3).

BREASTFEEDING SUMMARY

No reports describing the use of cinacalcet during human lactation have been located. The molecular weight (about 358 for the free base) and long terminal half-life (30–40 hours) suggest that the drug will be excreted into breast milk. However, the extensive metabolism and high plasma protein binding (93%–97%) should decrease the amount of parent drug in milk. The effect of this exposure on a nursing infant is unknown, but nausea/vomiting, the most common toxicity observed in adults, and hypocalcemia are potential adverse effects. The latter toxicity is particularly worrisome because of an infant's high requirements for calcium during bone accretion.

CINNARIZINE

[Withdrawn from the market. See 9th edition.]

CINOXACIN

Urinary Germicide (Quinolone)

PREGNANCY RECOMMENDATION: No Human Data—Animal Data
Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably
Compatible

PREGNANCY SUMMARY

No reports describing the use of cinoxacin during human pregnancy have been located. Because of the potential for cinoxacin-induced arthropathy in the fetus and the newborn, the manufacturer recommends that it should not be used in pregnancy (1).

FETAL RISK SUMMARY

Cinoxacin is a synthetic, oral quinolone antibacterial agent indicated for the treatment of urinary tract infections. Its actions and uses are similar to nalidixic acid. No evidence of impaired fertility or fetal harm was observed in reproduction studies in rats and rabbits at doses up to 10 times the daily human dose (1).

It is not known if cinoxacin crosses the placenta. The molecular weight (about 262) is low enough that transfer to the fetus should be expected.

BREASTFEEDING SUMMARY

No reports describing the use of cinoxacin during human lactation have been located. Because of the potential for arthropathy in a nursing infant, the manufacturer recommends that it should not be used in lactating women (1).

CIPROFLOXACIN

Anti-infective (Quinolone)

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

The use of ciprofloxacin during human gestation does not appear to be associated with an increased risk of major congenital malformations. Although a number of birth defects have occurred in the offspring of women who had taken this drug during pregnancy, the lack of a pattern among the anomalies is reassuring. However, a causal relationship with some of the birth defects cannot be excluded. Because of this and the available animal data, the use of ciprofloxacin during pregnancy, especially during the 1st trimester, should be used with caution, but the overall risk appears to be low. A 1993 review on the safety of fluoroquinolones concluded that these antibacterials should be avoided during pregnancy because of the difficulty in extrapolating animal mutagenicity results to humans and because interpretation of this toxicity is still controversial (1). The authors of this review were not convinced that fluoroquinolone-induced fetal cartilage damage and subsequent arthropathies were a major concern, even though this effect had been demonstrated in several animal species after administration to both pregnant and immature animals and in occasional human case reports involving children (1). Others have also concluded that fluoroquinolones should be considered contraindicated in pregnancy, because safer alternatives are usually available (2).

FETAL RISK SUMMARY

Ciprofloxacin is a synthetic, broad-spectrum antibacterial agent. As a fluoroquinolone, it is in the same class as enoxacin, levofloxacin, lomefloxacin, norfloxacin, ofloxacin, and sparfloxacin. Nalidixic acid and cinoxacin are also quinolone drugs.

Ciprofloxacin did not impair fertility and was not embryotoxic or teratogenic in

mice and rats at doses up to 6 times the usual human daily dose. A similar lack of embryo and fetal toxicity was observed in rabbits. As with other quinolones, multiple doses of ciprofloxacin produced permanent lesions and erosion of cartilage in weight-bearing joints, leading to lameness in immature rats and dogs (3).

A 2005 study measured the amount of three fluoroquinolones (ciprofloxacin, ofloxacin, levofloxacin) that crossed the perfused human placenta (4). All three agents crossed the placenta from the maternal to the fetal compartment, but the amounts crossing were small: 3.2%, 3.7%, and 3.9%, respectively.

A number of reports have described the use of ciprofloxacin during human gestation (2,5–16). In a 1993 reference, data on 103 pregnancies exposed to the drug were released by the manufacturer (5). Of these cases, there were 63 normal, live newborns (52 exposed during 1st trimester, 7 during the 2nd or 3rd trimesters, and 4 in which the exposure time was unknown), 18 terminations, 10 spontaneous abortions (SABs) (all 1st trimester), 4 fetal deaths (3 during 1st trimester, 1 in 3rd trimester), and 8 infants with congenital defects (7 exposed between 2 and 12 weeks postmenstruation and 1 on a single day of her last menstrual period) (these defects are included among those shown in reference 11 below).

No congenital malformations were observed in the infants of 38 women who received either ciprofloxacin (N = 10) or norfloxacin (N = 28) during pregnancy (35 in the 1st trimester) (6). Most (N = 35) received the drugs for the treatment of urinary tract infections. Matched to a control group, the fluoroquinolone-exposed pregnancies had a significantly higher rate of cesarean section for fetal distress and their infants were significantly heavier. No differences were found between the groups in infant development or in the musculoskeletal system (6).

A 1995 letter described seven pregnant women with multidrug-resistant typhoid fever who were treated with ciprofloxacin during the 2nd and 3rd trimesters (7). All delivered healthy infants who were doing well at 5 years of age without evidence of cartilage damage. The authors also described the healthy outcome of another pregnant woman treated with ciprofloxacin during the 1st trimester. That infant was doing well at 6 months of age. A subsequent letter, also in women with typhoid fever, described three pregnant women in the 2nd and 3rd trimesters who were treated with ciprofloxacin (8). A normal outcome occurred in one patient and the pregnancies of the other two were progressing satisfactory.

A surveillance study on the use of fluoroquinolones during pregnancy was

conducted by the Toronto Motherisk Program among members of the Organization of Teratology Information Services (OTIS) and briefly reported in 1995 (9). Pregnancy outcome data were available for 134 cases, of which 68 involved ciprofloxacin, 61 were exposed to norfloxacin, and 5 were exposed to both the drugs. Most (90%) were exposed during the first 13 weeks postconception. Fluoroquinolone-exposed pregnancies were compared to matched controls and there were no differences in live births (87% vs. 86%), terminations (3% vs. 5%), miscarriages (10% vs. 9%), abnormal outcomes (7% vs. 4%), cesarean section rate (12% vs. 22%), fetal distress (15% vs. 15%), and pregnancy weight gain (15 vs. 16 kg). The mean birth weight of the exposed infants was 162 g higher than those in the control group and their gestations were a mean 1 week longer (9).

A 16-year-old became pregnant about 1.5 years after a combined liver–kidney transplant for type 1 primary hyperoxaluria (10). She was treated with immunosuppressive agents (prednisone 10 mg/day, cyclosporine 200 mg/day, and azathioprine 75 mg/day) and penicillin 500 mg/day and ciprofloxacin 250 mg/day throughout pregnancy. A healthy 2860-g female infant was delivered by cesarean section at 38 weeks' gestation. Apgar scores were 4 and 9 at 1 and 5 minutes, respectively (10).

An abstract, published in 1996, described six pregnancies exposed to ciprofloxacin during the 1st trimester (11). Five healthy babies (one set of twins) had been born and two pregnancies were progressing normally. In another 1996 reference, no congenital anomalies were reported in 32 pregnancies exposed to a fluoroquinolone (9 ciprofloxacin, 13 norfloxacin, 10 ofloxacin) (12). In a 1997 reference, a pregnant woman with Q fever (*Coxiella burnetii*) at 28 weeks' gestation was treated with ciprofloxacin for 3 weeks (13). Because her symptoms did not resolve, a cesarean section was performed at 32 weeks' gestation with delivery of a healthy, female infant. No evidence of transplacental spread of the infection, which is known to cause stillbirth and abortion in animals and humans, was found (13).

A prospective follow-up study conducted by the European Network of Teratology Information Services (ENTIS) analyzed 549 pregnancies exposed to fluoroquinolones (70 to ciprofloxacin) (2). Data on another 116 prospective and 25 retrospective pregnancy exposures to the antibiotics were also included. From the 549 follow-up cases, 509 were treated during the 1st trimester, 22 after the 1st trimester, and in 18 cases the exposure occurred at an unknown gestational time. The liveborn infants were delivered at a mean gestational age of 39.4 weeks and had a mean birth weight of 3302 g, length of 50.3 cm, and

head circumference of 34.9 cm. Of the 549 pregnancies, there were 415 liveborn infants (390 exposed during the 1st trimester), 356 of which were normal-term deliveries (including one set of twins), 15 were premature, 6 were small-for-gestational age (IUGR, <10th percentile), 20 had congenital anomalies (19 from mothers exposed during the 1st trimester; 4.9%), and 18 had postnatal disorders unrelated to either prematurity, low birth weight, or malformations (11). Of the remaining 135 pregnancies, there were 56 spontaneous abortions or fetal deaths (none late) (1 malformed fetus), and 79 elective abortions (4 malformed fetuses). A total of 116 (all involving ciprofloxacin) prospective cases were obtained from the manufacturer's registry. Among these, there were 91 liveborn infants, 6 of whom had malformations. Of the remaining 25 pregnancies, 15 were terminated (no malformations reported), and 10 aborted spontaneously (one embryo with acardia, no data available on a possible twin). Thus, of the 666 cases with known outcomes, 32 (4.8%) of the embryos, fetuses or newborns had congenital malformations. Based on previous epidemiologic data, the authors concluded that the 4.8% frequency of malformations did not exceed the background rate. Finally, 25 retrospective reports of infants with anomalies, who had been exposed in utero to fluoroquinolones, were analyzed, but no specific patterns of major congenital malformations were detected (2).

The defects observed in the 10 infants followed prospectively and in the 8 infants reported retrospectively, all with 1st trimester ciprofloxacin exposure, were (2) as follows:

Teeth discoloration

Hypoplastic auricle, absence external auditory canal
Rubinstein–Taybi syndrome
Femur aplasia
Femur–fibula–ulna complex
Ectrodactyly
Defects of heart, trachea, esophagus, urethra, anus, gallbladder, skeleton,
heterotopic gastric mucosa, mucosa
Heart defect

The authors of the above study concluded that pregnancy exposure to quinolones was not an indication for termination, but that this class of antibacterials should still be considered contraindicated in pregnant women because safer alternatives are usually available (2). Because of their own and previously published findings, they further recommended that the focus of future studies should be on malformations involving the abdominal wall and urogenital system, and limb reduction defects. Moreover, this study did not address the issue of cartilage damage from quinolone exposure and the authors recognized the need for follow-up studies of this potential toxicity in children exposed in utero.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 132 newborns had been exposed to ciprofloxacin during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Three (2.3%) major birth defects were observed (six expected), one of which was a case of spina bifida (none expected). No anomalies were observed in five other categories of defects (cardiovascular defects, oral clefts, polydactyly, limb reduction defects, and hypospadias) for which specific data were available. These data do not support an association between the drug and congenital defects.

A 1998 prospective multicenter study reported the pregnancy outcomes of 200 women exposed to fluoroquinolones compared with 200 matched controls (14). Subjects were pregnant women who had called one of four teratogen information services concerning their exposure to fluoroquinolones. The agents, number of subjects, and daily doses were ciprofloxacin (N = 105; 500–1000 mg), norfloxacin (N = 93; 400–800 mg), and ofloxacin (N = 2; 200–400 mg). The most common infections involved the urinary tract (69.4%) or the respiratory tract (24%). The fewer live births in the fluoroquinolone group (173 vs. 188, $p = 0.02$) was attributable to the greater number of spontaneous abortions (18 vs. 10, ns) and induced abortions (9 vs. 2, ns). There were no differences between the groups in terms of premature birth, fetal distress,

method of delivery, low birth weight (<2500 g), or birth weight. Among the liveborn infants exposed during organogenesis, major malformations were observed in 3 of 133 subjects and 5 of 188 controls (ns). The defects in subject infants were two cases of ventricular septal defect and one case of patent ductus arteriosus, whereas those in controls were two cases of ventricular septal defect, one case of atrial septal defect with pulmonic valve stenosis, one case of hypospadias, and one case of displaced hip. There were also no differences between the children of the groups in gross motor development milestone achievements (musculoskeletal functions: lifting, sitting, crawling, standing, or walking) as measured by the Denver Developmental Scale (14).

A database cohort study from Denmark evaluated the pregnancy outcomes in two groups of women who had redeemed a fluoroquinolone prescription during pregnancy; those who had at any time in pregnancy and those who had during the 1st trimester or 30 days before conception (15). Among 87 women in the first group, the prevalence ratio of preterm birth was 1.4 (95% confidence interval [CI] 0.6–3.2), one woman had a stillbirth, and no infants died during the perinatal period. Among the 130 women in the second group, the prevalence ratio of congenital anomalies was 0.7 (95% CI 0.3–2.0) and the ratio of bone malformations was 2.2 (95% CI 0.7–6.7). Among the four infants with congenital anomalies, three had bone malformations: unsymmetrical closure of the cranial sutures (ofloxacin), extra toe (fleroxacin), and clubfoot (ciprofloxacin). Although a causal link between the bone defects and fluoroquinolones could not be determined, the authors suggested that future studies should look for this association (15).

A retrospective cohort study using data from Tennessee Medicaid included 30,049 infants born in 1985–2000 was published in 2009 (16). Infants with fetal exposures in the 1st trimester to four antibiotics recommended for potential bioterrorism attacks (ciprofloxacin, amoxicillin, azithromycin, and doxycycline) were compared to infants with no fetal exposure to any antibiotic. Erythromycin was included as a positive control. In the 439 infants exposed to ciprofloxacin and no other antibiotics, the number of cases, risk ratios, and 95% CI were as follows: any malformation (8, 0.64, 0.31–1.30), cardiac (3, 0.70, 0.22–2.26); musculoskeletal (0); genitourinary (2, 0.80, 0.19–3.40); gastrointestinal (2, 0.78, 0.18–3.48); CNS (0); and orofacial (1, 1.72, 0.18–17.55). The authors concluded that the four antibiotics should not result in a greater incidence of overall major malformations (see also Amoxicillin, Azithromycin, and Doxycycline) (16).

In a study investigating the pharmacokinetics of ciprofloxacin, 20 pregnant women, between 19 and 25 weeks' gestation (mean 21.16 weeks), were scheduled for pregnancy termination because the fetuses were affected with β -thalassemia major (17). Two doses of ciprofloxacin, 200 mg IV every 12 hours, were given prior to abortion. Serum and amniotic fluid concentrations were drawn concomitantly at 4, 8, and 12 hours after dosing. Mean maternal serum concentrations at these times were 0.28, 0.09, and 0.01 mcg/mL, respectively, compared with mean amniotic fluid levels of 0.12, 0.13, and 0.10 mcg/mL, respectively. The amniotic fluid:maternal serum ratios were 0.43, 1.44, and 10.0, respectively (17).

BREASTFEEDING SUMMARY

When first marketed, the administration of ciprofloxacin during breastfeeding was not recommended because of the potential for arthropathy (based on animal data) and other serious toxicity in the nursing infant (3). Phototoxicity has been observed with some members of the quinolone class of drugs when exposure to excessive sunlight (i.e., ultraviolet light) has occurred. Well-differentiated squamous cell carcinomas of the skin have been produced in mice who were exposed chronically to some quinolones and periodic ultraviolet light (e.g., see Lomefloxacin), but studies to evaluate the carcinogenicity of ciprofloxacin in this manner have not been conducted.

Ciprofloxacin is excreted into human milk (17–19). Ten lactating women were given three oral doses of ciprofloxacin, 750 mg each (17). Six simultaneous serum and milk samples were drawn between 2 and 24 hours after the third dose of the antibacterial. The mean peak serum level (2.06 mcg/mL) occurred at 2 hours, then steadily fell to 0.02 mcg/mL at 24 hours. Milk concentrations exhibited a similar pattern with a mean peak level measured at 2 hours, 3.79 mcg/mL, and the lowest amount at 24 hours, 0.02 mcg/mL. The mean milk:serum ratio varied from 0.85 to 2.14 with the highest ratio occurring 4 hours after the last dose (17).

A 24-year-old woman, 17 days postpartum, was given a single 500-mg dose of the antibacterial to treat a urinary tract infection (18). She was also suffering from acute renal failure and had undergone her final hemodialysis treatment 7 days prior to administration of ciprofloxacin. Her serum creatinine and blood urea nitrogen at the time of the dose were 740 mmol/L and 26.8 mmol/L, respectively. Milk samples were collected at 4, 8, 12, and 16 hours. Concentrations of ciprofloxacin at these times were 9.1, 9.1, 9.1, and 6.0 μ mol/L, respectively. (Note: 9.1 and 6.0 μ mol/L are approximately 3.0 and 2.0

mcg/mL, respectively.) Based on the volume of milk and concentrations, the potential cumulative dose for the infant, who was not allowed to breastfeed, was 1.331 $\mu\text{mol/L}$ (18).

In a 1992 case report, a 4-month-old female infant was being exclusively breastfed six times/day (19). The mother had taken a single night-time dose (500 mg) of the antibacterial for 10 days prior to the collection of simultaneous samples of milk, maternal serum, and infant serum, approximately 11 hours after a dose. On the day of sampling, breastfeeding occurred 8 hours after the mother's dose. Maternal serum, milk, and infant serum ciprofloxacin concentrations were 0.21, 0.98, and <0.03 mcg/mL (undetectable), respectively. The authors estimated the infant was consuming 0.92 mg/day (0.15 mg/kg/day) of ciprofloxacin. No adverse effects were observed in the infant (19).

In a second 1992 case report, a 2-month-old breastfed female infant presented with a 1-day history of anorexia, fever, and foul-smelling green diarrhea (20). She was admitted to the hospital with a diagnosis of pseudomembranous colitis. The infant had been hospitalized during the first 14 days of life with a history of necrotizing enterocolitis but had been doing well at home for the past month. Clostridium difficile toxin was found in the infant's stool. Following a left colectomy and 7 days of oral vancomycin, the infant was thriving at home. Upon inquiry, it was discovered that the infant's mother had self-administered ciprofloxacin (dose not specified) for 6 days before her infant's admission to the hospital. The cause of the pseudomembranous colitis was thought to be ciprofloxacin obtained from breast milk (20).

In unpublished studies available to the manufacturer, peak milk levels occurred approximately 4 hours after a ciprofloxacin dose and were about the same as serum levels (personal communication, Miles Pharmaceutical, June 1990). Levels of the antibacterial were undetectable 36–48 hours after a dose. Based on these data, the manufacturer recommends that 48 hours elapse after the last dose of ciprofloxacin before breastfeeding is resumed (personal communication, Miles Pharmaceutical, June 1990).

In an unusual report, follow-up of infants who had been treated as neonates with ciprofloxacin for severe Klebsiella pneumoniae revealed two of five infants with greenish-colored teeth on eruption (21). The teeth were stained uniformly with dyscalcification at the cervical part. The investigators could not determine the cause of the condition. Other reports of this condition have not been located and the clinical significance of this to a nursing infant exposed to fluoroquinolones via the milk is unknown.

Although there is a report of toxicity in a nursing infant that was thought to have been caused by ciprofloxacin, the contribution of the infant's medical history, as well as the mother's unknown ciprofloxacin dose, are confounding factors. Data are limited, but the amount of ciprofloxacin in breast milk does not appear to represent a significant risk to an infant, especially if nursing is held for several hours after a dose. Short courses of maternal therapy are probably compatible with nursing. The American Academy of Pediatrics, without citing the above case report of potential drug-induced toxicity, classified ciprofloxacin as compatible with breastfeeding (22).

CISAPRIDE

[Withdrawn from the market. See 9th edition.]

CISPLATIN

Antineoplastic

PREGNANCY RECOMMENDATION: Contraindicated—1st Trimester

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Exposure to cisplatin in the 1st trimester is limited to two cases. The drug is teratogenic and embryotoxic in two animal species. Because of the potential for embryo toxicity, the drug should be avoided during the 1st trimester. The reported use in the 2nd and 3rd trimesters and long-term follow-up of the offspring are too limited to assess for toxicity appearing later in life.

[See Carboplatin for additional data.]

FETAL RISK SUMMARY

Cisplatin is an antineoplastic used in the treatment of various cancers. This agent is mutagenic in bacteria, produces chromosomal aberrations in animal cells in tissue culture, and is teratogenic and embryotoxic in mice (1). Cisplatin is also a transplacental carcinogen in rats, producing tumors in the liver, lung, nervous system, and kidneys of adult offspring (2). The mechanism for the production of these tumors is probably the result of DNA damage in fetal rat tissues (3). A 1994 review also reviewed the animal teratogenicity of cisplatin (4).

Only nine cases of cisplatin usage during pregnancy have been located (5–13). In one case, the mother, in her 10th week of gestation, received a single intravenous dose of 50 mg/kg for carcinoma of the uterine cervix (5). Two weeks later, a radical hysterectomy was performed. The male fetus was morphologically normal for its developmental age.

A 25-year-old woman underwent surgery at 25 weeks' gestation for an endodermal sinus tumor of the ovary (6). The chemotherapy cycle consisting of cisplatin (75 mg/m²), vinblastine (0.25 mg/kg), and bleomycin (50 mg) was started 9 days later. Approximately 3 weeks later she received a second cycle of therapy. A normal, healthy 1900-g male infant was delivered by scheduled

cesarean section at 32 weeks' gestation. The infant was alive and growing normally at the time of the report.

A 1989 case report described the effect of maternal chemotherapy on a premature newborn delivered at approximately 27 weeks' gestation (7). The mother had been treated with cisplatin (55 mg), bleomycin (30 mg), and etoposide (165 mg) (all given daily for 3 days), 1 week prior to delivery, for an unknown primary cancer with metastases to the eye and liver. The mother developed profound neutropenia just prior to delivery. On the 3rd day after birth, the 1190-g female infant also developed a profound leukopenia with neutropenia, 10 days after in utero exposure to the antineoplastic agents. The condition resolved after 10 days. At 10 days of age, the infant began losing her scalp hair along with a rapid loss of lanugo. Etoposide was thought to be the most likely cause of the neutropenia and the alopecia (7). By 12 weeks of age, substantial hair regrowth had occurred, and at 1-year follow-up, the child was developing normally except for moderate bilateral hearing loss. The investigators could not determine whether the sensorineural deafness was due to the maternal and/or neonatal gentamicin therapy or to the maternal cisplatin chemotherapy (7).

A third case of cisplatin usage during pregnancy involved a 28-year-old woman with advanced epithelial ovarian carcinoma (8). Following surgical treatment at 16 weeks' gestation, the patient was treated with cisplatin, 50 mg/m², and cyclophosphamide, 750 mg/m², every 21 days for seven cycles. Labor was induced at 37–38 weeks' gestation, resulting in the delivery of a healthy, 3275-g male infant. Height, weight, and head circumference were in the 75th–90th percentile. No abnormalities of the kidneys, liver, bone marrow, or auditory-evoked potential were found at birth, and the infant's physical and neurologic growth was normal at 19 months of age.

In a report similar to that above, a 24-year-old woman was treated during the 2nd trimester of pregnancy for epithelial ovarian carcinoma (9). Surgery was performed at 15.5 weeks' gestation, followed by five courses of chemotherapy consisting of cisplatin (100 mg/m²) and cyclophosphamide (600 mg/m² × 2, 1000 mg/m² × 3). Spontaneous rupture of membranes occurred just prior to the sixth course of chemotherapy at 36.5 weeks' gestation, and she delivered a normal-appearing, 3060-g male infant, who, except for initial mild respiratory distress, has developed normally as of 28 months of age.

A 21-year-old woman with a dysgerminoma was treated surgically at 26 weeks' gestation, followed approximately 1 week later with cisplatin, 20 mg/m², and etoposide, 100 mg/m², daily for 5 days at 3- to 4-week intervals (10). A

healthy, 2320-g female infant was delivered at 38 weeks. The infant is developing normally at 9 months of age.

Three treatments of cisplatin (75 mg/m²; total dose 330 mg) were administered at 22, 25, and 28 weeks' gestation to a 34-year-old woman with a rapidly progressing cervical cancer (11). A cesarean section was performed at 32 weeks' gestation with delivery of a normal, 2120-g male infant, who was doing well at 12 months of age.

A 35-year-old woman with metastatic non-small-cell lung cancer was treated in the 1st and 2nd trimesters with chemotherapy of an unknown pregnancy (12). After undergoing a craniotomy to remove the metastatic tumor and whole brain irradiation early in pregnancy, she was treated with docetaxel and cisplatin on days 1 and 8 every 21 days for four cycles (gestational weeks 9–18). Because of lack of response, treatment was changed to two cycles of gemcitabine and cisplatin (gestational weeks 19 and 22). About 2 months after the last dose her pregnancy was diagnosed. At 33 weeks' gestation, a cesarean section delivered a normal 1490-g female infant (normal karyotype 46,XX) with Apgar scores of 8, 9, and 10 at 1, 5, and 10 minutes, respectively, and normal blood counts. An extensive examination of the infant failed to find any abnormalities. The infant was developing normally at 10 months of age (12).

A 32-year-old woman underwent surgery at 20 weeks' gestation (from in vitro fertilization) for a ruptured ovarian cyst (13). Ovarian cancer was diagnosed and she was given four cycles of docetaxel and cisplatin before a cesarean section at 34 weeks. The 2245-g female infant had Apgar scores of 3 and 6 at 1 and 10 minutes, respectively. The infant died at 5 days of age from multiple congenital anomalies that had been diagnosed before starting chemotherapy (13).

The long-term effects of cisplatin and other antineoplastic agents on menstrual function in females and reproductive function in females and males after treatment of various cancers have been described (14–16). Of the 76 women studied, cisplatin was used in 9 and in 25 men, cisplatin had been given to 4. The results of one of these studies (14) have been discussed in the monograph for cyclophosphamide (see Cyclophosphamide). In the second report, a normal-term infant was delivered from a woman treated with cisplatin, etoposide, dactinomycin, and intrathecal methotrexate 2 years prior to conception for choriocarcinoma (15). Similarly, no congenital malformations were observed in seven live-born offspring of four males and two females treated with cisplatin during childhood or adolescence (16).

A 1996 report described successful pregnancy outcomes in 14 women who had been treated prior to conception for ovarian germ cell tumors with a chemotherapy regimen (POMB/ACE) consisting of cisplatin (120 mg/m²), vincristine, methotrexate, bleomycin, dactinomycin, cyclophosphamide, and etoposide (17). No congenital malformations were observed.

Reversible azoospermia occurred in a male treated for teratoma of the testis with cisplatin, vinblastine, bleomycin, surgery, and radiation (18). Fifteen months after the end of therapy, the sperm count was <50,000 sperm/micro-L with 70% motile and a high percentage of abnormal forms. Three months later, the patient and his wife reported a pregnancy, which was terminated on their request.

A significant reduction in reproductive organ weights, sperm counts, sperm motility, fertility, and levels of testosterone, luteinizing hormone and follicle-stimulating hormone occurred in male rats treated with cisplatin 1 week prior to mating (19). After mating, a significant preimplantation loss and lower fetal weights in comparison with controls were observed.

Occupational exposure of the mother to antineoplastic agents during pregnancy may present a risk to the fetus. A position statement from the National Study Commission on Cytotoxic Exposure and a research article involving some antineoplastic agents are presented in the monograph for cyclophosphamide (see Cyclophosphamide).

BREASTFEEDING SUMMARY

Three studies, two with opposite results from the third, have examined the excretion of cisplatin into human milk. In a 1985 study, a 31-year-old woman, 7 months postpartum with ovarian cancer, was treated with doxorubicin and cisplatin (20). Doxorubicin (90 mg) was given IV over 15 minutes followed by IV cisplatin (130 mg, 100 mg/m²) infused over 26 hours. Blood and milk samples were collected frequently for cisplatin determination from 0.25 to 71.25 hours after the start of the infusion. Peak plasma concentrations of platinum reached 2.99 mcg/mL, but platinum was undetectable (sensitivity 0.1 mcg/mL) in the milk.

Opposite results were obtained in a 1989 study (21). A 24-year-old woman with an entodermal sinus tumor of the left ovary was treated with cisplatin, 30 mg/m² IV for 4 hours daily, for 5 consecutive days. Etoposide and bleomycin were also administered during this time. On the 3rd day of therapy, milk and serum samples were collected 30 minutes before the cisplatin dose was administered. Cisplatin concentrations in the milk and plasma were 0.9 and 0.8

mcg/mL, respectively, a milk:plasma ratio of 1.1. The infant was not allowed to breastfeed.

In the third study, cisplatin measured in breast milk was in the range of 0.1–0.15 mcg/mL (over 2 hours), with a milk:plasma ratio of about 0.1 over an 18-hour sampling period (22). The woman, who was still lactating 2 years after her last delivery, was treated with six courses of cisplatin (100 mg/course) and cyclophosphamide (1600 mg/course) for ovarian cancer.

The American Academy of Pediatrics did not cite either of these latter two studies and classifies cisplatin as compatible with breastfeeding (23). However, based on the two reports, breastfeeding during cisplatin therapy should be considered contraindicated.

CITALOPRAM

Antidepressant

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 3rd Trimester

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Citalopram does not appear to be a major human teratogen. Only one of the studies below observed an increase in defects or pattern of major anomalies over that expected in a nonexposed population. (See Paroxetine.) However, selective serotonin reuptake inhibitor (SSRI) antidepressants, including citalopram, have been associated with several developmental toxicities, including spontaneous abortions (SABs), low birth weight, prematurity, neonatal serotonin syndrome, neonatal behavioral syndrome (withdrawal), possibly sustained abnormal neurobehavior beyond the neonatal period, respiratory distress, and persistent pulmonary hypertension of the newborn (PPHN).

FETAL RISK SUMMARY

The antidepressant, citalopram, is an SSRI that has a chemical structure unrelated to those of other antidepressants (1). All the antidepressant agents in this class (citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline) share a similar mechanism of action, although they have different chemical structures. These differences could be construed as evidence against any conclusion that they share similar effects on the embryo, fetus, or newborn. In the mouse embryo, however, craniofacial morphogenesis appears to be regulated, at least in part, by serotonin. Interference with serotonin regulation by chemically different inhibitors produces similar craniofacial defects (2). Regardless of the structural differences, therefore, some of the potential adverse effects on the pregnancy may also be similar.

Both mating and fertility were reduced in male and female rats at oral doses approximately five times the maximum recommended human daily dose of 60

mg/day based on BSA (MRHD). The duration of gestation was increased at approximately eight times the MRHD. Citalopram demonstrated dose-related embryo and fetal growth restriction, reduced survival, and teratogenicity in rats dosed during organogenesis at about 18 times the MRHD (1). Fetal malformations included cardiovascular and skeletal defects, but the dose was maternal toxic (clinical signs, decreased weight gain). The developmental no-effect dose was about nine times the MRHD. In contrast, no developmental adverse effects were observed in the offspring of pregnant rabbits given doses up to about five times the MRHD (1).

Increased offspring mortality during the first 4 days after birth and persistent growth restriction were observed when pregnant rats were dosed at about five times the MRHD throughout gestation and early lactation. Similar effects were observed with doses about four times the MRHD in late gestation through weaning. The no-effect dose in this group was about twice the MRHD (1).

In an in vitro experiment using a single placental cotyledon, both citalopram and its metabolite desmethylcitalopram crossed to the fetal side (3). The mean steady-state placental transfer for the two compounds was 9.1% and 5.6%, respectively. A 2003 study of the placental transfer of antidepressants found cord blood:maternal serum ratios for citalopram and its metabolite that were 0.17–1.42 and 0.50–1.00, respectively (4). The dose-to-delivery interval was 14–48 hours, with the highest ratio for the parent drug and metabolite occurring at 48 hours.

In a 2002 study, 11 women took citalopram (20–40 mg/day) during pregnancy; 10 throughout gestation and 1 starting at 20 weeks' gestation (5). The mean ratio of two metabolites was significantly higher during pregnancy than at 2 months postdelivery, indicating induction of the CYP2D6 isoenzyme (5). The trough plasma concentrations of citalopram, desmethylcitalopram, and didesmethylcitalopram in the normal newborns were 64%, 66%, and 68% of the maternal concentrations, respectively. The neurodevelopment of the infants up to the age of 1 year was normal (5). All infants were breastfed (see Breastfeeding Summary).

Citalopram is at least eight times more potent in the inhibition of serotonin reuptake than its four metabolites (1). It has an elimination half-life of approximately 35 hours. This is in the same general range as the other SSRI agents with weakly active or inactive metabolites (elimination half-lives of parent compounds in parentheses): fluvoxamine (15.6 hours), paroxetine (21 hours), and sertraline (26 hours). All have much shorter elimination half-lives than fluoxetine (4–6 days) or fluoxetine's active metabolite (4–16 days).

A brief 1993 case report described a woman who was treated with citalopram for major depression during the first 6 weeks of an undiagnosed pregnancy (6). She received 40 mg/day during the first 3 weeks, and then the dose was increased to 60 mg/day. She also took several other drugs for coexisting panic disorder and migraine headaches. All medication was stopped in the sixth week of gestation when the pregnancy was diagnosed. Because of her deteriorating mental status and anxiety concerning fetal development, she requested an abortion, which was performed at 12 weeks' gestation. At autopsy, a thorough macroscopic and microscopic evaluation, including a detailed neuropathological examination, found no evidence of malformation (6).

Five male infants exposed to citalopram (30 mg/day), paroxetine (10–40 mg/day), or fluoxetine (20 mg/day) during gestation exhibited withdrawal symptoms at or within a few days of birth and lasting up to 1 month (7). Symptoms included irritability, constant crying, shivering, increased tonus, eating and sleeping problems, and convulsions.

A 2004 prospective study examined the effect of four SSRIs (citalopram, fluoxetine, paroxetine, and sertraline) on newborn neurobehavior, including behavioral state, sleep organization, motor activity, heart rate variability, tremulousness, and startles (8). Seventeen SSRI-exposed, healthy, full-birth-weight newborns and 17 nonexposed, matched controls were studied. A wide range of disrupted neurobehavioral outcomes were shown in the subject infants. After adjustment for gestational age, the exposed infants were found to differ significantly from controls in terms of tremulousness, behavioral states, and sleep organization. The effects observed on motor activity, startles, and heart rate variability were not significant after adjustment (8).

A 2003 prospective study evaluated the pregnancy outcomes of 138 women treated with SSRI antidepressants during gestation (9). Women using each agent were 73 fluoxetine, 36 sertraline, 19 paroxetine, 7 citalopram, and 3 fluvoxamine. Most (62%) took an SSRI throughout pregnancy and 95% were taking an SSRI at delivery. Birth complications were observed in 28 infants, including preterm birth (9 cases), meconium aspiration, nuchal cord, floppy at birth, and low birth weight. Four infants (2.9%) had low birth weight, all exposed to fluoxetine (40–80 mg/day) throughout pregnancy, including two of the three infants of mothers taking 80 mg/day. One infant had Hirschsprung disease, a major defect, and another had cavum septi pellucidi (neither the size of the cavum nor the SSRI agents were specified) (9). The clinical significance of the cavum septi pellucidi is doubtful as it is nearly always present at birth but resolves in the first several months (10).

The database of the World Health Organization (WHO) was used in a 2005 report on neonatal SSRI withdrawal syndrome (11). In this database, 93 suspected cases with either neonatal convulsions or withdrawal syndrome were identified in the WHO database. The agents were 63 paroxetine, 13 fluoxetine, 1 paroxetine plus fluoxetine, 9 sertraline, and 7 citalopram. The analysis suggested that paroxetine might have an increased risk of convulsions or withdrawal compared with other SSRIs (11).

Evidence for the neonatal behavioral syndrome that is associated with in utero exposure to SSRIs and serotonin and norepinephrine reuptake inhibitors (SNRIs) (collectively called serotonin reuptake inhibitors [SRIs]) in late pregnancy was reviewed in a 2005 reference (12). The report followed a recent agreement by the FDA and manufacturers for a class labeling change about the neonatal syndrome. Analysis of case reports, case series, and cohort studies revealed that late exposure to SRIs carried an overall risk ratio of 3.0 (95% confidence interval [CI] 2.0–4.4) for the syndrome compared with early exposure. The case reports (N = 18) and case series (N = 131) involved 97 cases of paroxetine, 18 fluoxetine, 16 sertraline, 12 citalopram, 4 venlafaxine, and 2 fluvoxamine. There were nine cohort studies analyzed. The typical neonatal syndrome consisted of central nervous system, motor, respiratory, and gastrointestinal signs that were mild and usually resolved within 2 weeks. Only one of 313 quantifiable cases involved a severe syndrome consisting of seizures, dehydration, excessive weight loss, hyperpyrexia, and intubation. There were no neonatal deaths attributable to the syndrome (12).

A significant increase in the risk of low birth weight (<10th percentile) and respiratory distress after prenatal exposure to SSRIs was reported in 2006 (13). The population-based study, representing all live births (N = 119,547) during a 39-month period in British Columbia, Canada, compared pregnancy outcomes of depressed mothers treated with SSRIs with outcomes in depressed mothers not treated with medication and in nonexposed controls. The severity of depression in the depressed groups was accounted for by propensity score matching (13).

A 30% incidence of SSRI-induced neonatal abstinence syndrome was found in a 2006 cohort study (14). Sixty neonates with prolonged in utero exposure to SSRIs were compared to nonexposed controls. The agents used were paroxetine (62%), fluoxetine (20%), citalopram (13%), venlafaxine (3%), and sertraline (2%). Assessment was conducted by the Finnegan score. Ten of the infants had mild and eight had severe symptoms of the syndrome. The maximum mean score in infants with severe symptoms occurred within 2 days

of birth, but some occurred as long as 4 days after birth. Because of the small numbers, a dose–response could only be conducted with paroxetine. Infants exposed to mean maternal doses that were <19 mg/day had no symptoms, <23 mg/day had mild symptoms, and 27 mg/day had severe symptoms (14).

A 2005 prospective comparative study of citalopram in pregnancy was reported in 2005 (15). Three groups, citalopram, disease, and nonteratogen, each containing 132 pregnant women were closely matched. In the citalopram group, 125 (95%) took the drug at least in the 1st trimester and 71 (54%) continued the drug throughout gestation. The outcomes in the citalopram-exposed pregnancies were 114 live births, 14 SABs, 2 elective abortions, and 2 stillbirths. One male infant, exposed during organogenesis, had a major anomaly (umbilical and scrotal hernia). There were no statistical differences among the three groups in terms of mean birth weight, structural defects, gestational age at birth, and fetal survival. However, for infants exposed in the 3rd trimester, there were increased risks for complications in general (relative risk [RR] 1.5, 95% CI 1.0–2.4) and for neonatal intensive care unit (NICU) admissions (RR 4.2, 95% CI 1.7–10.3) (i.e., poor neonatal adaptation syndrome) (15).

A meta-analysis of clinical trials (1990–2005) with SSRIs was reported in 2006 (16). The SSRI agents included were citalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline. The specific outcomes analyzed were major, minor, and cardiac malformations, and SABs. The odd ratio [OR] with 95% CI for the four outcomes were 1.394 (0.906–2.145), 0.97 (0.13–6.93), 1.193 (0.531–2.677), and 1.70 (1.28–2.25), respectively. Only the risk of SABs was significantly increased (16).

A brief 2005 report described significant associations between the use of SSRIs in the 1st trimester and congenital defects (17). The data were collected by the CDC-sponsored National Birth Defects Prevention Study in an on-going case–control study of birth defect risk factors. Case infants (N = 5357) with major birth defects were compared with 3366 normal controls. A positive association was found with omphalocele (N = 161; OR 3.0, 95% CI 1.4–6.1). Paroxetine, which accounted for 36% of all SSRI exposures, had the strongest association with the defect (OR 6.3, 95% CI 2.0–19.6). The study also found a significant association between the use of any SSRI and craniosynostosis (N = 372; OR 1.8, 95% CI 1.0–3.2) (17). An expanded report from this group was published in 2007 (see reference 25 below).

In 1999, the Swedish Medical Birth Registry compared the use of antidepressants in early pregnancy and delivery outcome for the years 1995–

1997 (18). There were no significant differences for birth defects, infant survival, or risk of low birth weight (<2500 g) among singletons between those exposed to any antidepressant, SSRIs only, and non-SSRIs only, but a shorter gestational duration (<37 weeks) was observed for any antidepressant exposure (OR 1.43, 95% CI 1.14–1.80). Fifteen (4.0%) of the citalopram-exposed infants had anomalies, but one was a trisomy 13 syndrome and five were classified as uncertain anomalies (18). A second Registry report, published in 2006 covering the years 1995–2003, analyzed the relationship between antidepressants and major malformations and cardiac defects (19). There was no significant increase in the risk of major malformations with any antidepressant. The strongest effect among cardiac anomalies was with ventricular or atrial septum defects (VSDs-ASDs). Significant increases were found with paroxetine (OR 2.22, 95% CI 1.39–3.55) and clomipramine (OR 1.87, 95% CI 1.16–2.99 (19). In 2007, the analysis was expanded to include the years 1995–2004 (20). There were 6481 women (6555 infants) who had reported the use of SSRIs in early pregnancy. The number of women using a single SSRI during the 1st trimester was 2579 citalopram, 1807 sertraline, 908 paroxetine, 860 fluoxetine, 66 escitalopram, and 36 fluvoxamine. After adjustment, only paroxetine was significantly associated with an increased risk of cardiac defects (N = 13, RR 2.62, 95% CI 1.40–4.50) or VSDs-ASDs (N = 8, RR 3.07, 95% CI 1.32–6.04). Analysis of the combined SSRI group, excluding paroxetine, revealed no associations with cardiac defects or VSDs-ASDs. The study also found no association with omphalocele or craniostenosis (20).

A 2007 study evaluated the association between 1st-trimester exposure to paroxetine and cardiac defects by quantifying the dose–response relationship (21). A population-based pregnancy registry was used by linking three administrative databases so that it included all pregnancies in Quebec between 1997 and 2003. There were 101 infants with major congenital defects, 24 involving the heart, among the 1403 women using only one type of antidepressant during the 1st trimester. The use of paroxetine or other SSRIs did not significantly increase the risk of major defects or cardiac defects compared with non-SSRI antidepressants. However, a paroxetine dose >25 mg/day during the 1st trimester was significantly associated with an increased risk of major defects (OR 2.23, 95% CI 1.19–4.17) and of cardiac defects (OR 3.07, 95% CI 1.00–9.42) (21).

A 2007 retrospective cohort study examined the effects of exposure to SSRIs or venlafaxine in the 3rd trimester on 21 premature and 55 term

newborns (22). The randomly selected unexposed control group consisted of 90 neonates of mothers not taking antidepressants, psychotropic agents, or benzodiazepines at the time of delivery. There were significantly more premature infants among the subjects (27.6%) than in controls (8.9%), but the groups were not matched. The antidepressants, number of subjects, and daily doses in the exposed group were paroxetine (46; 5–40 mg), fluoxetine (10; 10–40 mg), venlafaxine (9; 74–150 mg), citalopram (6; 10–30 mg), sertraline (3; 125–150 mg), and fluvoxamine (2; 50–150 mg). The behavioral signs that were significantly increased in exposed compared with nonexposed infants were central nervous system (CNS) —abnormal movements, shaking, spasms, agitation, hypotonia, hypertonia, irritability, and insomnia; respiratory system—indrawing, apnea/bradycardia, and tachypnea; and other—vomiting, tachycardia, and jaundice. In exposed infants, CNS (63.2%) and respiratory system (40.8%) signs were most common, appearing during the first day of life and lasting for a median duration of 3 days. All of the exposed premature infants exhibited behavioral signs compared with 69.1% of exposed term infants. The duration of hospitalization was significantly longer in exposed premature compared with nonexposed premature infants, 14.5 days vs. 3.7 days, respectively. In 75% of the term and premature infants, the signs resolved within 3 and 5 days, respectively. There were six infants in each group with congenital malformations, but the drugs involved were not specified (22).

A 2007 review conducted a literature search to determine the risk of major congenital malformations after 1st trimester exposure to SSRIs and SNRIs (23). Fifteen controlled studies were analyzed. The data were adequate to suggest that citalopram, fluoxetine, sertraline, and venlafaxine were not associated with an increased risk of congenital defects. In contrast, the analysis did suggest an increased risk with paroxetine. The data were inadequate to determine the risk for the other SSRIs and SNRIs (23).

A case–control study, published in 2006, was conducted to test the hypothesis that exposure to SSRIs in late pregnancy was associated with persistent pulmonary hypertension of the newborn (24). A total of 1213 women were enrolled in the study, 377 cases whose infants had PPHN and 836 matched controls and their infants. Mothers were interviewed by nurses who were blinded to the hypothesis. Fourteen case infants had been exposed to an SSRI after the 20th week of gestation compared with six control infants (adjusted odds ratio 6.1, 95% CI 2.2–16.8). The numbers were too small to analyze the effects of dosage, SSRI used, or reduction of the length of exposure before delivery. No increased risk of PPHN was found with the use of

SSRIs before the 20th week or with the use of non-SSRI antidepressants at any time in pregnancy. If the relationship was causal, the absolute risk was estimated to be about 1% (24).

Two large case–control studies assessing associations between SSRIs and major birth defects were published in 2007 (25,26). The findings related to SSRIs as a group, as well as to four specific agents: citalopram, fluoxetine, paroxetine, and sertraline. One of the studies did find a significant association between citalopram and a group of defects (anencephaly, craniosynostosis, and omphalocele) (25). An accompanying editorial discussed the findings and limitations of these and other related studies (27). Details of the studies and the editorial are described in the paroxetine review (see Paroxetine).

A prospective cohort study evaluated a large group of pregnancies exposed to antidepressants in the 1st trimester to determine if there was an association with major malformations (28). The patient population came from the Motherisk database and involved 928 cases that met their criteria. The 928 matched (for age, smoking, and alcohol use) controls were pregnancies not exposed to antidepressants or known teratogens. In addition to the 184 citalopram cases, the other cases were 113 bupropion, 21 escitalopram, 61 fluoxetine, 52 fluvoxamine, 68 mirtazapine, 39 nefazodone, 148 paroxetine, 61 sertraline, 17 trazodone, and 154 venlafaxine. In the antidepressant group, there were 24 (2.5%) major defects compared with 25 (2.6%) in controls (odds ratio 0.9, 95% CI 0.5–1.61). There were eight major anomalies in the citalopram group: umbilical hernia, duplex kidney, club foot, pyloric stenosis, neural tube defect, atrial septal defect, congenital pneumothorax, and hypospadias. There were no major defects in the pregnancies exposed to bupropion, escitalopram, or trazodone (28).

BREASTFEEDING SUMMARY

Citalopram is excreted into human milk. A 1997 report described breast milk concentrations of the antidepressant in two lactating women under treatment for depression and one healthy lactating volunteer (29). All three subjects were extensive metabolizers of citalopram with respect to the liver enzymes (CYP2C19 and CYP2D6) involved in the metabolism of the drug. The two women with depression were being treated with 20 mg/day and 40 mg/day at 2 and 4 months postpartum, respectively. The healthy volunteer was given a single dose of 40 mg at 10 months postpartum. The milk:serum ratio in the two women ranged from 1.16 to 1.88, whereas in the volunteer, the ratio was 1.00, based on the AUC. The dose ingested by an infant was calculated to range

from 4.3 to 17.6 mcg/kg/day (0.7%–5.9% of the weight-adjusted maternal dose) in the two women on chronic therapy, and 11.2 mcg/kg/day (1.8% of the weight-adjusted maternal dose based on AUC) in the volunteer. The two mothers on chronic therapy observed no adverse effects in their nursing infants. Compared with other SSRI antidepressants, the relative dose to the infant from citalopram (0.7%–5.9%) was comparable to fluoxetine and its active metabolite (1.2%–6.5%) but higher than that for fluvoxamine (0.5%), sertraline (0.45%), and paroxetine (0.34%). Based on these data, the authors recommended that caution should be used with the administration of citalopram during lactation (29).

In a second 1997 report, a 21-year-old mother developed severe depression 2 months after delivery of a female infant and was begun on citalopram (30). Blood and milk samples were collected after 8 days of a continuous 20 mg/day dose. The mean milk:serum ratio over a 24-hour period was approximately 3 for both citalopram and its inactive metabolite. The estimated citalopram weight-adjusted infant dose was 4.8% of the mother's dose. After 3 weeks of therapy, the citalopram serum concentration in the infant was about 1/15th of the mother's trough level; the metabolite was undetectable. The levels indicated that no accumulation of citalopram or the metabolite occurred in the infant. No adverse effects or unusual behavior were observed in the infant (30).

A 2000 report measured citalopram concentrations in the milk and plasma of seven women who were nursing their infants (mean age 4.1 months) (31). The median citalopram dose was 0.36 mg/kg/day. The mean milk:plasma ratios of citalopram and the metabolite, desmethylcitalopram, were 1.8 (range 1.2–3) and 1.8 (range 1.0–2.5), respectively. Citalopram was detected in the plasma of three infants (2.0–2.3 ng/mL), two of which also had detectable levels of the metabolite (2.2 ng/mL). The mean combined dose of citalopram and metabolite (expressed as a percentage of the maternal weight-normalized dose) was 4.4%–5.1%. No adverse effects were observed in the infants and all had normal Denver developmental quotients (31).

A 29-year-old woman, 4 weeks after delivery, was started on citalopram (40 mg/day) for postpartum depression (32). Eight days later, single samples of milk and maternal serum (time from last dose not specified) yielded concentrations of 205 ng/mL and 98.9 ng/mL, respectively. Uneasy sleep was noted in the breastfed infant starting about 2–3 days after initiation of drug therapy. The citalopram concentration in the infant's serum after 16 days of maternal therapy was 12.7 ng/mL. Reducing the dose to 20 mg/day and substituting two breastfeedings with artificial nutrition normalized the infant's

sleeping. One week later, the serum concentrations of citalopram in the mother and infant were 49.0 ng/mL and 4.5 ng/mL, respectively (32).

In their product information, the manufacturer describes two infants with excessive somnolence, decreased feeding, and weight loss associated with nursing from mothers receiving citalopram (1). Both cases involved reports to the manufacturer that apparently were not published. Although the information is incomplete, the manufacturer was able to obtain partial details of these cases (G. Fagen, personal communication, Forrest Pharmaceuticals, 2000). One full-term infant was born to a Danish woman who had been started on citalopram, 40 mg/day, shortly before delivery. The infant was presumably breastfed. When the adverse effects were noted 3–4 days after birth, the mother stopped the drug. The infant made a full recovery. The second case involved an 8-day-old Swedish baby who developed tiredness, weight loss, and decreased suckling. The mother had started taking citalopram, 20 mg/day, approximately 1 year earlier. She was also taking an antihistamine. Five days before the onset of the adverse symptoms, without medical advice, she increased her dose to 30 mg/day. A single milk sample (timing in relationship to the dose not specified) yielded a drug concentration of 377 nmol/L (about 0.122 mcg/mL) (1 mol of citalopram = 324.4 g (23)). The concentration of the metabolite was 111 nmol/L. These amounts are very close to those reported in the above published cases. No other details of the case were available, although it is known that the infant was doing well at 4 years of age.

Nine women treated with citalopram during pregnancy (see Fetal Risk Summary) continued to use the antidepressant while nursing their infants (5). Maternal plasma concentrations of the parent compound and metabolites demonstrated a tendency to rise at 2 weeks and 2 months postpartum. The milk:plasma ratios for citalopram, desmethylcitalopram, and didesmethylcitalopram ranged from 1.2 to 3.3, 1.3 to 4.1, and 1.1 to 4.6, respectively. In contrast, the infant plasma concentrations of the parent compound and two metabolites at various intervals up to 2 months of age all declined from those measured at birth. The weight and neurodevelopment of the infants up to 1 year of age were normal (5).

A prospective, observational cohort study designed to determine the frequency of adverse effects in nursing infants exposed to citalopram in milk was published in 2004 (33). Three groups of nursing women were formed: 31 women who were depressed and taking citalopram; 12 women who were depressed but who were taking other SSRI antidepressants; and 31 healthy women matched to the first group by maternal age and parity. There was no

statistically significant difference in the rate of adverse events among the nursing infants in the three groups (3/31 events, 0/12 events, and 1/31 events, respectively). In the citalopram group, two of the events were colic and decreased feeding, but both were considered nonspecific and insignificant and did not require intervention. The third event involved irritability and restlessness that were observed in the infant when the mother started citalopram at 2 months postpartum. Breastfeeding was stopped after 2 weeks and the symptoms resolved (33).

A 2004 study was conducted in 25 women (nursing 26 infants) to quantify the concentration of the SSRI or SNRI in their breast milk (34). The antidepressants taken by the women were citalopram (nine mothers/10 infants), paroxetine (six), sertraline (six), fluoxetine (one), and venlafaxine (three). The maternal mean dose of citalopram was 24 mg/day (20–50 mg/day). The mean milk concentration was 389 nmol/L (157–725 nmol/L, resulting in a theoretical maximum infant dose that was 5.2% of the mother's weight-adjusted dose. Citalopram was detected in six of the infants serum (mean 1.9 nmol/L, range 0–8 nmol/L). There was no evidence of adverse effects in the breastfeeding infants (34).

A 2010 study using human and animal models found that drugs that disturb serotonin balance such as SSRIs and SNRIs can impair lactation (35). The authors concluded that mothers taking these drugs may need additional support to achieve breastfeeding goals.

A 1999 review of SSRI agents concluded that if there were compelling reasons to treat a mother for postpartum depression, a condition in which a rapid antidepressant effect is important, the benefits of therapy with SSRIs would most likely outweigh the risks (36). Nevertheless, nursing women receiving citalopram, in particular those taking doses >20 mg/day or concurrently with other sedative agents, should be warned of the potential for toxicity in their infants. Moreover, the long-term consequences of exposure to SSRI antidepressants in breast milk on the infant's neurobehavior development are unknown (no such adverse effects have been reported to date, but additional research is needed). Avoiding nursing around the time of peak maternal concentrations (about 4 hours after a dose) may limit infant exposure. However, the long elimination half-lives of all SSRIs and their weakly basic properties, which are conducive to ion trapping in the relatively acidic milk, probably will lessen the effectiveness of this strategy. The American Academy of Pediatrics classifies other SSRIs as drugs whose effect on the nursing infant is unknown but may be of concern (see Fluoxetine, Fluvoxamine, Paroxetine,

and Sertraline).

CLADRIBINE

Antineoplastic

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of cladribine in human pregnancy have been located. However, other drugs that inhibit DNA synthesis (e.g., methotrexate and aminopterin) are known human teratogens. If possible, the drug should be avoided in pregnancy, especially during the 1st trimester. Because hairy cell leukemia usually has an indolent disease course, deferring treatment until after delivery may be appropriate (1).

FETAL RISK SUMMARY

The prodrug cladribine is a synthetic antineoplastic agent that is administered as a single course given by continuous IV infusion for 7 consecutive days. It is indicated for the treatment of active hairy cell leukemia as defined by clinically significant anemia, neutropenia, thrombocytopenia or disease-related symptoms. The drug is classified as an antimetabolite in the same subclass of purine analogs and related agents as clofarabine, fludarabine, mercaptopurine, pentostatin, and thioguanine. Cladribine undergoes intracellular metabolism to its active metabolite. About 20% is bound to plasma proteins and the mean terminal half-life is 5.4 hours (2).

Reproduction studies have been conducted in mice and rabbits (routes not specified but assumed to be oral). In mice, a significant increase in fetal variations was observed with a daily dose that was about 17 times the human dose based on body weight. The drug was embryotoxic in mice when given at doses equivalent to the human dose. When the daily dose was doubled, increased resorptions, reduced litter size, and fetal malformations were observed. Fetal death and malformations were observed in rabbits given a daily dose that was about 33 times the human dose based on body weight. The no-observed-effect-dose (NOEL) in these species was about 6 and 11 times the human dose, respectively (2).

Carcinogenic studies have not been conducted with cladribine. The drug was not mutagenic in various assays but was clastogenic. When given IV to monkeys, the drug caused suppression of rapidly generating cells, including testicular cells. The effect on human fertility is unknown (2).

It is not known if cladribine crosses the human placenta. The molecular weight (about 286), low plasma protein binding, terminal half-life, and long infusion time suggest that the drug will cross to the embryo–fetus.

In a letter correspondence, a woman at 10 week’s gestation was diagnosed with hairy cell leukemia (3). Because she wished to continue her pregnancy, treatment was deferred until after delivery. At 16 weeks’ gestation, during an otherwise normal pregnancy, she underwent a splenectomy for an enlarged spleen that was causing abdominal discomfort. She gave birth at term to a healthy female infant. Treatment was again deferred for 6 months while she breastfed her infant. Six weeks after treatment, a repeat bone marrow biopsy specimen and aspirate were normal (3).

A 37-year-old woman with hairy cell leukemia was treated with a 7-day infusion of cladribine and obtained a complete remission (4). Eleven months after completion of therapy, she became pregnant. Her pregnancy was uncomplicated and she gave birth to a term, healthy, female infant whose birth weight (actual birth weight not specified) was appropriate for gestational age. At 9 months of age, the infant was developing normally and meeting all developmental milestones (4).

BREASTFEEDING SUMMARY

No reports describing the use of cladribine during human lactation have been located. The molecular weight (about 286), low plasma protein binding (about 20%), terminal half-life (5.4 hours), and long infusion time (7 consecutive days) suggest that the drug will be excreted into breast milk. The effect of this exposure on a nursing infant is unknown. However, because of the risk for significant toxicity in a nursing infant, women receiving this antineoplastic agent should not breastfeed. Hairy cell leukemia usually has an indolent disease course and deferring treatment until breastfeeding is stopped appears to be an option (see above case report).

CLARITHROMYCIN

Antibiotic

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

The animal reproduction data suggest high risk, but the available human pregnancy experience suggests that the risk, if it exists, is low. The antibiotic has not been associated with an increased risk of pyloric stenosis.

FETAL RISK SUMMARY

Clarithromycin, a semisynthetic antibiotic structurally related to erythromycin, belongs to the same macrolide class of anti-infectives as azithromycin, dirithromycin, erythromycin, and troleandomycin.

The effects of clarithromycin on fertility and reproduction in rats, mice, rabbits, and monkeys have been reported by the manufacturer. Doses up to 1.3 times the recommended maximum human dose based on BSA (MRHD) (serum levels approximately 2 times the levels in humans) in male and female rats produced no adverse effects on the estrous cycle, fertility, parturition, or fetal outcome. No teratogenic effects were observed in four studies involving one rat strain using oral and IV doses up to 1.3 times the MRHD, but a low incidence of cardiovascular anomalies was seen in two studies, with a second rat strain at an oral dose about 1.2 times the MRHD. A variable incidence of cleft palate occurred in mice given oral doses about 2–4 times the MRHD (1).

In rabbits, IV doses 17 times less than the MRHD resulted in fetal death, but teratogenic effects were not observed with various oral or IV doses (1). Embryonic loss attributed to maternal toxicity occurred in monkeys administered oral doses 2.4 times the MRHD (serum levels three times the levels in humans). In monkeys, an oral dose approximately equal to the MRHD (serum levels about twice those obtained in humans) caused fetal growth restriction.

Clarithromycin crosses the human placenta (2). In an in vitro experiment

using perfused term placentas, the mean transplacental transfer of clarithromycin was 6.1%.

At a 1996 meeting, a teratogen information service (TIS) reported the outcomes of 34 exposures to clarithromycin during pregnancy (3). All of the exposures occurred during the 1st and early 2nd trimesters for the treatment of upper respiratory infections. Among the 29 known pregnancy outcomes (5 were pending), there were 8 (28%) abortions (4 spontaneous/4 voluntary), 20 (69%) normal newborns, and 1 (3%) infant with a 0.5-cm brown mark on the temple. One of the normal newborns, delivered at 26 weeks, died from complications of prematurity. Although follow-up of the remaining newborns had not been sufficiently long to exclude completely the presence of congenital malformations, these outcomes do not appear to be different from those expected in a nonexposed population.

Case reports of clarithromycin and congenital anomalies available to the FDA through June 1996 were limited to six diverse birth defects: cystic head, pregnancy terminated; craniofacial anomalies, absent clavicles, bilateral hip deformities, and underdeveloped left heart; spina bifida; cleft lip; pulmonary hypoplasia, anomalous infradiaphragmatic venous return; and CHARGE syndrome (F. Rosa, personal communication, FDA, 1996). By definition, infants having CHARGE association or syndrome must have two or more of the following: coloboma of the eye or eye defects, heart disease, choanal atresia, restricted growth and development with or without CNS anomalies, genital hypoplasia, and ear anomalies with or without deafness (4). The diversity of the malformations lessens the probability of an association with clarithromycin and any or all of these outcomes may have occurred by chance.

A 1998 prospective controlled multicenter study compared the outcomes of 157 pregnancies exposed to clarithromycin with an equal number of matched controls (5). All of the women had called a TIS. The most common indications for use of the antibiotic were respiratory infections. Of the subjects, 122 (78%) were exposed during the 1st trimester. The outcomes of subjects and controls were spontaneous abortions (SABs) (22 vs. 11, $p = 0.04$), elective abortions (EABs) (11 vs. 3, $p = 0.04$), live births (123 vs. 143, $p = 0.003$), stillbirths (1 vs. 0, ns), major malformations (3 vs. 2, ns), and minor malformations (7 vs. 7, ns). The major anomalies (exposure occurred in the 3rd trimester in one case) in the study group were hydrocephalus, Turner's syndrome, and stenosis uteropelvic junction and cranial synostosis. The minor malformations were a large birth mark, a reflux valve problem, an enlarged right ventricle (brain), a minor ventricular septal defect, undescended testes, a blocked tear ducts defect, and

excess breast tissue on the right. The types of malformations in controls were comparable, with no pattern of defects apparent in either group. Although the increased number of SABs in exposed women was within the expected background rate and may have been affected by confounding factors, the investigators concluded that it warranted further study (5).

A prospective, multicenter study published in 2008 compared pregnant women exposed to a new macrolide (azithromycin, clarithromycin, or roxithromycin) with two comparison groups (6). Of the 161 women exposed to a macrolide, 118 were exposed in the 1st trimester. The rate of major malformations in the study group was 4.1% compared with 2.1% of those exposed to other antibiotics (OR = 1.41, 95% confidence interval (CI) 0.47–4.23). The authors concluded that the use of the new macrolides did not represent an increased risk of congenital defects strong enough for an EAB (6).

A 2012 prospective, multicenter observational study was conducted by TISs in Italy, Israel, Czech Republic, the Netherlands, and Germany (7). Of the 608 women exposed to macrolides, 511 were exposed in the 1st trimester. The study group was compared with 773 women exposed to nonteratogens in the 1st trimester. The rate of major congenital defects were similar in the groups (3.4% vs. 2.4%, $p = 0.36$; OR 1.42, 95% CI 0.70–2.88) or in the rate of cardiovascular defects (1.6% vs. 0.9%). The rates for clarithromycin (N = 218) were 1.8% vs. 2.4%, $p = 0.80$; OR 0.76, 95% CI 0.25–2.27 and 0.5% vs. 0.9%, $p = 0.99$; OR 0.54, 95% CI 0.06–4.48 (7).

A register-based, nationwide cohort study conducted in Denmark, covering the period 1997–2007, was published in 2013 (8). The study identified 931,504 pregnancies (705,837 live birth, 77,553 SABs, and 148,114 EABs), 401 of whom were exposed to clarithromycin in the 1st trimester. The hazard ratio (HR) of having an SAB after exposure to clarithromycin was 1.56, 95% CI 1.14–2.13. A significant HR was not found with 1st trimester exposure to three other antibiotics and proton pump inhibitors (PPIs) (HR and 95% CI): amoxicillin (N = 4584, 0.92, 0.82–1.04); erythromycin (N = 6492, 1.03, 0.94–1.13); Penicillin V (N = 33,469, 1.00, 0.96–1.04); and PPIs (N = 3577, 1.03, 0.91–1.18). Among the 253 exposed offspring diagnosed with a major malformation, 9 (3.6%) were exposed to clarithromycin (odds ratio [OR] 1.03, 95% CI 0.53–2.00). The authors concluded that further research was required to examine the possible effects of treatment indications on the above association (8).

Three pregnant women with documented *Helicobacter pylori* infections, persistent nausea and vomiting, and epigastric pain were treated in the 2nd trimester with a 2-week course of clarithromycin combined with amoxicillin and

with famotidine, omeprazole, or ranitidine (9). The therapy was effective in eliminating the conditions. No adverse effects on the pregnancy outcomes were noted.

In a 2005 abstract, 145 pregnant women were exposed to a new macrolide (38 azithromycin, 53 clarithromycin, 54 roxithromycin), of which 103 were exposed in the 1st trimester (10). The rates of congenital anomalies compared with 928 exposed to a nonteratogen were similar (4.0% vs. 3.75%, $p = 0.156$). In a 2003 Danish study, 188 women received a macrolide (see Breastfeeding Summary) within 30 days of birth and none of their infants had infantile hypertrophic pyloric stenosis (11).

BREASTFEEDING SUMMARY

Clarithromycin is excreted into breast milk. In a 1993 study, 12 mothers were given clarithromycin 250 mg twice daily (12). Both the parent drug and metabolite were excreted into milk, with peak levels measured at 2.2 and 2.8 hours, respectively. The half-lives of the drug and metabolite were 4.3 and 9 hours, respectively. The combined exposure for an exclusively breastfed infant was about 2% of the mother's weight-adjusted dose (12).

A 2003 study investigated the association between maternal use of macrolides and infantile hypertrophic pyloric stenosis (11). The Danish population-based cohort study comprised 1166 women who had a prescribed macrolide (azithromycin, clarithromycin, erythromycin, spiramycin, or roxithromycin) from birth to 90 days postnatally compared with up to 41,778 controls. The OR for stenosis was 2.3–3.0, depending on the postnatal period of exposure (42, 56, 70, or 90 days), but none of the ORs was significant. When stratified by gender, the ORs for males were 1.8–3.1 and again were not statistically significant. For females, the ORs at 70 and 90 days postbirth were 10.3 and 7.5, but only the former was significant (95% CI 1.2–92.3) (11).

Investigators from Israel examined the possible association between macrolide (azithromycin, clarithromycin, erythromycin, or roxithromycin) exposure in milk and infantile hypertrophic pyloric stenosis in a 2009 study (13). They compared 55 infants exposed to a macrolide antibiotic to 36 infants exposed to amoxicillin. In the macrolide group, 7 (12.7%) had an adverse reaction (rash, diarrhea, loss of appetite, somnolence), whereas 3 infants (8.3%) in the amoxicillin group had an adverse reaction (rashes, somnolence). The rates of adverse reactions were comparable. No cases of infantile hypertrophic pyloric stenosis were observed (13).

CLAVULANATE, POTASSIUM

Anti-infective

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Several studies have described the use of amoxicillin and potassium clavulanate for various infections in pregnant women. Most studies have observed no adverse effects in the fetus or newborn attributable to the combination (see Amoxicillin and Ticarcillin). However, one study did report an association with necrotizing enterocolitis (NEC) in newborns.

FETAL RISK SUMMARY

Clavulanic acid is a β -lactamase inhibitor produced by *Streptomyces clavuligerus* that is combined, as the potassium salt, with the penicillin antibiotics, amoxicillin or ticarcillin, to broaden their antibacterial spectrum of activity. No adverse fetal effects were observed in mice, rats, and pigs administered potassium clavulanate in combination with amoxicillin or ticarcillin during gestation (1–5).

Following a single oral dose of amoxicillin (250 mg) and potassium clavulanate (125 mg) in humans, both agents crossed the placenta to the fetus (6,7). Cord blood levels were found 1 hour after the dose, with peak levels occurring at 2–3 hours. In one study, the mean peak maternal serum and umbilical cord blood levels occurred at 2 hours with values of 2.20 and 1.23 mcg/mL, respectively (fetal:maternal ratio 0.56) (7). Both amoxicillin and potassium clavulanate have been demonstrated in the amniotic fluid (6–8), with peak concentrations of clavulanate (0.44 mcg/mL) measured 5.5 hours after administration (7). A study using in vitro perfused human placentas demonstrated the transfer of potassium clavulanate when concentrations on the maternal side were 10–13 mcg/mL, but not at 2–6 mcg/mL (8). A fetal/maternal gradient of 1:1 was obtained at the higher concentrations.

In addition to the above, several studies have described the use of

amoxicillin–clavulanic acid (ACA) for various infections in pregnant women either without causing fetal or newborn harm (9–11) or causing newborn harm (12).

A 2001 randomized study (ORACLE 1) was conducted in patients with preterm, prelabor rupture of fetal membranes to determine neonatal health benefits of three antibiotic regimens (12). The regimens, compared with a placebo group (N = 1225) were erythromycin (250 mg) (N = 1197), amoxicillin (250 mg)–clavulanic acid (125 mg) (N = 1212), or both (N = 1192) four times daily for 10 days or until delivery. The primary outcome measures were specific outcomes or a composite of neonatal death, chronic lung disease, or major cerebral abnormality. For these neonatal outcomes, the two groups with ACA had no benefit over placebo, whereas erythromycin use resulted in significantly better outcomes (both composite and specific). When any-ACA exposure was compared with no-ACA for outcomes with suspected or proven NEC, the results were 92 (3.8%) and 58 (2.4%) ($p = 0.004$). The authors thought that a possible mechanism for this outcome was that the ACA combination selected for *Clostridium difficile* and that abnormal colonization of the neonatal intestinal tract was one possible mechanism for NEC (12).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 556 newborns had been exposed to clavulanic acid (presumably in combination with penicillins) during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 24 (4.3%) major birth defects were observed (24 expected). Specific data were available for six defect categories, including (observed/expected) 5/6 cardiovascular defects, 2/1 oral clefts, 1/2 polydactyly, 0/1 limb-reduction defects, 1/1 hypospadias, and 2/0.3 spina bifida. Only with the latter defect is there a suggestion of a possible association, but other factors, including the mother's disease, concurrent drug use, and chance, may be involved.

In a 1997 prospective, double-blind, randomized, controlled study, two antibiotic regimens (ampicillin–sulbactam for 72 hours followed by amoxicillin–clavulanate or ampicillin for 72 hours followed by amoxicillin) were effective for prophylaxis in women with preterm premature rupture of the membranes who had received antenatal corticosteroids alone (13). Although both combinations reduced the frequency of neonatal mortality, sepsis, and respiratory distress syndrome and increased birth weight compared with corticosteroids alone, statistical significance was reached only with the ampicillin–sulbactam/amoxicillin–clavulanate combination (26.3% vs. 48.6%; $p \leq 0.05$).

In a 2004 study, 191 women treated with amoxicillin–clavulanic acid (subjects) in the 1st trimester were matched with 191 controls exposed to

amoxicillin only (14). Maternal age, birth weight, gestational age at birth, and rates of live births and abortions were comparable between the two groups. The rates of major malformations in subjects (3/158, 1.9%) and controls (5/163, 3%) ($p = 0.49$; relative risk 0.62, 95% confidence interval 0.15–2.55) were within the expected baseline risk for the general population (14).

BREASTFEEDING SUMMARY

Both amoxicillin and ticarcillin are excreted into breast milk (see Amoxicillin and Ticarcillin), but data pertaining to potassium clavulanate have not been located. Excretion probably occurs because of the low molecular weight (about 237). The effects of the β -lactamase inhibitor on the nursing infant are unknown.

CLEMASTINE

Antihistamine

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

In general, antihistamines are considered compatible with pregnancy. However, a possible association with retrolental fibroplasia in premature infants has been reported.

FETAL RISK SUMMARY

Reproductive studies with the antihistamine, clemastine, in rats and rabbits have revealed no evidence of teratogenic effects (1). No published reports describing the use of clemastine in human pregnancy have been located.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 1617 newborns had been exposed to clemastine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 71 (4.4%) major birth defects were observed (68 expected). Specific data were available for six defect categories, including (observed/expected) 13/16 cardiovascular defects, 3/3 oral clefts, 3/1 spina bifida, 4/5 polydactyly, 4/4 hypospadias, and 5/1.9 limb-reduction defects. Only with the latter defect is there a suggestion of a possible association, but other factors, including the mother's disease, concurrent drug use, and chance, may be involved.

A 2002 study found no increased risk of teratogenicity or other pregnancy or newborn complications for antihistamines when used in early pregnancy for the treatment of nausea and vomiting (N = 12,394) and allergy (N = 5041) (2). Clemastine was used by 1230 women.

An association between exposure to antihistamines during the last 2 weeks of pregnancy and retrolental fibroplasia in premature infants has been reported. See Brompheniramine for details.

BREASTFEEDING SUMMARY

Clemastine is excreted into breast milk (3). A 10-week-old girl developed drowsiness, irritability, refusal to feed, neck stiffness, and a high-pitched cry 12 hours after the mother began taking the antihistamine, 1 mg twice daily. The mother also was also taking phenytoin and carbamazepine. Twenty hours after the last dose, clemastine levels in maternal plasma and milk were 20 and 5–10 ng/mL, respectively, a milk:plasma ratio of 0.25–0.5. The drug could not be detected in the infant's plasma. Symptoms in the baby resolved within 24 hours after the drug was stopped, although breastfeeding was continued. Examination 3 weeks later was also normal. Owing to the above case report, the American Academy of Pediatrics states that the drug should be used with caution during breastfeeding (4).

CLEVIDIPINE

Calcium Channel Blocker

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of clevidipine in human pregnancy have been located. The animal reproduction data suggest risk, but the absence of human pregnancy experience prevents a complete assessment of the embryo–fetal risk. However, other calcium channel blockers have been used extensively in human pregnancy as antihypertensives and tocolytics without evidence of developmental toxicity (e.g., see Nifedipine, Nifedipine, and Verapamil). Nevertheless, until human pregnancy data are available, other agents, such as IV labetalol, are probably preferred to treat severe hypertension in pregnancy if IV therapy is required.

FETAL RISK SUMMARY

Clevidipine is a calcium channel blocker that is given by IV infusion. It is indicated for the reduction of blood pressure when oral therapy is not feasible or desirable. Clevidipine is rapidly metabolized to inactive metabolites. One of the metabolites is formaldehyde. Plasma protein binding is high (>99.5%) and the terminal half-life is very short (about 15 minutes) (1).

Reproduction studies have been conducted in rats and rabbits. In these species, during organogenesis, doses that were 0.7 and 2 times, respectively, the maximum recommended human dose based on BSA (MRHD) decreased fetal survival. Clevidipine crosses the rat placenta. In rats dosed during late gestation and lactation, there were dose-related increases in maternal mortality, length of gestation, and prolonged parturition at doses that were about ≥ 0.17 times the MRHD. When mated, offspring of these dams had a lower conception rate than controls (1).

Long-term animal carcinogenicity studies have not been conducted with

clevidipine because of the intended short-term use in humans. Clevidipine was genotoxic in three in vitro assays but not in an in vivo test. The positive in vitro tests were thought likely to be due to the metabolite formaldehyde.

Fertility and mating performance was not affected in male and female rats at doses about equivalent to the MRHD, but female rats demonstrated pseudopregnancy and changes in estrus cycle at doses as low as one-fourth the MRHD.

It is not known if clevidipine crosses the human placenta. The molecular weight (about 456) is low enough, but the rapid metabolism, high plasma protein binding, and a very short terminal half-life suggests that little active drug will cross to the embryo or fetus.

BREASTFEEDING SUMMARY

No reports describing the use of clevidipine during human lactation have been located. The molecular weight (about 456) is low enough, but the rapid metabolism, high plasma protein binding, and a very short terminal half-life suggests that little of the active drug will be excreted into breast milk. Moreover, the drug is given as an IV infusion for hypertension when oral medication is not feasible or desirable. In such cases, it is doubtful if the mother would be nursing a child.

CLIDINIUM

Parasympatholytic

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The limited human pregnancy experience and absence of relevant animal data prevent a complete assessment of the embryo–fetal risk.

FETAL RISK SUMMARY

Clidinium is an anticholinergic quaternary ammonium bromide. In a large prospective study, 2323 patients were exposed to this class of drugs during the 1st trimester, 4 of whom took clidinium (1). A possible association was found between the total group and minor malformations.

BREASTFEEDING SUMMARY

No reports describing the use of clidinium during human lactation have been located (see also Atropine).

CLINDAMYCIN

Antibiotic

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

No reports linking the use of clindamycin with congenital defects have been located.

FETAL RISK SUMMARY

Reproduction studies in mice and rats with oral doses up to about 1.1 and 2.1 times the maximum recommended human adult dose based on BSA (MRHD), respectively, revealed no evidence of teratogenicity. In addition, SC doses in the two species up to 0.5 and 0.9 times the MRHD, respectively, failed to show teratogenicity (1).

The drug crosses the placenta, achieving maximum cord serum levels of approximately 50% of the maternal serum (2,3). Levels in the fetus were considered therapeutic for susceptible pathogens. A study published in 1988 measured a mean cord:maternal ratio of 0.15 in three women given an unknown amount of clindamycin in labor for the treatment of chorioamnionitis (4). At the time of sampling, mean maternal blood, cord blood, and placental membrane concentrations of the antibiotic were 1.67 mcg/mL, 0.26 mcg/mL, and 1.86 mcg/g, respectively (placenta:maternal ratio 1.11). Fetal tissue levels increase following multiple dosing with the drug concentrating in the fetal liver (2). Maternal serum levels after dosing at various stages of pregnancy were similar to those of nonpregnant patients (3,5). Clindamycin has been used for prophylactic therapy prior to cesarean section (6).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 647 newborns had been exposed to clindamycin during the 1st trimester (includes both maternal systemic and nonsystemic administration) (F. Rosa, personal communication, FDA, 1993). A total of 31 (4.8%) major birth defects were observed (28 expected). Specific data were available for six defect categories, including

(observed/expected) 5/6 cardiovascular defects, 0/1 oral clefts, 1/0.5 spina bifida, 1/2 polydactyly, 0/1 limb-reduction defects, and 3/2 hypospadias. These data do not support an association between the drug and congenital defects.

BREASTFEEDING SUMMARY

Clindamycin is excreted into breast milk. In two patients receiving 600 mg IV every 6 hours, milk levels varied from 2.1 to 3.8 mcg/mL (0.2–3.5 hours after drug) (7). When the patients were changed to 300 mg orally every 6 hours, levels varied from 0.7 to 1.8 mcg/mL (2–7 hours after drug). Maternal serum levels were not given.

Two grossly bloody stools were observed in a nursing infant whose mother was receiving clindamycin and gentamicin (8). No relationship to either drug could be established. However, the condition cleared rapidly when breastfeeding was stopped. Except for this one case, no other adverse effects in nursing infants have been reported.

Three potential problems that may exist for the nursing infant are modification of bowel flora, direct effects on the infant, and interference with the interpretation of culture results if a fever workup is required. The American Academy of Pediatrics classifies clindamycin as compatible with breastfeeding (9).

CLOBAZAM

Anticonvulsant

PREGNANCY RECOMMENDATION: Limited Human Data—Potential Toxicity

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

There is limited information on the effects of clobazam in human pregnancy, but the animal data suggest risk. Clobazam, a benzodiazepine, is usually used in combination with other anticonvulsants. It is well known that antiepileptic polytherapy increases the risk to the embryo and/or fetus. Although the risk of structural anomalies appears to be low with agents in this class, benzodiazepines can cause clinically significant neonatal toxicity when used close to birth. These toxicities have been described with diazepam (see Diazepam) and include the floppy infant syndrome and a withdrawal syndrome. Folic acid 5 mg/day is recommended before and during pregnancy for women taking clobazam (1). Pregnant women taking clobazam are encouraged to enroll in the North American Antiepileptic Drug Pregnancy Registry by calling the toll-free number 1-800-233-2334.

FETAL RISK SUMMARY

Clobazam is an antiepileptic drug available as oral tablets. It is in the same class of benzodiazepine agents as alprazolam, chlordiazepoxide, clonazepam, diazepam, flunitrazepam, lorazepam, midazolam, oxazepam, quazepam, temazepam, and triazolam. Although it is approved as an anticonvulsant, clobazam causes somnolence or sedation similar to that caused by all drugs in this class. Clobazam is indicated for the adjunctive treatment of seizures associated with Lennox-Gastaut syndrome in patients 2 years of age or older. The drug undergoes extensive hepatic metabolism to an active metabolite. The relative potency of the active metabolite compared to clobazam ranges from 20% to equal potency. Plasma protein binding of the parent drug and active metabolite are about 80%–90% and 70%, respectively, whereas the mean

elimination half-lives are about 36–42 and 71–82 hours, respectively (2).

A 1979 reproduction study in rats and mice conducted by the manufacturer found no teratogenic or fertility-disturbing effects from administration of clobazam in food (3). In contrast, the current product information states that animal data suggest developmental toxicity, including an increased incidence of fetal abnormalities following oral administration of doses similar to those used in humans (2). However, the animal species and specific doses were not reported.

Rats were used in a 2005 report on the central nervous system (CNS) effects of clobazam (4). Pregnant rats were given clobazam 125 mg/kg daily (comparison to human dose not specified) during the first 7 days of gestation and fetuses were examined on day 20 of gestation. Although there were no gross abnormalities, histologic examination revealed extensive teratogenic effects that included necrosis and hypoplasia of the brain (4).

The manufacturer states that the carcinogenic potential has not been adequately studied, but a 2-year limited study in rats found an increased incidence of thyroid follicular cell adenomas in males at the highest dose (100 mg/kg) of clobazam tested. The drug and the active metabolite were not mutagenic in multiple assays. There are no studies on the effect of the drug on fertility (2).

Clobazam and its active metabolite cross the human placenta at term. In a 1982 study, women at term were given a single 20 mg dose of the drug before giving birth (5). Clobazam was detectable in the umbilical blood in 16 of 19 newborns at birth and in the blood in 9 of 14 infants at 5 days of age. The maternal vein and umbilical vein concentrations were nearly the same. In an in vitro test using human placentas, both the parent drug and its active metabolite crossed the placenta (5). The above results are compatible with the molecular weight (about 301) of clobazam, lipophilic nature, moderate plasma protein binding, and prolonged elimination half-life. These characteristics suggest that the drug will cross the placenta throughout gestation.

A 1984 study described the effect of clobazam on seizure control in 14 women (6). Two of the women had been taking the drug for 12–15 months but only around the time of menstruation. The drug was discontinued when they became pregnant. Pregnancy outcome was not described in either case (6).

In a 2011 study, there were 109,344 pregnant women in the Quebec Pregnancy Registry of whom 349 (0.32%) were epileptic (7). Of these, 42 used no antiepileptic drugs (non-use), 217 used monotherapy, and 90 took polytherapy. During pregnancy, the three most prevalent antiepileptic agents

used were carbamazepine (29.9%), valproic acid (19.7%), and phenytoin (11.5%). For polytherapy, the most common drug combinations were carbamazepine combined with clobazam (2.5%), phenytoin (1.6%), or valproic acid (1.6%). Although pregnancy outcomes were provided for non-use, monotherapy, and polytherapy, specific agents associated with the outcomes were not identified. The outcomes in the non-use, monotherapy, and polytherapy groups, respectively, were as follows: planned abortions—45.2%, 40.5%, 44.4%; spontaneous abortions—0%, 2.8%, 4.4%; stillbirths—2.4%, 0%, 2.4%; live births—95.0%, 100%, 51.1%; major defects—10.5%, 9.9%, 19.0%; low birth weight—10.5%, 8.2%, 7.1%; small for gestational age—5.3%, 18.2%, 11.9%; and prematurity (<37 weeks)—15.8%, 10.0%, 9.5%. Because the number of outcomes analyzed in each group declined depending on the specificity of the analysis, none of the differences was statistical significant (7).

The Lamotrigine Pregnancy Registry, an ongoing project conducted by the manufacturer, was first published in January 1997 (8). The final report was published in July 2010. The Registry is now closed. Among 13 prospectively enrolled pregnancies exposed to clobazam and lamotrigine in the 1st trimester, with or without other anticonvulsants, there were 12 live births without defects, and 1 induced abortion with a birth defect. The woman in the birth defect case was taking lamotrigine and clobazam before and during gestation. The fetus had a lumbar neural tube defect with early evidence of ventriculomegaly and a derangement of the posterior fossa (8).

Retrospective cases (reported after the pregnancy outcome was known) are often biased (only adverse outcomes are reported), but they are useful in identifying specific patterns of anomalies suggestive of a common cause (8). There were nine pregnancies with birth defects exposed to clobazam with other antiepileptics reported retrospectively to the Registry, five involving earliest exposure to clobazam in the 1st trimester, two in the 2nd and 3rd trimesters, and one in the 3rd trimester of exposure. No specific pattern was observed (8).

BREASTFEEDING SUMMARY

Clobazam is excreted into breast milk. This is consistent with the molecular weight (about 301), lipophilic nature, moderate plasma protein binding (80%–90%), and prolonged elimination half-life (36–42 hours). Its active metabolite is also present in milk because of its characteristics (plasma protein binding about 70% and mean elimination half-life about 71–82 hours).

Neonatal withdrawal due to clobazam in milk was described in a 2000 review

(9). Both clobazam and its metabolite were excreted into milk with an a milk:plasma (parent drug plus metabolite) after 2 days of treatment of 0.13–0.36. After 5 days, the M:P declined to 0.13 possibly because of accumulation of the metabolite in the maternal plasma. The average infant weight-adjusted dose was estimated to be 4.6%, with a maximum dose of 7.5%. The authors of the review thought that breastfeeding should be allowed but the infant should be monitored for sedation and poor sucking (9).

Another 2000 review concluded that the use of clobazam would be safe during breastfeeding if the maternal dose was low and if the exposure was short (10). The authors estimated that the maximum infant exposure would be 10% of the usual therapeutic pediatric dose that was used in the treatment of seizures. However, long-term maternal use could result in infant toxicity and the same monitoring, as described above, was recommended (10).

CLOFARABINE

Antineoplastic

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of clofarabine in human pregnancy have been located. The animal pregnancy data suggest risk, as does the potential for impaired fertility. The absence of human pregnancy experience prevents a complete assessment of the embryo–fetal risk. Women of reproductive age should use effective contraceptive methods to prevent pregnancy while receiving this drug (1). However, lymphoblastic leukemia is a potential fatal disease. Thus, if a woman does conceive and informed consent is obtained, clofarabine should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Clofarabine is a purine nucleoside antimetabolite antineoplastic that is sequentially metabolized intracellularly to the active 5'-triphosphate metabolite that inhibits DNA synthesis. The drug is classified as an antimetabolite in the same subclass of purine analogs and related agents as cladribine, fludarabine, pentostatin, mercaptopurine, and thioguanine. Clofarabine is indicated for the treatment of pediatric patients (1–21 years of age) with relapsed or refractory acute lymphoblastic leukemia after at least two prior regimens. Plasma protein binding, primarily to albumin, is 47%. The terminal half-life is about 5.2 hours with 49%–60% of the drug excreted unchanged in the urine within 24 hours (1).

Reproduction studies have been conducted in rats and rabbits. In pregnant rats and rabbits, doses that were about equal to and 0.23 times, respectively, the recommended human clinical dose based on BSA (RHCD) resulted in increased incidences of malformations and variations (gross external, soft tissue, skeletal and retarded ossification) and developmental toxicity (reduced fetal body weight and increased postimplantation loss) (1).

Studies for carcinogenicity have not been conducted with clofarabine. Although not mutagenic in one assay, the drug was clastogenic in two assays. Fertility studies have been conducted in mice, rats, and dogs. Toxicity was observed in male reproductive organs in these species at doses that were about 0.17, 3, and 0.14 times, respectively, the RHCD. In female mice, a dose 4 times the RHCD resulted in ovarian atrophy or degeneration and uterine mucosal apoptosis (1).

It is not known if clofarabine crosses the human placenta. The molecular weight (about 304), plasma protein binding, and elimination half-life suggest that exposure of the embryo and fetus will occur.

BREASTFEEDING SUMMARY

No reports describing the use of clofarabine during human lactation have been located. The molecular weight (about 304), plasma protein binding (47%), and elimination half-life (5.2 hours) suggest that the drug will be excreted into breast milk. The effects of this exposure on a nursing infant are unknown, but severe toxicity potentially involving multiple systems throughout the body is a concern. Thus, the best course is to not breastfeed while receiving clofarabine therapy.

CLOFAZIMINE

Anti-infective (Leprostatic)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Limited human pregnancy experience and the animal data suggest that the risk of developmental toxicity is low, if it exists at all. Pigmentation of the newborn's skin is a potential complication.

FETAL RISK SUMMARY

Clofazimine, a bright-red dye with antibacterial properties against *Mycobacterium leprae*, is used for the treatment of lepromatous leprosy. Animal studies involving mice and rats with doses up to 50 mg/kg/day, and rabbits, 15 mg/kg/day, found no evidence of teratogenicity (1). Fetotoxicity in mice at doses 12–25 times the human dose, however, included retardation of fetal skull ossification, increased incidence of abortions and stillbirths, and decreased neonatal survival (2).

A number of studies have reported the use of clofazimine throughout human pregnancies (3–9). In 13 pregnancies, three exposed newborns died shortly after birth, but none of the outcomes could be attributed to clofazimine. The causes of death were unspecified (died 3 hours after birth), prematurity and antemortem hemorrhage, and gastroenteritis (5,7). The mother of the newborn who died at 3 hours was steroid dependent, but she had stopped her prednisolone 4 weeks before delivery (5). No congenital anomalies were observed in any of the 13 infants, although some of the infants were pigmented at birth. In at least 3 infants (data not provided in 10 infants), the pigmentation gradually resolved over a 1-year period (8).

A 1982 case report described the effects of clofazimine exposure during pregnancy on two newborns (10). The first case involved a woman with erythema nodosum leprosum who was treated throughout gestation with

clofazimine, 300 mg/day, and prednisone. Rifampin was also used early in pregnancy. Oligohydramnios developed just prior to delivery after a gestation of uncertain dates. Thick, foul-smelling, meconium-stained fluid was present, and the placenta showed signs of acute severe amnionitis. A 2575-g male infant was delivered vaginally, who appeared normal except for his skin, which was “not excessively pigmented.” Bilateral hydrocele and iron deficiency anemia were diagnosed at 14 days of age with fever of unknown origin occurring then and again at 5 months of age. The infant was doing well at 12 months of age. In the second case, a woman was treated throughout pregnancy with clofazimine, 300 mg/day, for tuberculoid leprosy. A normal, healthy 3070-g female infant was delivered vaginally at an unspecified gestational age, and she is growing and developing normally at 3 years of age. Skin pigmentation was not mentioned.

A 1984 reference examined the results of 79 pregnancies from 76 women with lepromatous leprosy, of whom 4 (5 pregnancies) were treated with clofazimine (300 mg/week) (11). No information was given on the outcome of these pregnancies, although the authors stated that clofazimine was the best drug available, if given after the 1st trimester, to prevent transient relapses and to prevent or treat erythema nodosum leprosy (11).

BREASTFEEDING SUMMARY

Clofazimine is excreted into breast milk, and pigmentation of the nursing infant may result. In one case, a mother was ingesting clofazimine, between 100 and 300 mg/day (exact dose not specified), 6 days/week, for a 6-month period (3). Her nursing infant became “ruddy and then slightly hypermelanotic.” The baby’s skin returned to a normal color 5 months after the mother’s medication was stopped.

The American Academy of Pediatrics classifies clofazimine as a drug whose effect on the nursing infant is unknown (other than the skin pigmentation) but may be of concern (12).

CLOFIBRATE

[Withdrawn from the market. See 9th edition.]

CLOMIPHENE

Fertility Agent (Nonhormonal)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

Patients requiring the use of clomiphene should be cautioned that each new course of the drug should be started only after pregnancy has been excluded.

FETAL RISK SUMMARY

Clomiphene is used to induce ovulation and is contraindicated after conception has occurred. Multiple pregnancies, most often twins, may be a complication of ovulation induction with clomiphene (1).

Shepard reviewed five animal reproduction studies involving the use of clomiphene in mice, rats, and monkeys (2). Hydramnios, cataracts, dose-related fetal mortality, and multiple abnormalities of the genital tract were observed in fetal mice and rats, but no congenital anomalies resulted after exposure of monkeys during the embryonic period. In mice, preovulatory administration of clomiphene produced a decrease in implantation rates, and growth restriction and an increased incidence of exencephaly in surviving fetuses (3). The decreased rate of implantation and growth restriction, which were most pronounced when the drug was given immediately before ovulation, apparently were caused by impairment of uterine function, rather than by a direct effect on the embryo itself (3).

Several case reports of neural tube defects have been reported after stimulating ovulation with clomiphene (4–8). However, an association between the drug and these defects has not been established (9–17). In one review, the percentage of congenital anomalies after clomiphene use was no greater than in the normal population (9). Similarly, another study involving 1034 pregnancies after clomiphene-induced ovulation found no association with the incidence or type of malformation (18). Recent studies have also failed to find an

association between ovulation induction with clomiphene and neural tube defects (19–25) or any defects (19,23). Congenital malformations reported in patients who received clomiphene before conception include the following (8,9,26–40):

- Hydatidiform mole
- Retinal aplasia
- Syndactyly
- Clubfoot
- Pigmentation defects
- Microcephaly
- Congenital heart defects
- Cleft lip/palate
- Down's syndrome
- Ovarian dysplasia
- Hypospadias
- Polydactyly
- Hemangioma
- Anencephaly
- Persistent hyperplastic primary vitreous

A 1996 prospective study examined the possible relationship between clomiphene and spontaneous abortions (41). The outcomes of 1744 clomiphene-induced pregnancies were compared with the outcomes of 3245 spontaneous pregnancies. The incidence of spontaneous abortion (clinical and preclinical) was higher in clomiphene-induced pregnancies than in spontaneous pregnancies (23.7% vs. 20.4%, $p < 0.01$).

Acardius acephalus in a monozygotic twin was observed in a pregnancy occurring after ovulation induced with clomiphene (42). Because monozygotic twinning is associated with an increased incidence of congenital defects, and because clomiphene-induced ovulation increases the incidence of multiple gestation and possibly of monozygotic twins, the investigators thought that the drug may have had a causative role, either directly or indirectly, in the defect. Another case of acardius acephalus similar to the one above was published in 1995 (43). The authors also mentioned a third case that had been published in 1990 (44). However, they concluded that there was insufficient evidence to establish a relationship between clomiphene and acardiac twinning (43).

A single case of hepatoblastoma in a 15-month-old female was thought to be caused by the use of clomiphene and follicle-stimulating/luteinizing hormone

prior to conception (45).

Inadvertent use of clomiphene early in the 1st trimester has been reported in two patients (32,38). A ruptured lumbosacral meningocele was observed in one infant exposed during the 4th week of gestation (32). There was no evidence of neurologic defect in the lower limbs or of hydrocephalus. The second infant was delivered with esophageal atresia with fistula, congenital heart defects, hypospadias, and absent left kidney (38). The mother also took methyldopa throughout pregnancy for mild hypertension.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 41 newborns may have been exposed to clomiphene during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Three (7.3%) (two expected) major birth defects were observed, one of which was a cardiovascular defect (0.5 expected). No anomalies were observed in five other categories of defects (oral clefts, spina bifida, polydactyly, limb-reduction defects, and hypospadias) for which specific data were available. Although the number of exposures is small, these data do not support an association between the drug and congenital defects.

BREASTFEEDING SUMMARY

No reports describing the use of clomiphene during lactation have been located. The drug may reduce lactation in some patients (46).

CLOMIPRAMINE

Antidepressant

PREGNANCY RECOMMENDATION: Human Data Suggest Risk in 1st and 3rd Trimesters

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Clomipramine was not teratogenic in animals, but a statistically significant association between clomipramine and cardiac defects was found in a human study. These results require confirmation. In addition, newborn toxicity may occur due to apparent drug withdrawal. In two cases, in utero exposure to a benzodiazepine sedative may have contributed to the observed symptoms. Although the data are very limited, no long-term effects of in utero exposure to clomipramine have been observed.

FETAL RISK SUMMARY

Clomipramine is a tricyclic antidepressant in the same class as amitriptyline, doxepin, imipramine, and trimipramine. No teratogenic effects were observed after dosing with clomipramine via the oral (mice and rats), SC (mice and rats), and IV (mice and rabbits) routes (1). Congenital malformations (2,3) and toxic symptoms (caused by apparent drug withdrawal) (4–10) have been reported in human fetuses exposed to clomipramine.

In a 1996 descriptive large case series, the European Network of the Teratology Information Services (ENTIS) prospectively examined the outcomes of 689 pregnancies exposed to antidepressants (2). Multiple drug therapy occurred in about two-thirds of the mothers. Clomipramine (134 exposures) was the most commonly used tricyclic antidepressant. The outcomes of these pregnancies were 20 elective abortions, 22 spontaneous abortions, 4 stillbirths, 76 normal newborns (includes 2 premature infants), 9 normal infants with neonatal disorder (primarily withdrawal symptoms), and 3 infants with congenital defects. The defects (all exposed in the 1st trimester or longer) were Down's syndrome, bilateral talipes (also exposed to prazepam), and

Harlequin syndrome with multiple anomalies (exposed to multiple other agents).

A 2003 case–control study, using data from three Swedish health registers, was conducted to identify drug use in early pregnancy that was associated with cardiac defects (3). Cases (cardiovascular defects without known chromosome anomalies) (N = 5015) were compared with controls consisting of all infants born in Sweden (1995–2001) (N = 577,730). Associations were identified for several drugs, some of which were probably due to confounding from the underlying disease or complaint or multiple testing, but some were thought to be true drug effects (2). For all antidepressants, there were 40 cases in 4068 exposures (odds ratio [OR] 1.14, 95% confidence interval [CI] 0.83–1.56). There was an increased OR for the tricyclic/tetracyclic antidepressants (16 cases, 1018 exposures; OR 1.77, 95% CI 1.07–2.91), but the association was due to clomipramine (15 cases, 838 exposures; OR 2.03, 95% CI 1.22–3.40). The lack of an association with other antidepressants suggested to the investigators that it was unlikely that the underlying disease itself caused the association with clomipramine (3).

A mother took clomipramine 25 mg three times daily throughout a normal pregnancy (4). Twelve hours after birth, the 3140-g male infant became dusky and was hypothermic (rectal temperature 35.4°C). Hypothermia persisted for 4 days and was aggravated by feeding and handling. Jitteriness, attributed to drug withdrawal, developed on the 2nd day and persisted for 48 hours. The symptoms were controlled with phenobarbital. Plasma levels of clomipramine and its metabolite, chlordesipramine, were <20 and 116 ng/mL, respectively, at 1 day of age, and <20 and 96 ng/mL, respectively, at age 3 days. Recovery was uneventful and normal development was noted at 3 and 6 months of age (4).

Drug withdrawal was observed in two newborns exposed throughout gestation to clomipramine (5). A 3550-g infant, exposed to 200 mg/day, appeared normal at birth but became lethargic, cyanotic, and tachypneic with moderate respiratory acidosis within a few hours. Oxygen therapy corrected the cyanosis and respiratory acidosis. Jitteriness and tremors developed by the end of the 1st day, followed by intermittent hypertonia and hypotonia, tachypnea, and feeding problems. Phenobarbital was used to control the symptoms, which resolved completely in 1 week. A 4020-g newborn, whose mother had taken 100 mg/day of clomipramine, had symptoms similar to those observed in the first infant. Oxygen and phenobarbital therapy were used, and although the neurologic symptoms had resolved within a few days, tachypnea and feeding difficulties persisted for 16 days. Both infants were developing

normally at 5 months of age (5).

Neonatal convulsions were observed in two male infants after in utero exposure to clomipramine (maternal doses not specified) (6). The onset of seizures occurred at 8 and 7 hours. The first infant, a 3420-g newborn whose mother had been treated with clomipramine during the last 7 weeks of gestation, had persistent intermittent convulsions, despite treatment with phenobarbital and paraldehyde, until 53 hours of age, after which he remained hypertonic and jittery with ankle clonus until the 11th day. The second infant, exposed throughout gestation to clomipramine and flurazepam (dose not specified), delivered at 33 weeks' gestation with a birth weight of 2360 g, had convulsions that were unresponsive to phenobarbital. At 24 hours of age, 0.4 mg of clomipramine was given intravenously over 2 hours, resulting in complete cessation of the symptoms for 11 hours. Upon their recurrence, a dose of 0.5 mg over 2 hours was given, followed by a continuous tapering infusion until age 12 days when oral therapy was started (doses not given). No additional convulsions were observed, but he remained jittery. All therapy was stopped at age 17 days without adverse effect. No follow-up of either infant was mentioned. The combined concentrations of drug and metabolite in the mothers were 610 and 549 ng/mL, respectively, both higher than the suggested therapeutic range of 200–500 ng/mL. Although the exact values could not be obtained from the graphs used in the reference, the initial combined serum levels of clomipramine and metabolite in the infants appear to be in the range of 250–400 ng/mL. The authors attributed the convulsions to the initial steep decline in serum drug levels, with clomipramine therapy in the second infant permitting a more gradual decline in concentrations and, thus, control of the infant's symptoms. Neurologic symptoms in the infants did not resolve completely until the concentration of clomipramine was <10 ng/mL (6).

Six cases of fetal exposure to clomipramine were described in a 1991 report (7). One infant, with meconium-stained fluid in the trachea, had mild respiratory distress with acidosis, mild hypotonia, and a tremor at birth. At 12 hours of age, the newborn developed jitteriness that resolved spontaneously, along with the other symptoms, by 6 days of age. At birth, clomipramine concentrations were 474.4 ng/mL in the maternal serum and 266.6 ng/mL in the neonatal plasma (ratio 1.8). Levels of the metabolite were not determined. The mother's dose at this time was 125 mg/day. The elimination half-life of clomipramine in the infant during the first week, when the male infant was not breastfeeding, was 92.8 hours. Among the other five cases, one woman had a therapeutic abortion at 9 weeks' gestation, one stopped clomipramine therapy when she

realized she was pregnant, and the remaining three continued therapy with daily doses between 75 and 250 mg throughout gestation. Mild hypotonia, persisting for several weeks, was observed in one of the four liveborn infants, and transient tachypnea requiring oxygen therapy was observed in another. No other symptoms or signs of toxicity were noted (7).

Three additional cases of drug withdrawal to clomipramine have been reported (8–10). A short 1990 case report described symptoms of drug withdrawal in a newborn exposed during the last 8–9 weeks of gestation to daily doses of 125 mg of clomipramine and 3 mg of lorazepam (8). The 3900-g infant was normal until 8 hours of age, when tachypnea, with a respiratory rate of 100–120 breaths/minute, and recessions developed. Other symptoms noted in the infant over the next 10 days were intermittent hypertonia and marked diaphoresis. Treatment consisted of intravenous fluids, oxygen, and empiric antibiotic therapy. No follow-up of the infant was reported (8). In the second case, a 33-year-old woman with an obsessive-compulsive disorder was treated with clomipramine, 100–150 mg/day, from the 12th week of gestation through the 32nd week (9). At that time, the mother decided on her own to discontinue the drug and, 4 days later, she presented in premature labor and imminent delivery, and a 2.7-kg infant was delivered by cesarean section. Repetitive seizures, rigidity, irritability, and decerebrate-like posturing, which was unresponsive to phenobarbital and phenytoin, occurred 10 minutes after birth. After 3 days of convulsions, 0.5 mg of clomipramine was given via gastric tube with resolution of the seizures within 30 minutes. When the seizures recurred 10 hours later, clomipramine, 0.5 mg three times daily, was started and the phenobarbital discontinued. The clomipramine was gradually tapered over the next 20 days. An EEG shortly after birth showed a left temporal epileptogenic focus, but was normal after 20 days of clomipramine therapy. The infant was discharged home at the age of 1 month with no signs or symptoms of neurological damage (9). The third case involved a term male infant who had been exposed throughout gestation to 100 mg/day (10). Generalized, stimulate sensitive, status myoclonus developed at age 2 days (clomipramine serum level <10 ng/mL) that were successfully treated with 0.5 mg clomipramine. Previous treatment with clonazepam and phenobarbital was unsuccessful. At 3 weeks of age, only mild jitteriness in response to touch was noted (10).

A 2002 prospective study compared two groups of mother–child pairs exposed to antidepressants throughout gestation (46 exposed to tricyclics—7 to clomipramine; 40 to fluoxetine) to 36 nonexposed, not depressed controls (11). Offspring were studied between the ages 15 and 71 months for effects of

antidepressant exposure in terms of IQ, language, behavior, and temperament. Exposure to antidepressants did not adversely affect the measured parameters, but IQ was significantly and negatively associated with the duration of depression, and language was negatively associated with the number of depression episodes after delivery (11).

BREASTFEEDING SUMMARY

Clomipramine is excreted into human milk (7). A woman taking 125 mg/day of the antidepressant had milk and plasma concentrations determined on the 4th and 6th postpartum days. Her infant was not breastfeeding during this time. Milk levels were 342.7 and 215.8 ng/mL, respectively, compared with plasma levels of 211.0 and 208.4 ng/mL, respectively. The milk:plasma ratios on the 4th and 6th days were 1.62 and 1.04, respectively. Neonatal plasma concentrations of clomipramine, from drug obtained in utero, declined from 266.6 ng/mL at birth to 94.8 ng/mL on the 6th day. The baby was allowed to breastfeed commencing at 7 days of age; at the same time, the mother's dose was increased to 150 mg/day. Repeat determinations of milk and plasma clomipramine concentrations were made between 10 and 14 hours after the daily dose on the 10th, 14th, and 35th days after delivery. Milk levels ranged from 269.8 to 624.2 ng/mL compared with plasma concentrations of 355.0–509.8 ng/mL, corresponding to milk:plasma ratios of 0.76–1.22. The highest concentrations for both the milk and the plasma occurred on the 35th day, but neonatal drug levels continued to decline from 45.4 ng/mL on the 10th day to 9.8 ng/mL on the 35th day. No adverse effects were noted in the infant during breastfeeding (7).

A 1996 review of antidepressant treatment during breastfeeding found no information that clomipramine exposure during nursing resulted in quantifiable amounts in an infant or that the exposure caused adverse effects (12).

Ten nursing infants of mothers taking antidepressants (two with clomipramine 75–125 mg/day) were compared with 15 bottle-fed infants of mothers with depression who did not breastfeed (13). Concentrations of clomipramine in fore-milk and hind-milk ranged from 32 to 212 ng/mL and 32 to 436 ng/mL, respectively. The milk:maternal plasma ratios were 0.4–1.2 and 0.4–3.0, respectively. One infant had plasma levels of 3.2 ng/mL when the mother was taking 75 mg/day and 5.5 ng/mL when the dose was increased to 125 mg/day. No toxic effects or delays in development were observed in the infants. The estimated daily dose consumed by the infants was about 1% of the mother's weight-adjusted dose (13).

The American Academy of Pediatrics classifies clomipramine as a drug whose effect on the nursing infant is unknown but may be of concern (14).

CLONAZEPAM

Anticonvulsant

PREGNANCY RECOMMENDATION: Human Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Compatible*

PREGNANCY SUMMARY

Clonazepam was teratogenic in one animal species but not in another. Published human pregnancy experience in the 1st trimester is limited to 71 cases. In these exposures, one major congenital defect was observed. Fetal and neonatal toxicity also has been reported. Although the true incidence of teratogenicity and toxicity cannot be determined, the risk of adverse pregnancy outcome appears to be low, but additional study is needed. Until such data are available, the safest course is to avoid the drug during the 1st trimester. However, if clonazepam is indicated, it should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Clonazepam is a benzodiazepine anticonvulsant that is chemically and structurally similar to diazepam (1). The drug is used either alone or in combination with other anticonvulsants.

Reproduction studies in mice and rats during organogenesis at doses up to 4 and 20 times, respectively, the maximum recommended human dose of 20 mg/day for seizures [MRHD-S], and 20 and 100 times, respectively, the maximum recommended human dose of 4 mg/day for panic disorders [MRHD-P], based on BSA, revealed no evidence of embryo or fetal effects (2). In rabbits administered doses that were 0.2–10 times the MRHD-S and 1–50 times the MRHD-P, a low, non-dose-related incidence of a similar pattern of malformations (cleft palate, open eyelid, fused sternebrae, and limb defects) was observed in all dosage groups (2). At the highest dose (twice the dose that produced reductions in maternal weight gain), intrauterine growth restriction was also observed.

In a small series of patients (N = 150) matched with nonepileptic controls, anticonvulsant therapy, including five women using clonazepam, had no effect

on the incidence of gestational hypertension, albuminuria, premature contractions, premature labor, bleeding in pregnancy, duration of labor, blood loss at delivery, cesarean sections, and vacuum extractions (3).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 19 newborns had been exposed to clonazepam during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Three (15.8%) major birth defects were observed (one expected), two of which were cardiovascular defects (0.2 expected). No anomalies were observed in five other categories of defects (oral clefts, spina bifida, polydactyly, limb-reduction defects, and hypospadias) for which specific data were available.

A prospective study published in 1999 described the outcomes of 517 pregnancies of epileptic mothers identified at one Italian center from 1977 (4). Excluding genetic and chromosomal defects, malformations were classified as severe structural defects, mild structural defects, and deformations. Minor anomalies were not considered. Spontaneous (N = 38) and elective (N = 20) abortions were excluded from the analysis, as were 7 pregnancies that delivered at other hospitals. Of the remaining 452 outcomes, 427 were exposed to anticonvulsants; of which, 313 involved monotherapy: clonazepam (N = 6), carbamazepine (N = 113), phenobarbital (N = 83), valproate (N = 44), primidone (N = 35), phenytoin (N = 31), and other (N = 1). There were no defects in the 25 pregnancies not exposed to anticonvulsants. Of the 42 (9.3%) outcomes with malformations, 24 (5.3%) were severe, 10 (2.2%) were mild, and 8 (1.8%) were deformities. There were no malformations with clonazepam monotherapy. The investigators concluded that the anticonvulsants were the primary risk factor for an increased incidence of congenital malformations (see also Carbamazepine, Phenobarbital, Phenytoin, Primidone, and Valproic Acid) (4).

A 2001 report described the pregnancy outcomes of 38 women treated during gestation with clonazepam for panic disorder (5). Twenty-nine of the women were taking clonazepam at the time of conception and 27 were taking the drug at delivery. The Apgar scores were within normal limits. Hospital records were available for 27 infants, 17 of whom were exposed to the agent at delivery. In the 27 infants, there was no evidence of neonatal withdrawal or congenital anomalies, but 2 infants had minor defects: hydrocele; two-vessel umbilical cord. One infant had cardiac disease (no specific details) but was not exposed to clonazepam in the 1st trimester (5).

The database of the Hungarian Case–Control Surveillance of Congenital

Abnormalities (1980–1996) was used in a 2002 report that evaluated the teratogenicity of five benzodiazepines: clonazepam, alprazolam, medazepam, nitrazepam, and tofisopam (6). There were 22,865 women who delivered infants with congenital abnormalities, 57 (0.25%) of whom used one of the benzodiazepines in pregnancy. Clonazepam was used throughout gestation in four cases (cleft lip and/or palate, cardiovascular defect, hypospadias, and multiple defects). Although the data were limited, no teratogenic risk was found for clonazepam or the other agents (6).

In a 2004 report, the medical records of 28,565 infants were surveyed to identify cases exposed to anticonvulsants (7). Of 166 cases, 52 had been exposed to clonazepam, 43 as monotherapy. Thirty-three of the monotherapy cases had been exposed in the 1st trimester. Congenital defects were noted in one (3.0%) infant: dysmorphic facial features (small eyes, ptosis, and external auditory canal stenosis), tetralogy of Fallot, 11 pair of ribs, and growth restriction (length and head circumference <5th percentile). As with other case series, the data are limited but no increase in congenital malformations was observed (7).

The Lamotrigine Pregnancy Registry, an ongoing project conducted by the manufacturer, was first published in January 1997 (8). The final report was published in July 2010. The Registry is now closed. Among 103 prospectively enrolled pregnancies exposed to clonazepam and lamotrigine, with or without other anticonvulsants, 98 were exposed in the 1st trimester, resulting in 88 live births without defects, 5 spontaneous abortions, 2 elective abortions, and 3 birth defects. There were five exposures in the 2nd/3rd trimesters resulting in three live births, one fetal death, and one birth defect (8).

Toxicity in the newborn, apparently related to clonazepam, has been reported. Apnea, cyanosis, lethargy, and hypotonia developed at 6 hours of age in an infant of 36 weeks' gestational age exposed throughout pregnancy to an unspecified amount of clonazepam (9). There was no evidence of congenital defects in the 2750-g newborn. Cord and maternal serum levels of clonazepam were 19 and 32 ng/mL, respectively, a ratio of 0.59. Both levels were within the therapeutic range (5–70 ng/mL). At 18 hours of age, the clonazepam level in the infant's serum measured 4.4 ng/mL. Five episodes of prolonged apnea (16–43 seconds/occurrence) were measured by pneumogram over the next 12 hours. Hypotonia and lethargy resolved within 5 days, but overt clinical apnea persisted for 10 days. Follow-up pneumograms demonstrated apnea spells until 10 weeks of age, but the presence of the drug in breast milk may have contributed to the condition (see Breastfeeding Summary). The authors

concluded that apnea due to prematurity was not a significant factor. Neurologic development was normal at 5 months (9).

A 1995 case report described paralytic ileus of the small bowel in a fetus at 32 weeks' gestation associated with polyhydramnios (10). The fetal stomach was enlarged (more than 2 standard deviations above the mean). The mother had been treated with clonazepam (4 mg/day) and carbamazepine (1800 mg/day) for epilepsy throughout gestation. A 2420-g male infant was delivered by cesarean section at 36 weeks' gestation. Normal bowel movements started after three gastrographin enemas. No evidence of cystic fibrosis or Hirschsprung disease was found and the child was developing normally at 20 months of age. The ileus was attributed to clonazepam (10).

A study published in 2009 examined the effect of AEDs on the head circumference in newborns (11). Significant reductions in mean birth-weight-adjusted mean head circumference (bw-adj-HC) was noted for monotherapy with carbamazepine and valproic acid. No effect on bw-adj-HC was observed with gabapentin, phenytoin, clonazepam, and lamotrigine. A significant increase in the occurrence of microcephaly (bw-adj-HC smaller than 2 standard deviations below the mean) was noted after any AED polytherapy but not after any monotherapy, including carbamazepine and valproic acid. The potential effects of these findings on child development warrant study (11).

BREASTFEEDING SUMMARY

Clonazepam is excreted into breast milk. In a woman treated with an unspecified amount of the anticonvulsant, milk concentrations remained constant between 11 and 13 ng/mL (9). The milk:maternal serum ratio was approximately 0.33. After 7 days of nursing, the infant, described above, had a serum concentration of 2.9 ng/mL. A major portion of this probably resulted from in utero exposure because the elimination half-life of clonazepam in neonates is thought to be prolonged. No evidence of drug accumulation after breastfeeding was found. Persistent apneic spells, lasting until 10 weeks of age, were observed, but it was not known whether breastfeeding contributed to the condition. Based on this case, the authors recommended that infants exposed in utero or during breastfeeding to clonazepam should have serum levels of the drug determined and be closely monitored for central nervous system depression or apnea (9).

A 1988 report described a woman who was treated with clonazepam (4 mg/day) and phenytoin (400 mg/day) throughout gestation and during nursing (12). The healthy, 3930-g infant was delivered at term. Maternal serum and

milk samples were collected several times over postpartum days 2–4 at 0–11 hours after a dose. The concentrations of clonazepam in the serum ranged from 51 to 104 nmol/L (about 16–33 ng/mL), whereas those in the milk ranged from <10 to 34 nmol/L (about 3–11 ng/mL). The infant's serum level of clonazepam in the pooled sample from days 2 to 4 was 15 nmol/L (about 5 ng/mL). The study could not determine the proportions of the infant drug level that resulted from placental transfer and ingestion from milk. No effects on the infant were mentioned (12).

A 2006 report described six women taking quetiapine and other psychotropic agents during breastfeeding (13). Milk samples in one woman at 17.5 weeks postpartum were obtained after doses of clonazepam (0.5 mg), quetiapine (25 mg), and paroxetine (60 mg) (timing of samples and daily doses were not specified). None of the drugs was detected in the milk (<30 nmol/L). The estimated infant daily dose for all three drugs was <0.01 mg/kg/day. In addition, the infant's behavior was assessed with the Bayley Scales of Infant Development, Second Edition. The results suggested normal development (13).

The effects of exposure to benzodiazepines during breastfeeding were reported in a 2012 study (14). In a 15-month period spanning 2010–2011, 296 women called the Motherisk Program in Toronto, Ontario, seeking advice on the use of these drugs during lactation and 124 consented to the study. The most commonly used benzodiazepines were lorazepam (52%), clonazepam (18%), and midazolam (15%). Neonatal sedation was reported in only two infants. Clonazepam was not taken by either mother. There was no significant difference between the characteristics of these 2 and the 122 that reported no sedation in terms of maternal age, gestational age at birth, daily amount of time nursing, amount of time infant slept each day, and the benzodiazepine dose (mg/kg/day). The only difference was in the number of CNS depressants that the mothers were taking: 3.5 vs. 1.7 ($p = 0.0056$). In one of the two infants with sedation, the mother reported using clonazepam (0.25 mg twice daily), flurazepam (1 mg/day), bupropion (1 mg/day), and risperidone (0.75 mg/day). The infant also was exposed in utero. The investigators concluded that their results supported the recommendation that the use benzodiazepines was not a reason to avoid breastfeeding (14).

*Potential toxicity if combined with other CNS depressants.

CLONIDINE

Antihypertensive/Central Analgesic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports linking the use of clonidine with congenital defects have been located. The drug has been used during all trimesters, but experience during the 1st trimester is very limited. Adverse fetal effects attributable to clonidine have not been observed (1–8).

FETAL RISK SUMMARY

Reproduction studies in rats at doses as low as 1/3 the oral maximum recommended daily human dose MRDHD-W (based on weight) or 1/15 times the MRDHD-BSA (based on BSA), started before gestation, resulted in increased resorptions (9). Decreased embryo–fetal survival was not observed when these doses were used on gestation days 6–15, but did occur in both mice and rats at doses 40 times the MRDHD-W or 4 to 8 times the MRDHD-BSA. No embryo or fetal toxicity or teratogenicity was observed in rabbits given doses up to 3 times the MRDHD-W (9).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 59 newborns had been exposed to clonidine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Three (5.1%) major birth defects were observed (three expected), two of which were cardiovascular defects (0.6 expected). No anomalies were observed in five other categories of defects (oral clefts, spina bifida, polydactyly, limb-reduction defects, and hypospadias) for which specific data were available. The number of exposures is too small to draw any conclusions.

The pharmacokinetics of clonidine during pregnancy have been reported (10). The mean maternal and cord serum concentrations in 10 women were 0.46 and

0.41 ng/mL, respectively, corresponding to a cord:maternal ratio of 0.89. The mean amniotic fluid concentration was 1.50 ng/mL. The mean maternal dose was 330 mcg/day. Results of neurologic examinations and limited blood chemistry tests in the exposed infants were similar to those in untreated controls. No neonatal hypotension was observed.

BREASTFEEDING SUMMARY

Clonidine is secreted into breast milk (8,10). Following a 150-mcg oral dose, milk concentrations of 1.5 ng/mL may be achieved (milk:plasma ratio 1.5) (P.A. Bowers, personal communication, Boehringer Ingelheim, Ltd., 1981). In a study of nine nursing women taking mean daily doses of 391.7 mcg (postpartum days 1–5), 309.4 mcg (postpartum days 10–14), and 241.7 mcg (postpartum days 45–60), milk concentrations were approximately twice those in maternal serum (10). Mean milk levels were close to 2 ng/mL or higher during the three sampling periods. Hypotension was not observed in the nursing infants, although clonidine was found in the serum of the infants (mean levels less than maternal). The long-term significance of this exposure is not known.

CLOPIDOGREL

Hematologic Agent (Antiplatelet)

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Clopidogrel is not teratogenic in two animal species, but the limited human pregnancy experience prevents a more complete assessment of the embryo–fetal risk. However, the known benefits to a woman appear to far outweigh the unknown embryo–fetal risks. If a patient’s condition requires clopidogrel, the treatment should not be withheld because of pregnancy.

FETAL RISK SUMMARY

Clopidogrel is a direct inhibitor of adenosine diphosphate (ADP)-induced platelet aggregation. It is a prodrug that must be biotransformed to an active metabolite to inhibit platelet aggregation. Neither clopidogrel nor its main circulating metabolite has platelet-inhibiting activity. The active metabolite, which has not been identified, acts by irreversibly inhibiting ADP binding to its receptor and the subsequent ADP-mediated activation of the glycoprotein GPIIb/IIIa complex. Clopidogrel is indicated for the reduction of atherosclerotic events (myocardial infarction, stroke, and vascular death) in patients with atherosclerosis documented by recent occurrences of myocardial infarction, stroke, or established peripheral arterial disease (1).

Reproduction studies have been conducted in pregnant rats and rabbits at doses up to 65 and 78 times, respectively, the recommended daily human dose based on BSA (1). No evidence of impaired fertility or fetotoxicity was seen in either species.

It is not known if clopidogrel, or its active and inactive metabolites, cross the human placenta. The molecular weight of the inactive parent drug (about 420 for the bisulfate) is low enough that some drug probably crosses to the embryo or fetus. The identity and characteristics of the active metabolite, however,

have not been determined.

A woman with a history of essential thrombocythemia and myocardial infarction received treatment with chemotherapy (details not specified) to normalize her platelet count and then cardiac bypass surgery (2). After surgery, she conceived while taking aspirin (300 mg/day) and ticlopidine (500 mg/day) but aborted the pregnancy in the 2nd trimester (6 months after surgery). Her treatment was then changed to clopidogrel (150 mg/day) combined with intermittent low-molecular-weight heparin (dalteparin), which she took throughout a second pregnancy. Clopidogrel was discontinued 10 days before vaginal delivery of a healthy, 3170-g female infant. The Apgar scores were 9, 10, 10, and 10 at 1, 5, 10, and 60 minutes, respectively. The mother had no unusual bleeding at delivery and the repair of a mediolateral episiotomy was uneventful. There was no evidence of infarcts or areas of fibrin deposits in the normal placenta. The bottle-fed infant was discharged home with her mother 5 days after delivery (2).

A 43-year-old woman, with a history of diabetes and hypertension, was in her sixth pregnancy when she had an acute myocardial infarction (AMI) at 20 weeks' gestation (3). She was treated with aspirin, nitroglycerin, and then tirofiban with heparin for percutaneous transluminal coronary angioplasty and intracoronary stenting. She was discharged home, 5 days after the procedure, on aspirin, clopidogrel, and metoprolol (doses not specified). The mother and fetus were apparently doing well with appropriate follow-up (3).

A 44-year-old woman at 8 weeks' gestation presented with an AMI (4). She was treated with intracoronary stent placement and clopidogrel (600 mg), heparin, and a 24-hour IV infusion of eptifibatide. The next day, she was started on clopidogrel, aspirin, and propranolol and discharged home on these agents. At 36 weeks' gestation, she underwent a planned cesarean section for a healthy infant (no further details on the newborn were provided) (4).

A 38-year-old woman with severe coronary artery disease and hypertension was started on clopidogrel 75 mg/day, aspirin 75 mg/day, labetalol 200 mg/day, and enoxaparin at about 27 weeks' gestation (5). One week later, she underwent percutaneous coronary intervention to place a sirolimus-eluting stent. At 35 weeks' gestation, a cesarean section under general anesthesia delivered a 2.03-kg male infant with Apgar scores of 5 and 8 at 1 and 5 minutes, respectively. No further information on the newborn was provided (5).

A 43-year-old woman, with a history of diabetes and hypertension, was in her sixth pregnancy when she had an AMI at 20 weeks' gestation (6). She was treated with aspirin, nitroglycerin, and then tirofiban with heparin for

intracoronary stenting. She was discharged home, 5 days after the procedure, on clopidogrel, aspirin, and metoprolol (doses not specified). The pregnancy was ongoing at the time of the report (6).

In another case similar to those above, a 43-year-old woman at 21 weeks' gestation had an AMI and underwent stent placement (7). She was then treated with clopidogrel 75 mg/day and aspirin 100 mg/day for 2 weeks. The aspirin was continued until 1 week before a planned cesarean section at 32 weeks' gestation and heparin therapy was started. A healthy, 1.967-kg infant with an Apgar of 9 was delivered. Both mother and infant were discharged 8 days later (7).

A brief 2009 case report described a 39-year-old woman at 6 weeks' gestation who developed an AMI and was started on clopidogrel, aspirin, and heparin (8). Following placement of a stent, the woman again experienced chest pain, and thrombus was discovered in three coronary arteries that were removed under coverage of abciximab and intracoronary adenosine. She was maintained on clopidogrel and aspirin throughout pregnancy. At 41 weeks, she was given platelet concentrates and a cesarean section delivered a female infant with appropriate weight (not specified). Defects in the infant included a patent foramen ovale, a muscular ventricular septal defect, and moderate mitral regurgitation. The authors considered the anomalies relatively common with a benign prognosis (8).

Five other case reports have described the use of clopidogrel in pregnancy, two throughout gestation (9,10) and the others starting at 10, 25, and 31 weeks' gestation (11–13). No congenital anomalies were observed in the five newborns.

BREASTFEEDING SUMMARY

No reports describing the use of clopidogrel during human lactation have been located. The molecular weight of the inactive parent drug (about 420 for the bisulfate) suggests that it will be excreted into breast milk. The effect of this possible exposure on a nursing infant is unknown.

CLORAZEPATE

Sedative/Anticonvulsant

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

The effects of benzodiazepines on the human embryo and fetus are controversial. Although some studies have reported an association with various types of congenital defects, other studies have not found such associations (see also Chlordiazepoxide or Diazepam). Maternal denial of exposure and concurrent exposure to other toxic drugs and substances (e.g., alcohol and smoking) may be confounding factors. If the maternal condition requires use of the drug during pregnancy, the lowest possible dose should be taken.

FETAL RISK SUMMARY

Clorazepate is a member of the benzodiazepine class of agents. The drug undergoes rapid metabolism to an active metabolite, nordiazepam, so there is essentially no circulating parent drug. Plasma protein binding of nordiazepam and its elimination half-life is about 40–50 hours. No teratogenic effects were observed in rats and rabbits fed large doses of the drug during gestation (1). The pharmacokinetics of clorazepate have been determined in pregnant women (2,3).

Consistent with the molecular weight (about 409) of the parent drug, the active metabolite, nordiazepam, crosses the human placenta and has been measured in amniotic fluid at 13 to 40 weeks' gestation, umbilical cord blood (both arterial and venous), and in milk (2).

One report described multiple anomalies in an infant exposed to clorazepate during the 1st trimester (4). Exposure may have commenced as early as the 3rd week of gestation (5th week after the last menstrual period). The woman reportedly consumed 23 doses of the drug during the 1st trimester. Deformities present in the infant at birth were distended abdomen, oval mass in the

suprapubic area, skin tag at site of penis without a urethral opening, absent scrotum and anus, marked shortening of the right thigh, bifid distal part of left foot, left great toe abnormality, right foot with four toes and an abnormal great toe, short digit attached to right finger in place of the thumb on left hand, deformities of the sacrum and fourth and fifth lumbar vertebrae with a narrowed pelvis, underdeveloped right femur, absent right fibula, absence of two left metacarpal bones, hypoplasia of first right metacarpal bone, patent ductus arteriosus, absence of right lung lobe, cecum, rectum, and right kidney, and the presence of several supernumerary spleens. The infant died 24 hours after birth (4).

In an unconfirmed, retrospective report of oral contraceptive drug interactions, one woman became pregnant while taking a combination tablet of ethinyl estradiol 80 mcg/norethindrone 1 mg (5). The only other medications consumed immediately prior to the pregnancy were clorazepate and an unidentified cold tablet. The authors speculated that a possible interaction may have occurred between the antihistamine in the cold tablet and the contraceptive. Although the woman claimed she did not miss any doses of the oral contraceptive, there was no confirmation of compliance (5). Interpretation of this interaction, if it exists, is not possible.

The Lamotrigine Pregnancy Registry, an ongoing project conducted by the manufacturer, was first published in January 1997 (6). The final report was published in July 2010. The Registry is now closed. In two prospectively enrolled pregnancies exposed in the 1st trimester to clorazepate and lamotrigine, with or without other anticonvulsants, there was one fetal death and one spontaneous abortion (6).

BREASTFEEDING SUMMARY

No reports describing the use of clorazepate during human lactation have been located.

However, following a single 20-mg clorazepate dose administered IM to seven women during labor, low concentrations of nordiazepam, the active metabolite, were found in milk at 2 days postdose (average 10.0 ng/mL, range 7.5–15.5 ng/mL) and at 4 days (average 9.4 ng/mL, range 6–12 ng/mL). The milk:maternal blood ratios were 0.18 and 0.23, respectively. In infant blood at 2 days, only trace amounts were measured in five with 4 ng/mL and 7.5 ng/mL levels in the other two. In five infants at 4 days, the average concentration was 5.7 ng/mL (range 4–8.5 ng/mL). In the other two infants, one had trace amounts and the other had a coagulated sample. In absolute terms, the

amounts were considered negligible (2).

Other benzodiazepines accumulate in human milk, and adverse effects in the nursing infant have been reported (see Diazepam). The American Academy of Pediatrics classifies other benzodiazepines as drugs whose effect on the nursing infant is unknown but may be of concern (e.g., see Diazepam).

CLOTRIMAZOLE

Antifungal

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Compatible

PREGNANCY SUMMARY

The absorption of clotrimazole from the skin and vagina is minimal. Three large surveillance studies found no association between clotrimazole and birth defects. However, one study did find a significant increase in the risk of spontaneous abortions (SABs) with 1st trimester vaginitis treatment. A later study speculated that this effect might have been due to inhibition of the critical enzyme aromatase. Until there are more data regarding this possible association, the best course is to avoid the use of clotrimazole for vaginitis treatment in the 1st trimester or the application of the antifungal to large areas of skin at any time in pregnancy.

FETAL RISK SUMMARY

Clotrimazole is in the same antifungal class of imidazole derivatives as butoconazole, econazole, ketoconazole, miconazole, oxiconazole, sertaconazole, sulconazole, and tioconazole. No reports linking the use of clotrimazole with congenital defects have been located. The topical use of the drug in pregnancy has been studied (1–4). No adverse effects attributable to clotrimazole were observed. Absorption of the agent from the skin and vagina is minimal (5).

Suspected birth defect diagnoses occurred in 6564 offspring of 104,339 women in a retrospective analysis of women who had delivered in Michigan hospitals during 1980–1983 (6). First-trimester vaginitis treatment with clotrimazole occurred in 74 of the 6564 deliveries linked to birth defect diagnoses and in 1012 of the 97,775 cases not linked to such diagnoses. The estimated relative risk of birth defects when clotrimazole was used was 1.09 (95% confidence interval [CI] 0.9–1.4). An estimated relative risk for SABs of 1.36 (95% CI 1.1–1.6) was calculated based on 112 clotrimazole exposures among 4264 abortions compared with 1086 1st trimester exposures among

55,736 deliveries. Although an increased relative risk for birth defects was not found, this study could not exclude the possibility of an association with a specific birth defect (6).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 2624 newborns had been exposed to clotrimazole (maternal vaginal use) during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 118 (4.5%) major birth defects were observed (112 expected). Specific data were available for 6 defect categories, including (observed/expected) 27/26 cardiovascular defects, 4/4 oral clefts, 3/1 spina bifida, 9/7 polydactyly, 1/4 limb-reduction defects, and 6/6 hypospadias. These data do not support an association between vaginal use of clotrimazole and congenital defects.

Data from the Hungarian Case-Control Surveillance of Congenital Abnormalities (1980–1992) were used to examine the potential teratogenic effects of vaginal and/or topical use of clotrimazole (7). Although clotrimazole use was not associated with an increase in the prevalence of any birth defect (fetal and live births), there was a suggestion that it was associated with a decrease in the prevalence of undescended testis (prevalence odds ratio 0.72, 95% CI 0.54–0.95) (7).

A 2002 study evaluated azole antifungals commonly used in pregnancy for their potential to inhibit placental aromatase, an enzyme that is critical for the production of estrogen and for the maintenance of pregnancy (8). The authors speculated that the embryotoxicity observed in animals and humans (see also Miconazole and Sulconazole) might be explained by inhibition of aromatase. They found that the most potent inhibitors of aromatase were (shown in order of decreasing potency) econazole, bifonazole (not available in United States), sulconazole, clotrimazole, and miconazole. However, an earlier study reported a pregnancy that was maintained even when there was severe fetal and placental aromatase deficiency (<0.3% of that of controls) caused by a rare genetic defect (9). In this case, both the fetus and mother were virilized because of diminished conversion of androgens to estrogen. Because the pregnancy was maintained and the virilization, the case suggested that the main function of placental aromatase was to protect the mother and fetus from exposure to adrenal androgens (9).

BREASTFEEDING SUMMARY

The absorption of clotrimazole from the skin and vagina is minimal (5). Therefore, it is doubtful if measurable amounts of the antifungal agent appear in

milk.

CLOXACILLIN

[Withdrawn from the market. See 9th edition.]

CLOZAPINE

Antipsychotic

PREGNANCY RECOMMENDATION: Compatible—Maternal Benefit >>
Embryo–Fetal Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports have linked clozapine with congenital malformations, but the data are limited. There is no evidence of embryo or fetal harm with other agents in this subclass. Because clozapine is indicated for severe debilitating mental disease, the benefits to the mother appear to outweigh the unknown embryo–fetal risk. However, there is a risk of extrapyramidal and/or withdrawal symptoms in the newborn if the drug is used in the 3rd trimester. Moreover, clozapine may cause agranulocytosis and other adverse reactions, so it is available only through a restricted program (1). Because of the limited human pregnancy experience with atypical antipsychotics, the American College of Obstetricians and Gynecologists does not recommend the routine use of these agents in pregnancy, but a risk–benefit assessment may indicate that such use is appropriate (2). A 1996 review on the management of psychiatric illness concluded that patients with histories of chronic psychosis represent a high-risk group (for both the mother and the fetus) and should be maintained on pharmacologic therapy before and during pregnancy (3). Folic acid, 4 mg/day, has been recommended for women taking atypical antipsychotics because they may have a higher risk of neural tube defects due to inadequate folate intake and obesity (4).

FETAL RISK SUMMARY

Clozapine is an atypical antipsychotic indicated for treatment-resistant schizophrenia. It belongs to the antipsychotic subclass of dibenzapine derivatives that includes asenapine, loxapine, olanzapine, and quetiapine. Clozapine is almost completely metabolized to weakly active and inactive

metabolites. Plasma protein binding is about 97% and the dose-dependent mean elimination half-life is about 12 hours at steady state (1).

Reproduction studies in rats and rabbits at doses up to 0.4 and 0.9 times, respectively, the maximum recommended human dose based on BSA found no evidence of impaired fertility or fetal harm (1).

A brief 1993 report described a woman who was treated prior to and throughout gestation with clozapine (dose not given) for treatment-resistant chronic undifferentiated schizophrenia (5). An apparently healthy, about 3689-g male infant was delivered at term. The authors cited information on 14 other women who had taken clozapine during gestation apparently without fetal adverse effects (6).

Consistent with the molecular weight (about 327), clozapine crosses the placenta, at least at term. A 1994 report described a woman who was maintained on 100 mg/day before and during the first 32 weeks of gestation (7). The dose was then lowered to 50 mg/day until she delivered at term a normal female infant. No psychomotor abnormalities were observed in the infant up to 6 months of age. Clozapine plasma levels, measured in the mother throughout her pregnancy, ranged from 38–55 ng/mL (100 mg/day) to 14.1–15.4 ng/mL (50 mg/day). At birth, the cord blood concentration was 27 ng/mL (maternal 14.1 ng/mL), representing a ratio of approximately 2. The amniotic fluid concentration was 11.6 ng/mL (7).

Nine diverse case reports of adverse pregnancy outcomes involving the use of clozapine during pregnancy have been reported to the FDA (F. Rosa, personal communication, FDA, 1995). In the absence of a cohort denominator, the cases do not suggest a fetal risk and may have been caused by chance. The cases were neonatal hypocalcemia, convulsions; asymmetry of buttock crease; Turner's syndrome (chromosomal abnormality); spontaneous abortion (SAB), hydropic villous degeneration (chromosomal abnormality); SAB 8th week (abnormal gestational sac); multiple congenital defects (unspecified) (pregnancy terminated); congenital blindness; clinodactyly thumbs and big toes; and neonatal cerebral hemorrhage.

A case report in 1996 described an otherwise healthy male infant, exposed throughout gestation to clozapine (200–300 mg/day) and lorazepam (7.5–12.5 mg/day), who developed transient, mild floppy infant syndrome after delivery at 37 weeks' gestation (8). The mother had taken the combination therapy for the treatment of schizophrenia. The hypotonia, attributed to lorazepam because of the absence of such reports in pregnancies exposed to clozapine alone, resolved 5 days after birth (8).

A 2005 study, involving women from Canada, Israeli, and England, described 151 pregnancy outcomes in women using atypical antipsychotic drugs (9). The exposed group was matched with a comparison group (N = 151) who had not been exposed to these agents. The drugs and number of pregnancies were olanzapine (N = 60), risperidone (N = 49), quetiapine (N = 36), and clozapine (N = 6). In those exposed, there were 110 live births (72.8%), 22 SABs (14.6%), 15 elective abortions (9.9%), and 4 stillbirths (2.6%). Among the live births, one infant exposed in utero to olanzapine had multiple anomalies, including midline defects (cleft lip, encephalocele, and aqueductal stenosis). The mean birth weight was 3341 g. There were no statically significant differences, including rates of neonatal complications, between the cases and controls, with the exceptions of low birth weight (10% vs. 2%, $p = 0.05$) and elective abortions (9.9% vs. 1.3%, $p = 0.003$). The low birth weight may have been caused by the increased rate of cigarette smoking (38% vs. 13%, $p \leq 0.001$) and heavy/binge alcohol use (5 vs. 1) in the exposed group (9).

BREASTFEEDING SUMMARY

Clozapine is concentrated in breast milk (7). While taking clozapine 50 mg/day, a mother (described above) on her first postpartum day had a plasma concentration of 14.7 ng/mL and a concentration of 63.5 ng/mL from the first portion of her breast milk (milk:plasma ratio [M:P] 4.3). One week postpartum, 4 days after the dose was increased to 100 mg/day, the two concentrations were 41.4 and 115.6 ng/mL (M:P ratio 2.8), respectively. The infant was not allowed to breastfeed (7).

In a 1995 report, four mothers taking clozapine were breastfeeding their infants, one of whom had drowsiness and another developed agranulocytosis that was possibly due to clozapine. No further details were provided (10).

A 2007 report described a case in which the mother took clozapine 100 mg/day throughout pregnancy and breastfeeding (11). She gave birth to a healthy female infant who was breastfed up to 1 year of age. The infant's development was normal except for her speech that was delayed. She did not achieve normal, fluent speech until 5 years of age. The cause of the developmental delay could not be determined (11).

The American Academy of Pediatrics classifies clozapine as a drug whose effect on the nursing infant is unknown but may be of concern (12).

COCAINE

Sympathomimetic

PREGNANCY RECOMMENDATION: Contraindicated (Systemic)
Compatible (Topical)

BREASTFEEDING RECOMMENDATION: Contraindicated (Systemic)
Compatible (Topical)

PREGNANCY SUMMARY

The widespread abuse of cocaine has resulted in major toxicity in the mother, the fetus, and the newborn. The use of cocaine is often significantly correlated with the heavy use of other abuse drugs. Many of the studies reviewed here were unable completely to separate this usage in their patient populations or were unable to verify self-reported usage of cocaine, thus resulting in the possible misclassification of patients into the various groups. Whether the reported consequences of maternal cocaine exposure are due to these biases, to cocaine itself, to other drugs acting independently or in conjunction with cocaine, to poor lifestyles, or to other maternal characteristics are not presently clear. It is clear, however, that women who use cocaine during pregnancy are at significant risk for shorter gestations, premature delivery, spontaneous abortions, abruptio placentae, and death. The drug decreases uterine blood flow and induces uterine contractions. An increased risk may exist for premature rupture of the membranes but apparently not for placenta previa. The unborn children of these women may be growth restricted or severely distressed, and they are at risk for increased mortality. In utero cerebrovascular accidents with profound morbidity and mortality may occur. Congenital abnormalities involving the genitourinary tract, heart, limbs, and face may occur, and cocaine abuse should be considered teratogenic. Bowel atresias have also been observed in newborn infants, which may be due to intrauterine bowel infarctions. The exact mechanism of cocaine-induced malformations is presently uncertain, but it may be related to the placental vasoconstriction and fetal hypoxia produced by the drug, with the resulting intermittent vascular disruptions and ischemia actually causing the fetal damage. Interactions with other drugs, however, may play a role. In addition to the

above toxicities, the newborn child exposed to cocaine during gestation is at risk for severe neurobehavior and neurophysiologic abnormalities that may persist for months. An increased incidence of sudden infant death syndrome in the first few months after birth may also be a consequence of maternal cocaine abuse in conjunction with other factors. Long-term studies of cocaine-exposed children need to be completed before a true assessment of the damage caused by this drug can be determined.

FETAL RISK SUMMARY

Cocaine, a naturally occurring alkaloid, is legally available in the United States as a topical anesthetic, but its illegal use as a central nervous system stimulant far exceeds any medicinal market for the drug. Cocaine is a sympathomimetic, producing hypertension and vasoconstriction as a result of its direct cardiovascular activity. The increasing popularity of cocaine is due to its potent ability to produce euphoria, an effect that is counterbalanced by the strong addictive properties of the drug (1). As of 1985, an estimated 30 million Americans had used cocaine and 5 million were believed to be using it regularly (1). Although the exact figures are unknown, current usage probably exceeds these estimates. Preliminary results of a study conducted between July 1984 and June 1987 in the Boston area indicated that 117 (17%) of 679 urban women used cocaine at least once during pregnancy as determined by prenatal and postpartum interviews and urine assays for cocaine metabolites (2). Final results from this study, now involving a total of 1226 mothers, found that 216 (18%) used cocaine during pregnancy, but that only 165 (76%) of these women would have been detected by history alone (3). Fifty-one women who had denied use of cocaine had positive urine assays for cocaine metabolites. Other investigators have reported similar findings (4). Of 138 women who had positive urine screens for cocaine at delivery, only 59 (43%) would have been identified by drug history alone. In this same study, the increasing prevalence of maternal cocaine abuse was demonstrated (4). Over a 24-month period (September 1986–August 1988), the incidence of positive urine screens for cocaine in women at delivery rose steadily, starting at 4% in the first 6-month quarter and increasing to 12% in the final quarter. The total number of women (1776) was approximately equally divided among the four quarters.

Illicitly obtained cocaine varies greatly in purity, and it is commonly adulterated with substances such as lactose, mannitol, lidocaine, and procaine (5). Cocaine is detoxified by liver and plasma cholinesterases (1,5). Activity of

the latter enzyme system is much lower in the fetus and in infants and is decreased in pregnant women, resulting in slower metabolism and elimination of the drug (1,5). Moreover, most studies have found a correlation between cocaine use and the use of other drugs of abuse such as heroin, methadone, methamphetamine, marijuana, tobacco, and alcohol. Compared with drug-free women, this correlation was highly significant ($p < 0.0001$) and, further, users were significantly more likely to be heavy abusers of these substances ($p < 0.0001$) (2).

Research on the effects of maternal and fetal cocaine exposure has focused on several different areas. It reflects the wide-ranging concerns for fetal safety this drug produces:

- Placental transfer of cocaine
- Pregnancy complications
- Placental receptor function
- Premature labor and delivery
- Spontaneous abortions
- Premature rupture of membranes (PROM)
- Placenta previa
- Gestational hypertension
- Abruptio placentae
- Ruptured ectopic pregnancy
- Maternal mortality
- Fetal complications
- Growth restriction
- Fetal distress
- Cerebrovascular accidents
- Congenital anomalies
- Infant complications
- Neurobehavior
- Mortality
- Hospitalizations

Placental Transfer

Although the placental transfer of cocaine has not been quantified in humans, cocaine metabolites are frequently found in the urine of in utero-exposed newborns. Because cocaine has high water and lipid solubility, low molecular weight (about 340), and low ionization at physiologic pH, it should freely cross to the fetus (5). In pregnant sheep given IV cocaine, 0.5 mg/kg, to produce

plasma levels similar to those observed in humans, fetal plasma levels at 5 minutes were 46.8 ng/mL compared with simultaneous maternal levels of 405 ng/mL (fetus 12% of mother) (6). At 30 minutes, the levels for fetal and maternal plasma had decreased to 11.8 and 83 ng/mL, respectively (fetus 14% of mother). Uterine blood flow was decreased in a dose-dependent manner by 36% after the above dose (6). Decreases in uterine blood flow of similar magnitude have also been observed in other studies with pregnant sheep (7,8). In one report, the reduction was accompanied by fetal hypoxemia, hypertension, and tachycardia, which were more severe than when cocaine was administered directly to the fetus (8).

Pregnancy Complications

PLACENTAL RECEPTOR FUNCTION In a study examining the effects of prenatal cocaine exposure on human placental tissue, significant decreases, as compared with nonexposed controls, were found for the total number of β -adrenergic receptor-binding sites (202 vs. 313 fmol/mg, $p < 0.01$), μ -opiate receptor-binding sites (77 vs. 105 fmol/mg, $p < 0.05$), and δ -opiate receptor-binding sites (77 vs. 119 fmol/mg, $p < 0.01$) (9). These effects were interpreted as a true down-regulation of the receptor population and may be associated with increased levels of adrenergic compounds (9,10). The authors speculated that if a similar down-regulation of the fetal adrenergic receptor-binding sites also occurred, it could result in disruption of synaptic development of the fetal nervous system. However, the clinical significance of these findings has not yet been determined (9).

PREMATURE LABOR/DELIVERY The effect of maternal cocaine use on the duration of gestation has been included in several research papers (3,4,11–25). When compared with non-drug-using controls, in utero cocaine exposure invariably resulted in significantly shortened mean gestational periods ranging up to 2 weeks. A statistically significant mean shorter (1.9 weeks) gestational period was also observed when cocaine–polydrug users (20% used heroin) were compared with noncocaine–polydrug users (26% used heroin) (13). Two other studies, comparing cocaine/amphetamine (18) or cocaine/methadone (17) consumption with noncocaine heroin/methadone-abusing women, found nonsignificant shorter gestational lengths, 37.9 vs. 38.3 weeks and 37.2 vs. 38.1 weeks, respectively. A third study classified some of their subjects into two subgroups: cocaine only (N = 24) and cocaine plus polyabuse drugs (N = 46) (20). No statistical differences were measured for gestational age at delivery (36.6 vs. 37.4 weeks) or for the incidence of preterm (<37 weeks)

delivery (25.0% vs. 23.9%). When included as part of the research format, the incidence of premature labor and delivery was significantly increased in comparison to that in drug-free women (4,11,18–25). When comparisons were made with noncocaine opiate abusers, the incidences were higher but not significant. One investigation also found that cocaine use significantly increased the incidence of precipitous labor (11). Although objective data were not provided, a 1985 report mentioned that several cocaine-exposed women had noted uterine contractions and increased fetal activity within minutes of using cocaine (26). This same group reported in 1989 that infants who had been exposed to cocaine throughout pregnancy (N = 52) (average maternal dose/use = 0.5 g) had a significantly shorter mean gestational age than infants of drug-free women (N = 40), 38.0 weeks vs. 39.8 weeks ($p < 0.001$), respectively (24). The gestational period of those who used cocaine only during the 1st trimester was a mean 38.9 weeks, which was not significantly different from that of either of the other two groups. The incidence of preterm delivery (defined as < 38 weeks) in the three groups was 17% (4 of 23; 1st trimester use only), 31% (16 of 52; cocaine use throughout pregnancy), and 3% (1 of 40; drug-free controls) (24). Only the difference between the latter two groups was statistically significant ($p < 0.003$). In another 1989 study, bivariate comparisons of 114 cocaine users (as determined by positive urine assays) with 1010 nonusers (as determined by interview and negative urine assays) indicated the difference in gestational length to be statistically significant (38.8 weeks vs. 39.3 weeks, $p < 0.05$) (3). However, multivariate analyses to control the effect of other substances and maternal characteristics known to affect pregnancy outcome adversely resulted in a loss of significance, thus demonstrating that, in this population, cocaine exposure alone did not affect the duration of gestation (3).

SPONTANEOUS ABORTIONS A 1985 report found an increased rate of spontaneous abortions (SABs) in previous pregnancies of women using cocaine either alone or with narcotics compared with women using only narcotics and women not abusing drugs (26). These data were based on patient recall, so the authors were unable to determine whether a causal relationship existed. In a subsequent report on this patient population, the incidence of previous abortions (not differentiated between elective and spontaneous) was significantly greater in women who predominantly used cocaine either alone or with opiates when compared with those who used only opiates or with non-drug-using controls (25). A statistically significant ($p < 0.05$) higher incidence of one or more SABs was found in 117 users (30%) compared with 562 nonusers

(21%) (2). Other studies, examining cocaine consumption in current pregnancies, found no correlation between the drug and SABs (5,15–17,22).

PREMATURE RUPTURE OF MEMBRANES Premature rupture of membranes (PROM) was observed in 2% of 46 women using cocaine and/or methamphetamine vs. 10% of 49 women using narcotics vs. 4.4% of 45 drug-free controls (differences not significant) (18). Similarly, no difference in PROM rates was noted between two groups of women admitted in labor without previous prenatal care (cocaine group N = 124, noncocaine group N = 218) (23). However, a 1989 report found a statistically significant increase in the incidence of PROM in women with a positive urine screen for cocaine (29 of 138, 21%) in comparison with non-cocaine-using controls (3 of 88, 3%) ($p < 0.0005$) (4). Although not statistically significant, the risk of PROM was higher in women who predominantly used cocaine either alone (10%, 6 of 63) or with opiates (14%, 4 of 28) than in drug-free controls (2%, 3 of 123) (26). The incidence of placenta previa was also not increased by cocaine use in this study (22). In contrast, 33% of 50 “crack” (alkaloidal cocaine that is smoked) users had PROM compared with 18% of non-drug-using controls ($p = 0.05$) (21). Drug abuse patterns in both groups were determined by interview, which may have introduced classification error into the results, but the authors reasoned that any error would have underestimated the actual effect of the cocaine exposure (21).

GESTATIONAL HYPERTENSION Two studies have measured the incidence of gestational hypertension in their patients (22,23). In one, the rate of this complication in cocaine-exposed and nonexposed women was too low to report (22). In the second, 25% (13 of 53) of cocaine-exposed women vs. 4% (4 of 100) of nonexposed controls had the disorder ($p < 0.05$) (23). Other factors such as maternal age, race, use of multiple abuse drugs, small numbers, and self-reported cocaine exposure may have accounted for this difference.

ABRUPTIO PLACENTAE Two cases of abruptio placentae after IV and intranasal cocaine use were reported in 1983 (27). Since this initial observation, a number of similar cases of this complication have been described (1,4,5,11,14,18,19,21,24–26,28–30), although some investigators either did not observe any cases (31) or the number of cases in the studied patients was too low to report (22). The findings of one study indicated that abruptio placentae-induced stillbirths in cocaine users (N = 50), multiple drug users (some of whom used cocaine) (N = 110), and drug-free controls (N = 340) were 8%, 4.5%, and 0.8%, respectively (5). The difference between the cocaine-only group and the controls was significant ($p < 0.001$). The four mothers in the cocaine group

suffered placental abruption after IV and intranasal administration (one each) and smoking (two cases). Two of the five mothers in the multiple drug use group suffered the complication after injection of a “speed ball” (heroin plus cocaine) (5). Thus, 6 of the 12 cases were associated with cocaine use. Onset of labor with abruptio placentae was observed in 4 of 23 women after the use of IV cocaine (25). Additional information was provided by these investigators in a series of papers extending into 1989 (11,14,20,24,25). The latest data indicated that in women who had used cocaine during pregnancy (N = 75; 23 of whom used cocaine only during the 1st trimester), 10 (13.3%) had suffered abruptio placentae compared with none of the 40 drug-free controls ($p < 0.05$) (24). Retroplacental hemorrhages, including placental abruption, were significantly increased in a cocaine and/or methamphetamine group (13% of 46) in comparison with either opiate users (2% of 49) or drug-free controls (2.2% of 45) ($p < 0.05$) (18). Two cases of abruptio placentae were observed in 55 women using “crack” (none in 55 drug-free controls) (21) and one case in a woman using cocaine in 102 consecutive deliveries at a Texas hospital (28). Three additional cases of sonographically diagnosed abruption probably related to cocaine use were described in a 1988 report (29). Although the exact mechanism of cocaine-induced abruptio placentae is still unknown, the pharmacologic effects of the drug offer a reasonable explanation. Cocaine prevents norepinephrine reuptake at nerve terminals, producing peripheral and placental vasoconstriction, reflex tachycardia with acute hypertension, and uterine contractions. The net effect of these actions in some cases may be abruptio placentae (1,5,11,18,24,26,27,32).

RUPTURED ECTOPIC PREGNANCY Two cases of rupture of ectopic pregnancies were reported in 1989 (33). In both incidences, the women described severe abdominal pain immediately after consuming cocaine (smoking in one, nasally in the other). While the authors of this report could not totally exclude spontaneous rupture of the tubal pregnancies, they concluded that the short time interval between cocaine ingestion and the onset of symptoms made the association appear likely (33).

Maternal Mortality

Fatalities following adult cocaine use have been reported frequently, but only two cases have been located that involve pregnant women (34,35). A 24-year-old woman, who smoked “crack” daily, presented at 34 weeks’ gestation with acute onset of severe headache and photophobia (34). Her symptoms were determined to be due to subarachnoid hemorrhage resulting from a ruptured

aneurysm. Following surgery to relieve intracranial pressure and an unsuccessful attempt to isolate the aneurysm, the patient gave birth to a normal 2400-g male infant. Her condition subsequently worsened on postpartum day 21 and she died 4 days later from recurrent intracranial hemorrhage. The second case involved a 21-year-old in approximately her 16th week of pregnancy (35). She was admitted to the hospital in a comatose condition after about 1.5 g of cocaine had been placed in her vagina. She was maintained on life support systems and eventually delivered, by cesarean section, a female infant at 33 weeks' gestation with severe brain abnormalities. The infant died at 10 days of age, and the mother died approximately 4 months later.

Fetal Complications

GROWTH RESTRICTION Fetal complications reported after exposure to cocaine include growth restriction, fetal distress, cerebrovascular accidents, and congenital anomalies. A large number of studies have examined the effect of in utero cocaine exposure on fetal growth parameters (birth weight, length, and head circumference) (2–5,11–26,36–39). Most of these studies found, after correcting for confounding variables, that cocaine exposure, when compared with non-drug-abuse populations, was associated with reduced fetal growth. This reduction was comparable, in most cases, with that observed in fetuses exposed to opiates, such as heroin or methadone. A survey of 117 users compared to 562 nonusers discovered that 14% of the former had given birth to a low-birth-weight infant vs. 8% of the nonexposed women ($p < 0.05$) (2). In one investigation, when maternal drug use included both cocaine (or amphetamines) and narcotics, the infants ($N = 9$) had a significant reduction in birth weight, length, and head circumference compared to either stimulant or narcotic use alone (18). In an earlier report, no significant differences were observed in fetal growth parameters between groups of women consuming cocaine ($N = 12$), cocaine plus methadone ($N = 11$), methadone ($N = 15$), and noncocaine/nonmethadone controls ($N = 15$) (26). However, in a subsequent publication from these researchers, women who used cocaine throughout gestation (as opposed to those who only used it during the 1st trimester) were significantly more likely than drug-free controls to deliver low-birth-weight infants; 25% (13 of 52) vs. 5% (2 of 40) ($p < 0.003$), respectively (24). Fetal growth parameters (birth weight, length, and head circumference) were also significantly ($p < 0.001$) depressed compared with those of controls if the woman used cocaine throughout pregnancy (24). Exposure during the 1st trimester only resulted in reduced growth, but the difference was not significant.

Some investigators have suggested that the decrease in fetal growth in two studies may have been due to poor nutrition or to alcohol intake (40,41). In both instances, however, women abusing alcohol either had been excluded or their exclusion would not have changed the findings (42,43). In one study that found no statistical difference in birth weights between infants of cocaine users and noncocaine users, only 10 cocaine-exposed newborns were involved (28). The cocaine group had been identified from obstetric records of 102 consecutively delivered women. However, the sample size is very small and the character of cocaine use (e.g., dose, frequency, etc.) could not always be determined. In addition, recent research has shown that self-reporting of cocaine use probably underestimates the actual usage (3,4).

A single case of oligohydramnios at 17 weeks' gestation with two increased serum α -fetoprotein levels (125 and 168 mcg/L) has been described, but any relationship between these events and the mother's history of cocaine abuse is unknown (44). Intrauterine growth restriction was diagnosed at 26 weeks' gestation followed shortly thereafter by fetal death in utero. Analysis of fetal whole blood showed a cocaine level of 1 mcg/mL, within the range associated with fatalities in adults (44).

In a prospective 1989 study involving 1226 mothers, 18% used cocaine as determined by interview or urine assay (3). After controlling for potentially confounding variables and other substance abuse, infants of women with positive urine assay for cocaine, compared with infants of nonusers, had lower birth weights (93 g less, $p = 0.07$), lengths (0.7 cm less, $p = 0.01$), and head circumferences (0.43 cm less, $p = 0.01$). The effect of cocaine on birth weight was even greater if prepregnancy weight and pregnancy weight gain were not considered. The mean reduction in infant birth weight was now 137 g vs. 93 g when these factors were considered ($p < 0.01$). In those cases where the history of cocaine use was positive but the urine assay was negative, no significant differences were found by multivariate analyses. The authors concluded not only that cocaine impaired fetal growth but also that urine assays (or another biologic marker) were important to show the association (3).

Multiple ultrasound examinations (two to four) were used to evaluate fetal growth in a series of 43 women with primary addiction to cocaine (45). An additional 24 women were studied, but their ultrasound examinations were incomplete in one aspect or another and they were not included in the analysis. Careful attention was given to establishing gestational age. Complete ultrasonic parameters included biparietal diameter, femur length, and head and abdominal circumferences. The number of addicted infants with birth weight, head

circumference, and femur length at ≤ 50 th, ≤ 25 th, and ≤ 10 th percentile ranks did not differ significantly from expected standard growth charts. However, the number of examinations yielding values for biparietal diameter and abdominal circumference at the ≤ 50 th and ≤ 25 th percentile ranks was significantly more than expected ($p = 0.001$). Because biparietal diameter and head circumference are not independent parameters, each being an indicator of fetal head size, the authors speculated that the most logical explanation for their findings was late-onset dolichocephalia (45). Based on these findings, the study concluded that maternal cocaine use had adversely affected fetal growth. If only birth weight had been used as a criterion, this effect may have been missed (45).

FETAL DISTRESS Several studies have included measurements of fetal distress in their research findings (11,15–21,23,26,31,37,39). In some reports, perinatal distress was significantly ($p < 0.05$) increased in cocaine abusers over women using heroin/methadone (11,12) and drug-free controls (19). Perinatal distress was also noted more frequently in other studies comparing cocaine users with drug-free controls (10% vs. 5.7% and 11.1% vs. 3.7%, respectively), but the differences were not significant (20,21). Compared with nondrug users, higher rates of fetal tachycardia (2% vs. 0%) and bradycardia (17% vs. 6%) have been observed, but, again, the differences were not significant (18). One-minute Apgar scores were lower after in utero cocaine exposure in several studies (4,15–17,20,23,37) but only statistically significant in some (15–17,23) and no different in another (25). In contrast, only two studies, one a series of three reports on the same group of patients, found a significant lowering of the 5-minute Apgar score (15–17,25). Other studies observed no difference in this value (4,20,23,26,31,37,39). Significantly more ($p < 0.05$) meconium-stained infants were observed in studies comparing cocaine users with methadone-maintained women (25% vs. 8.2%) (10) and with noncocaine/other drug-exposed subjects (25% vs. 4%) (23). Three other studies observed nonsignificant increased rates of meconium staining or passage (22% vs. 17%, 29% vs. 23%, and 73% vs. 58%) (18,20,25), and a fourth reported a lower incidence (22% vs. 27%), compared with non-drug-using controls (21).

CEREBROVASCULAR ACCIDENTS Eight reports have described perinatal or newborn cerebrovascular accidents and resulting brain damage in infants exposed in utero to cocaine (11,14,18,46–50). The first report of this condition was published in 1986 (46). A mother who had used an unknown amount of cocaine intranasally during the first 5 weeks of pregnancy and approximately 5 g during the 3 days before delivery, gave birth to a full-term, 3660-g male

infant. The last dose of approximately 1 g had been consumed 15 hours before delivery. Fetal monitoring during the 12 hours before delivery showed tachycardia (180–200 beats/minute) and multiple variable decelerations. At birth, the infant was limp, he had a heart rate of 80 beats/minute, and thick meconium staining (without aspiration) was noted. Apnea, cyanosis, multiple focal seizures, intermittent tachycardia (up to 180 beats/minute), hypertension (up to 140 mmHg by palpation), abnormalities in tone (both increased and decreased depending on the body part), and miotic pupils were noted beginning at 16 hours of age. Noncontrast computed tomographic scan at 24 hours of age showed an acute infarction in the distribution of the left middle cerebral artery. Repeat scans showed a persistent left-sided infarct with increased gyral density (age 7 days) and a persistent area of focal encephalomalacia at the site of the infarction (age 2.5 months). One other infant with perinatal cerebral infarction associated with maternal cocaine use in the 48–72 hours prior to delivery has been mentioned by these investigators (11,14,24). A separate report described a mother who had used cocaine and multiple other abuse drugs during gestation had delivered a female infant (gestational age not specified) with bilateral cerebrovascular accident and resulting porencephaly (47). The infant died at 2.5 months of age. In another study of 55 infants exposed to cocaine (with or without opiates), one infant with perinatal asphyxia had a cerebral infarction (18). A severely depressed male infant delivered at 38 weeks' gestation had an electroencephalogram and cranial ultrasound suggestive of hemorrhagic infarction (48). Follow-up during the neonatal period indicated mild-to-moderate neurodevelopmental abnormalities. Brain lesions were described in 39% (11 of 28) of infants with a positive urine assay for cocaine and in 33% (5 of 15) of newborns with a positive assay for methamphetamine (49). The brain injuries, which were not differentiated by drug type, were hemorrhagic infarction in the deep brain (six cases; three around the internal capsule/basal ganglion), cystic lesions in the deep brain (four cases), large posterior fossa hemorrhage (three cases), absent septum pellucidum with atrophy (one case), diffuse atrophy (one case), and brain edema (one case) (49). In a control group of 20 term infants with severe asphyxia, only one had a similar brain lesion. A second report also described brain lesions in infants exposed in utero to cocaine (50). The 11 infants all had major CNS anomalies, and 10 of the infants also had craniofacial defects (described later). The CNS defects were hydranencephaly (one case), porencephaly (two cases), hypoplastic corpus callosum with unilateral parietal lobe cleft and heterotopias (one case), intraparenchymal hemorrhage (five

cases), unilateral three-vessel hemispheric infarction (one case), and encephalomalacia (one case). In addition, three infants had arthrogryposis multiplex congenita of central origin (50). Four of the infants died, and the other seven had serious neurodevelopmental disabilities (50).

Echoencephalography (ECHO) was performed within 3 days of birth on 74 term (>37 weeks) infants who had tested positive for cocaine or methamphetamine but who otherwise had uncomplicated perinatal courses (51). The infants had no other known risk factors for cerebral injury. The 74 newborns were classified into three groups: 32 (43%) cocaine exposed, 24 (32%) methamphetamine exposed, and 18 (24%) exposed to cocaine plus heroin or methadone, or both. Two comparison groups were formed: a group of 87 term, drug-free infants studied by ECHO because of clinical concerns for hypoxic–ischemic encephalopathy and a normal group of 19 drug-free term newborns. Both groups of comparison infants were also studied by ECHO within 3 days of birth. Only one structural anomaly, consisting of an absent septum pellucidum, was observed in the infants examined. The affected newborn, exposed to methamphetamine, was also found to have bilateral optic nerve atrophy and diffuse attenuation of the white matter. Twenty-six (35.1%) of the drug-exposed infants had cranial abnormalities detected by ultrasonography, which was similar to the 27.6% (24 of 87) incidence in the comparison group with possible hypoxic–ischemic encephalopathy ($p = 0.7$). The normal controls had an incidence of 5.3% (1 of 19) ($p < 0.01$ in comparison to both of the other groups). The lesions observed in the drug-exposed infants were intraventricular hemorrhage, echodensities known to be associated with necrosis, and cavitory lesions. Lesions were concentrated in the basal ganglion, frontal lobes, and posterior fossa (51). Cerebral infarction was found in two cocaine-exposed infants. The ECHO abnormalities that were not predicted by standard neonatal clinical assessment were believed to be consistent with those observed in adult abusers of cocaine and amphetamines (51).

CONGENITAL ANOMALIES Maternal cocaine abuse has been associated with numerous other congenital malformations. In a series of publications extending from 1985 to 1989, a group of investigators described the onset of ileal atresia (with bowel infarction in one) within the first 24 hours after birth in two infants and genitourinary tract malformations in nine infants (11,13,20,24,26). The abnormalities in the nine infants were prune belly syndrome with urethral obstruction, bilateral cryptorchidism (one also had absence of third and fourth digits on the left hand and a second-degree hypospadias) (two males), female pseudohermaphroditism (one case) (defects included hydronephrosis,

ambiguous genitalia with absent uterus and ovaries, anal atresia, absence of third and fourth on the left hand, and clubfoot), secondary hypospadias (two cases), hydronephrosis (three cases), and unilateral hydronephrosis with renal infarction of the opposite kidney (one case). Data from the metropolitan Atlanta Birth Defects Case–Control study, involving 4929 liveborn and stillborn infants with major defects compared with 3029 randomly selected controls, showed a statistically significant association between cocaine use and urinary tract malformations (adjusted odds ratio 4.81, 95% CI 1.15–20.14) (52,53). The adjusted risk for anomalies of the genitalia was 2.27 (ns). Cocaine exposure for this analysis was based on self-reported use any time from 1 month before conception through the first 3 months of pregnancy (52,53).

The rates of major congenital malformations in a study involving 50 cocaine-only users, 110 cocaine plus polydrug users, and 340 drug-free controls were 10% (five cases), 4.5% (five cases), and 2% (seven cases), respectively (4). The groups were classified by history and infant urine assays; chronic alcohol abusers were excluded. The difference between the first and last groups was significant ($p < 0.01$). The incidence of minor abnormalities (e.g., hypertelorism, epicanthal folds, and micrognathia) was similar among the groups (5). Congenital heart defects were observed in all three groups as follows: cocaine-only, transposition of the great arteries (one case) and hypoplastic right heart syndrome (one case); cocaine plus polydrug, ventricular septal defects (three cases); controls, ventricular septal defect (one case), patent ductus arteriosus (one case), and pulmonary stenosis (one case). Skull defects were observed in three infants in the cocaine-only group: exencephaly (stillborn), interparietal encephalocele, and parietal bone defects without herniation of meninges or cerebral tissue. One infant in the cocaine plus polydrug group had microcephalia. Significantly more major and minor malformations were seen in a group of cocaine-exposed infants ($N = 53$) (five major/four minor) than in a matched, nonexposed sample ($N = 100$) (two major/four minor) ($p < 0.05$) (23). Congenital heart defects occurred in four of the cocaine-exposed infants: atrial septal defect (one case), ventricular septal defects (two cases), and cardiomegaly (one case). None of the infants born from controls had heart defects ($p < 0.01$). The authors noted, however, that their findings were weakened by the self-reported nature of the drug histories (23).

A 1989 report of 138 women at delivery with positive urine cocaine tests found 10 (7%) infants with congenital anomalies: ventricular septal defect (two), atrial septal defect (one), complete heart block (one), inguinal hernia (two), esophageal atresia (one), hypospadias (one), cleft lip and palate with trisomy

13 (one), and polydactyly (one) (4). Only two (2%) infants of 88 non-cocaine-using controls had congenital defects, but the difference between the two groups was not significant. When the cocaine group was divided into cocaine only (114 women) and cocaine plus other abuse drugs (24 women), five infants in each group were found to have a malformation. The difference between these subgroups was highly significant ($p < 0.005$).

Necrotizing enterocolitis has been described in two infants after in utero cocaine exposure (48). One of the infants was also exposed to heroin and methamphetamine. The proposed mechanism for the injuries was cocaine-induced ischemia of the fetal bowel, followed by invasion of anaerobic bacteria (48). In another report, three newborns (two may have been described immediately above) presented with intestinal defects: one each with midcolonic atresia, ileal atresia, and widespread infarction of the bowel distal to the duodenum (54). Five other infants plus one of those with intestinal disruption had congenital limb-reduction defects: unilateral terminal transverse defect (three), Poland sequence (one) (i.e., unilateral defect of pectoralis muscle and syndactyly of hand (55)), bilateral upper limb anomalies including ulnar ray deficiencies (one), and bilateral radial ray defects (two) (54). The defects were thought to be caused by cocaine-induced vascular disruption or hypoperfusion (54).

Facial defects seen in 10 of 11 infants exposed either to cocaine alone (6 of 11) or to cocaine plus other abuse drugs (5 of 11) included blepharophimosis (two), ptosis and facial diplegia (one), unilateral oro-orbital cleft (one), Pierre Robin anomaly (one), cleft palate (one), cleft lip and palate (one), skin tags (two), and cutis aplasia (one) (50). All of the infants had major brain abnormalities, which have been described above.

Ocular defects consisting of persistent hyperplastic primary vitreous in one eye and changes similar to those observed in retinopathy of prematurity in the other eye were described in a case report of an infant exposed throughout gestation to cocaine and multiple other abuse drugs (56). The association of the two defects was thought to be coincidental and not likely due to cocaine (56). Thirteen newborns with cocaine toxicity (each infant with multiple symptoms and positive urine assay) had a complete ophthalmic examination; six were discovered to have marked dilation and tortuosity of the iris vasculature (57). The five infants who were most severely affected were followed for at least 3 months and all showed a gradual resolution of the defects without apparent visual impairment. Transient iris vasculature defects have also been found in infants of diabetic mothers (both gestational and

insulin-dependent) (58) and in non-cocaine-exposed controls (57,59). However, the vascular changes have not yet been observed in infants of mothers abusing methadone, heroin, amphetamines, marijuana, or a combination of these drugs (specific data on the number of infants examined in these categories were not given) (58).

Two mothers who had used cocaine during the 1st trimester produced infants with unusual abnormalities (60,61). Both mothers used other abuse drugs, heroin in one case and marijuana and methaqualone in the other. The anomalies observed were chromosomal aneuploidy 45,X, bilaterally absent fifth toes, and features consistent with Turner's syndrome in one (60) and multiple defects including hypothalamic hamartoblastoma in the other (61). Hydrocephaly was noted in one infant (from a group of 10) exposed in utero to cocaine, marijuana, and amphetamines (28). No major anomalies were seen in 8 infants exposed to cocaine (all had positive urine assays for cocaine) and other abuse drugs, but two infants had minor defects consisting of a sacral exostosis and capillary hemangioma in one and a capillary hemangioma in the other (37). In the latter case, the mother claimed to have used cocaine only during the month preceding delivery. Cocaine was not considered a causative agent in any of these cases (28,37,60,61).

In contrast to the above reports, no congenital abnormalities were observed in several series of cocaine-exposed women totaling 55 (21), 39 (31), 56 (39), and 38 (62) subjects. A prospective 1989 study mentioned previously found cocaine metabolites in the urine assays from 114 (9.3%) of 1226 women (3). After controlling for the effects of other substances and maternal characteristics known to affect pregnancy outcome adversely, no significant association was found between cocaine and one or more minor anomalies, a constellation of three minor anomalies, or one major anomaly (3). An association with the latter two, however, was suggested by the data ($p = 0.10$) (3). Although animal data cannot be directly extrapolated to humans, administration of cocaine to pregnant rats and mice did not increase the incidence of congenital abnormalities (63).

Infant Complications

NEUROBEHAVIOR Newborn infants who have been exposed in utero to cocaine may have significant neurobehavior impairment in the neonatal period. An increased degree of irritability, tremulousness, and muscular rigidity has been observed by a number of researchers (4,11,15–19, 21,23,26,62,64). Gastrointestinal symptoms (vomiting, diarrhea) have also been observed

(4,21). The onset of these symptoms usually occurs 1–2 days after birth with peak severity of symptoms occurring on days 2 and 3 (19,21,62,64). Seizures, which may have been related to withdrawal, have been observed (14,23). The overall incidence of severe withdrawal symptoms, however, is apparently not increased over that expected in opiate-addicted newborns (15–17). In one report that identified 138 infants whose mothers tested positive for cocaine, 24 (17%) of the mothers also tested positive for other abuse substances, usually opiates (4). The incidence of withdrawal in infants of the cocaine-only group was 25% (28 of 114) vs. 54% (13 of 24) in infants of the multiple abuse drug group ($p < 0.005$).

The Neonatal Behavior Assessment Scale (NBAS) has been used in several studies to quantify the observed symptoms (11,24,26,64). In a blinded study comparing infants of methadone-maintained women with those of cocaine-exposed women, the latter group had a significantly increased degree of irritability, tremulousness, and state lability ($p < 0.03$) (11). Expansion of this study to include drug-free controls and cluster analysis of the NBAS revealed that the cocaine group had significant impairment in state organization compared with either the opiate group infants or controls (24,26). The NBAS was used to evaluate 16 term newborn infants with cocaine-positive urine assays (65). All demonstrated no to very poor visual attention and tracking, abnormal state regulation, and mild-to-moderate hypertonicity with decreased spontaneous movement (65). Flash-evoked visual potentials were abnormal in 11 of 12 infants studied, and the disturbances remained in six infants studied at 4–6 months (65).

Ultrasound was used in a study published in 1989 to evaluate the behavior of 20 fetuses exposed to cocaine as a predictor of neonatal outcome (66). All fetuses were exposed to cocaine during the 1st trimester; 4 during the 1st trimester only, 7 during the 1st and 2nd trimesters, and 9 throughout gestation. The investigators were able to document that fetal state organization was predictive of newborn neurobehavioral well-being and state organization. In this study, the most frequent indicators of neurobehavioral well-being were excessive tremulousness of the extremities, unexplained tachypnea, or both (66). Abnormal state organization was shown by hyperresponsiveness and difficulty in arousal (66).

Electroencephalographic (EEG) abnormalities indicative of cerebral irritation have been documented in cocaine-exposed neonates (31,64, 65). Normalization of the EEG abnormalities may require up to 12 months (31,64).

MORTALITY Increased perinatal mortality was observed in a study published in

1989, although in comparison to controls, the higher incidence was not significant (4). Seven (5%) of 140 infants (138 mothers, two sets of twins) whose mothers tested positive for cocaine at delivery died compared with none of 88 infants whose mothers did not test positive for cocaine at delivery. The seven cases included three intrauterine fetal deaths and four neonatal deaths.

An increased risk of sudden infant death syndrome (SIDS) has been suggested by three studies (11,17,67). Two infants, from a group of 50 exposed in utero to cocaine and methadone, died of SIDS, one at 1 month of age and the other at 3 months (17). It could not be determined whether a relationship existed between the deaths and maternal cocaine use (17). In one study, 10 of 66 infants (15%) exposed to cocaine in utero died of SIDS over a 9- to 180-day interval (mean 46 days) following birth (11). This incidence was estimated to be approximately 30 times that observed in the general population and almost 4 times that seen in the infants of opiate-abusing women (11). Based on this experience, a prospective study was commenced and the results were reported in 1989 (67). Of cocaine-using mothers, 32 infants were compared with 18 infants of heroin/methadone-addicted mothers. Eight of the mothers in the cocaine group also used heroin/methadone. The mothers of both groups received similar prenatal care, and they used similar amounts of alcohol, cigarettes, and marijuana. Infants in both groups were delivered at a gestational age of 38 weeks or more, and mean birth weight, length, and head circumference were identical. Cardiorespiratory recordings (pneumograms), conducted in most cases at 8–14 days of age, were abnormal in 13 infants, 12 cocaine exposed and 1 opiate exposed ($p < 0.05$). Five of the cocaine-exposed infants had an episode of life-threatening apnea of infancy requiring home resuscitation before the pneumograms could be performed. The 13 infants were treated with theophylline until age 6 months, or longer if the pneumogram had not yet normalized. No cases of SIDS were observed in any of the 50 infants. In an earlier study, pneumograms were used to quantify abnormal sleeping ventilatory patterns in infants of substance-abusing mothers (68). Of three cocaine-exposed infants, one had an abnormal pneumogram. Apnea and/or abnormal pneumograms were observed in 20 (14%) of 138 infants whose mothers tested positive for cocaine at delivery (4). None of the 88 control infants whose mothers tested negative for cocaine at delivery had apnea or abnormal pneumograms ($p < 0.0005$). In a large study examining the relationship between SIDS and cocaine exposure, 1 of 175 infants exposed to cocaine died of SIDS compared with 4 of 821 infants who were not exposed (36). The risks per 1000 in the two groups were similar, 5.6 and 4.9,

respectively, corresponding to a relative risk for SIDS among infants of cocaine-abusing women of 1.17 (95% CI 0.13–10.43) (36). Based on these data, the study concluded that the increased rates reported previously probably reflected other risk factors that were independently associated with SIDS (36). However, because the study relied on self-reported cocaine use and urine screens (only detects recent exposure), some of the women may have been misclassified as nonusers (69). Analysis of the hair, where the drug accumulates for months, has been advocated as a technique to ensure accurate assessment of past exposure (69).

HOSPITALIZATION Increased neonatal hospitalization in infants whose mothers tested positive for cocaine at delivery has been reported (4). In 137 infants (138 mothers, 2 sets of twins, 3 fetal deaths excluded), the mean number of days hospitalized was 19.2 compared with 5.1 for 88 infants of mothers who tested negative for cocaine at delivery ($p < 0.0001$). Moreover, the incidences of neonatal hospitalization for longer than 3 and 10 days were both significantly greater for the cocaine group (80% vs. 24%, respectively, $p < 0.00001$; 35% vs. 10%, respectively, $p < 0.0005$). The implications of these findings on the limited resources available to hospitals are, obviously, very important.

BREASTFEEDING SUMMARY

Milk:plasma ratios of cocaine in breast milk have not been determined. In one case, the urine of a normal, breastfed, 6-week-old boy was positive for a cocaine metabolite (70). The mother was using an unspecified amount of cocaine. In another patient, a milk sample 12 hours after the last dose of approximately 0.5 g taken intranasally over 4 hours contained measurable levels (specific data not given) of cocaine and the metabolite, benzoylecgonine, that persisted until 36 hours after the dose (71). The 14-day-old infant was breastfed five times over the 4-hour period during which the mother ingested the cocaine. Approximately 3 hours after the first dose, the child became markedly irritable with onset of vomiting and diarrhea. Other symptoms observed upon examination were tremulousness, increased startle response, hyperactive Moro reaction, increased symmetrical deep tendon reflexes with bilateral ankle clonus, and marked lability of mood (71). The irritability and tremulousness steadily improved over the next 48 hours. Large amounts of cocaine and the metabolite were found in the infant's urine 12 hours after the mother's last dose, which persisted until 60 hours postdose. On discharge (time not specified), the physical and neurologic examinations were normal. Additional follow-up of the infant was not reported.

In an unusual case report, a mother applied cocaine powder to her nipples to relieve soreness shortly before breastfeeding her 11-day-old infant (72). Although a breast shield was used, the unsheathed nipple protruded to allow feeding. Three hours after feeding, the infant was found gasping, choking, and blue. Seizures, which occurred with other symptoms of acute cocaine ingestion, stopped 2 hours after admission to the hospital. The mother's milk was negative for cocaine and metabolites but the infant's urine was positive. Physical and neurologic examinations were normal on discharge 5 days later and again at 6 months. Computed tomography (CT) scan during hospitalization showed a small area of lucency in the left frontal lobe and an EEG at this time was abnormal. A repeat CT scan and EEG were normal at 2 months of age.

Based on the toxicity exhibited in the infant after exposure via the milk, maternal cocaine use during breastfeeding should be strongly discouraged and considered contraindicated. Obviously, mothers should also be warned against using the drug topically for nipple soreness. The American Academy of Pediatrics classifies the use of cocaine as contraindicated during breastfeeding (73).

CODEINE

Narcotic Agonist Analgesic, Respiratory Drug (Antitussive)

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Human Data Suggest Potential Toxicity

PREGNANCY SUMMARY

Various reports have described associations between 1st-trimester exposure to opioid analgesics, including codeine, and congenital defects. Although the studies contained some unavoidable confounders that could have affected the results, such as the doses used, the reasons for use (e.g., maternal diseases and addiction), and exposures to other drugs, some data do suggest a small absolute risk of congenital birth defects if exposure occurs during organogenesis. Moreover, there is evidence of fetal and newborn toxicity if the mother is addicted to codeine or other opioids, or consumes high doses of these agents during the later half of pregnancy or close to delivery. Consequently, if possible, these agents should be avoided in pregnancy, especially in the 1st and 3rd trimesters.

FETAL RISK SUMMARY

Codeine is an opioid analgesic that is indicated for the control of pain. It is often combined with other agents, such as acetaminophen. In addition, an unproved indication for codeine is suppression of cough. Codeine is metabolized by the liver to morphine, hydrocodone, norcodeine, normorphine, and other metabolites (1). The analgesic effects appear to be primarily due to morphine and unmetabolized codeine. Codeine and its metabolites are excreted almost entirely by the kidneys, with a plasma elimination half-life of 3–4 hours (1).

Reproduction studies have been conducted in mice, rats, hamsters, and rabbits. In hamsters, high SC doses ranging from 73 to 360 mg/kg resulted in an incidence of 6%–8% of cranioschisis; no dose response was found (2). In another hamster study, maternal-toxic oral doses of 150 mg/kg resulted in increased resorptions, reduced fetal weight, and a small increase in meningoencephaloceles (2,3). SC doses in mice caused skeletal abnormalities,

but no teratogenicity was observed with oral doses (3). Further, codeine was not teratogenic in rats and rabbits (3).

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 563 of whom had 1st trimester exposure to codeine (4, pp. 287–295). No evidence was found to suggest a relationship to large categories of major or minor malformations. Associations were found with six individual defects (4, pp. 287–295, 471) (independent confirmation is required for all associations found in this study): respiratory (8 cases); genitourinary (other than hypospadias) (7 cases); Down’s syndrome (1 case); tumors (4 cases); umbilical hernia (3 cases); and inguinal hernia (12 cases). For use anytime during pregnancy, 2522 exposures were recorded (4, p. 434). With the same qualifications, possible associations with four individual defects were found (4, p. 484): hydrocephaly (7 cases); pyloric stenosis (8 cases); umbilical hernia (7 cases); and inguinal hernia (51 cases).

In an investigation comparing 1427 malformed newborns with 3001 controls, 1st trimester use of narcotic analgesics (most commonly codeine) was associated with inguinal hernias, cardiac and circulatory system defects, cleft lip and palate, dislocated hip and other musculoskeletal defects. Second-trimester use was associated with alimentary tract defects (5). In a large retrospective Finnish study, the use of opiates (mainly codeine) during the 1st trimester was associated with an increased risk of cleft lip and palate (6,7). Finally, a survey of 390 infants with congenital heart disease matched with 1254 normal infants found a higher rate of exposure to several drugs, including codeine, in the offspring with defects (8).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 7640 newborns had been exposed to codeine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 375 (4.9%) major birth defects were observed (325 expected). Specific data were available for six defect categories, including (observed/expected) 74/76 cardiovascular defects, 14/13 oral clefts, 4/4 spina bifida, 25/22 polydactyly, 15/13 limb-reduction defects, and 14/18 hypospadias. Only with the total number of defects is there a suggestion of an association between codeine and congenital defects, but other factors, including the mother’s disease, concurrent drug use, and chance, may be involved.

Results of a National Birth Defects Prevention Study (1997–2005) were published in 2011 (9). This population-based case–control study examined the association between maternal use of opioid analgesics and >30 types of major

structural birth defects. In 17,449 case mothers, therapeutic opioid use was reported by 454 (2.6%) compared with 134 (2.0%) of 6701 control mothers. Indications for use of opioid analgesics were surgical procedures (41%), infections (34%), chronic diseases (20%), and injuries (18%). Dose, duration, or frequency were not evaluated. The exposure period evaluated was from 1 month before to 3 months after conception. Limiting the exposure period to the first 2 months after conception produced similar results. Infants with >1 defect were included in multiple birth defect categories. The following opioids were included (number of cases for each agent not specified): codeine, hydrocodone, hydromorphone, fentanyl, meperidine, methadone, morphine, oxycodone, pentazocine, propoxyphene, and tramadol. The birth defect, total number, number exposed, and the adjusted odds ratio (aOR) with 95% confidence interval (CI) were as follows:

| Birth Defect | Total | Cases | aOR (95% CI) |
|--|-------|-------|---------------|
| Spina bifida | 718 | 26 | 2.0 (1.3–3.2) |
| <i>Any heart defect (20 types)</i> | 7724 | 211 | 1.4 (1.1–1.7) |
| Atrioventricular septal defect | 175 | 9 | 2.4 (1.2–4.8) |
| Teratology of Fallot | 672 | 21 | 1.7 (1.1–2.8) |
| Conotruncal defect | 1481 | 41 | 1.5 (1.0–2.1) |
| Conoventricular septal defect | 110 | 6 | 2.7 (1.1–6.3) |
| Left ventricular outflow tract obstruction defect | 1195 | 36 | 1.5 (1.0–2.2) |
| Hypoplastic left heart syndrome | 357 | 17 | 2.4 (1.4–4.1) |
| Right ventricular outflow tract obstruction defect | 1175 | 40 | 1.6 (1.1–2.3) |
| Pulmonary valve stenosis | 867 | 34 | 1.7 (1.2–2.6) |
| Atrial septal defect (ASD) | 511 | 17 | 2.0 (1.2–3.6) |
| Ventricular septal defect + ASD | 528 | 17 | 1.7 (1.0–2.9) |
| Hydrocephaly | 301 | 11 | 2.0 (1.0–3.7) |
| Glaucoma/anterior chamber defects | 103 | 5 | 2.6 (1.0–6.6) |
| Gastroschisis | 726 | 26 | 1.8 (1.1–2.9) |

The authors speculated that the activity of opioids and their receptors as growth regulators during the development of the embryo might be a mechanism to explain the above findings. The exposure data were obtained by retrospective maternal self-report; the authors acknowledged that recall bias and misclassification might have affected their results. They concluded that the

absolute risk was a modest absolute increase above the baseline risk for birth defects (9).

A large Norwegian population-based cohort study, also published in 2011, reported results for codeine that were the opposite of the above study (10). In this report, 2666 women who used codeine during pregnancy were compared with 65,316 women who used no opioids during pregnancy. There was no statistical difference in the congenital malformation rate (aOR 0.9, 95% CI 0.8–1.1) between codeine-exposed and unexposed infants. There also was no difference in the infant survival rate (aOR 0.9, 95% CI 0.6–1.5) (10).

A 2003 report described an association between opiate-dependent mothers and strabismus in their infants (11). In an 18-month period from 1998 to 2000, 72 infants born to opiate-dependent mothers, 50 of whom had been treated for neonatal abstinence syndrome, were identified. During pregnancy, 57% of the mothers took methadone alone, 30% methadone and heroin, 8% heroin alone, and 4% morphine or codeine. Benzodiazepines and amphetamines were also used in some cases. The investigators were able to contact the mothers of 49 infants, 29 of whom had a full ophthalmological examination. The remaining 20 cases completed a telephone interview. The age of the 49 children ranged from 6 to 39 months. Strabismus was found in seven (14%) of the infants and another 14% had a history of strabismus. The mean age at which the eye abnormality was noted in the 14 cases was 8.5 months. The incidence of strabismus was at least 10 times that in the general population (11).

Use of codeine during labor produces neonatal respiratory depression to the same degree as other opioid analgesics (12). The first-known case of neonatal codeine addiction was described in 1965 (13). The mother had taken analgesic tablets containing 360–480 mg of codeine/day for 8 weeks before delivery.

A second report described neonatal codeine withdrawal in two infants of nonaddicted mothers (14). The mother of one infant began consuming a codeine cough medication 3 weeks before delivery. Approximately 2 weeks before delivery, analgesic tablets with codeine were taken at a frequency of up to six tablets/day (48 mg of codeine/day). The second mother was treated with a codeine cough medication consuming 90–120 mg of codeine/day for the last 10 days of pregnancy. Apgar scores of both infants were 8–10 at 1 and 5 minutes. Typical symptoms of narcotic withdrawal were noted in the infants shortly after birth but not in the mothers (14).

A 25-year-old woman with well-controlled insulin-dependent diabetes underwent a cesarean section at 34 weeks' gestation because of spontaneous rupture of the membranes (15). The 2.5-kg (75th centile) male infant had Apgar

scores of 9, 10, and 10 at 1, 5, and 10 minutes, respectively. He was admitted to the neonatal unit because of hypoglycemia. Between 24 and 48 hours of age, he developed a tremor and became restless and irritable with a strong cry and with other symptoms of drug withdrawal. A brief seizure occurred at 36 hours of age and he became hypertonic with loose stools at 48 hours of age. The mother was interviewed and admitted taking a drug containing codeine and acetaminophen for severe headache and lower back pain throughout the last 2 months of pregnancy. The estimated daily dose of codeine was 90 mg. The infant recovered but specific details were not provided (15).

In Washington State, neonatal abstinence syndrome rates increased significantly between 2000 and 2008 and, in 2008, were higher than the national figures (3.3 compared with 2.8 per 1000 births $p < 0.05$) (16). The broad categories of drug exposures associated with the syndrome were opioids and related narcotics, cocaine, and other psychotropic agents. The proportion of neonates exposed prenatally to opioids increased from 26.4% in 2000 to 41.7% in 2008 ($p < 0.05$) (16).

BREASTFEEDING SUMMARY

Codeine, and its metabolite morphine, pass into breast milk in very small amounts that are usually considered insignificant (17–20). However, three reports provide evidence that this low-risk classification requires reassessment (21–23).

In a 1993 study, concentrations of codeine and morphine were determined in the breastmilk of 7 mothers and in the plasma of 11 healthy, term neonates at 1–5 days of age (20). Milk samples were not obtained from four mothers for various reasons. The mean birth weight was 3.3 kg. The mothers were treated with codeine 60 mg every 6 hours and milk samples were collected 16–54 hours postpartum. In milk, codeine and morphine levels were 33.8–314 ng/mL and 1.9–20.5 ng/mL, respectively, 20–240 minutes after a 60-mg codeine dose. Neonatal plasma samples were collected 1–4 hours after breastfeeding that had been completed 1 hour after a dose. The mean number of codeine doses taken by the mothers before neonatal sampling was 4.1 (range 1–12). Neonatal codeine and morphine plasma concentrations were < 0.8 –4.5 ng/mL and < 0.5 –2.2 ng/mL, respectively. Because no toxicity was observed in the neonates, the authors concluded that short-term use of codeine (up to four 60-mg doses) was safe for healthy, full-term infants in the first days of life (20).

A 2006 case report described the death of a nursing infant secondary to

maternal codeine use (21). On the first postpartum day, the mother took an oral analgesic product containing codeine 30 mg and acetaminophen 500 mg, 2 tablets every 12 hours, for episiotomy pain. The mother reduced the dose by one-half on day 2 because of sedation and constipation, and continued this dose for 2 weeks. On day 7, the healthy, full-term, male infant was lethargic and had difficulty feeding but, by day 11, had regained his birth weight. On day 12, his skin was gray and his milk intake had fallen. He was found dead on day 13. At postmortem, his blood morphine concentration was 70 ng/mL. Because of the infant's decreased milk intake, the mother had stored milk on day 10. Analysis of this milk yielded a morphine concentration of 87 ng/mL. An analysis for cytochrome P450 2D6 (CYP2D6), the enzyme responsible for metabolizing codeine to morphine, was conducted on family members and the infant. The mother was heterozygous for a CYP2D6*2A allele with CYP2D6*2×2 gene duplication, classified as an ultrarapid metabolizer, thus converting codeine to morphine at an increased rate. The sedation and constipation she experienced were consistent with this genotype. The maternal grandmother was also an ultrarapid metabolizer, whereas the father, maternal grandfather, and infant had two functional CYP2D6 alleles (CYP2D6*1/*2 genotypes) and were classified as extensive metabolizers. The authors considered the polymorphism to be clinically important because of the frequency of CYP2D6 ultrarapid metabolizers (CYP2D6UMs): 1% in Finland and Denmark; 10% in Greece and Portugal; and 29% in Ethiopia (21).

The pharmacogenetics of neonatal opioid toxicity was examined in a 2009 report (22). Among 72 mother–child pairs who had contacted the Motherisk Program in Toronto, 17 (24%) breastfed infants exhibited central nervous system (CNS) depression when their mothers took codeine. In each case, there was observable sedation in the infant while feeding and a marked improvement after codeine or breastfeeding was stopped. There also was concordance between maternal and infant CNS depression as 12 (71%) of the 17 mothers also showed signs of toxicity. As expected, a dose–effect relationship was found as the 17 mothers of symptomatic infants took a higher codeine dose than the 55 mothers of asymptomatic infants, 1.62 vs. 1.02 mg/kg/day. Two mothers whose infants had severe toxicity (one of whom is described in reference 21) were CYP2D6UMs and of the UGT2B7*2/*2 genotype. The investigators concluded that nursing infants of mothers who are CYP2D6UMs combined with the genotype were at risk of life-threatening CNS depression (22).

A 2009 report searched the medical literature to find other reports of CNS

depression from exposure to codeine in breast milk (23). In addition to the 17 cases described in references 21 and 22, the authors found reports of toxicity in 18 other breastfeeding infants (total 35). The ages of the infants ranged from 3 days to 4 months. The adverse drug reactions reported included apnea, poor breathing, bradycardia, CNS depression, cyanosis, drowsiness, sedation, and constipation (23).

In 2007, the FDA released a statement regarding use of codeine by nursing mothers (24). Although codeine is considered to be the safest choice among narcotic pain relievers, some mothers may be CYP2D6UMs and could put their nursing infants at risk. If a physician prescribes a codeine-containing product, the lowest dose needed for the shortest amount of time should be prescribed (24).

A 2009 study used coupled physiologically based pharmacokinetic models for the mother and child to estimate the risk of maternal consumption of codeine products during breastfeeding (25). The investigators considered combinations of genotype, assuming typical breastfeeding schedules and maternal doses of ≤ 2.5 mg/kg/day. Their stimulations showed that potentially toxic morphine plasma concentrations in the neonate could be reached within 4 days after repeated codeine dosing to the mother (25).

Based on the above, long-term consumption of codeine-containing products should be avoided during breastfeeding. Short-term therapy, such as 1–2 days, and close monitoring of the infant should be standard (21,23). If the mother or infant demonstrates symptoms of opioid toxicity, such as sedation, lethargy, or poor milk intake, breastfeeding should be stopped. A trial of naloxone, a narcotic antagonist, could be diagnostic. Guidelines developed by Motherisk in Canada for the safe use of codeine-containing drugs during breastfeeding were published in 2009 (26).

COLCHICINE

Antigout

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

Although colchicine is teratogenic in animals, the human pregnancy experience suggests that the risk to the embryo–fetus is low, if it exists at all. The use of colchicine by the father before conception does not appear to represent a significant reproductive risk, but azoospermia may be a rare complication. Because some reports suggested a risk of chromosome abnormalities, routine amniocentesis was recommended in cases of familial Mediterranean fever (FMF) treated with colchicine (1). However, more recent data suggest that routine amniocentesis is not justified (2,3).

FETAL RISK SUMMARY

Colchicine is used in the treatment of gout and FMF. Seven animal studies, reviewed by Shepard (4), indicated that colchicine, or its derivative, demecolcine (desacetylmethylcolchicine), were teratogenic in mice and rabbits at low doses and embryocidal in mice, rats, and rabbits at higher doses. Mutagenic effects were also observed in rabbit blastocysts. No adverse fetal effects were observed in limited studies with pregnant monkeys (4).

A number of reports have described the use of colchicine or demecolcine in human pregnancy (2,3,5–23). In these reports, no evidence of teratogenicity or other forms of developmental toxicity was found when these agents were used at recommended doses. In a woman treated throughout pregnancy with colchicine 1 mg/day, drug concentrations in the mother and cord blood at 38 weeks' gestation were 3.15 ng/mL and 0.47 ng/mL, respectively (23).

A 2011 case report described a successful 15 course of colchicine 1 mg/day, prednisolone 15 mg/day, and azathioprine 100 mg/day in a woman at 28 weeks' gestation with idiopathic granulomatous mastitis (24). No information on the pregnancy outcome was provided.

The mutagenic effects of colchicine and the possible relationship of this drug to sperm abnormalities and congenital malformations were the subjects of several publications (25–32). A 1965 report described three pregnancies occurring in a woman between the ages of 24 and 27 years, two of which ended abnormally (25). Her first pregnancy resulted in an SAB of a macerated fetus at 4.5 months, her second in the delivery of a normal girl, and her third in the delivery of a male with atypical Down's syndrome (trisomy 21), who died 24 hours after birth. The infant had palmar transverse folds on the hands, inner epicanthic folds, unspecified cardiac malformations, trigger thumbs, syndactyly in the second and third toes, hypognathous, cleft palate, low-set ears, and an incompletely developed scapha helix. The father was 27–30 years of age during these pregnancies and was being treated for gout on an intermittent basis with 1–2 mg/day of colchicine. Cultures of leukocytes obtained from him demonstrated mutagenic changes when exposed to colchicine, but blood and sperm samples, collected 3 months after the end of colchicine therapy, were normal. The investigators theorized that the colchicine therapy may have caused diploid spermatozoa that resulted in the production of triploid children (25).

A brief report, from the same laboratory as the reference above, described the analysis of lymphocyte cultures from three male patients being treated with colchicine (26). Compared with controls, a significant increase in the number of cells with abnormal numbers of chromosomes was found in the colchicine-exposed men. The investigators proposed that this finding indicated that these men were at higher risk of producing trisomic offspring than were nonexposed men. Of 54 children with Down's syndrome in their clinic, two had been fathered by men being treated with colchicine (26). The validity of this proposed association between colchicine and Down's syndrome was the subject of several references (27–30). One of the arguments against the association included the high possibility of Down's syndrome and colchicine therapy occurring at the same time in an older population (28). Moreover, several references have described healthy children fathered by men who were being treated with colchicine (6–8,31,32).

A 2005 study analyzed the reproductive histories of 326 couples in which at least one of the partners had FMF (236 women—628 pregnancies; 90 men—273 pregnancies) (1). Among the 901 pregnancies, there were 891 singletons and 10 sets of twins. After excluding abortions and fetal deaths, there were 777 viable pregnancies to determine if colchicine was teratogenic. Amniocentesis to detect chromosomal abnormalities was conducted in 558 of

the viable pregnancies. Seven numerical chromosomal abnormalities were found (4.99 expected, ns), six of which were unbalanced structural abnormalities (3.22 expected; ns). There were seven major malformations, also lower than expected. Although not significant, the authors concluded that the higher number of chromosomal abnormalities justified continuing the policy of routine amniocentesis in this patient population (1). However, two reports concluded that amniocentesis was not justified (2,3).

The effect of colchicine on sperm production is controversial. Hamsters and mice treated chronically with SC injections of demecolcine developed extensive damage to the germinal epithelium, resulting in azoospermia within 35–45 days (33). One study observed azoospermia in a 36-year-old patient induced by 1.2 mg/day of colchicine, but not with 0.6 mg/day (34). A second study, however, using 1.8–2.4 mg/day in seven healthy men 20–25 years old, measured no effect on sperm production or on serum levels of testosterone, luteinizing hormone, or follicle-stimulating hormone (35). The authors of this second report, however, could not exclude the fact that some men may be unusually sensitive to the drug, resulting in testicular toxicity (35). A 1998 review concluded that colchicine by itself may not have a significant direct adverse effect on sperm production or function (36).

BREASTFEEDING SUMMARY

Colchicine is excreted into breast milk (9–11). A 31-year-old woman, receiving long-term therapy with colchicine (0.6 mg twice daily) for FMF, was treated throughout a normal pregnancy, labor, and delivery (9). Milk, urine, and serum samples were obtained from her between 16 and 21 days after delivery. Colchicine was detected in three of five milk samples collected on days 16–20 with levels ranging from 1.2 to 2.5 ng/mL (test sensitivity 0.5 ng/mL). However, the authors could not determine whether their analysis was recovering all of the drug in the milk because of the high lipid content of the samples. Two serum samples collected on days 19 and 21 measured 0.7 and 1.0 ng/mL of the drug, indicating that the milk:plasma ratio exceeded 1.0. Daily urine colchicine concentrations (days 16–20) ranged from 70 to 390 ng/mL. No apparent effects were observed in the nursing infant over the first 6 months of life (9).

In four lactating women on long-term colchicine therapy (1–1.5 mg/day for at least 7 years) for FMF, serum and milk samples were drawn before a dose and at 1, 3, and 6 hours after a dose (10). Maximum breast milk drug concentrations ranged between 1.9 and 8.6 ng/mL, whereas maximum serum concentrations ranged from 3.6 to 6.46 ng/mL. The peak concentrations in milk

and serum both occurred at 1 hour and the colchicine concentration time curves for milk and serum were parallel. No apparent effects in the nursing infants were observed over a 10-month period. The authors concluded that nursing was safe for women taking colchicine, but that waiting 12 hours after a dose to breastfeed would minimize exposure of the nursing infant (10).

Much higher colchicine milk concentrations were measured in a second study. A 21-year-old woman had taken colchicine (1 mg/day) throughout gestation and continued while breastfeeding her normal infant (11). On postpartum days 5 and 15, colchicine concentrations in the mother's 24-hour urine sample were 276,000 and 123,000 ng/24 hours, respectively, while none was detected (test sensitivity 5 ng/mL) in the infant's 12-hour urine collection. Milk samples were collected four times each on day 5 (2, 4, 15, and 21 hours after a dose) and day 15 (0, 4, 7, and 11 hours after a dose). Colchicine concentrations in the 2-hour and 4-hour samples on day 5 were 31 and 24 ng/mL, respectively, and below the level of detection at 15 and 21 hours. On day 15, levels at 0 and 11 hours were below detection, while those at 4 and 7 hours were 27 and 10 ng/mL, respectively. Assuming 100% of the dose in milk was absorbed, the infant's estimated dose during the 8-hour period after a dose was 10% of the mother's weight-adjusted dose. Although no adverse effects were observed in the infant, the authors recommended that a mother could minimize drug exposure from her milk by taking her dose at bedtime and waiting 8 hours to breastfeed (11).

Because of the absence of infant toxicity observed during nursing in one of the above cases (9), the American Academy of Pediatrics classified colchicine as compatible with breastfeeding (37).

COLESEVELAM

Antilipemic Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The effect of colesevelam on the absorption of vitamins and other nutrients from the gastrointestinal tract in pregnant women has not been studied (1). Fat-soluble vitamin deficiency, especially vitamin K, is a potential complication if this agent is used during pregnancy.

FETAL RISK SUMMARY

This nonabsorbed, polymeric, lipid-lowering agent binds bile acids to prevent their absorption. Because cholesterol is the sole precursor of bile acids, this action eventually results in the lowering of low-density lipoprotein (LDL) cholesterol levels in the blood. It is indicated, either alone or in combination with an HMG-CoA reductase inhibitor (atorvastatin, cerivastatin, fluvastatin, lovastatin, pravastatin, or simvastatin), as adjunctive therapy to diet and exercise for the reduction of elevated LDL cholesterol in patients with primary hypercholesterolemia (1). Because the drug is not absorbed, no direct embryo or fetal exposure will occur.

Reproduction studies have been conducted in pregnant rats and rabbits (1). Doses that were about 50 and 17 times, respectively, the maximum human dose based on body weight (MHD) revealed no evidence of fetal harm. In addition, no effect on rat fertility was seen at 50 times the MHD (1). In rats, doses >30 times the MHD caused vitamin K deficiency and hemorrhage, but the absorption of fat-soluble (A, D, E, and K) vitamins was not significantly impaired (1).

A 2012 report described five cases of familial hypercholesterolemia in pregnancy that occurred between 2004 and 2010 (2). Colesevelam (625 mg twice daily) was started before pregnancy. Two women stopped the therapy

less than 4 weeks into their pregnancies, but the other three continued the drug throughout gestation. All five women had uncomplicated pregnancies and gave birth to healthy infants at term (2).

BREASTFEEDING SUMMARY

No reports describing the use of colesevelam in lactation have been located. The drug is not absorbed after oral administration so the nursing infant will not be exposed to the drug via breast milk. However, maternal deficiency of fat-soluble vitamins, especially vitamin K (see above), is a potential complication. This may result in lower fat-soluble vitamin concentrations in milk because these vitamins are natural constituents of breast milk.

COLESTIPOL

Antilipemic Agent

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The actions of colestipol are similar to those of cholestyramine, another exchange resin (see also Cholestyramine). It is not absorbed into the systemic circulation, so it should have no direct effect on the fetus. However, as with cholestyramine, prolonged use of colestipol may result in reduced intestinal absorption of the fat-soluble vitamins, A, D, E, and K. Because the interruption of cholesterol-lowering therapy during pregnancy should have no effect on the long-term treatment of hyperlipidemia, the use of colestipol should probably be halted during gestation.

FETAL RISK SUMMARY

The anion exchange resin, colestipol, is used to bind bile acids in the intestine into a nonabsorbable complex that is excreted in the feces. The prevention of the systemic reabsorption of the bile acids lowers the total amount of cholesterol in the patient. Because less than 0.17% of a dose is absorbed systemically, it is not expected to cause fetal harm when administered during pregnancy in recommended doses (1).

In a reproductive study with rats and rabbits, doses up to 1000 mg/kg/day produced no adverse effects on the fetuses (2). No published or unpublished cases involving the use of colestipol during human pregnancy have been located. Rosa also reported finding no recipients of this drug in his 1994 presentation on the outcome of pregnancies following exposure to anticholesterol agents (3).

BREASTFEEDING SUMMARY

Because colestipol is poorly absorbed (less than 0.17% of a dose) into the

systemic circulation, its use by the lactating woman should have no direct effect on the nursing infant. Prolonged use of the exchange resin, however, may result in decreased maternal absorption of the fat-soluble vitamins, A, D, E, and K. The resulting deficiencies in the mother would lessen the amounts of these vitamins in her milk.

COLISTIMETHATE

Antibiotic

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports linking the use of colistimethate with congenital defects have been located. The drug crosses the placenta at term (1).

FETAL RISK SUMMARY

Colistimethate was not teratogenic in rats at IM doses about 0.13 and 0.30 times the maximum recommended human dose based on BSA (MRHD) (2). The same weight doses in rabbits (about 0.25 and 0.55 times the MRHD) resulted in talipes varus in 2.6% and 2.9% of the fetuses, respectively. Increased resorption of rabbit embryos occurred at the highest dose.

BREASTFEEDING SUMMARY

Colistimethate is excreted into breast milk. The milk:plasma ratio is 0.17–0.18 (3). Although this level is low, three potential problems exist for the nursing infant: modification of bowel flora, direct effects on the infant, and interference with the interpretation of culture results if a fever workup is required.

COLLAGENASE CLOSTRIDIUM HISTOLYTIICUM

Dermatologic Agent

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of collagenase Clostridium histolyticum in human pregnancy have been located. Reproduction studies in rats revealed no evidence of harm to the fetus, but the comparison to the human dose was based on body weight and may not be interpretable. However, in humans, quantifiable levels of the drug did not occur in the systemic circulation after injection into a Dupuytren cord. Almost all patients treated with collagenase C. histolyticum develop antiproduct antibodies after treatment. The clinical significance of antiproduct antibody formation on a developing fetus is not known.

FETAL RISK SUMMARY

Collagenase Clostridium histolyticum is a polypeptide consisting of two microbial collagenases (proteinases), collagenase AUX-I and collagenase AUX-II, isolated from the fermentation of C. histolyticum bacteria. It is indicated for the treatment of adult patients with Dupuytren contracture with a palpable cord. The drug is given by local injection into the hand. After injection into a Dupuytren cord, neither of the collagenases had quantifiable levels in the systemic circulation (the lower limit of quantification for AUX I and AUX II in human plasma is 5 and 25 ng/mL, respectively).

Reproduction studies have been performed in rats. No evidence of fetal harm was observed in pregnant rats given IV doses up to about 45 times the IV human dose based on body weight (HD) (1).

Carcinogenicity studies with collagenase C. histolyticum have not been conducted. Various assays for mutagenic and clastogenic effects were negative. The polypeptide did not impair fertility or early embryonic

development when administered IV to rats at doses up to about 45 times the HD (1).

It is not known if the two collagenases cross the human placenta. The molecular weights of collagenase AUX-1 and collagenase AUX-II are 114,000 and 113,000, respectively, and nonquantifiable systemic levels suggest that clinically significant exposure of the embryo or fetus is unlikely.

BREASTFEEDING SUMMARY

No reports on the use of collagenase *C. histolyticum* during lactation have been located. The molecular weights of collagenase AUX-1 and collagenase AUX-II are 114,000 and 113,000, respectively, and, combined with the nonquantifiable systemic levels, suggest that the presence in milk of clinically significant amounts is unlikely.

CONIVAPTAN

Vasopressin Receptor Antagonist

PREGNANCY RECOMMENDATION: No Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

No reports describing the use of conivaptan during human pregnancy have been located. Developmental toxicity (death) was observed in one of two animal species. Because of the administration method, exposure of the embryo and fetus will probably occur. The absence of human pregnancy experience prevents a more complete assessment of the embryo–fetal risk. If a pregnant woman requires conivaptan therapy, she should be advised of the potential risk (abortion or fetal/neonatal death).

FETAL RISK SUMMARY

Conivaptan is a nonpeptide, dual antagonist of arginine vasopressin receptors. It is indicated for the treatment of euvolemic hyponatremia (e.g., the syndrome of inappropriate secretion of antidiuretic hormone, or in the setting of hypothyroidism, adrenal insufficiency, pulmonary disorders, etc) in hospitalized patients. It is given as a continuous IV infusion over several days. The mean terminal elimination half-life after conivaptan infusion is 5 hours. The drug is extensively bound to plasma proteins (99%). Some of the metabolites have activity equivalent to the parent compound but, overall, the activity of the metabolites was only 7% that of conivaptan (1).

Reproduction studies have been conducted in rats and rabbits. When female rats were given daily IV bolus doses that resulted in systemic exposures that were less than the human therapeutic exposure based on AUC (HTE) before mating and during the first 7 days of pregnancy, prolonged diestrus, decreased fertility, and increased pre- and postnatal implantation loss occurred. No effects were observed with these doses on male fertility. No significant maternal or fetal effects were observed at daily doses resulting in systemic exposures that

were less than the HTE during organogenesis (days 7–17). When dosing was continued through lactation day 20 (weaning), no maternal toxicity was observed, but pups showed decreased neonatal viability, weaning indices, delayed growth and physical development (including sexual maturation), and delayed reflex development. No pup adverse effects were observed when the daily dose was reduced by one-half or more. In pregnant rabbits given daily IV doses resulting in systemic exposures less than the HTE during organogenesis, there were no fetal adverse effects, but maternal toxicity was evident at all doses tested (1).

During labor, daily doses given orally to rats that resulted in systemic exposures equivalent to the HTE delayed delivery. Daily IV doses that resulted in systemic exposures less than the HTE caused increased peripartum pup mortality. These effects may have been secondary to conivaptan activity on oxytocin receptors in rats (1).

No carcinogenicity was observed in mice and rats given daily doses by gavage for 2 years that resulted in systemic exposures that were up to six and two times, respectively, the HTE. Conivaptan was not mutagenic or clastogenic, with or without metabolic activation, in several tests (1).

Conivaptan crosses the rat placenta with fetal tissue concentrations <10% of maternal plasma levels, but placental levels were 2.2 times higher than maternal plasma levels. Moreover, conivaptan was slowly cleared from fetal tissues, suggesting that fetal accumulation may occur (1). It is not known if conivaptan crosses the human placenta. The molecular weight (about 499 for the free base) and the administration of a continuous intravenous infusion over several days suggest that the drug will cross to the human embryo and fetus.

BREASTFEEDING SUMMARY

No reports describing the use of conivaptan during human lactation have been located. It is not known if conivaptan is excreted into breast milk. The molecular weight (about 499 for the free base) and the administration of a continuous intravenous infusion over several days suggest that the drug will be excreted into milk. Although the effects on a nursing infant are unknown, there is a potential for severe toxicity in several organ systems as observed in adults receiving IV infusions. Moreover, as a weak base, ion trapping in the relatively acidic milk will allow conivaptan to accumulate in milk. Therefore, until data relating to milk concentrations are available, women receiving conivaptan should probably not breastfeed.

CORTICOTROPIN/COSYNTROPIN

Corticosteroid Stimulating Hormone

PREGNANCY RECOMMENDATION: Limited Human Data—No Relevant Animal Data

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Studies reporting the use of corticotropin in pregnancy have not demonstrated adverse fetal effects (1–4). However, corticosteroids have been suspected of causing malformations (see Hydrocortisone). Because corticotropin stimulates the release of endogenous corticosteroids, this relationship should be considered when prescribing the drug to women in their reproductive years.

BREASTFEEDING SUMMARY

No reports describing the use of corticotropin during human lactation have been located. The use of this agent during breastfeeding probably is compatible.

CORTISONE

Corticosteroid

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Cortisone (Compound E) is an inactive corticosteroid precursor that is secreted by the adrenal cortex. It is converted by reduction to hydrocortisone, primarily in the liver. See Hydrocortisone.

BREASTFEEDING SUMMARY

See Hydrocortisone.

COUMARIN DERIVATIVES

Anticoagulant

PREGNANCY RECOMMENDATION: Contraindicated—1st Trimester

BREASTFEEDING RECOMMENDATION: Compatible; Contraindicated (Phenindione)

PREGNANCY SUMMARY

The use of coumarin derivatives during the 1st trimester carries with it a significant risk to the fetus. For all cases, only about 70% of pregnancies are expected to result in a normal infant. Exposure in the 6th–9th weeks of gestation may produce a pattern of defects termed the fetal warfarin syndrome with an incidence up to 25% or greater in some series. Infants exposed before and after this period have had other congenital anomalies, but the relationship between warfarin and these defects is unknown. Infrequent central nervous system defects, which have greater clinical significance to the infant than the defects of the fetal warfarin syndrome, may be deformations related to hemorrhage and scarring, with subsequent impaired growth of brain tissue. Spontaneous abortions, stillbirths, and neonatal deaths may also occur. If the mother's condition requires anticoagulation, the use of heparin from the start of the 6th gestational week through the end of the 12th gestational week, and again at term, may lessen the risk to the fetus of adverse outcome.

FETAL RISK SUMMARY

Coumarin derivatives (dicumarol, ethyl biscoumacetate, and warfarin) are oral anticoagulants, as are the indandione derivatives (anisindione and phenindione). Use of any of these agents during pregnancy may result in significant problems for the fetus and newborn. Since the first case of fetal coumarin embryopathy described by DiSaia in 1966 (1), a large volume of literature has accumulated. Hall and coworkers (2) reviewed this subject in 1980 (167 references). In the 3 years following this review, a number of other reports have appeared (3–12). The principal problems confronting the fetus and newborn are as follows:

Embryopathy (fetal warfarin syndrome)

Central nervous system defects

Spontaneous abortion

Stillbirth

Prematurity

Hemorrhage

First-trimester use of coumarin derivatives may result in the fetal warfarin syndrome (FWS) (1–4). The common characteristics of the FWS are nasal hypoplasia because of failure of development of the nasal septum and stippled epiphyses. The bridge of the nose is depressed, resulting in a flattened, upturned appearance. Neonatal respiratory distress occurs frequently because of upper airway obstruction. Other features that may be present are as follows:

Birth weight <10th percentile for gestational age

Eye defects (blindness, optic atrophy, microphthalmia) when drug also used in 2nd and 3rd trimesters

Hypoplasia of the extremities (ranging from severe rhizomelic dwarfing to dystrophic nails and shortened fingers)

Developmental retardation

Seizures

Scoliosis

Deafness/hearing loss

Congenital heart disease

Death

The critical period of exposure, based on the work of Hall and coworkers (2), seems to be the 6th–9th weeks of gestation. All of the known cases of FWS were exposed during at least a portion of these weeks. Exposure after the 1st trimester carries the risk of central nervous system (CNS) defects. No constant grouping of abnormalities was observed, nor were there an apparent correlation between time of exposure and the defects, except that all fetuses were exposed in the 2nd and/or 3rd trimesters. After elimination of those cases that were probably caused by late fetal or neonatal hemorrhage, the CNS defects in 13 infants were thought to represent deformations that occurred as a result of abnormal growth arising from an earlier fetal hemorrhage and subsequent scarring (2). Two patterns were recognized: (a) dorsal midline dysplasia characterized by agenesis of corpus callosum, Dandy-Walker malformations, and midline cerebellar atrophy (encephaloceles may be present); and (b) ventral midline dysplasia characterized by optic atrophy (eye anomalies).

Other features of CNS damage in the 13 infants were (number of infants shown in parenthesis):

- Mental retardation (13)
- Blindness (7)
- Spasticity (4)
- Seizures (3)
- Deafness (1)
- Scoliosis (1)
- Growth failure (1)
- Death (3)

Long-term effects in the children with CNS defects were more significant and debilitating than those from the fetal warfarin syndrome (2).

Fetal outcomes for the 471 cases of in utero exposure to coumarin derivatives reported through 1983 are summarized below (2–12):

1ST TRIMESTER EXPOSURE (263):

- Normal infants—167 (63%)
- Spontaneous abortions—41 (16%)
- Stillborn/neonatal death—17 (6%)
- FWS—27 (10%)
- CNS/other defects—11 (4%)

2ND TRIMESTER EXPOSURE (208):

- Normal infants—175 (84%)
- Spontaneous abortions—4 (2%)
- Stillborn/neonatal death—19 (9%)
- CNS/other defects—10 (5%)

TOTAL INFANTS EXPOSED (471):

- Normal infants—342 (73%)
- Spontaneous abortions—45 (10%)
- Stillborn/neonatal death—36 (8%)
- FWS/CNS/other defects—48 (10%)

Hemorrhage was observed in 11 (3%) of the normal newborns (premature and term). Two of the patients in the 2nd- and 3rd trimester groups were treated with the coumarin derivatives, phenprocoumon and nicoumalone. Both infants were normal.

Congenital abnormalities that did not fit the pattern of the FWS or CNS defects were reported in 10 infants (2,9). These were thought to be incidental

malformations that were probably not related to the use of coumarin derivatives (see also three other cases, in which the relationship to coumarin derivatives is unknown, described in the text below, references 16,20,22).

Asplenia, two-chambered heart, agenesis of pulmonary artery

Anencephaly, spina bifida, congenital absence of clavicles

Congenital heart disease, death

Fetal distress, focal motor seizures

Bilateral polydactyly

Congenital corneal leukoma

Nonspecified multiple defects

Asplenia, congenital heart disease, incomplete rotation of gut, short broad phalanges, hypoplastic nails

Single kidney, toe defects, other anomalies, death

Cleft palate

A 1984 study examined 22 children, with a mean age of 4.0 years, who were exposed in utero to warfarin (13). Physical and mental development of the children was comparable to that of matched controls.

Since publication of the above data, a number of additional reports and studies have appeared, describing the outcomes of pregnancies treated at various times with coumarin derivatives (13–25). The largest series involved 156 women with cardiac valve prostheses who had 223 pregnancies (14). During a period of 19 years, the women were grouped based on evolving treatment regimens: group I—68 pregnancies treated with acenocoumarol until the diagnosis of pregnancy was made, and then treated with dipyridamole or aspirin, or both; group II—128 pregnancies treated with acenocoumarol throughout gestation; group III—12 pregnancies treated with acenocoumarol, except when heparin was substituted from pregnancy diagnosis to the 13th week of gestation, and again from the 38th week until delivery; and group IV—15 pregnancies in women with biologic prostheses who were not treated with anticoagulant therapy. The fetal outcomes in the four groups were as follows: spontaneous abortions, 10.3% vs. 28.1% vs. 0% vs. 0% ($p < 0.0005$); stillbirths, 7.4% vs. 7.1% vs. 0% vs. 6.7%; and neonatal deaths, 0% vs. 2.3% vs. 0% vs. 0%. (See reference for maternal outcomes in the various groups.) Of the 38 children examined in group II, 3 (7.9%) had features of the FWS.

In a subsequent report from these investigators, the outcomes of 72 pregnancies studied prospectively were described in 1986 (15). The pregnancies were categorized into three groups according to the anticoagulant

therapy: group I—23 pregnancies treated with acenocoumarol except for heparin from the 6th to 12th week of gestation; group II—12 pregnancies treated the same as group I except that heparin treatment was started after the 7th week; and group III—37 pregnancies treated with acenocoumarol throughout gestation (pregnancies in this group were not detected until after the 1st trimester). In most patients, heparin was substituted for the coumarin derivative after the 38th week of gestation. The fetal outcomes in the three groups were spontaneous abortions, 8.7% vs. 25% vs. 16.2%; and stillbirths, 0% vs. 8.3% vs. 0%. Not all of the infants born to the mothers were examined, but of those that were, the FWS was observed in 0% of group I (0 of 19), 25.0% of group II (2 of 8), and 29.6% of group III (8 of 27). Thus, 10 (28.6%) of the 35 infants examined who were exposed at least during the first 7 weeks of gestation had warfarin embryopathy.

A 1983 report described 14 pregnancies in 13 women with a prosthetic heart valve who were treated throughout pregnancy with warfarin (16). Two patients had spontaneous abortions, two delivered premature stillborn infants (one infant had anencephaly), and two newborns died during the neonatal period. The total fetal and neonatal mortality in this series was 43%. Other defects noted were corneal changes in two, brachydactyly and dysplastic nails in two, and nasal hypoplasia in one.

In 18 pregnancies of 16 women with an artificial heart valve, heparin was substituted for warfarin when pregnancy was diagnosed (between 6 and 8 weeks after the last menstrual period) and continued until the 13th week of gestation (17). Nine of the 18 pregnancies aborted, but none of the nine liveborn infants had congenital anomalies or other complications.

Three reports described the pregnancy outcomes in mothers with prosthetic heart valves and who were treated with anticoagulants (18–20). A study published in 1991 described the outcomes of 64 pregnancies in 40 women with cardiac valve replacement, 34 of whom had mechanical valves (18). Warfarin was used in 47 pregnancies (23 women), heparin in 11 pregnancies (11 women), and no anticoagulation was given in 6 pregnancies (6 women). Fetal wastage (spontaneous abortions, neonatal death after preterm delivery, and stillbirths) occurred in 25 (53%) of the warfarin group, 4 (36%) of those treated with heparin, and 1 (17%) of those not treated. Two infants, both exposed to warfarin, had congenital malformations: single kidney and toe, and finger defects in one; cleft lip and palate in the other.

Two groups of pregnant patients with prosthetic heart valves were compared in a study published in 1992 (19). In group 1 (N = 40), all treated with

coumarin-like drugs until near term when therapy was changed to heparin, 34 (85%) had mechanical valves, whereas none of those in group 2 (N = 20) were treated with anticoagulation and all had biological valves. The pregnancy outcomes of the two groups were as follows: spontaneous abortions 7 and 0, prematurity 14 and 2 ($p < 0.05$), low birth weight 15 and 2 ($p < 0.05$), stillbirth 1 and 0, neonatal mortality 5 and 0, and birth defects 4 and 0. The 4 infants from group 1 with birth defects included 3 with typical features of FWS (1 with low birth weight and upper airway obstruction) and 1 with left ventricular hypoplasia and aortic atresia (died in neonatal period). The other 4 neonatal deaths involved 3 from respiratory distress syndrome and 1 from a cerebral hemorrhage.

A 1994 reference compared retrospectively two groups of pregnant women: Group 1 (56 pregnancies in 31 women) with mechanical valve replacements, all of whom were treated with warfarin; and group 2 (95 pregnancies in 57 women) with porcine tissue valves, none of whom received anticoagulation (20). Twenty women in group 1 either continued the warfarin throughout delivery (N = 12) or discontinued the drug (N = 8) 1–2 days before delivery. The pregnancy outcomes of the two groups were as follows: induced abortion 9 and 22, fetal loss before 20 weeks' gestation 7 and 8, fetal loss after 20 weeks' gestation 6 and 1 ($p < 0.01$), total fetal loss 13 and 9 ($p < 0.05$), and live births 34 and 64 ($p < 0.05$). Two infants, both in group 1 had birth defects—a ventricular septal defect in 1 and a hypoplastic nose in the other (20).

Five reports have described single cases of exposure to warfarin during pregnancy (21–25). A woman with Marfan's syndrome had replacement of her aortic arch and valve combined with coronary artery bypass performed during the 1st week of her pregnancy (1–8 days after conception) (21). She was treated with warfarin throughout gestation. A normal female infant was delivered by elective cesarean section at 34 weeks' gestation. Warfarin was used to treat a deep vein thrombosis during the 3rd trimester in a 34-year-old woman because of heparin-induced maternal thrombocytopenia (22). A normal infant was delivered at term. In another case involving a woman with a deep vein thrombosis that had occurred before the present pregnancy, warfarin therapy was continued through the first 14 weeks of gestation (23). At term, a 3660-g infant was delivered, who did not breathe and who died after 35 minutes. At autopsy, an almost total agenesis of the left diaphragm and hypoplasia of both lungs were noted. The relationship between warfarin and the defect is unknown.

The use of warfarin to treat a deep vein thrombosis associated with

circulating lupus anticoagulant during pregnancy has been described (24). Therapy was started after the ninth week of gestation. Because of severe pregnancy-induced hypertension, a 1830-g female infant was delivered by cesarean section at 31 weeks. No information was provided about the condition of the infant.

A woman with a mitral valve replacement 8 months before pregnancy was treated continuously with warfarin until 6 weeks after her last menstrual period (25). Warfarin was then stopped and except for cigarette smoking, no other drugs were taken during the pregnancy. A growth-restricted (2340 g, 3rd percentile; 50 cm length, 50th percentile; 35 cm head circumference, 50th percentile) female infant was delivered at term. Congenital abnormalities noted in the infant were triangular face with broad forehead, micrognathia, microglossia, hypoplastic fingernails and toenails, and hypoplasia of the distal phalanges. No epiphyseal stippling was seen on a skeletal survey. A normal female karyotype, 46,XX, was found on chromosomal analysis. Psychomotor development was normal at 1 year of age, but physical growth remained restricted (3rd percentile). The authors concluded that the pattern of defects represented the earliest teratogenic effects of warfarin, but they could not exclude a chance association with the drug.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 22 newborns had been exposed to warfarin during the 1st trimester (F. Rosa, personal communication, FDA, 1993). One (4.5%) major birth defect was observed (one expected), a cardiovascular defect (0.2 expected).

A report published in 1994 assessed the neurological, cognitive, and behavioral development of 21 children (8–10 years of age) who had been exposed in utero to coumarin derivatives (26). A control group of 17 children was used for comparison. Following examination, 32 of the children were classified as normal (18 exposed and 14 control children), 5 had minor neurological dysfunction (2 exposed and 3 control children), and 1 child had severe neurological abnormalities, which were thought to be due to oral anticoagulants. Although no significant differences were measured between the groups, the children with the lowest neurological assessments and the lowest IQ scores had been exposed to coumarin derivatives (26).

In a 2013 report, a 19-year-old primigravid woman at 32 weeks' gestation was admitted to the hospital with coagulopathy (27). She had spontaneous bleeding from the oral mucosa and from nicks on her legs from shaving and frank hematuria. Her international normalized ratio (INR) was >9. The fetus

showed evidence of acidosis. Fresh-frozen plasma was given and bleeding stopped after about 1 hour. A 2180-g female infant was delivered by emergent cesarean section with Apgar scores of 0, 2, and 3 at 1, 5, and 10 minutes, respectively. The infant's INR was >9. She died on day 4 of life. Further history was obtained from the mother and it was learned that she had ingested brodifacoum, a second-generation rodenticidal anticoagulant. The agent was identified in maternal serum and cord blood. Because brodifacoum is lipophilic and has a very long half-life (up to several months), the mother required IV vitamin K (35 mg over several days) and high oral doses (up to 60 mg/day). Thirty days after presentation, her INR had decreased to 1.8 (27).

BREASTFEEDING SUMMARY

Excretion of coumarin (dicumarol, ethyl biscoumacetate, and warfarin) and indandione (anisindione and phenindione) derivatives into breast milk is dependent on the agent used. Three reports on warfarin have been located, totaling 15 lactating women (28–30). Doses ranged between 2 and 12 mg/day in 13 patients (7 nursing, 6 not nursing) with serum levels varying from 1.6 to 8.5 $\mu\text{mol/L}$ (28,29). Warfarin was not detected in the milk of any of the 13 patients or in the plasma of the 7 nursing infants. No anticoagulant effect was found in the plasma of the three infants tested. In another report, the warfarin doses in two breastfeeding women were not specified nor were maternal plasma drug levels determined (30). However, no spectrophotometric evidence for the drug was found in the milk of one mother and no anticoagulant effect was measured in either nursing infant.

Exposure to ethyl biscoumacetate in milk resulted in bleeding in 5 of 42 exposed infants in one report (31). The maternal dosage was not given. An unidentified metabolite was found in the milk that may have led to the high complication rate. A 1959 study measured ethyl biscoumacetate levels in 38 milk specimens obtained from four women taking 600–1200 mg/day (32). The drug was detected in only 13 samples with levels varying from 0.09 to 1.69 mcg/mL. No correlation could be found between the milk concentrations and the dosage or time of administration. Twenty-two infants were breastfed from these and other mothers receiving ethyl biscoumacetate. No adverse effects were observed in the infants, but coagulation tests were not conducted (32).

More than 1600 postpartum women were treated with dicumarol to prevent thromboembolic complications in a 1950 study (33). Doses were titrated to adjust the prothrombin clotting time to 40%–50% of normal. No adverse effects or any change in prothrombin times were noted in any of the nursing infants.

Phenindione use in a lactating woman resulted in a massive scrotal hematoma and wound oozing in a 1.5-month-old breastfed infant shortly after a herniotomy was performed (34). The mother was taking 50 mg every morning and alternating between 50 and 25 mg every night for suspected pulmonary embolism that developed postpartum. Milk levels varying from 1 to 5 mcg/mL have been reported after 50- or 75-mg single doses of phenindione (35). When the dose was 25 mg, only 18 of 68 samples contained detectable amounts of the anticoagulant.

Maternal warfarin consumption apparently does not pose a significant risk to normal, full-term, breastfed infants. Other oral anticoagulants should be avoided by the lactating woman. The American Academy of Pediatrics classifies phenindione (which is not used in the United States) as contraindicated during breastfeeding because of the risk of hemorrhage in the infant (36). Both warfarin and dicumarol (bishydroxycoumarin) are classified by the Academy as compatible with breastfeeding.

CRIZOTINIB

Antineoplastic (Tyrosine Kinase Inhibitor)

PREGNANCY RECOMMENDATION: Contraindicated

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

No reports describing the use of crizotinib during human pregnancy have been located. Developmental toxicity was observed in two animal species at doses close to the human dose. Based on the drug's mechanism of action, crizotinib should be avoided in pregnancy.

FETAL RISK SUMMARY

Crizotinib is an oral receptor tyrosine kinase inhibitor that is indicated for the treatment of patients with locally advanced or metastatic non-small cell lung cancer that is anaplastic lymphoma kinase (ALK)-positive as detected by an FDA-approved test. The drug is administered orally in 250 mg doses given twice daily. Crizotinib is metabolized to inactive metabolites and plasma protein binding is moderately high (91%). The mean terminal half-life is 42 hours following a single dose but may be lengthened by multiple dosing (1).

In rats treated during organogenesis, postimplantation loss was increased at doses that were about 1.2 times the recommended human dose (RHD) based on AUC (RHD-AUC). No increase in structural anomalies was observed in rats at doses up to the maternally toxic dose that was about 5 times the RHD-AUC or in rabbits at doses of up to about 3 times the RHD-AUC. However, fetal body weights were reduced at these doses (1).

Carcinogenicity studies with crizotinib have not been conducted. Crizotinib was genotoxic in multiple assays but not mutagenic in one assay. No studies have been conducted in animals to evaluate the effect on fertility. However, in toxicity studies in rats, males exhibited testicular pachytene spermatocyte degeneration when given doses that were greater than 3 times the RHD-AUC for 28 days. In female rats, single-cell necrosis of ovarian follicles occurred at doses that were about 10 times the RHD based on BSA given for 3 days (1).

It is not known if crizotinib crosses the human placenta. The molecular weight

(about 450) and the long elimination half-life suggest that it will cross to the embryo–fetus. However, the amount crossing may be limited by the moderately high plasma protein binding.

BREASTFEEDING SUMMARY

No reports describing the use of crizotinib during human lactation have been located. The molecular weight (about 450) and the long elimination half-life (42 hours after a single dose) suggest that the drug will be excreted into breast milk, but the amount excreted may be limited by the moderately high (91%) plasma protein binding. Until additional data on the amount in breast milk are available, the safest course is to not breastfeed when taking this drug.

CROFELEMER

Gastrointestinal Agent (Antidiarrheal)

PREGNANCY RECOMMENDATION: No Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

No reports describing the use of crofelemer in human pregnancy have been located. Doses used in animal reproduction studies were compared with the human dose based on body weight and, in one species, maternal toxicity occurred, so the results are not interpretable. Nevertheless, the botanical drug is minimally absorbed, so clinically significant exposure of the embryo–fetus probably does not occur.

FETAL RISK SUMMARY

Crofelemer, a botanical drug substance, is an oral inhibitor of two functions of intestinal epithelial cells that regulate fluid secretion, thus preventing high-volume water loss in diarrhea. It is indicated for symptomatic relief of noninfectious diarrhea in patients with HIV/AIDS on anti-retroviral therapy. The drug is minimally absorbed and concentrations of crofelemer in plasma are below the level of quantitation (50 ng/mL). No metabolites have been identified (1).

Reproduction studies have been conducted in rats and rabbits. In rats, oral doses up to 177 times the recommended daily human dose of 4.2 mg/kg (RHD) revealed no evidence of fetal harm. There also was no evidence of adverse prenatal or postnatal effects in offspring. In rabbits, a dose that was about 96 times the RHD caused abortions and resorptions of fetuses, but maternal toxicity also was evident.

Long-term studies of carcinogenicity have not been conducted, but three assays for mutagenicity were negative. At doses up to 177 times the RHD, crofelemer had no effects on fertility or reproductive performance of male and female rats (1).

It is not known if crofelemer crosses the human placenta. Although high, the molecular weight of the botanical drug cannot be determined because of extensive polymerization. Moreover, systemic concentrations of the drug are minimal, so exposure of an embryo or fetus probably appears to be nil.

BREASTFEEDING SUMMARY

No reports describing the use of crofelemer during human lactation have been located. Because the drug is minimally absorbed, clinically significant amounts of crofelemer in milk probably do not occur.

CROMOLYN SODIUM

Respiratory Drug (Anti-inflammatory)

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

Neither the human nor the animal reproduction data suggest a risk of structural anomalies.

FETAL RISK SUMMARY

Cromolyn sodium is an inhaled anti-inflammatory agent used for the prevention of bronchial asthma. The drug is generally considered safe for use during pregnancy (1–6). Although small amounts are absorbed systemically from the lungs, it is not known whether the drug crosses the placenta to the fetus (6).

Reproductive studies using SC doses of cromolyn in mice, rats, and both SC and IV in rabbits have not revealed teratogenicity (7,8). In one source, the doses used in the three animal species were 27, 16, and 98 times the maximum recommended human dose based on BSA, respectively (8). Increased resorptions and decreased fetal weight were observed only with high parenteral doses that were associated with maternal toxicity (8).

A 1984 study, cited by Shepard, reported over 300 pregnancies in which cromolyn was used in combination with other drugs, most often with isoproterenol, without a link with congenital defects (9).

Congenital malformations were noted in four (1.35%) newborns in a 1982 study of 296 women treated throughout gestation with cromolyn sodium (10). This incidence is less than the expected rate of 2%–3% in a nonexposed population. The defects observed were patent ductus arteriosus, clubfoot, nonfused septum, and harelip alone. The author concluded that there was no association between the defects and cromolyn sodium (10).

As of 1983, the manufacturer had reports of 185 women treated during all or parts of pregnancy, but the small number probably reflects underreporting of the actual usage (personal communication, Fisons Corporation, 1983). From

these cases, 10 infants had been born with congenital defects, at least 3 of which appeared to be genetic in origin. Multiple drug exposure was common. In none of the 10 cases was there evidence to link the defects with cromolyn sodium.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 191 newborns had been exposed to cromolyn during the 1st trimester (F. Rosa, personal communication, FDA, 1993). Seven (3.7%) major birth defects were observed (eight expected). Specific data were available for six defect categories, including (observed/expected) 1/2 cardiovascular defects, 1/0.5 oral clefts, 0/0 spina bifida, 1/0.5 polydactyly, 0/0.5 limb-reduction defects, and 0/0.5 hypospadias. These data do not support an association between the drug and congenital defects.

BREASTFEEDING SUMMARY

No reports describing the use of cromolyn sodium during lactation have been located.

CYCLACILLIN

[Withdrawn from the market. See 9th edition.]

CYCLAMATE

Artificial Sweetener

PREGNANCY RECOMMENDATION: Limited Human Data—Probably Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The very limited human pregnancy data does not suggest a major risk of structural anomalies.

FETAL RISK SUMMARY

Cyclamate crosses the placenta to produce fetal blood levels of about 25% of maternal serum (1). The drug has been suspected of having cytogenetic effects in human lymphocytes (2). One group of investigators attempted to associate these effects with an increased incidence of malformations and behavioral problems, but a causal relationship could not be established (3).

BREASTFEEDING SUMMARY

No reports describing the use of cyclamate during human lactation have been located.

CYCLANDELATE

[Withdrawn from the market. See 9th edition.]

CYCLAZOCINE

[Withdrawn from the market. See 8th edition.]

CYCLIZINE

Antihistamine/Antiemetic

PREGNANCY RECOMMENDATION: Compatible

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

In general, antihistamines are considered low risk in pregnancy. However, exposure near birth of premature infants has been associated with an increased risk of retrolental fibroplasia.

FETAL RISK SUMMARY

Cyclizine is a piperazine antihistamine that is used as an antiemetic (see Buclizine and Meclizine for closely related drugs). The drug is teratogenic in animals but apparently not in humans. In 111 patients given cyclizine during the 1st trimester, no increased malformation rate was observed (1). Similarly, the Collaborative Perinatal Project found no association between 1st trimester cyclizine use and congenital defects, although the number of exposed patients (N = 15) was small compared with the total sample (2). The Food and Drug Administration's OTC Laxative Panel acting on this data concluded that cyclizine is not teratogenic (3). In 1974, investigators searching for an association between antihistamines and oral clefts found no relationship between this defect and the cyclizine group (4). Finally, a retrospective study in 1971 found that significantly fewer infants with malformations were exposed to antihistamines/antiemetics in the 1st trimester as compared with controls (5). Cyclizine was the fifth most commonly used antiemetic.

An association between exposure during the last 2 weeks of pregnancy to antihistamines in general and retrolental fibroplasia in premature infants has been reported. See Brompheniramine for details.

BREASTFEEDING SUMMARY

No reports describing the use of cyclizine during human lactation have been located.

CYCLOBENZAPRINE

Skeletal Muscle Relaxant

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Potential Toxicity

PREGNANCY SUMMARY

The animal reproduction data and human pregnancy experience suggest that the use of cyclobenzaprine in pregnancy is low risk.

FETAL RISK SUMMARY

Cyclobenzaprine is a centrally acting skeletal muscle relaxant that is closely related to the tricyclic antidepressants (e.g., imipramine). The agent is not teratogenic or embryotoxic in mice, rats, and rabbits given doses up to 20 times the human dose (1). No published reports of its use in human pregnancy have been located.

It is not known if cyclobenzaprine crosses the human placenta. The molecular weight (about 276 for the free base) is low enough that exposure of the embryo or fetus probably occurs.

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 545 newborns had been exposed to cyclobenzaprine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 24 (4.4%) major birth defects were observed (23 expected), including (observed/expected) 5/5 cardiovascular defects, 1/1 oral clefts, and 2/2 polydactyly. No anomalies were observed in three other categories of defects (spina bifida, limb-reduction defects, and hypospadias) for which data were available. Earlier data, obtained from the same source between 1980 and 1983, totaled 168 1st-trimester exposures with 12 defects observed (10 expected). These combined data do not support an association between the drug and congenital defects.

BREASTFEEDING SUMMARY

No reports have been located on the excretion of cyclobenzaprine into milk. The molecular weight (about 276 for the free base) is low enough that excretion into milk should be expected. In addition, the closely related tricyclic antidepressants (e.g., see Imipramine) are excreted into milk and this should be considered before cyclobenzaprine is used during lactation.

CYCLOPENTHIAZIDE

[Withdrawn from the market. See 9th edition.]

CYCLOPHOSPHAMIDE

Antineoplastic

PREGNANCY RECOMMENDATION: Contraindicated—1st Trimester

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

Cyclophosphamide is known to cause congenital defects when exposure occurs during organogenesis. Fetal bone marrow suppression is a potential toxicity when exposure occurs later in pregnancy. [See Rituximab for additional data.]

FETAL RISK SUMMARY

Cyclophosphamide is an alkylating antineoplastic agent. Both normal and malformed newborns have been reported following the use of cyclophosphamide in pregnancy (1–33). Ten malformed infants have resulted from 1st trimester exposure (1–8). Radiation therapy was given to most of the mothers, and at least one patient was treated with other antineoplastics (1,2,4). Defects observed in four of the infants are shown in the list below, and three other infants are described in the text that follows:

Flattened nasal bridge, palate defect, skin tag, four toes each foot,
hypoplastic middle phalanx fifth finger, bilateral inguinal hernia sacs

Toes missing, single coronary artery

Hemangioma, umbilical hernia

Imperforate anus, rectovaginal fistula, growth restricted

A newborn exposed in utero to cyclophosphamide during the 1st trimester presented with multiple anomalies (6). The mother, who was being treated for a severe exacerbation of systemic lupus erythematosus, received two IV doses of 200 mg each between 15 and 46 days' gestation. Except for prednisone, 20 mg daily, no other medication was given during the pregnancy. The 3150-g female infant was delivered at 39 weeks' gestational age with multiple abnormalities, including dysmorphic facies: multiple eye defects including bilateral blepharophimosis with left microphthalmos; abnormally shaped, low-

set ears; cleft palate, bilaterally absent thumbs, and dystrophic nails. Borderline microcephaly, hypotonia, and possible developmental delay were observed at 10 months of age.

A 1993 publication reported a 29-year-old woman with twins who was treated for acute lymphocytic leukemia throughout gestation with cyclophosphamide (200 mg/day) and intermittent prednisone (7). Therapy was stopped at 33 weeks' gestation and she delivered 4 weeks later. Both infants recovered from their severe respiratory distress syndromes. The 1250-g female twin has developed normally and is now 22 years of age. Except for strabismus repair at age 9, she has not required any further hospitalizations (7). In contrast, the 1190-g male twin required hospitalization until 10 months of age due to multiple congenital anomalies: dyschondrosteosis (Madelung's deformity) of the right arm, esophageal atresia, abnormal inferior vena cava, abnormal renal collecting system later diagnosed as cross-renal atopia, and a rudimentary left testicle (found later) (7). Chromosomal analysis of the child revealed a normal karyotype (46, XY). Developmental and neurologic problems were diagnosed at about 8 years of age and an IQ test performed at 11 years of age was in the low average range (full scale IQ of 81) with even lower verbal skills (7). At 14 years of age, a stage III neuroblastoma arising from the left adrenal gland was diagnosed and was treated with surgery and radiation. At 16 years of age, metastatic papillary thyroid cancer was found and this was treated with surgery. In addition, three courses of radioactive iodine were administered to treat the primary cancer and two recurrences (7). The authors speculated that the different outcomes in the twins might have been due to differences in metabolism, either by the individual placentas or by the hepatic cytochrome P-450 activity of the fetuses (7). In either case, two cyclophosphamide active metabolites, phosphoramidate mustard and acrolein, may have actually caused the malformations. Moreover, because of the timing of the two malignancies in the boy, the authors also thought it was possible that they were the result of in utero exposure to cyclophosphamide (7).

A 23-year-old woman with hypertension and lupus nephritis received four IV doses of cyclophosphamide (20 mg/kg/dose), three of which were given before conception and one during the 6th week of gestation (8). She delivered a female, 1705-g (<5th percentile) infant at 37 weeks' gestation with Apgar scores of 5 and 7 at 1 and 5 minutes, respectively. The infant's length was 46 cm (5th–10th percentile) and the head circumference 30.2 cm (<5th percentile). Other medications received throughout gestation were prednisone, nifedipine, atenolol, clonidine, potassium chloride, and aspirin. In addition to respiratory

distress syndrome, multiple anomalies were noted, including microbrachycephaly, coronal craniosynostosis, blepharophimosis, shallow orbits, proptosis, hypertelorism, broad, flat nasal bridge, bulbous nasal tip, overfolded small ears, left preauricular pit, microstomia, high-arched palate, micrognathia, hypoplastic thumbs, 5th finger clinodactyly, and absent 4th and 5th toes bilaterally (8). Other malformations were detected in the skeleton and central nervous system during diagnostic workups. Growth delay (<3rd percentile in all growth parameters) and gross motor skills continued to be impaired at age 17.5 months. Based on their comparisons with previous cases of cyclophosphamide-induced congenital defects, the authors concluded that cyclophosphamide was a human teratogen and that a distinct phenotype existed (8).

A case report of a 16-year-old woman with ovarian endodermal sinus tumor presenting in two pregnancies was published in 1979 (19). Conservative surgery, suction curettage to terminate a pregnancy estimated to be at 8–10 weeks' gestation, and chemotherapy with cyclophosphamide, dactinomycin, and vincristine (VAC) produced a complete clinical response for 12 months. The patient then refused further therapy and presented a second time, 6 months later, with tumor recurrence and a pregnancy estimated at 18–20 weeks' gestation. She again refused chemotherapy, but her disease progressed to the point where she allowed VAC chemotherapy to be reinstated 4 weeks later. At 33 weeks' gestation, 2 weeks after her last dose of chemotherapy, she spontaneously delivered a normal 2213-g female infant. The infant was developing normally when last seen at 8 months of age. In a similar case, a woman, treated with surgery and chemotherapy in her 15th week of pregnancy for an ovarian endodermal sinus tumor, delivered a normal 2850-g male infant at 37 weeks' gestation (20). Chemotherapy, begun during the 16th gestational week, included six courses of VAC chemotherapy. The last course was administered 5 days prior to delivery. No information was provided on the subsequent growth and development of the infant.

Following surgical treatment at 16 weeks' gestation, a 28-year-old woman with advanced epithelial ovarian carcinoma was treated with cyclophosphamide, 750 mg/m², and cisplatin, 50 mg/m², every 21 days for seven cycles (21). Labor was induced at 37–38 weeks' gestation resulting in the delivery of a healthy, 3275-g male infant. Height, weight, and head circumference were in the 75th–90th percentiles. No abnormalities of the kidneys, liver, bone marrow, or audiometry-evoked potential were found at birth, and the infant's physical and neurologic growth was normal at 19 months

of age.

Pancytopenia occurred in a 1000-g male infant exposed to cyclophosphamide and five other antineoplastic agents in the 3rd trimester (14). In a similar case, maternal treatment for leukemia was begun at 12.5 weeks' gestation and eventually included cyclophosphamide, five other antineoplastic agents, and whole brain radiation (25). A normally developed, premature female infant was delivered at 31 weeks, who subsequently developed transient severe bone marrow hypoplasia in the neonatal period. The myelosuppression was probably due to mercaptopurine therapy.

In a brief 1997 report, three pregnant women with breast cancer were successfully treated with two or three courses of vinorelbine (20–30 mg/m²) and fluorouracil (500–750 mg/m²) at 24, 28, and 29 weeks' gestation, respectively (33). Delivery occurred at 34, 41, and 37 weeks' gestation, respectively. One patient also required six courses of epidoxorubicin and cyclophosphamide. Her infant developed transient anemia at 21 days of age that resolved spontaneously. No adverse effects were observed in the other two newborns. All three infants were developing normally at about 2–3 years of age (33).

A 1999 report from France described the outcomes of pregnancies in 20 women with breast cancer who were treated with antineoplastic agents (34). The first cycle of chemotherapy occurred at a mean gestational age of 26 weeks, with delivery occurring at a mean 34.7 weeks. A total of 38 cycles were administered during pregnancy with a median of two cycles per woman. None of the women received radiation therapy during pregnancy. The pregnancy outcomes included two spontaneous abortions (SABs) (both exposed in the 1st trimester), one intrauterine death (exposed in the 2nd trimester), and 17 live births, one of whom died at 8 days of age without apparent cause. The 16 surviving children were developing normally at a mean follow-up of 42.3 months (34). Cyclophosphamide (C), in combination with various other agents (doxorubicin [D], epirubicin [E], fluorouracil [F], or mitoxantrone [M]), was administered to 13 of the women at a mean dose of 600 mg/m² (range 300–1200 mg/m²). The outcomes were one SAB (CEF; 1st trimester), one stillbirth (one cycle of CE at 23 weeks' gestation), one neonatal death (one cycle of CEF 32 days before birth), and 11 surviving liveborn infants (one CE, six CEF, two CDF, and two CFM; all in the 3rd trimester). One of the infants, exposed to two cycles of CEF with the last at 25 days before birth, had transient leukopenia and another was growth restricted (1460-g, born at 33 weeks' gestation after two cycles of CFM) (34).

Data from one review indicated that 40% of the patients exposed to anticancer drugs during pregnancy delivered low-birth-weight infants (35). This finding was not related to the timing of exposure. Use of cyclophosphamide in the 2nd and 3rd trimesters does not seem to place the fetus at risk for congenital defects. Except in a few individual cases, long-term studies of growth and mental development in offspring exposed to cyclophosphamide during the 2nd trimester, the period of neuroblast multiplication, have not been conducted (36).

Cyclophosphamide is one of the most common causes of chemotherapy-induced menstrual difficulties and azoospermia (37–45). Permanent secondary amenorrhea with evidence of primary ovarian damage has been observed after long-term (20 months) use of cyclophosphamide (45). In contrast, successful pregnancies have been reported following high-dose therapy (39,40,46–50). Moreover, azoospermia appears to be reversible when the drug is stopped (41–44,51).

One report associated paternal use of cyclophosphamide and three other antineoplastics prior to conception with congenital anomalies in an infant (52). Defects in the infant included syndactyly of the first and second digits of the right foot and tetralogy of Fallot. In a group of men treated over a minimum of 3.5 years with multiple chemotherapy for acute lymphocytic leukemia, one man fathered a normal child whereas a second fathered two children, one with multiple anomalies (53). Any relationship between these outcomes and paternal use of cyclophosphamide is doubtful because of the lack of experimental evidence and confirming reports.

Cyclophosphamide-induced chromosomal abnormalities are also of doubtful clinical significance but have been described in some patients after use of the drug. A study published in 1974 reported chromosome abnormalities in patients treated with cyclophosphamide for rheumatoid arthritis and scleroderma (54). In contrast, chromosomal studies were normal in a mother and infant treated during the 2nd and 3rd trimesters in another report (16). In another case, a 34-year-old woman with acute lymphoblastic leukemia was treated with multiple antineoplastic agents from 22 weeks' gestation until delivery of a healthy female infant 18 weeks later (22). Cyclophosphamide was administered three times between the 26th and 30th weeks of gestation. Chromosomal analysis of the newborn revealed a normal karyotype (46,XX) but with gaps and a ring chromosome. The clinical significance of these findings is unknown, but because these abnormalities may persist for several years, the potential existed for an increased risk of cancer as well as for a risk of genetic damage

in the next generation (22).

The long-term effects of cyclophosphamide on female and male reproductive function have been reported (55,56). In a 1988 publication, 40 women who had been treated with combination chemotherapy for malignant ovarian germ cell tumors (median age at diagnosis 15 years, range 6–29 years) were evaluated approximately 10 years later (median age 25.5 years, range 14–40 years) (55). Cyclophosphamide had been used in 33 (83%) of the women. Menstrual function in these women after chemotherapy was as follows: premenarchal (N = 1), regular menses (N = 27), irregular menses (N = 5), oligomenorrhea (N = 2), amenorrhea (N = 4), and premature menopause (N = 1). Of the 12 women with menstrual difficulties, only 3 of the difficulties were considered serious or persistent. Evaluation of the reproductive status after chemotherapy revealed that 24 had not attempted to become pregnant, 9 had problem-free conceptions, 3 had initial infertility followed by conceptions, and 4 had chronic infertility. Of the 12 women who had conceived on one or more occasions, 1 had an elective abortion at 10 weeks' gestation, and 11 had delivered 22 healthy infants, although 1 had amelogenesis imperfecta.

A study published in 1985 examined 30 men to determine the effect of cyclophosphamide on male hormone levels and spermatogenesis (56). The men had been treated at a mean age of 9.4 years for a mean duration of 280 days. The mean age of the men at the time of the study was 22 years with a mean interval from end of treatment to evaluation of 12.8 years. Four of the men were azoospermic, 9 were oligospermic, and 17 were normospermic. Compared with normal controls, however, the 17 men classified as normospermic had lower ejaculate volumes (3.1 mL vs. 3.3 mL), lower sperm density ($54.5 \times 10^6/\text{mL}$ vs. $79 \times 10^6/\text{mL}$), decreased sperm motility (42% vs. 61%, $p < 0.05$), and less normal sperm forms (61% vs. 70%, $p < 0.05$). Concentrations of testosterone, dehydroepiandrosterone sulfate, and prolactin were not significantly different between patients and controls. One oligospermic man (sperm density $12 \times 10^6/\text{mL}$) had fathered a child.

The effect of occupational exposure to antineoplastic agents on pregnancy outcome was examined in a 1985 case–control study involving 124 nurses in 17 Finnish hospitals compared with 321 matched controls (57). The cases involved nurses working in 1979 and 1980 in hospitals that used at least 100 g of cyclophosphamide (the most commonly administered antineoplastic agent in Finland) per year or at least 200 g of all antineoplastic drugs per year. The average total antineoplastic drug use for all hospitals was 1898 g, but a lower total use, 887 g, occurred for intravenous drugs (58). Moreover, the nurses had

to be 40 years of age or younger in 1980 and had to work in patient areas where antineoplastic agents were mixed and administered (57). The agents were prepared without the use of vertical-airflow biologic-safety hoods or protective clothing (58). Exposure to these agents during the 1st trimester was significantly associated with early fetal loss (odds ratio [OR] 2.30, 95% confidence interval [CI] 1.20–4.39) ($p = 0.01$) (57). Cyclophosphamide, one of four individual antineoplastic agents to which at least 10 women had been exposed, had an OR for fetal loss of 2.66 (95% CI 1.25–5.71). Other significant associations were found for doxorubicin (OR 3.96, 95% CI 1.31–11.97) and vincristine (OR 2.46, 95% CI 1.13–5.37). The association between fluorouracil and fetal loss (OR 1.70, 95% CI 0.55–5.21) was not significant. Based on the results of their study and data from previous studies, the investigators concluded that nursing personnel should exercise caution in handling these agents (57).

Although there is no current consensus on the danger posed to pregnant women from the handling of antineoplastic agents (e.g., the above study generated several letters that questioned the observed association (59–62)), pharmacy and nursing personnel should take precautions to avoid exposure to these potent agents. The National Study Commission on Cytotoxic Exposure published a position statement on this topic in January 1987 (63). Owing to the importance of this issue, the statement is quoted in its entirety below:

“The Handling of Cytotoxic Agents by Women Who Are Pregnant, Attempting to Conceive, or Breast Feeding”

“There are substantial data regarding the mutagenic, teratogenic and abortifacient properties of certain cytotoxic agents both in animals and humans who have received therapeutic doses of these agents. Additionally the scientific literature suggests a possible association of occupational exposure to certain cytotoxic agents during the first trimester of pregnancy with fetal loss or malformation. These data suggest the need for caution when women who are pregnant or attempting to conceive, handle cytotoxic agents. Incidentally, there is no evidence relating male exposure to cytotoxic agents with adverse fetal outcome.

There are no studies which address the possible risk associated with the occupational exposure to cytotoxic agents and the passage of these agents into breast milk. Nevertheless, it is prudent that women who are breast feeding should exercise caution in handling cytotoxic agents.

If all procedures for safe handling, such as those recommended by the

Commission are complied with, the potential for exposure will be minimized.

Personnel should be provided with information to make an individual decision. This information should be provided in written form and it is advisable that a statement of understanding be signed.

It is essential to refer to individual state right-to-know laws to insure compliance.”

BREASTFEEDING SUMMARY

Cyclophosphamide is excreted into breast milk (64). Although the concentrations were not specified, the drug was found in milk up to 6 hours after a single 500-mg IV dose. The mother was not nursing. A brief 1977 correspondence from investigators in New Guinea described neutropenia in a breastfed infant whose mother received weekly injections of 800 mg of cyclophosphamide, 2 mg of vincristine, and 30-mg daily oral doses of prednisolone for 6 weeks (65). Absolute neutropenia was present 9 days after breastfeeding had been stopped, which persisted for at least 12 days (65). Serial determinations of the infant's white cell and neutrophil counts were begun 2 days after the last exposure to breast milk. The lowest measured absolute lymphocyte count was 4750/microL. Except for the neutropenia and a brief episode of diarrhea, no other adverse effects were observed in the infant.

A 1979 report involved a case of an 18-year-old woman with Burkitt's lymphoma diagnosed in the 26th week of gestation (66). She was treated with a 7-day course of cyclophosphamide, 10 mg/kg IV, as a single daily dose (total dose 3.5 g). Six weeks after the last chemotherapy dose, she delivered a normal, 2160-g male infant. Analysis of the newborn's blood counts was not conducted. The tumor recurred in the postpartum period and treatment with cyclophosphamide, 6 mg/kg/day IV, was started 20 days after delivery. Although she was advised not to nurse her infant, she continued to do so until her sudden death after the third dose of cyclophosphamide. Blood counts were conducted on both the mother and the infant during therapy. Immediately prior to the first dose, the infant's leukocyte and platelet counts were 4800/mm³ (abnormally low for age) and 270,000/mm³, respectively. After the third maternal dose, the infant's counts were 3200/mm³ and 47,000/mm³, respectively. Both counts were interpreted by the investigator as signs of cyclophosphamide-induced toxicity. It was concluded that breastfeeding should be stopped during therapy with the agent (66).

The American Academy of Pediatrics classifies cyclophosphamide as a drug that may interfere with cellular metabolism of the nursing infant (67). Because

of the reported cases of neutropenia and thrombocytopenia, and the potential for adverse effects relating to immune suppression, growth, and carcinogenesis, women receiving this drug should not nurse.

CYCLOSERINE

Antituberculosis Agent

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Moderate Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Probably Compatible

PREGNANCY SUMMARY

The limited animal and human pregnancy data prevent a complete assessment of the embryo–fetal risk. The best course is to avoid cycloserine during gestation. However, the drug should not be withheld because of pregnancy if the maternal condition requires the antibiotic.

FETAL RISK SUMMARY

Cycloserine is a broad-spectrum antibiotic used primarily for active pulmonary and extrapulmonary tuberculosis. No teratogenic effects were observed in rats given doses up to 100 mg/kg/day through two generations (1).

The Collaborative Perinatal Project monitored 50,282 mother–child pairs, 3 of whom had 1st trimester exposure to cycloserine (2). No evidence of adverse fetal effects was suggested by the data. The American Thoracic Society recommends avoidance of cycloserine during pregnancy, if possible, due to the lack of information on the fetal effects of the drug (3).

BREASTFEEDING SUMMARY

Cycloserine is excreted into breast milk. Milk concentrations in four lactating women taking 250-mg of the drug four times daily ranged from 6 to 19 mcg/mL, an average of 72% of serum levels (4). Approximately 0.6% of the mother's daily dose was estimated to be in the milk (5). No adverse effects were observed in the nursing infants (4). The American Academy of Pediatrics classifies cycloserine as compatible with breastfeeding (6).

CYCLOSPORINE

Immunologic Agent (Immunosuppressant)

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: Limited Human Data—Potential Toxicity

PREGNANCY SUMMARY

Based on relatively small numbers, the use of cyclosporine during pregnancy apparently does not pose a major risk to the fetus. Cyclosporine is not an animal teratogen (1,2), and the limited experience in women indicates that it is unlikely to be a human teratogen. No pattern of defects has emerged in the few newborns with anomalies. Skeletal defects, other than the single case of osseous malformation, have not been observed. When used as an immunosuppressant, the disease process itself makes these pregnancies high risk and subject to numerous potential problems, of which the most common is growth restriction. This latter problem is probably related to the mother's disease rather than to her drug therapy, but a contribution from cyclosporine and corticosteroids cannot be excluded. Long-term follow-up studies are warranted, however, to detect latent effects, including those in subsequent generations. If cyclosporine is used in pregnancy for the treatment of rheumatoid arthritis or psoriasis, healthcare professionals are encouraged to call the toll-free number (877-311-8972) for information about patient enrollment in the OTIS Rheumatoid Arthritis study.

FETAL RISK SUMMARY

Cyclosporine (cyclosporin A), an antibiotic produced by certain fungi, is used as an immunosuppressive agent to prevent rejection of kidney, liver, or heart allografts. Other indications for the drug are the treatment of severe, active rheumatoid arthritis and severe (i.e., extensive and/or disabling), recalcitrant, plaque psoriasis (1).

In reproduction studies, cyclosporine produced embryo and fetal toxicity only

at maternally toxic dose levels in rats (0.8 times the human transplant dose of 6 mg/kg corrected for BSA) and in rabbits (5.4 times the human dose). Toxic effects included increased pre- and postnatal mortality, and reduced fetal weight and related skeletal restriction. No teratogenic effects were observed (1).

Cyclosporine readily crosses the placenta to the fetus (3–7). In a 1983 study, the cord blood:maternal plasma ratio at delivery was 0.63 (3). In a second study, cord blood and amniotic fluid levels 8 hours after a dose of 325 mg were 57 and 234 ng/mL, respectively (4). Concentrations in the newborn fell to 14 ng/mL at 14 hours and were undetectable (<4 ng/mL) at 7 days. Cord blood:maternal plasma ratios in twins delivered at 35 weeks' gestation were 0.35 and 0.57, respectively (5). A similar ratio of 0.40 was reported in a case delivered at 31 weeks' gestation (6).

Several case reports describing the use of cyclosporine throughout gestation have been published (3–14). Maternal doses ranged between 260 and 550 mg/day (3–5,8,10,11,14). Cases usually involved maternal renal transplantation (3–5,7–13), but one report described a successful pregnancy in a woman after heart transplantation (6), one involved a combined transplant of a kidney and paratropic segmental pancreas in a diabetic woman (11), and one involved a patient with a liver transplant (14). In addition, a report has described a successful pregnancy in a woman with aplastic anemia who was treated with bone marrow transplantation (15). In this case, however, cyclosporine therapy had been stopped prior to conception. Guidelines for counseling heart transplant patients who wish to become pregnant have been published (16).

As of October 1987, the manufacturer had knowledge of 34 pregnancies involving cyclosporine (A. Poploski and D. A. Colasante, personal communication, Sandoz Pharmaceuticals Corporation, 1987) (16). Some of these cases are described above. These pregnancies resulted in six abortions (one after early detection of anencephaly, three elective, and two spontaneous abortions, one at 20 weeks' gestation), one pregnancy still ongoing, and 27 live births. One of the newborns died at age 3 days. Autopsy revealed a complete absence of the corpus callosum.

A 1989 case report described an infant with hypoplasia of the right leg and foot after in utero exposure to cyclosporine (12). The right leg was 2 cm shorter than the left. Hypoplasia of the muscles and subcutaneous tissue of the right leg was also present. The authors proposed a possible mechanism for the defect, which involved cyclosporine inhibition of lymphocytic interleukin-2 release and subsequent interference with the differentiation of osteoclasts (12).

Many of the liveborn infants were growth restricted (4,8,10–14). Birth weights of full-term newborns ranged from 2160 to 3200 g (13,14) (A. Poploski and D.A. Colasante, personal communication, 1987). A 1985 review article observed that growth restriction was common in the offspring of renal transplant patients, occurring in 8%–45% of reported pregnancies (17). Although the specific cause of the diminished growth could not be determined, the most likely processes involved were considered to be maternal hypertension, renal function, and immunosuppressive drugs (17).

Follow-up of children exposed in utero to cyclosporine has been conducted in a few cases (5,11) (A. Poploski and D.A. Colasante, personal communication, 1987). In 15 of 27 surviving neonates, early postnatal development was normal except for one infant with slight growth restriction. Postnatal development of 10 children followed from 1 to 13 months revealed normal physical and mental development. No abnormal renal or liver function has been reported in the exposed newborns (5,11) (A. Poploski and D.A. Colasante, personal communication, 1987).

A 2006 report described 71 pregnancies among 45 women after liver transplantation (2). Tacrolimus and cyclosporine were used in 42 and 29 of the pregnancies, respectively. The outcomes of the pregnancies were live births (29 vs. 21), spontaneous abortions (7 vs. 6), elective abortions (5 vs. 1), molar pregnancy (1 vs. 0), and intrauterine death (0 vs. 1) (all ns). The median gestation and birth weight were 37.5 vs. 37 weeks, and 2660 vs. 2951 g, respectively (all ns). Pregnancies occurring within 1 year of transplantation had the highest incidence of prematurity and lowest birth weight. There were no congenital anomalies observed (2).

Two reviews discussing the treatment of psoriasis, one in 2002 (18) and the other in 2005 (19), considered the use of cyclosporine to be appropriate for the management of severe psoriasis.

BREASTFEEDING SUMMARY

Cyclosporine is excreted into breast milk. In a patient taking 450 mg of cyclosporine/day, milk levels on postpartum days 2, 3, and 4 were 101, 109, and 263 ng/mL, respectively (3). No details were given about the relationship of maternal doses with these levels. In another patient, milk concentrations 22 hours after a dose of 325 mg were 16 ng/mL, whereas maternal blood levels were 52 ng/mL, a milk:plasma ratio of 0.31 (4). A milk:plasma ratio of 0.40 was reported in one study (6) and a ratio of approximately 0.17 was measured in another (7). Breastfeeding was not allowed in any of these studies and has

been actively discouraged by most sources because of concerns for potential toxicity in the nursing infant (13,14,16).

A 2001 study reported the use of cyclosporin in a woman who was breastfeeding (20). The woman had a simultaneous kidney–pancreas transplant 13 months before conception. She was treated before, during, and after pregnancy with cyclosporine (300 mg twice daily), azathioprine (100 mg/day), and prednisone (10 mg/day). At 34 weeks' gestation, she delivered an 1800-g male infant with Apgar scores of 5 and 8 at 1 and 5 minutes, respectively. Mild hyperbilirubinemia, treated with phototherapy, was the infant's only complication. The mother's cyclosporine levels during pregnancy were 75–173 ng/mL (therapeutic range 100–125 ng/mL in whole blood) but were not determined at birth. The cord blood cyclosporine concentration was 67 ng/mL. Breastfeeding was initiated 2 hours after birth and continued exclusively for the first 10.5 months of life. Random cyclosporine levels in the infant's serum were <25 ng/mL at approximately 1, 1.5, 2.5, 4, and 10.5 months of age. Maternal serum cyclosporine levels at approximately 1, 1.5, and 2.5 months were 193, 273, and 123 ng/mL, respectively, and breast milk levels were 160, 286, and 79 ng/mL, respectively. No adverse effects from exposure to cyclosporine were observed in the infant. At 12 months of age, his weight and height were at the 46th and 55th percentile, respectively. The mother has subsequently delivered a second child that was also breastfed (20).

Infant cyclosporine exposure was quantified in five mother–infant pairs in a 2003 report (21). The five mothers had taken cyclosporine throughout pregnancy and continued the drug while nursing their infants. In two cases, the milk:maternal blood ratios were 0.45 and 1.4 (not specified in the other three cases). In the latter case, the infant's dose from milk was about 1% of the therapeutic dose (weight basis). The infant's blood levels were as high as 78% of the corresponding maternal trough concentrations that were in the therapeutic range. Cyclosporine was not detected in the blood of three other infants (not tested in one infant). In the five cases, the estimated infant dose from milk, based on a milk consumption of 150 mL/kg/day, ranged from 0.2% to 2.1% of the mother's weight-adjusted dose. No adverse effects in the infants were observed, but specific immunologic effects were not investigated (21).

The American Academy of Pediatrics classifies cyclosporine as a drug that may interfere with cellular metabolism in the nursing infant (22).

CYCLOTHIAZIDE

[Withdrawn from the market. See 9th edition.]

CYCRIMINE

[Withdrawn from the market. See 8th edition.]

CYPROHEPTADINE

Antihistamine/Antiserotonin

PREGNANCY RECOMMENDATION: Limited Human Data—Animal Data Suggest Low Risk

BREASTFEEDING RECOMMENDATION: No Human Data—Probably Compatible

PREGNANCY SUMMARY

The animal reproduction data and limited human pregnancy experience suggest that cyproheptadine is low risk for structural anomalies. Although reporting bias is evident, preterm birth occurred in three women exposed to the drug during pregnancy. Because preterm birth has been associated with other serotonin antagonists (e.g., selective serotonin reuptake inhibitors), there might be a causal association with cyproheptadine.

FETAL RISK SUMMARY

Cyproheptadine has been used as a serotonin antagonist to prevent habitual abortion in patients with increased serotonin production (1,2). No congenital defects were observed when the drug was used for this purpose.

Reproductive studies in mice, rats, and rabbits with oral or SC doses up to 32 times the maximum recommended human dose found no evidence of impaired fertility or fetal harm (3,4). In contrast, Shepard cited a 1982 study that observed dose-related fetotoxicity characterized by skeletal retardation, hydronephrosis, liver and brain toxicity, and increased mortality in fetuses of rats administered 2–50 mg/kg/day intraperitoneally during organogenesis (5).

Two patients, who were being treated with cyproheptadine for Cushing's syndrome, conceived while taking the drug (6,7). Therapy was stopped at 3 months in one patient but continued throughout gestation in the second. Apparently healthy infants were delivered prematurely (33–34 weeks and 36 weeks) from both mothers. Fatal gastroenteritis developed at 4 months of age in the 33- to 34-week gestational infant who was exposed throughout pregnancy to the drug (6). The use of cyproheptadine to treat a pregnant woman with Cushing's syndrome secondary to bilateral adrenal hyperplasia

was described in a 1990 reference (8). Specific details were not provided on the case, except that the fetus was delivered prematurely at 33 weeks' gestation. In a separate case, a woman with Cushing's was successfully treated with cyproheptadine; 2 years after stopping the drug, she conceived and eventually delivered a healthy male infant (9).

In a surveillance study of Michigan Medicaid recipients involving 229,101 completed pregnancies conducted between 1985 and 1992, 285 newborns had been exposed to cyproheptadine during the 1st trimester (F. Rosa, personal communication, FDA, 1993). A total of 12 (4.2%) major birth defects were observed (12 expected), including (observed/expected) 2/3 cardiovascular defects, 2/0.6 oral clefts, and 2/0.7 hypospadias. Only with the latter two defects is there a suggestion of an association with this drug, but other factors, including the mother's disease, concurrent drug use, and chance, may be involved. No anomalies were observed in three other categories of anomalies (spina bifida, polydactyly, and limb-reduction defects) for which specific data were available.

A woman at 4 weeks' gestation attempted suicide with cyproheptadine (400 mg), diazepam (200 mg), and trimetozine (12,000 mg) (an antianxiety agent that is no longer available) (10). A 2.65-kg male infant was born at 40 weeks' gestation. No congenital abnormalities were noted in the infant.

BREASTFEEDING SUMMARY

No reports describing the use of cyproheptadine during lactation have been located. Chronic use of cyproheptadine will lower serum prolactin levels and it has been used in the management of galactorrhea (11). No studies have been found, however, that evaluated its potential to interfere with the normal lactation process. Because of the increased sensitivity of newborns to antihistamines and the potential for adverse reactions, the manufacturer considers cyproheptadine to be contraindicated in nursing mothers (3).

CYTARABINE

Antineoplastic

PREGNANCY RECOMMENDATION: Human Data Suggest Risk

BREASTFEEDING RECOMMENDATION: Contraindicated

PREGNANCY SUMMARY

The limited human pregnancy experience and the use of combination therapy prevent a complete assessment of the embryo–fetal risk. In addition to the potential for structural anomalies, cytarabine may cause fetal bone marrow suppression.

FETAL RISK SUMMARY

Cytarabine is an antineoplastic agent used in the treatment of various types of leukemia. It is classified as an antimetabolite in the subclass of pyrimidine analogs. Other antineoplastic agents in the subclass are capecitabine, floxuridine, fluorouracil, and gemcitabine.

The drug is teratogenic in the hamster and rat (1). Cytarabine is classified as an antimetabolite in the subclass of pyrimidine analogs. Other antineoplastic agents in the subclass are capecitabine, floxuridine, and gemcitabine.

Normal infants have resulted following in utero exposure to cytarabine during all stages of gestation (2–27). Follow-up of seven infants exposed in utero during the 2nd trimester to cytarabine revealed normal infants at 4–60 months (20,22–26). Two cases of intrauterine fetal death after cytarabine combination treatment have been located (20,23). In one case, maternal treatment for 5 weeks starting at the 15th week of gestation ended in intrauterine death at 20 weeks' gestation of a fetus without abnormalities or leukemic infiltration (20). The second case also involved a woman treated from the 15th week who developed severe pregnancy-induced hypertension at 29 weeks' gestation (23). An apparently normal fetus died 1 week later, most likely as a consequence of the preeclampsia.

Use during the 1st and 2nd trimesters has been associated with congenital and chromosomal abnormalities (21,28–30). One leukemic patient treated during the 2nd trimester elected to have an abortion at 24 weeks' gestation
