Figure 31.1 **A**, Section of a vagina showing dysplasia. The epithelium appears thickened and shows abnormal maturation. Immature hyperchromatic cells occupy the lower two to four layers. The middle and upper thirds of mucosa show evidence of cytoplasmic differentiation with well-defined cellular borders. Nuclei in these areas are enlarged and pleomorphic. Parakeratosis is apparent on the surface. Because immature cells are confined to the lower third of the mucosa, dysplasia is classified as mild (hematoxylin and eosin [H&E] stain, $\times 250$). **B**, Cytologic specimen showing mild dysplasia. Note the sheet of dysplastic cells. Cells show well-defined cytoplasmic borders. Nuclei are enlarged, and the nuclear contour is smooth. Chromatin is uniformly and finely granular. Focal condensations of chromatin (chromocenters) are present in some nuclei. Nucleoli are not present (Pap stain, $\times 1000$). **C**, Section showing severe dysplasia to carcinoma in situ. The entire epithelial thickness is occupied by hyperchromatic dysplastic cells. Marked nuclear variation and mitoses are seen. Because of occasional cells with squamous differentiation (spindle-shaped cells, cells with well-defined cytoplasmic borders) in superficial layers, this lesion is sometimes classified as severe dysplasia. In carcinoma in situ, immature cells replace the full thickness, and there is no evidence of squamous differentiation on the surface (H&E stain, $\times 400$). **D**, Cytologic specimen showing carcinoma in situ. Several isolated immature cells with a high nuclei-to-cytoplasm ratio and poorly defined cytoplasmic borders can be seen. Chromatin is coarsely granular, and no nucleoli are present. In the background are several polymorphonuclear leukocytes and strings of mucus (Pap stain, $\times 1000$). **E**, Section showing invasive squamous carcinoma. Cords and sheets of poorly differentiated tumor cells infiltrate the stroma. Nuclei are pleomorphic and nucleoli are distinct. The mitotic rate is high. Squamous differentiation (keratin pearl formation, single-cell keratinization) was present in other areas of tumor (H&E stain, $\times 200$). **F**, Cytologic specimen showing invasive squamous cell carcinoma. Note aggregate of tumor cells. Cellular boundaries are poorly defined, and nuclear orientation is lacking. Chromatin is irregularly distributed and has areas of clumping and clearing. Note nucleoli in some cells, which were absent in cells of patients with dysplasia and carcinoma in situ (Pap stain, $\times 800$).

Table 31.1 Common Primary Vaginal Cancers

Tumor Type	Predominant Age (Years)	Clinical Correlations
Endodermal sinus tumor (adenocarcinoma)	<2	Extremely rare, α -fetoprotein secretion, often fatal, multimodality therapy
Sarcoma botryoides	<8	Aggressive malignancy, multimodality therapy
Clear cell adenocarcinoma	>14	Associated with intrauterine exposure to diethylstilbestrol
Melanoma	>50	Very rare, poor survival
Squamous cell carcinoma	>50	Most common primary vaginal cancer

Figure 31.2 Eppendorf (*upper*) and Kevorkian (*lower*) punch biopsy instruments.

with their large nuclei, are a common cause of false-positive Pap tests in this age group.

A biopsy is performed with small instruments, such as the Kevorkian or Eppendorf punch biopsy forceps (Fig. 31.2) or similar instruments that are also used for the cervix. Occasionally, it is necessary to use a fine instrument, such as a nerve hook, to provide traction on the vaginal epithelium to obtain a biopsy sample. Most patients experience some discomfort during the biopsy. Local anesthesia is often helpful, although injection of the anesthetic may be as uncomfortable as the biopsy itself. Vaginal neoplasia is often multifocal. Although the process is most often located in the vaginal apex, it can occur anywhere along the vaginal canal, necessitating examination of the vagina in its entirety (Jentschke, 2015).

TREATMENT

There is limited information regarding the natural history of VAIN. The risk of progression to invasive cancer is thought to be low, approximately 9%. Those at highest risk of progression are women with high-risk strains of HPV, those with VAIN-3, cigarette smokers, and immunocompromised women (Gadducci, 2015). Significantly, Aho and colleagues have found that 28% of women undergoing evaluation for VAIN-3 have an underlying invasive carcinoma (Aho, 1991). This has led many to recommend surgical excision rather than destructive procedures for the treatment of VAIN-3.

The principles of managing VAIN are to rule out and prevent invasive disease and preserve vaginal function. As is true for cervical dysplasia, biopsy-proved VAIN-1, particularly those lesions associated with low-risk strains of HPV, can be observed, provided that the woman is compliant with follow-up. VAIN-2 and VAIN-3 are generally treated. Treatment options include CO₂ laser vaporization, topical 5-fluorouracil (5-FU) cream, and wide local excision. The choice of treatment depends largely upon the number of lesions, their location, and the level of concern for possible invasion. Radiation therapy, previously used to treat VAIN-2 and VAIN-3, often leads to scarring and fibrosis and is generally not recommended for the treatment of noninvasive disease. Because of the proximity of the bladder and rectum, cryotherapy is generally not used.

The main advantage of the CO₂ laser is that it vaporizes the abnormal tissue without shortening or narrowing the vagina, thereby preserving vaginal function. Criteria for CO₂ laser vaporization include a lesion that is discrete and easily visible and proof that invasive cancer has been ruled out. The beam is directed colposcopically. Iodine staining of the vagina can help outline those areas requiring therapy. Treatment is occasionally performed on an outpatient basis with a local anesthetic and an analgesic. More frequently, general or regional anesthesia is required. The intensity of therapy is regulated by adjusting the wattage of the laser, most commonly 15 to 20 W carried to a depth of 1.5 to 2 mm. Care must be taken not to apply the laser too deeply because of the proximity of the bladder and bowel, particularly in older women whose vaginal epithelium may be quite thin. The woman will experience a discharge for 1 to 2 weeks after therapy. Healing usually requires a few weeks. The success rates of laser in treating VAIN vary in the literature but are generally in the range of 60% to 85% (Petrilli, 1980). Regular follow-up every 4 months, including a Pap smear and colposcopy, is required during the first year and usually 6 to 12 months thereafter. The primary disadvantages of laser treatment are the lack of a pathologic specimen for evaluation of the adequacy of margins and the fact that the procedure can be tedious and difficult because of the many folds and crevices at the vaginal apex. It is often difficult to obtain a uniform depth of destruction in these areas (Piovano, 2015).

Topical chemotherapy, 5% 5-FU cream, can be self-administered to cover the entire area at risk. It is most often used for widespread multifocal lesions of HPV-associated VAIN-1 or VAIN-2. Half of a vaginal applicator (approximately 5 g) is inserted into the vagina at bedtime for 7 days. Because the cream is irritating, protective ointment such as zinc oxide should be applied to the vulva. If excess leakage occurs, less than half of an applicator should be used. In addition, the treatment should be discontinued before the 7-day course is completed if the woman notes excessive irritation. A cycle of therapy should be repeated in 3 to 4 weeks if intraepithelial neoplasia persists. In some cases, the application of 5-FU is continued for 10 to 14 days, in which case the nontherapy interval is increased to 2 or 3 months. In contrast, many postmenopausal women tolerate only small doses of 5-FU, presumably because of relatively thin vaginal epithelium. In one study, patients used one third of an applicator of 5% 5-FU weekly for 10 weeks. Seventeen of 20 patients with vaginal condyloma were free of disease at 3 months. Three patients received a second cycle, and 16 of 18 were free of disease at 10 to 20 months. Success rates of 80% to 90% for patients

with VAIN after multiple treatment cycles have been reported. The disadvantage of topical therapy with 5-FU cream is related to the high level of motivation required to complete therapy. The 5-FU cream causes exfoliation and erosion of the vaginal mucosa and can be extremely painful. Only a small percentage of patients are able to complete a full course. Thus use of this topical therapy is limited. Imiquimod has been evaluated for the treatment of vaginal intraepithelial neoplasia. Complete regression of neoplasia has been reported in 26% to 100% of patients, whereas 0 to 60% have partial regression. Recurrence of neoplasia was identified in 0 to 37% of the patients. The most commonly reported side effects were local burning and tenderness, although not severe enough to discontinue treatment. Because patients who experience disease partial regression will require less extensive excision, this treatment may prove to be a promising option (de Witte, 2015).

Wide local excision (upper vaginectomy) is the treatment of choice for VAIN-3, especially for lesions occurring at the cuff after hysterectomy. Excision gives the surgeon the ability to excise the specimen to rule out invasion and ascertain margin adequacy. Excision also has a high success rate (84%). Upper vaginectomy, however, can result in vaginal shortening, which can be ameliorated by the use of topical estrogen cream and a vaginal dilator (or frequent intercourse) once healing is complete (Ait Menguellet, 2007).

MALIGNANT DISEASE OF THE VAGINA

SYMPTOMS AND DIAGNOSIS

Primary vaginal cancers usually occur as squamous cell carcinomas in women older than 60 years. To be considered a primary vaginal tumor, the malignancy must arise in the vagina and not involve the external os of the cervix superiorly or the vulva inferiorly. If this occurs, the tumor is classified as cervical or vulvar. Biopsies are mandatory if the cervix is intact in order to rule out primary carcinoma of the cervix. This is also an important therapeutic consideration, insofar as the same management techniques apply to small tumors of the upper third of the vagina and cervical carcinomas. Tumors of the lower third of the vagina are treated similarly to vulvar cancers (see Chapter 32). Table 31.2 lists the staging criteria for vaginal cancers according to the International Federation of Gynecology and Obstetrics (FIGO), which are illustrated in Figure 31.3 (Rajaram, 2015).

Delay in the diagnosis of these cancers frequently occurs, in part due to their rarity. Lack of recognition that abnormal symptoms may be caused by malignancy can also contribute to a delay. The most common symptom of vaginal cancer is abnormal bleeding or discharge. Pain is usually a symptom of an advanced tumor. Urinary frequency is also reported occasionally, particularly in the case of anterior wall tumors, whereas constipation or tenesmus may be reported when the tumors involve the posterior vaginal wall. In general, the longer the delay in diagnosis, the poorer the prognosis and the more difficult the therapy. Vaginal cancer is usually diagnosed by direct biopsy of the tumor mass (see Fig. 31.1, E). Abnormal cytologic findings (see Fig. 31.1, F) may prompt a thorough pelvic examination that will lead to diagnosis of vaginal cancer. It is important during the course of the pelvic examination to inspect and palpate the entire vagina and to rotate the speculum carefully to visualize the entire vagina, because a small tumor may occupy the anterior or posterior vaginal wall.

Table 31.2 International Federation of Gynecology and Obstetrics Staging Classification for Vaginal Cancer

Stage	Characteristics
I	Carcinoma limited to vaginal wall
II	Carcinoma involves subvaginal tissue but has not extended to pelvic wall
III	Carcinoma extends to pelvic wall
IV	Carcinoma extends beyond true pelvis or involves mucosa of bladder or rectum (bullous edema as such does not assign a patient to stage IV)

TUMORS OF THE ADULT VAGINA

SQUAMOUS CELL CARCINOMA

Squamous cell carcinoma is the most common vaginal malignancy and accounts for 90% of primary vaginal cancers. Although reported in women in their 30s, the disease occurs primarily in women older than 60, and 20% are older than 80 years. Most squamous cell carcinomas occur in the upper third of the vagina, but primary tumors in the middle and lower thirds may also occur. Grossly, the tumor appears as a fungating, polypoid, or ulcerating mass, often accompanied by a foul smell and discharge related to secondary infection. Microscopically (see Fig. 31.1, E), the tumor demonstrates the classic findings of an invasive squamous cell carcinoma infiltrating the vaginal epithelium.

Treatment of these tumors is based on the size, vaginal tumor stage, and location of the lesion. Therapy is limited by the proximity of the bladder anteriorly and the rectum posteriorly. It is also influenced by the location of the tumor in the vagina, which determines the area of lymphatic spread (Fig. 31.4).

The lymphatics of the vagina envelop the mucosa and anastomose with lymphatic vessels in the muscularis. Those of the mid to upper vagina communicate superiorly with the lymphatics of the cervix and drain into the pelvic nodes of the obturator and internal and external iliac chains. In contrast, the lymphatics of the distal third of the vagina drain to the inguinal nodes and pelvic nodes, similar to the drainage of the vulva. The posterior wall lymphatics anastomose with the rectal lymphatic system and then to the nodes that drain the rectum, such as the inferior gluteal, sacral, and rectal nodes.

Treatment

Once the diagnosis of vaginal malignancy is established, a thorough bimanual and visual examination documenting the size and location of the tumor and assessment of spread to adjacent structures (submucosa, vaginal sidewall, bladder, rectum) should be performed to determine the clinical stage. Cystoscopy or proctoscopy may be helpful, depending on clinical concern, to rule out bladder or rectal invasion. Distant spread may be evaluated by computed tomography (CT) of the chest, abdomen, and pelvis or positron emission tomography (PET).

Similar to cervical carcinoma, early stage vaginal carcinoma, without lymph node involvement (stage I or II), may be treated with surgery or radiation. Young patients with early stage disease and upper vaginal lesions may be treated with radical upper vaginectomy, parametrectomy, and pelvic lymphadenectomy (Davis, 1991). Radiation therapy is the most frequently used mode of treatment and can be used for early and advanced

Figure 31.3 Staging of vaginal cancer.

disease. Radiation is the most common therapy because most women with vaginal carcinoma are older and have a poorer surgical risk; radiation is highly effective. Pelvic exenteration can be used primarily to treat advanced disease in the absence of lymph node metastasis, but it is usually reserved for patients with localized recurrence after radiation. Cisplatin-based chemotherapy administered concurrently with radiation has been used with increasing frequency for squamous cell carcinomas of the vagina because of the well-documented improvements in outcomes for patients with squamous lesions of the cervix treated in this fashion. Although there have been no randomized prospective trials proving its effectiveness in this disease, the numerous similarities in pathophysiology between squamous lesions of the cervix and vagina would lead to the logical conclusion that concurrent chemotherapy with radiation will have increased efficacy over radiation alone in the treatment of vaginal carcinoma.

Stage I vaginal carcinoma may be treated with brachytherapy alone, without external beam therapy. Grigsby has recommended vaginal brachytherapy using vaginal cylinders, in one or two applications, delivering a dose of 65 to 80 Gy to the entire length of the vagina (Grigsby, 2002). For more advanced lesions, a combination of external beam and brachytherapy is used. External radiation therapy with megavoltage equipment is initially used to shrink the tumor. The size and extent of the

radiation field will be determined by the presence or absence of nodal disease, as determined by the pretreatment PET or CT scan. The whole pelvis is generally treated to a dose of approximately 5040 cGy. This is followed by a local cesium or radium implant placed interstitially with needles or by intracavitary radiation using a vaginal cylinder or tandem and ovoids, if the cervix is still present. The brachytherapy will bring the total dose to between 7000 and 8500 cGy. The prognosis appears to improve if the interval from the end of external therapy to the initiation of brachytherapy is less than 28 days (Gadducci, 2015).

DiSaia and coworkers have reported using a fixed perineal template (Syed-Neblett applicator) to achieve reproducible isodose delivery to a large vaginal tumor volume (DiSaia, 1990). For lesions of the upper vagina after hysterectomy, a laparoscopy may be performed to remove any bowel loops from the vaginal apex. The omentum may be used to provide additional layer of separation of the bowel from the vaginal apex. Paley and associates have reported using a retropubic approach in a small series of six patients to achieve direct visualization of needle placement (Paley, 1998). Treatment is individualized, depending on tumor size and stage. For larger lesions, the dose of the external component of radiation therapy is increased, with a concomitant reduction in the local vaginal component of treatment of the primary tumor. Usually, a total tumor dosage of approximately 7500 cGy

Figure 31.4 Lymphatic drainage of the vagina. Predominant pathways from various parts of the vagina are shown.

is administered. Implants cannot be used in some patients with stage III or IV carcinoma; in such cases, only external therapy can be used, and a central boost is given after an initial 5000-cGy whole-pelvis treatment. Severe complications have been noted if the vaginal dose exceeds 9800 cGy. Kucera and Vavra, in a series of 434 patients treated with irradiation, noted that results were best for low-stage tumors, those in the upper third of the vagina, and when the tumor was well-differentiated (Kucera, 1991). Kirkbride and colleagues have reported that stage, tumor size, and tumor grade are prognostic and that the tumor dose must reach at least 7000 cGy, consistent with other studies (Kirkbride, 1995). Treatment time is also important; as noted by Lee and colleagues, it is preferable to complete the radiation therapy within 9 weeks (Lee, 1994).

Survival

Overall 5-year survival rates for patients with primary carcinoma of the vagina have been reported to be approximately 45%. The stage of the tumor is the most important predictor of prognosis. In one series of 89 patients treated with surgery or irradiation, 5-year survival rates were 82% and 53%, respectively, for stage I and stage II disease. The use of concomitant chemotherapy with radiation can be expected to produce improved survival rates (Creasman, 1998).

CLEAR CELL ADENOCARCINOMA

Clear cell adenocarcinomas in young women have been seen more frequently since 1970 as a result of the association of

Table 31.3 5- and 10-Year Survival Rates for 588 Patients with Clear Cell Adenocarcinoma of the Vagina and Cervix

Stage	5-Year Survival (%)	10-Year Survival (%)
I	91	85
IIA	80	67
IIB	56	47
II (vagina)	82	67
III	37	25
IV	0	0

Modified from Registry Data, University of Chicago; Herbst A; Anderson D. Clear cell adenocarcinoma of the vagina and cervix secondary to intrauterine exposure to diethylstilbestrol. *Semin Surg Oncol.* 1990;6(6):343-346.

many of these cancers with intrauterine exposure to DES (Herbst, 1971). Therapeutic considerations are similar to those for squamous cell carcinoma, taking into account the young age of the patients undergoing therapy. Cervical clear cell adenocarcinomas are treated in the same manner as primary cervical carcinomas. The results of therapy for vaginal and cervical clear cell adenocarcinoma in young women are discussed together in this section. These tumors are also staged according to FIGO classification (see Table 31.2). Most tumors (80%) have been diagnosed as stage I or II. The overall results of therapy, based on the stage of the tumor at the time of treatment, are shown in Table 31.3. The survival rate is related directly to the stage of the tumor, similar to other gynecologic malignancies at these sites.

In general, surgery is the primary treatment modality because of the young age of the patients. For stage I and early stage II tumors, radical hysterectomy with partial or complete vaginectomy, pelvic lymphadenectomy, and reconstruction of the vagina with split-thickness skin grafts has been the most common approach. In most cases, ovarian function is preserved. In addition, efforts have been made to preserve fertility in patients who have small tumors of the vagina by the use of local irradiation of the primary tumor and immediate adjacent tissues to spare the ovaries. Because metastases to regional pelvic nodes can occur, even with small stage I tumors, retroperitoneal lymph node dissections are usually performed before local therapy.

Local excision of the tumor can be performed before irradiation to facilitate local application. Senekjian and associates have noted that the survival of patients with small vaginal tumors treated by local excision and then local irradiation is comparable with that obtained with conventional extensive therapy (Senekjian, 1989). The best candidates are those with tumors smaller than 2 cm in diameter, a predominant tubulocystic pattern (Fig. 31.5, A), and depth of invasion less than 3 mm. After wide local excision, the pelvic nodes are sampled to rule out tumor spread. If these are negative, local irradiation can then be given. Patients treated in this manner have become pregnant. Patients with larger tumors, however, receive full pelvic irradiation, in addition to an intracavitary implant. In a few cases, exenterative surgery has been successfully performed. This procedure is preferably applied to central recurrences that develop after primary irradiation. Local vaginal excision as the sole therapy is not usually adequate for small tumors because the tumor frequently recurs.

Three predominant histologic patterns are found in patients with clear cell adenocarcinoma (see Fig. 31.5). In addition, a number of prognostic factors have been identified. Older patients

Figure 31.5 **A**, Tubulocystic cell pattern. Note hobnail cells extruding into the lumina of tubular structures (H&E stain, $\times 180$). **B**, Solid pattern (H&E stain, $\times 300$). **C**, Papillary pattern (H&E stain, $\times 50$). (**A** and **B**, from Scully RE, Robboy SJ, Herbst AL. Vaginal and cervical abnormalities, including clear cell adenocarcinoma, related to prenatal exposure to stilbestrol. *Ann Clin Lab Sci*. 1974;4[4]:222-233. **C**, from Scully RE, Robboy SJ, Welch WR. Pathology and pathogenesis of diethylstilbestrol-related disorders of the female genital tract. In: Herbst AL, ed. *Intrauterine Exposure to Diethylstilbestrol in the Human*. Washington, DC: American College of Obstetricians and Gynecologists; 1978.)

(>19 years) have been found to have a more favorable prognosis in comparison to younger patients (<15 years). This difference is associated with a more favorable outcome for those with the tubulocystic pattern of clear cell adenocarcinoma, the most frequent histologic pattern found in older patients. In addition, smaller tumor diameter and superficial depth of invasion correlate with improved patient survival. Waggoner and coworkers have shown that patients with clear cell adenocarcinoma and a maternal history of DES use survive longer than those without a maternal history of DES use (Waggoner, 1994). If the regional

pelvic nodes are free of tumor, the prognosis is also more favorable. It is more likely that the regional pelvic lymph nodes will be free of tumor if other factors are favorable.

Clear cell adenocarcinomas can spread locally, as well as via lymphatics and blood vessels. Metastases to regional pelvic nodes are found in approximately one sixth of stage I cases. Spread to regional pelvic nodes becomes more frequent in higher stage tumors. Depending on the location of the tumor recurrence, therapy has consisted of additional radical surgery or extensive radiation in localized pelvic disease and systemic chemotherapy

in cases of metastatic disease. Unfortunately, no single agent or combination of chemotherapeutic agents has emerged as an effective therapy. Prolonged follow-up is necessary for these patients because recurrences have been reported as long as 20 years after primary therapy, particularly in the lungs and supraclavicular areas. Data from the Registry on Hormonal Transplacental Carcinogenesis (Herbst, 1990) indicate that ovarian preservation with concomitant estrogen stimulation does not adversely affect survival in patients with clear cell adenocarcinoma of the vagina.

MALIGNANT MELANOMA

Vaginal melanomas are rare and highly malignant. Only approximately 2% to 3% of primary vaginal cancers are melanomas. The most common presenting symptoms are vaginal discharge, bleeding, and a palpable mass. These lesions appear as darkly pigmented, irregular areas and may be flat, polypoid, or nodular. The average age of affected women is 57 years. Vaginal melanomas tend to metastasize early, via the bloodstream and lymphatics, to the iliac or inguinal nodes, lungs, liver, brain, and bones. Patients with vaginal melanoma have a poorer prognosis than those with vulvar melanoma, in part probably because of delay in diagnosis in comparison with vulvar carcinomas and in part because of their mucosal location, which seems to predispose patients to developing early metastasis (Kirschner, 2013).

Treatment usually consists of surgery with wide excision of the vagina and dissection of the regional nodes (pelvic, inguinal-femoral, or both), depending on the location of the lesion. Improved outcomes have been associated with the removal of all gross disease (Buchanan, 1998). Therapy is usually tailored to the extent of disease. Surgery, radiation, chemotherapy, and immunotherapy have all been described, but no single therapy or combination treatment is uniformly successful.

Local and distant recurrences are common, and the disease is usually fatal. Even with local control, distant failure is common in patients with melanoma. The overall 5-year survival rate is 8.4%, with an overall median survival of 20 months. Prognostic indicators include tumor size, mitotic index, and Breslow tumor thickness. Improved survival has been noted for patients whose tumors had fewer than six mitoses/10 high-power fields (HPF). Van Nostrand and associates have reported a 2-year survival for three of four patients with tumors smaller than 10 cm²—that is, approximately 3 cm in diameter (Van Nostrand, 1994). However, Neven and coworkers have noted that among nine patients, all those with melanomas more than 2 mm thick died or had a recurrence regardless of type of therapy, emphasizing the importance of tumor thickness in melanoma prognosis (Neven, 1994).

VAGINAL ADENOCARCINOMAS ARISING IN ENDOMETRIOSIS

The malignant transformation of extraovarian endometriosis is rare but has been reported with increasing frequency. The reason for this increase is not known. The rectovaginal septum is the most common extragonadal location (Yazbeck, 2005). When these tumors occur in the vagina or rectovaginal septum, the typical clinical presentation is pain, vaginal bleeding, or the presence of a vaginal mass in a woman who has previously

undergone prior extirpative surgery for endometriosis. Risk factors include use of unopposed estrogen and tamoxifen use. The most common histology is endometrioid adenocarcinoma, followed by sarcomas (25%) and other tumors of müllerian differentiation. Treatment usually includes surgery plus radiation or chemotherapy. Leiserowitz and colleagues have reported a relatively favorable prognosis for women with endometriosis-related malignancies, with 70% alive at a mean follow-up of 31 months (2003).

VAGINAL TUMORS OF INFANTS AND CHILDREN

ENDODERMAL SINUS TUMOR (YOLK SAC TUMOR)

Endodermal sinus tumor, a type of adenocarcinoma, is a rare germ cell tumor that usually occurs in the ovary. This tumor secretes α -fetoprotein, which provides a useful tumor marker to monitor patients treated for these neoplasms. Approximately 69 cases of this unusual malignancy originated in the vagina of infants, predominantly those younger than 2 years of age. This tumor is aggressive, and most patients have died (Anderson, 1985). Young and Scully reported on six patients who were free of disease 2 to 9 years after surgery, irradiation, or both, who also received vincristine, actinomycin D, and cyclophosphamide (VAC) chemotherapy (Young, 1984). Copeland and colleagues have reported similar good results with combination chemotherapy and excision (Copeland, 1985). The combination of bleomycin, etoposide, and cisplatin (BEP) has also been used to treat this disease (Tao, 2012).

SARCOMA BOTRYOIDES (EMBRYONAL RHABDOMYOSARCOMA)

Sarcoma botryoides is an uncommon vaginal sarcoma that is usually diagnosed in young girls. Rarely does it occur in a young child older than 8 years, although cases in adolescents have been reported. The most common symptom is abnormal vaginal bleeding, with an occasional mass present at the introitus (Fig. 31.6). The tumor grossly resembles a cluster of grapes forming multiple polypoid masses (Copeland, 1985).

These tumors are believed to begin in the subepithelial layers of the vagina and expand rapidly to fill the vagina. They are often multicentric. Histologically, they have a loose myxomatous stroma with malignant pleomorphic cells and occasional eosinophilic rhabdomyoblasts that often contain characteristic cross-striations (strap cells; Fig. 31.7).

Sarcoma botryoides lesions were treated in the past by radical surgery, such as pelvic exenteration. However, effective control with less radical surgery has been achieved with a multimodality approach consisting of multiagent chemotherapy (VAC) combined with surgery. Radiation therapy has also been used. Andrassy and associates have reported 21 patients with vaginal rhabdomyosarcomas who received chemotherapy (1995). Seven relapsed, five of whom had residual disease after incomplete resection. One had disseminated disease. In 17 patients who received chemotherapy for 8 to 48 weeks, a delayed excision could be performed. Long-term survival data for a large number of patients are not available, but such a combined approach appears to result in effective

Figure 31.6 Sarcoma botryoides protruding through the vaginal introitus. (From Herbst AL. Cancer of the vagina. In: Gusberg SB, Frick HC, eds. *Gynecologic Cancer*. 5th ed. Baltimore: Williams & Wilkins; 1978.)

treatment with less mutilating surgery (Piver, 1988). A multimodality approach, including chemotherapy, was used by Flamant and coworkers in 17 females with rhabdomyosarcoma of the vagina or vulva (Flamant, 1990). At the time of their report, 15 appeared cured; 11 of 12 pubescent females had experienced menses, whereas 2 had successfully conceived and delivered healthy children. This was emphasized in a report

Figure 31.7 Vaginal mucosa with sarcoma botryoides showing condensation of malignant cells under the epithelium (H&E, $\times 100$). Insert, Immunohistochemical stain for desmin illustrating strap cells ($\times 240$). (Courtesy of Dr. A. Montag, University of Chicago.)

from the Intergroup Rhabdomyosarcoma Study by Andrassy and colleagues (1995). They found VAC chemotherapy to be effective for disease confined to the vagina without nodal spread. This therapy was effective without irradiation for disease that was locally resected, suggesting that for these patients, chemotherapy plus surgery can be effective therapy.

PSEUDOSARCOMA BOTRYOIDES

Pseudosarcoma botryoides refers to a rare, benign vaginal polyp that resembles sarcoma botryoides and is found in the vagina of infants and pregnant women. Although large atypical cells may be present microscopically, strap cells are absent. Grossly, these polyps resemble the grapelike appearance of sarcoma botryoides and are therefore called “pseudosarcoma botryoides.” Treatment by local excision is effective (Lin, 1995).

KEY POINTS

- Predisposing factors associated with the development of vaginal intraepithelial neoplasia include infection with HPV, previous radiation therapy to the vagina, immunosuppressive therapy, and HIV infection.
- The tendency of intraepithelial squamous neoplasia to develop anywhere in the lower female genital tract is termed a *field defect* and describes the increased risk of premalignant changes occurring in the cervix, vagina, or vulva.
- Most cases of VAIN occur in the upper third of the vagina.
- VAIN can be treated by excision, laser, 5-FU, or imiquimod. Excision is often used for VAIN-3. Laser treatment is generally used for discrete lesions once invasion has been ruled out, and 5-FU and imiquimod cream are used to treat diffuse, multicentric, low-grade disease.
- The most common primary vaginal malignancy is squamous cell carcinoma (90%).
- Most cancers occurring in the vagina are metastatic.
- Vaginal cancers constitute less than 2% of gynecologic malignancies.
- Tumors of the upper vagina have a lymphatic drainage to the pelvis similar to cervical tumors. Tumors of the lower third of the vagina drain to the pelvic nodes and also to the inguinal nodes, similar to vulvar tumors.
- Radical surgery may be used to treat low-stage tumors, primarily of the upper vagina, in younger patients.
- Radiation therapy is the most frequently used modality for the treatment of squamous cell carcinoma of the vagina. Ideally, at least 7000 to 7500 cGy is administered in less than 9 weeks. Concurrent chemoradiation should strongly be considered.
- The overall 5-year survival rate of patients treated for squamous cell carcinoma of the vagina is approximately 45%.

KEY POINTS—cont'd

- Clear cell adenocarcinoma is often associated with prenatal DES exposure. Prognosis is improved if the patient is older than 19 years, the tumor has a predominant tubulocystic tumor pattern, and the disease is low stage. Those with a positive DES maternal history have a better prognosis.
- Local therapy for small, stage I clear cell adenocarcinoma of the vagina is best considered if the tumor is smaller than 2 cm in diameter, invades less than 3 mm, and is predominantly of the tubulocystic histologic type. Pelvic nodes should be sampled and be free of tumor.
- The overall 5-year survival rate of patients treated for clear cell adenocarcinoma is approximately 80%, partially because of the high proportion of low-stage cases.
- Vaginal melanomas are usually fatal. They occur primarily in patients older than 50 years.
- Endometrioid adenocarcinomas of the vagina may occur through the malignant transformation of endometriosis, often associated with the use of unopposed estrogen or tamoxifen.
- Endodermal sinus tumors occur in children younger than 2 years. They secrete α -fetoprotein and are usually treated by multiagent chemotherapy, followed by surgical excision.
- Sarcoma botryoides occurs primarily in children younger than 8 years. It is treated by a multimodality approach using multiagent chemotherapy with surgical removal and occasionally irradiation.

Neoplastic Diseases of the Uterus Endometrial Hyperplasia, Endometrial Carcinoma, Sarcoma: Diagnosis and Management

Pamela T. Soliman, Karen H. Lu

Endometrial carcinoma is the most common malignancy of the lower female genital tract in the United States. Approximately 54,870 new cases develop in the United States each year, according to 2015 figures from the American Cancer Society. This is approximately two times the frequency of ovarian cancer and more than four times the number of new cases of cervical cancer. Approximately 10,000 deaths occurred annually from uterine cancer, more than for cervical cancer (4100) and fewer than the estimated 14,000 for ovarian cancer. Overall, approximately 3 women in 100 in the United States will develop this disease during their lives.

This chapter reviews the clinical and pathologic features of endometrial hyperplasias and carcinomas, the factors that contribute to the development of these diseases, and the appropriate methods of management. Sarcomas of the uterus and their clinical behavior and therapy are also presented.

EPIDEMIOLOGY

Adenocarcinoma of the endometrium affects women primarily in the perimenopausal and postmenopausal years and is most frequently diagnosed in those between the ages of 50 and 65. However, these cancers can also develop in young women during their reproductive years. Approximately 5% of the cases are diagnosed in women younger than 40 and approximately 10% to 15% in women younger than age 50. Women diagnosed under the age of 50 years are also at risk for having a synchronous ovarian cancer (Soliman, 2004). Figure 32.1 plots a typical age-incidence curve for cancers of the endometrium. The curve rises sharply after age 45 and peaks between 55 and 60; then there is a gradual decrease.

Complex atypical hyperplasia results from increased estrogenic stimulation of the endometrium and is a precursor to endometrioid endometrial cancer. Some endometrial cancers develop without previous hyperplasia. These non-estrogen-related carcinomas including serous histology tend to be poorly differentiated and clinically more aggressive (see the later discussion).

Multiple factors increase the risk of developing endometrial carcinoma (and hyperplasia) (Box 32.1). Obesity

is a strong risk factor for endometrial cancer. Women who are obese (body mass index >30) have a two- to threefold increased risk, and this risk increased with increasing weight (Brinton, 1992). The association is believed to be due in part to increased circulating estrogen levels that result from conversion of androstenedione to estrone in the adipose tissue, decreased sex hormone-binding globulin, and other factors including insulin resistance. Although more historical than clinically relevant, unopposed estrogen stimulation is strongly associated with endometrial cancer, increasing the risk four to eight times for a woman using estrogen alone for menopausal replacement therapy. The risk increases with higher doses of estrogen (>0.625 mg conjugated estrogens), and more prolonged use but can be markedly reduced with the use of progestin (see Chapter 14). Similarly, combination (progestin-containing) oral contraceptives decrease the risk. As noted by Grimes and Economy, combination oral contraceptives protect against endometrial cancer, with most studies showing a relative risk reduction to approximately 0.5. The protection begins after 1 year of use and lasts approximately 15 years after discontinuation. Other conditions leading to long-term estrogen stimulation of the endometrium, including the polycystic ovary syndrome (Stein-Leventhal syndrome) and the much more rare feminizing ovarian tumors, are also associated with increased risk of endometrial carcinoma.

Patients who receive the selective estrogen receptor modulator (SERM) tamoxifen are also at increased risk of developing endometrial carcinoma. In the National Surgical Adjuvant Bowel and Breast B-14 trial examining tamoxifen as adjuvant therapy in women with breast cancer, risk of endometrial cancer was elevated 7.5-fold. This may be an overestimate as the risk of endometrial cancer in the control group was lower than expected. In the National Surgical Adjuvant Bowel and Breast P-1 trial examining tamoxifen as a chemopreventive agent, risk of endometrial cancer was elevated 2.5-fold. Risk increased with duration of use. The majority of endometrial cancers that developed in tamoxifen users were endometrioid histology and low grade and stage. However, high-grade endometrial cancers and sarcomas have also been reported in women taking tamoxifen. Screening strategies including transvaginal ultrasound and

Figure 32.1 Incidence curve for carcinoma of the endometrium by age. (From Elwood JM, Cole P, Rothman KJ, Kaplan SD. Epidemiology of endometrial cancer. *J Natl Cancer Inst.* 1977;59:1055.)

Box 32.1 Endometrial Carcinoma Risk Factors

Increases the Risk

- Unopposed estrogen stimulation
- Unopposed menopausal estrogen (4-8×) replacement therapy
- Menopause after 52 years (2.4×)
- Obesity (2-5×)
- Nulliparity (2-3×)
- Diabetes (2.8×)
- Insulin resistance
- Estrogen secreting ovarian tumors
- Polycystic ovarian syndrome
- Tamoxifen therapy for breast cancer

Diminishes the Risk

- Ovulation
- Progestin therapy
- Combination oral contraceptives
- Menopause before 49 years
- Multiparity

office endometrial sampling have been studied in this cohort. There is a high false-positive rate with transvaginal ultrasonography because tamoxifen causes subendometrial cyst formation, which makes the endometrial stripe appear abnormally thick. Barakat and colleagues performed endometrial Pipelle sampling on a large cohort of women taking tamoxifen. They found very few cancers and concluded that women do not benefit from endometrial screening. Rather women should be counseled that tamoxifen increases the risk of endometrial cancer, and all women on tamoxifen who have irregular vaginal bleeding (if premenopausal) or any vaginal bleeding (if postmenopausal)

should undergo endometrial sampling or dilation and curettage (D&C).

Various other factors increase the risk of endometrial cancer. Nulliparity is associated with a 2-fold increased risk in endometrial cancer. Diabetes increases the risk by 2.8-fold and has been found to be an independent risk factor. Hypertension is often related to obesity and diabetes but is not considered an independent risk factor. Insulin resistance or metabolic syndrome has also been recognized as a risk factor for endometrial cancer (Burzawa, 2011). Regarding racial factors, the incidence of endometrial cancer among white women is approximately twice the rate in black women. However, studies of Hill and coworkers demonstrated that black women tend to develop a much higher percentage of poorly differentiated tumors. The National Cancer Database report by Partridge and colleagues confirmed that patients who are black and have a low income do present at an advanced stage and have a poor survival compared with non-Hispanic whites (Partridge, 1996). The difference in survival between blacks and non-Hispanic whites does not appear to be solely based on access to care issues, and there are likely biologic differences that account for the disparity in survival.

Lynch syndrome, or hereditary nonpolyposis colorectal cancer syndrome (HNPCC), is an autosomal dominant hereditary cancer susceptibility syndrome caused by a germline defect in a DNA mismatch repair gene (MLH1, MSH2, or MSH6). Women with Lynch syndrome have a 40% to 60% lifetime risk for developing endometrial cancer, a 40% to 60% lifetime risk of developing colon cancer, and a 12% lifetime risk of developing ovarian cancer. This contrasts sharply with the general population risk of 3% for endometrial cancer, 5% for colon cancer, and 1.7% risk of ovarian cancer. Endometrial cancers in Lynch syndrome can be of any histology and grade. Broaddus and Lu reported that although most endometrial cancers in women with Lynch syndrome were in the early stage, approximately one fourth were high grade, high stage, or poor histology. Given that there are few longitudinal cohort studies, screening recommendations for gynecologic cancers are based on expert opinion and include annual endometrial biopsy and transvaginal ultrasound to evaluate the ovaries. Schmeler reported on the efficacy of prophylactic hysterectomy and salpingo-oophorectomy to decrease endometrial and ovarian cancer risk. Women with Lynch syndrome should be offered this option after childbearing is complete. Lynch syndrome is likely to account for approximately 2% of all endometrial cancers. Women with endometrial cancer and a family history of colon, endometrial, or ovarian cancer should be referred for genetic evaluation and colonoscopy. In addition, women who have a personal history of both endometrial and colon cancer have a significant risk for Lynch syndrome and should be referred. Although synchronous endometrial and ovarian cancers are fairly common, Soliman and colleagues estimated the risk of Lynch syndrome in this cohort to be less than 10%.

The molecular alterations present in endometrial cancer are well documented and are related to histologic cell type. PTEN mutations are frequently seen in endometrioid endometrial cancer and have also been seen in complex endometrial hyperplasia. Microsatellite instability occurs in approximately 25% to 30% of all endometrial cancers and is the result of either germline mutations in DNA mismatch repair proteins (MLH1, MSH2, or MSH6) or more frequently from the somatic methylation

of the MLH1 promoter. In contrast to endometrioid endometrial cancers, uterine serous carcinomas have a high frequency of p53 mutations. HER-2/neu amplification is seen in 10% to 20% of uterine serous carcinomas and is likely associated with advanced stage and poor prognosis. Future studies will continue to elucidate our understanding of the molecular alterations of endometrial cancer.

ENDOMETRIAL HYPERPLASIA

The normal morphologic changes that occur in the endometrium during the menstrual cycle are reviewed in Chapter 4. Endometrial hyperplasia is believed to result from an excess of estrogen or an excess of estrogen relative to progestin, such as occurs with anovulation. Kurman and Norris introduced terminology that the World Health Organization has adopted to describe endometrial hyperplasias and their premalignant potential. There are two important separate categories: atypical hyperplasia and hyperplasia without atypia. In these categories, two subgroups are recognized: simple hyperplasia and complex hyperplasia (Table 32.1).

SIMPLE HYPERPLASIA

This term defines an endometrium with dilated glands that may contain some outpouching and abundant endometrial stroma (Fig. 32.2). The term *cystic hyperplasia* has been used to

Table 32.1 Classifications of Endometrial Hyperplasias

World Health Organization
Simple hyperplasia
Complex hyperplasia
Atypical simple hyperplasia
Atypical complex hyperplasia

Figure 32.2 Benign simple hyperplasia. (From Kurman RJ, Kaminski PF, Norris HJ. Behavior of endometrial hyperplasia: a long-term study of “untreated” hyperplasias in 170 patients. *Cancer*. 1985;56:403.)

describe dilation of the endometrial glands, which often occurs in a hyperplastic endometrium in a menopausal or postmenopausal woman (cystic atrophy). It is considered to be weakly premalignant.

COMPLEX HYPERPLASIA (WITHOUT ATYPIA)

In this condition, glands are crowded with very little endometrial stroma and a complex gland pattern and out-pouching formations (Fig. 32.3). In traditional terminology, this is a variant of adenomatous hyperplasia with moderate to severe degrees of architectural atypia but with no cytologic atypia. These hyperplasias have a low malignant potential.

COMPLEX ATYPICAL HYPERPLASIA

This term refers to hyperplasias that contain glands with cytologic atypia and are considered premalignant. There is an increase in the nuclear/cytoplasmic ratio with irregularity in the size and shape of the nuclei (Fig. 32.4). Cytologic atypia occurs primarily with complex hyperplasia. Simple hyperplasia with atypia is rarely seen. Complex atypical hyperplasia has the greatest malignant potential.

A study from the Gynecologic Oncology Group highlighted the challenge in making the diagnosis of complex atypical hyperplasia. In this large prospective study, a gynecologic pathologist reviewed cases with a diagnosis of complex hyperplasia with atypia. One third of the cases were confirmed as complex atypical hyperplasia, one third were deemed to be “less than” complex atypical hyperplasia, and one third were considered endometrial cancers. This variability in diagnosis should be considered when determining treatment for these patients.

NATURAL HISTORY

The rate at which endometrial hyperplasia progresses to endometrial carcinoma has not been accurately determined,

Figure 32.3 Complex hyperplasia characterized by crowded back-to-back glands with complex outlines. (From Kurman RJ, Kaminski PF, Norris HJ. Behavior of endometrial hyperplasia: a long-term study of “untreated” hyperplasias in 170 patients. *Cancer*. 1985;56:403.)

as many of the studies have been retrospective. Kurman and associates studied 170 patients with endometrial hyperplasia diagnosed by D&C at least 1 year before hysterectomy (Kurman, 1985). Table 32.2 shows the results of their study. Overall, complex atypical hyperplasias had the highest risk of progression to carcinoma. Simple hyperplasia had a 1% rate of progression to cancer, complex hyperplasia without atypia had a 3% rate of progression to cancer, and complex atypical hyperplasia had a 29% rate of progression to cancer. In addition to possible progression to cancer, 40% of women who undergo hysterectomy for complex atypical hyperplasia have a concurrent endometrial cancer in their hysterectomy specimen. This high rate of cancer suggests that complex atypical hyperplasia may frequently be present with low-grade endometrial cancer and that endometrial sampling may not identify an endometrial cancer when admixed with a complex atypical hyperplasia. Clearly, there is a spectrum of histology that makes a definitive diagnosis of complex atypical

hyperplasia difficult, and the clinician must be aware of this fact when planning management strategies.

DIAGNOSIS AND ENDOMETRIAL SAMPLING

Abnormal vaginal bleeding is the most frequent symptom of endometrial hyperplasia. In younger patients, hyperplasia may develop during anovulatory cycles and may even be detected after prolonged periods of oligomenorrhea or amenorrhea. It can occur at any time during the reproductive years but is most common with abnormal bleeding in the perimenopausal period. Premenopausal women with irregular vaginal bleeding and postmenopausal women with any vaginal bleeding should be evaluated with an office endometrial sampling or a D&C. The office sampling instruments, such as a thin plastic Pipelle, are introduced through the cervical os into the endometrial cavity and can provide very accurate information (see Chapter 10). Many patients tolerate office endometrial sampling without an analgesic agent, but paracervical block can be an effective anesthetic aid, particularly in nulliparous women. Some patients benefit from an oral nonsteroidal antiinflammatory drug taken approximately 30 minutes before biopsy.

Transvaginal ultrasonography has been evaluated as an adjunct for the diagnosis of endometrial hyperplasia and cancer. These studies have been performed in different populations, including asymptomatic postmenopausal women, women taking tamoxifen, and women presenting with postmenopausal bleeding. Langer and associates, in a study of 448 asymptomatic postmenopausal women, found a threshold of 5-mm endometrial thickness had only a 9% predictive value for detecting endometrial abnormalities (Langer, 1997). Its greater use was eliminating the diagnosis of neoplasia for those with thickness less than 5 mm (negative predictive value of 99%). These findings were confirmed in a literature review by Smith-Bindman and colleagues, who found that 96% of women with carcinoma had an abnormal ultrasound scan (endometrial thickness >5 mm). Conversely, 8% of postmenopausal women with an abnormal scan had no histologic abnormality, and the percentage grew to 23% for those on hormone replacement therapy. However, both of these studies were conducted in postmenopausal asymptomatic women.

Cecchini and coworkers performed biopsies on 108 postmenopausal patients on long-term tamoxifen with endometrial

Figure 32.4 Severely atypical hyperplasia (complex) of the endometrium with marked irregularity of nuclei ($\times 720$). (From Welch WR, Scully RE. Precancerous lesions of the endometrium. *Hum Pathol*. 1977;8:503.)

Table 32.2 Endometrial Hyperplasia Follow-up

*A total of 34 patients with simple hyperplasia, 7 with complex hyperplasia and 15 with atypical hyperplasia, had no further therapy.

†Benign proliferation of the glands.

‡Greater crowding of glands, no cytologic atypia present.

thickness greater than 6 mm. One case of hyperplasia and one of carcinoma were found, and most patients had atrophic endometrium. The authors concluded that the false-positive rate of transvaginal ultrasonography in this population was too high to warrant its use as a screening modality, and they recommended using irregular vaginal bleeding as an indication for endometrial sampling (Cecchini, 1996). Similarly, Love and associates found that endometrial thickness is not necessarily a useful guide for biopsy in tamoxifen. In the study by Barakat and colleagues, routine screening with transvaginal ultrasonography was not of value, and they concluded that sampling should be done if the patient experiences bleeding.

In postmenopausal women with any vaginal bleeding, Gull and colleagues found that an endometrial stripe of less than 4 mm had a 100% negative predictive value (Gull, 2000). A finding of endometrial thickness less than 4 mm is a reasonable predictor of lack of endometrial pathology, even in a postmenopausal patient with bleeding. However, persistent vaginal bleeding should lead to endometrial sampling regardless of the ultrasound findings.

Endometrial ablation is sometimes undertaken to control severe uterine bleeding (see Chapter 26). However, pathologic evaluation of the endometrium should be performed before ablation in order to rule out an underlying endometrial hyperplasia or cancer.

MANAGEMENT

The therapy employed for endometrial hyperplasia depends on the patient's age and the degree of atypia. For women with simple hyperplasia or complex hyperplasia without atypia, the risk of developing endometrial cancer is low, 1% and 3%, respectively. A diagnostic D&C can also be therapeutic, and progestins or combination oral contraceptive agents will likely be effective.

For complex atypical hyperplasia, the risk of developing endometrial cancer may be 29%, and, as stated previously, a concurrent endometrial cancer may be present. Women who desire preservation of childbearing function are treated with high-dose progestin therapy, usually megestrol acetate 40 mg three times daily to four times daily. The patient should have long-term follow-up and periodic sampling, the first at 3 months and at least every 6 months thereafter (Fig. 32.5, A). In these patients, the risk factors that led to the development of complex atypical hyperplasia are likely to remain. Therefore once the complex atypical hyperplasia is cleared, consideration should be given to periodic progestin treatment or oral contraception until the patient chooses to attempt pregnancy.

For older patients with complex atypical hyperplasia, the risk of carcinoma may be increased. Kurman and associates studied the uteri of patients after curettage had been performed, and atypical hyperplasia was found in the curettages. In their study, 11% of those younger than age 35, 12% of those 36 to 54, and 28% of those older than age 55 with atypical hyperplasia were found to have carcinoma in their uterus. Thus in older patients with moderate or severe atypical hyperplasia generally a hysterectomy is recommended. In addition, those who fail progestin therapy and especially those with severe cytologic atypia should also be considered for hysterectomy (see Fig. 32.5, B). If hysterectomy is not medically advisable, long-term high-dose progestin therapy can be used (megestrol acetate 160 mg/day or its equivalent depending on the endometrial response). Studies are being performed to evaluate the role of the progesterone containing intrauterine device. Periodic sampling of the endometrium is also performed. Figure

32.5 displays a flowchart guide to the management of endometrial hyperplasia. It is important to emphasize that the diagnoses are not distinct and these proliferative disorders are a continuum from mild abnormalities to malignant change.

ENDOMETRIAL CARCINOMA

SYMPTOMS, SIGNS, AND DIAGNOSIS

Postmenopausal bleeding, abnormal premenopausal bleeding, and perimenopausal bleeding are the primary symptoms of endometrial carcinoma. The diagnosis of endometrial carcinoma is established by histologic examination of the endometrium. Initial diagnosis can frequently be made on an outpatient basis, with an office endometrial biopsy. If endometrial carcinoma is found, endocervical curettage may be performed to rule out invasion of the endocervix. A routine cytologic examination (Pap smear) from the exocervix, which screens for cervical neoplasia, detects endometrial carcinoma in only approximately 50% of the cases.

If adequate outpatient evaluation cannot be obtained or if the diagnosis or cause of the abnormal bleeding is not clear from the tissue obtained, a hysteroscopy and fractional D&C should be performed. The endocervix is first sampled to rule out cervical involvement by endometrial cancer, hysteroscopy is done to visualize the endometrial cavity, and then a complete uterine curettage is performed.

HISTOLOGIC TYPES

The various histologic types are listed in Box 32.2. Figure 32.6 illustrates typical adenocarcinomas of the endometrium and demonstrates varying degrees of differentiation (G1, well differentiated; G2, intermediate differentiation; G3, poorly differentiated). Grading is determined by the percentage of solid components found in the tumor: grade 1 has less than 5% solid components, grade 2 has 6% to 50% solid components, and grade 3 has more than 50% solid components.

Squamous epithelium commonly coexists with the glandular elements of endometrial carcinoma. Previously, the term *adenocanthoma* was used to describe a well-differentiated tumor and *adenosquamous carcinoma* to describe a poorly differentiated carcinoma with squamous elements. More recently, the term *adenocarcinoma with squamous elements* has been used with a description of the degree of differentiation of both the glandular and squamous components. Zaino and colleagues, in a Gynecologic Oncology Group (GOG) study of 456 cases with squamous elements, showed that prognosis was related to the grade of the glandular component and the degree of myometrial invasion. They suggested the term *adenocarcinoma with squamous differentiation*, and this has been generally adopted.

Uterine serous carcinomas are a highly virulent and a less common histologic subtype of endometrial carcinomas (5% to 10%). These tumors histologically resemble papillary serous carcinomas of the ovary (Fig. 32.7). Slomovitz and associates evaluated 129 patients with uterine serous carcinoma (USC) and found a high rate of extrauterine disease even in cases without myometrial invasion (Slomovitz, 2003). They recommended a thorough operative staging (see next section) in all cases of these tumors because of the high risk of extrauterine disease even in cases admixed with other histologic types (endometrial or clear cell).

Figure 32.6 **A**, Well-differentiated adenocarcinoma of the endometrium. The glands are confluent ($\times 130$). **B**, Moderately differentiated adenocarcinoma of the endometrium. The glands are more solid, but some lumens remain ($\times 100$). **C**, Poorly differentiated adenocarcinoma of the endometrium. The epithelium shows solid proliferation with only a rare lumen ($\times 100$). (From Kurman RJ, Norris HJ. Endometrial neoplasia: hyperplasia and carcinoma. In: Blaustein A, ed. *Pathology of the Female Genital Tract*. 2nd ed. New York: Springer-Verlag; 1982.)

Figure 32.7 Serous carcinoma characterized by a complex papillary architecture resembling serous carcinoma of the ovary. (From Kurman RJ. *Blaustein's Pathology of the Female Genital Tract*. 3rd ed. New York: Springer-Verlag; 1987.)

Clear-cell carcinomas of the endometrium are less common (<5%). Histologically, they resemble clear-cell adenocarcinomas of the ovary, cervix, and vagina. Clear-cell tumors tend to develop in postmenopausal women and carry a prognosis much worse than typical endometrial adenocarcinomas. Survival rates of 39% to 55% have been reported, much less than the 65% or better usually recorded for endometrial carcinoma. Abeler and Kjorstad reviewed 97 cases and noted the best prognosis (90%) for those without myometrial invasion. Patients whose tumors had vascular invasion experienced a 15% 5-year survival (Abeler, 1991). Carcangiu and Chambers reviewed 29 cases and found 5-year survival rates for stages I and II of 72% and 59%, respectively (Carcangiu, 1995).

STAGING

In 2009, a revised International Federation of Gynecology and Obstetrics (FIGO) surgical staging classification was introduced (Table 32.3). The surgical staging was modified to better define clinically relevant risk strata based on the FIGO annual report and other supporting publications.

PROGNOSTIC FACTORS

Many variables affect the behavior of endometrial adenocarcinomas. These variables can be conveniently divided into clinical and pathologic factors. The clinical determinants are patient age at diagnosis, race, and clinical tumor stage. The pathologic determinants are tumor grade, histologic type, tumor size, depth of myometrial invasion, microscopic involvement of vascular spaces in the uterus by tumor, and spread of tumor outside the uterus to the retroperitoneal lymph nodes, peritoneal cavity, or uterine adnexa.

CLINICAL FACTORS

Older patients have tumors of a higher stage and grade when compared to younger patients. White patients have a higher

Table 32.3 Revised FIGO Staging for Endometrial Cancer (Adopted 2009)

Stages*	Characteristic
I	Tumor confined to the corpus uteri
IA	No or less than half myometrial invasion
IB	Invasion equal to or more than half of the myometrium
II	Tumor invades cervical stroma but does not extend beyond the uterus†
III	Local or regional spread of the tumor
IIIA	Tumor invades serosa of the corpus uteri or the adnexa‡
IIIB	Vaginal or parametrial involvement‡
IIIC	Metastases to pelvic or paraaortic lymph nodes‡
IIIC1	Positive pelvic nodes
IIIC2	Positive paraaortic lymph nodes with or without positive pelvic lymph nodes
IV	Tumor invades bladder or bowel mucosa, or distant metastasis
IVA*	Tumor invasion of bladder or bowel mucosa
IVB	Distant metastases, including intraabdominal or inguinal lymph nodes

*G1, G2, or G3.

†Endocervical glandular involvement only should be considered as stage I and no longer as stage II.

‡Positive cytology has to be reported separately without changing the stage.

Table 32.4 Carcinoma of the Corpus Uteri: Patients Treated in 1990-1992: Survival by 1988 FIGO Surgical Stage, N = 5562

Stage	5-Year Survival Rate
IA	90.9%
IB	88.2%
IC	81.0%
II	71.6%
III	51.4%
IV	8.9%

Modified from Pecorelli S, Creasman WT, Pettersson F, et al. FIGO annual report on the results of treatment in gynaecological cancer. Milano, Italy. *J Epidemiol Biostat*. 1998;23.

survival rate than black patients, a finding partially explained by higher-stage and higher-grade tumors among black women. In addition, black women are more likely to develop uterine serous cancers. The 10-year survival of 136 black patients in the series of Aziz and coworkers was 40% compared with 72% for 135 white patients.

PATHOLOGIC FACTORS

Tumor stage is a well-recognized prognostic factor for endometrial carcinoma (Table 32.4). Fortunately, most cases are diagnosed in stage I, which provides a favorable prognosis.

The histologic grade of the tumor is a major determinant of prognosis. Endometrial carcinomas are divided into three grades: grade 1, well differentiated; grade 2, intermediate differentiation; and grade 3, poorly differentiated. Figure 32.8 shows the survival of 895 patients studied by the GOG that relates endometrial carcinoma survival to tumor grade and demonstrates the worsening of prognosis with advancing grade.

The histologic type of the endometrial carcinoma (Fig. 32.9) is also related to prognosis, with the best prognosis associated

Figure 32.8 Recurrence-free interval by histologic grade. (Modified from Morrow CP, Bundy BN, Kurman RJ, et al. Relationship between surgical-pathologic risk factors and outcome in clinical stage I and II carcinoma of the endometrium: a Gynecologic Oncology Group study. *Gynecol Oncol.* 1991;40:55.)

with endometrioid adenocarcinomas, as well as better differentiated tumors with or without squamous elements, and secretory carcinomas. Approximately 80% of all endometrial carcinomas fall into the favorable category. Poor prognostic histologic types are serous carcinomas, clear-cell carcinomas, and poorly differentiated carcinomas with or without squamous elements, as previously noted.

The degree of myometrial invasion correlates with the risk of tumor spread outside the uterus, but the higher grade and higher stage tumors in general are more likely to have deep myometrial penetration (Fig. 32.10). The importance of tumor grade and myometrial invasion is also illustrated by a study of their relationship to their spread to the retroperitoneal pelvic and paraaortic lymph nodes. Studies of 142 patients by Schink and colleagues indicate that tumor size is also prognostic. Only 4% of those with tumors 2 cm or less in size had lymph node metastases. The rate increased to 15% for those with tumors greater than 2 cm to 35% when the entire endometrial cavity was involved (Schink, 1991). Table 32.5 summarizes the clinical and pathologic factors affecting outcome in early stage tumors. Peritoneal cytology has been studied as a prognostic factor, and the results are conflicting. In a study of 567 surgical stage I cases, Turner and associates found that positive peritoneal cytology was an independent prognostic factor. In contrast, Grimshaw and coworkers evaluated 322 clinical stage I cases and found that positive peritoneal cytology was an

Figure 32.9 Spread of Endometrial Carcinoma. The major pathways of tumor spread are illustrated (see text).

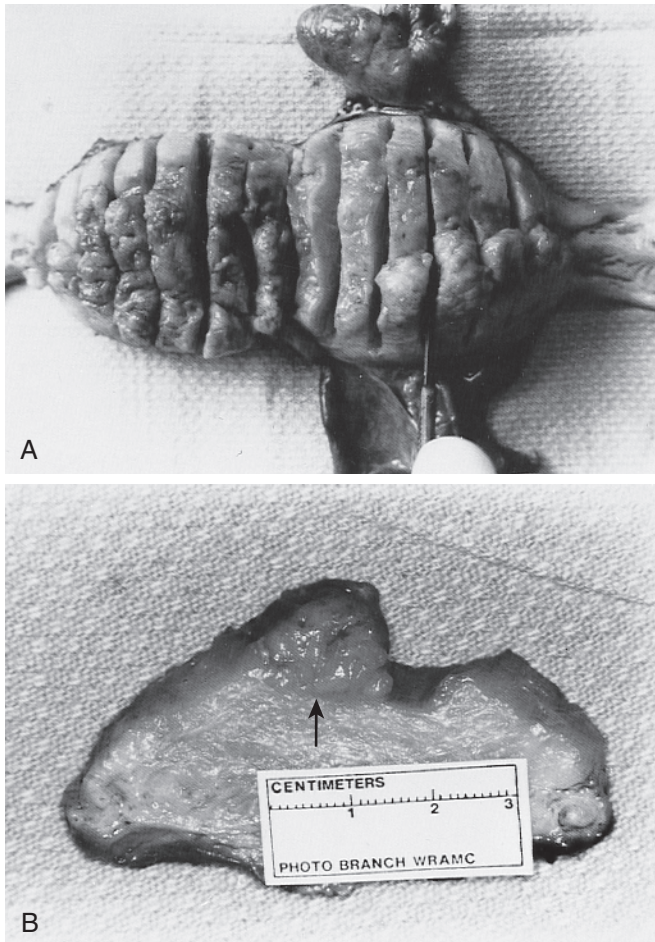

Figure 32.10 **A**, Technique for intraoperative assessment of the depth of myometrial invasion. **B**, Cross section of uterine wall demonstrating superficial myometrial invasion. Arrow shows the tumor-myometrial junction. (From Doering DL, Barnhill DR, Weiser EB, et al. Intraoperative evaluation of depth of myometrial invasion in stage I endometrial adenocarcinoma. *Obstet Gynecol.* 1989;74:930.)

adverse prognostic factor, but they did not find it to be an independent risk factor when other variables were considered. More recently, Kadar and associates and Lurain and colleagues noted that positive peritoneal cytology was associated primarily with adverse features such as extrauterine disease and that therapy (see the following discussion) for positive peritoneal cytology as an isolated finding did not appear to improve survival. In the revised FIGO surgical staging (2009), positive cytology is no longer classified as stage IIIA.

Patterns of Spread of Endometrial Carcinoma

Plentl and Friedman noted four major channels of lymphatic drainage from the uterus that serve as sites for extrauterine spread of tumor: (1) a small lymphatic branch along the round ligament that runs to the inguinal femoral nodes, (2) branches from the tubal and (3) ovarian pedicles (infundibulopelvic ligaments), which are large lymphatics that drain into the paraaortic nodes, and (4) the broad ligament lymphatics that drain directly to the pelvic nodes. The pelvic and paraaortic node drainage sites (2, 3, and 4) are the most important clinically. In addition, direct peritoneal spread of

tumor can occur through the uterine wall or via the lumen of the fallopian tube. Clinically, therefore the clinician must assess the retroperitoneal nodes, the peritoneal cavity, and the uterine adnexa for the spread of endometrial carcinoma (see Fig. 32.9).

Extensive studies by the GOG have elucidated both the frequency of lymph node metastases in endometrial carcinoma and the pathologic factors that modify this risk in stage I disease. Tumor grade, size of the uterus, and degree of myometrial invasion were studied (Creasman, 1999). Table 32.6 illustrates the frequency of lymph node metastases according to uterine size and tumor grade. There are differences in the proportion of positive nodes between stages IB and IA (pre-1988 staging) cases as well as tumor grade. Table 32.7 shows the effects of tumor grade and depth of myometrial invasion. The frequency of nodal involvement becomes much greater with higher-grade tumors and with greater depth of myometrial invasion. The risk of lymph node involvement appears to be negligible for endometrial carcinoma involving only the endometrium. With invasion of the inner third of the myometrium, there is negligible risk of node involvement for grade 1 and 2 cases. If the outer third of the myometrium is involved, the risk of nodal metastases is greatly increased. These data emphasize the importance of myometrial invasion and tumor spread, providing the basis for the FIGO Surgical Staging System. Table 32.8 summarizes the risk of nodal metastases based on the GOG studies published by Creasman and colleagues. In a more recent GOG study cited previously, Morrow and coworkers noted that for patients without metastases at operation, the greatest risk of future recurrence was grade 3 histology. Furthermore, among 48 patients with histologically documented aortic node metastases, 47 were found to have positive pelvic nodes, adnexal metastases, or tumor invasion to the outer one third of the myometrium, emphasizing the poor prognostic aspects of these three findings. Mariani and colleagues at the Mayo Clinic found that tumor size can also be incorporated into a staging paradigm to identify patients at highest risk for nodal spread. They found that in grade 1 and 2 tumors with less than 50% invasion and tumor size less than 2 cm, the risk of lymph node involvement was virtually none (Mariani 2000a).

EVALUATION

In addition to the usual routine preoperative evaluation, the patient should have a chest radiographic examination or a chest and abdominal pelvic computed tomography scan. However, a study by Connor and associates noted that preoperative computed tomography scan had only a 50% positive predictive value for nodal disease. Furthermore, postoperative computed tomography monitoring did not appear to improve survival. The measurement of cancer antigen 125 (CA 125), usually used in cases of ovarian carcinoma, may occasionally be useful. An elevated CA125 preoperatively can often indicate extrauterine disease (Sood, 1997). It may be a particularly useful marker for those with serous carcinoma of the endometrium.

MANAGEMENT

Stage I

Surgery is the primary treatment modality for patients with endometrial carcinoma. Complete surgical staging includes hysterectomy with or without bilateral salpingo-oophorectomy,

and pelvic and paraaortic lymphadenectomy. According to Orr and Chamberlin, the exceptions include women with significant medical comorbidities and young, premenopausal women who desire future fertility with grade 1 endometrial adenocarcinoma associated with endometrial hyperplasia.

Surgical staging allows accurate surgical and histologic assessment of (1) tumor spread within the uterus, (2) degree of penetration into the myometrium, and (3) extrauterine spread to retroperitoneal nodes, adnexa, or the peritoneal cavity. This approach is used for cases that are staged according to the 2009 FIGO system (see Table 32.3).

Minimally invasive surgery in the treatment of early stage endometrial cancer has become standard of care. The GOG published a phase III randomized trial of surgical staging for

Table 32.9 Summary of Randomized Trials of Adjuvant Radiotherapy in Stage I Endometrial Carcinoma

Trial	Surgery	Randomization	Locoregional Recurrences	Survival
Norwegian 1968-1974	TAH-BSO	Brachytherapy vs. brachy and pelvic RT	7% vs. 2% at 5 years, $P < .01$	89% vs. 91% at 5 years, $P = \text{NS}$
PORTEC	TAH-BSO	Obs vs. pelvic RT	14% vs. 4% at 5 years, $P < 0.001$	85% vs. 81% at 5 years, $P = .31$
GOG	TAH-BSO, nodes	Obs vs. pelvic RT	12% vs. 3% at 2 years, $P < .01$	86% vs. 92% at 4 years, $P = .56$

GOG, Gynecologic Oncology Group; PORTEC, Post Operative Radiation Therapy in Endometrial Carcinoma; TAH-BSO, total abdominal hysterectomy-bilateral salpingo-oophorectomy; Obs, Obstetric; RT, radiotherapy.

endometrial carcinoma comparing the laparoscopic approach to the more traditional abdominal approach (Walker, 2009). The pathologic outcomes were the same, and a majority of patients in the laparoscopy arm were able to have the surgery completed. There were some benefits in the minimally invasive arm, including shorter hospital stay and improved quality of life in the postoperative period. Minimally invasive surgery can be used particularly for patients who are incompletely staged at the time of initial operation and require a second staging procedure.

The role of sentinel lymph node (SLN) mapping in the staging of endometrial cancer is currently being defined. The use of SLN could potentially maximize the identification of positive lymph nodes while minimizing the risks of full lymphadenectomy. A number of studies have described SLN detection rates as greater than 80% for any SLN and greater than 50% for bilateral sentinel lymph nodes (Barlin, 2012). Several authors have shown high sensitivity and a high negative predictive value. Although the data are promising, validation studies that require a comprehensive surgical staging are ongoing.

For patients with significant medical comorbidities, radiation therapy alone can be used. However, radiation as the sole method of therapy yields inferior results, as Bickenbach and colleagues noted, with an 87% 5-year survival rate for patients with stage I carcinoma treated by surgery alone, in comparison with a 69% survival rate for those treated with radiation therapy alone. For those who cannot tolerate surgery or external beam therapy, treatment by intracavitary radiation alone offers some benefit. Lehoczy and associates reported on 170 elderly patients treated with brachytherapy alone with uncorrected 5-year survival rates for stages IA and IB of 46% and 30%, respectively. For patients with grade 1 cancers, progesterone therapy could also be considered if patients are not medically fit for surgery or radiation therapy.

Occasionally, morbidly obese patients are encountered for whom an abdominal operation is risky. Sood and coworkers noted that for stage I patients with preoperative CA 125 less than 20 U/mL, the risk of extrauterine disease was only 3%, making vaginal hysterectomy a therapeutic option. Dotters reported CA 125 more than 35 U/mL usually predicted extrauterine disease, although approximately one third of patients needing full operative staging were not identified by an elevated CA 125 for grade 1 or 2 cases, whereas for grade 3, the sensitivity increased to 88%. However, a few false positive cases were noted, making the results a useful guide but not sufficiently precise to be the sole criterion for performing lymphadenectomy.

Stage I, Grade 1

The risk of spread of a grade 1 tumor to pelvic nodes is extremely small (see Table 32.7). At the time of surgery, the abdomen is explored, peritoneal cytology is obtained, and an extrafascial

total abdominal hysterectomy with bilateral salpingo-oophorectomy is performed. Pelvic and paraaortic lymph node dissection should be considered in cases at risk for lymph node involvement. In patients with stage I, grade 1 tumors, postoperative radiation (vaginal brachytherapy or external beam irradiation) may be considered if there is deep myometrial invasion.

Stage I, Grades 2 and 3

Patients considered at risk of lymph node involvement (grade 1/2 tumors greater than 2 cm in size and any grade 3 tumor) should undergo complete surgical staging. Mariani and coworkers reported improved survival in patients at high risk of nodal disease who underwent paraaortic lymphadenectomy in compared with those who did not have this procedure. Use of postoperative irradiation depends on the pathologic findings (Mariani, 2000b).

Three phase III randomized trials evaluating the use of adjuvant radiotherapy in patients with high-risk stage I endometrial cancer have shown no improvement in overall survival (Table 32.9). In a Norwegian study comparing brachytherapy to brachytherapy and pelvic radiation, local recurrences were decreased in the group of patients receiving pelvic radiation. In the Post Operative Radiation Therapy in Endometrial Carcinoma (PORTEC) trial from The Netherlands, Creutzberg and colleagues reported on 714 patients with presumed stage I disease (Creutzberg, 2000). Patients received full pelvic radiotherapy or observation. Although locoregional control was better in the treatment arm, there was no difference in overall survival. In a GOG trial, Keys and associates randomized almost 400 patients who underwent complete surgical staging to whole pelvic radiation versus observation. Similar to the PORTEC trial, there was a decrease in local recurrences in the radiation arm with no difference in overall survival (Keys, 2004).

Stage II

Three therapeutic options have been employed for the treatment of stage II carcinoma of the endometrium that also involves the endocervix: (1) primary operation (radical hysterectomy and pelvic and paraaortic lymph node dissection), (2) primary radiation (intrauterine and vaginal implant and external irradiation) followed by an operation (extrafascial hysterectomy), and (3) simple hysterectomy followed by external beam irradiation.

Radical hysterectomy and pelvic dissection have been used as effective therapy. Mariani and colleagues reported on 57 patients with endocervical involvement at the time of diagnosis (Mariani, 2001). Of these, 61% underwent radical hysterectomy and staging. There were no recurrences in the radical hysterectomy group if their nodes were negative at the time of surgery. Five-year disease-related survival and recurrence-free survival in the radical hysterectomy patients were 76% and 71%.

Another option for patients with stage II carcinoma of the endometrium is treatment with a combination of radiation and extrafascial hysterectomy. A protocol includes external radiation (45 Gy) and a single brachytherapy implant usually followed by extrafascial total abdominal hysterectomy, bilateral salpingo-oophorectomy, and paraaortic node sampling. Podczaski and coworkers noted that those with gross cervical tumor had a poor prognosis and were likely to have extrauterine disease at operation. For patients with cervical involvement on biopsy but no gross tumor, Trimble and Jones found radiation treatment by a single implant alone followed by a hysterectomy to be effective, and they added external therapy depending on the nodal findings and myometrial invasion. Andersen reported on 54 patients with stage II tumors and found a 70.6% survival rate in patients treated by abdominal hysterectomy followed by radiation.

Comparable outcomes have been reported using high-dose-rate brachytherapy approaches in stage I–II patients unable to undergo surgery. Nguyen and coworkers reported a 3-year disease-free survival rate of 85% in 36 stage I patients treated with definitive radiation therapy (Nguyen, 1998). Nineteen patients were considered inoperable due to morbid obesity, and the remainder had significant medical problems precluding anesthesia. All patients were treated as outpatients with five weekly Brach-therapy applications performed under conscious sedation. At a median follow-up of 32 months, the 3-year actuarial uterine-control rate was 88%.

Adjuvant Systemic Therapy for Early Stage Endometrioid Endometrial Cancer

In addition to radiation therapy, adjuvant chemotherapy is being explored for patients with endometrial cancer and high-risk features. Although the addition of postoperative radiation to high-risk patients does reduce the local recurrence rate, distant metastasis continues to be problematic. In approximately 25% of patients with low-stage, grade 3 lesions, the disease will recur at a distant site. In addition, 20% of clinical stage II patients and at least 30% of patients who present with extrauterine disease recur at distant sites even after patients have received adjuvant pelvic radiation.

Adjuvant chemotherapy may also be useful in this group of patients. The Japanese GOG compared pelvic radiation to combination chemotherapy in high-risk early stage patients and found an improvement in both progression-free and overall survival in the chemotherapy arm. A GOG study evaluating the role of vaginal brachytherapy and chemotherapy versus pelvic radiation as adjuvant treatment in patients with high intermediate-risk disease recently completed accrual. Preliminary results show no difference in survival between the two treatment arms.

Stage I or II Uterine Serous Carcinoma

The best treatment for early stage uterine serous cancers is still unknown. Even with minimal disease within the uterus, patients with USC often have extrauterine spread of disease. In a retrospective, multi-institutional study, Huh and associates reported on 60 patients with stage I USC who underwent comprehensive surgical staging. The investigators found that recurrence rates were lower than previously reported and inferred that complete staging may provide a potential benefit. In their study, none of

the seven patients who received chemotherapy had a recurrence. In a multi-institutional retrospective study of early stage USC, Dietrich and colleagues found that the combination of carboplatin and paclitaxel in the adjuvant setting was effective in improving survival and limiting recurrences (Dietrich, 2005).

Combined chemotherapy and radiation therapy may play a role in the management of patients with early stage disease. Turner and associates reported the application of vaginal irradiation at a high-dose rate in combination with chemotherapy in surgical stage I patients. The 5-year survival rate was 94%, which is higher than that of most other studies for patients with stage I disease.

Management of Stage III/IV or Recurrent Endometrial Cancer

Because of the hematogenous and lymphatic spread of endometrial cancer, patients with recurrent or advanced disease often present with tumor outside of the pelvis. Systemic therapy therefore plays an important role in the management of these patients. Both hormonal and cytotoxic agents have activity in patients with advanced or recurrent endometrial cancer. In addition, there continues to be a role of radiation therapy to obtain local control or to treat disease in the pelvis.

In stage III carcinoma, the disease has spread outside the uterus but remains confined to the pelvis or the retroperitoneal nodes. Patients with stage IIIA disease include those with disease spread to the adnexa or the serosa of the uterus. Stage IIIB involves the vagina and stage IIIC includes spread to the retroperitoneal lymph nodes. In the revised FIGO staging, stage IIIC has been further divided into those with positive pelvic nodes only (stage IIIC1) and those with positive paraaortic nodes (stage IIIC2). Stage III accounts for approximately 7% of all endometrial carcinomas and occur in patients who are older than those with lower stage tumors and often medically less able to undergo an operation. Adjuvant treatment is often a combination of tumor-directed radiation and systemic chemotherapy.

Approximately 3% of endometrial carcinomas are stage IV, and many of these patients have tumor metastases outside the pelvis. If possible, optimal surgical debulking has been associated with a prolonged survival. Bristow and coworkers reported that the amount of residual disease after cytoreductive surgery, age, and performance status appear to be important determinants of survival in patients with stage IVB endometrial carcinoma (Bristow, 2000).

Several chemotherapeutic agents or combinations have demonstrated activity in patients with endometrial cancer. Combination therapy is more effective than single-agent therapy in treating this disease. Doxorubicin was one of the first drugs identified with good activity against endometrial cancer. Single-agent doxorubicin has a response rate of approximately 25% with a median duration of response of less than 1 year. Single-agent cisplatin also has demonstrated response rates between 20% and 42% when used as a first-line agent. The duration of response was again very short (3 to 5 months). In several phase II studies, adding cisplatin to doxorubicin resulted in response rates between 45% and 60%. In a GOG randomized phase III study, cisplatin and doxorubicin in combination had a higher response rate compared with single-agent doxorubicin (45% versus 27%), but there was no difference in overall survival. The European Organisation for Research

and Treatment of Cancer (EORTC) performed a similar trial comparing the same two regimens. Again, the combination arm had a higher response rate than doxorubicin alone. In this study, there was a modest survival advantage in those patients who received the combination regimen. The median overall survival in cisplatin- and doxorubicin-treated patients was 9 months compared with 7 months in the patients who received doxorubicin alone ($P = .065$).

Single agent paclitaxel has shown significant activity in chemo-naïve patients with recurrent endometrial cancer with a response rate of 36%. The antitumor effect of single-agent paclitaxel led to the incorporation of paclitaxel into combination therapy regimens. In a phase II study, the combination of cisplatin and paclitaxel demonstrated a 67% response rate. In a phase III study, the GOG found similar activity between the combination of cisplatin and doxorubicin versus doxorubicin and paclitaxel. Following this study, the GOG performed a phase III trial evaluating doxorubicin and cisplatin compared with doxorubicin, cisplatin, and paclitaxel (TAP) with granulocyte-colony-stimulating factor (Miller, 2012). The TAP regimen yielded a superior response rate (57% versus 34%, $P < .001$), longer progression-free survival (8.3 versus 5.3 months, $P < .001$), and longer overall survival (15.3 versus 12.3 months, $P = .037$).

In an attempt to decrease the toxicity related to cisplatin therapy, carboplatin has been investigated. Single-agent carboplatin demonstrates modest activity in chemo-naïve patients with little or no activity in patients pretreated with chemotherapy. In a phase II study, the combination of paclitaxel and carboplatin was evaluated in patients with advanced and recurrent disease. In patients with advanced endometrioid endometrial cancer, there was a 78% response rate to this combination. The median failure-free survival time was 23 months, and the 3-year overall survival rate was 62%. In patients with recurrent disease, the response rate was 56%, and the median failure-free interval was 6 months.

The combination of carboplatin and paclitaxel has a more favorable toxicity profile than TAP. The GOG completed accrual to a phase III randomized, noninferiority study to compare TAP with carboplatin and paclitaxel. The preliminary results showed that paclitaxel and carboplatin were not inferior to TAP in terms of progression-free and overall survival. As a result, paclitaxel and carboplatin are now considered first-line standard of care for advanced and recurrent endometrial cancer.

Prognosis is very poor for patients who fail first-line chemotherapy. The response rates for second- and third-line agents are often less than 10%, and the overall survival is less than 9 months. Paclitaxel may have better activity than other agents in this setting. In patients who have failed previous chemotherapy, paclitaxel has response rates up to 27%. In particular, in a cohort of patients who were refractory to platinum, paclitaxel was shown to have a 22% response rate. Preliminary data suggest that retreatment with a platinum/paclitaxel-based regimen may be effective in patients who previously responded to these agents. Clinical trials and in particular targeted therapies should be considered in women who fail first-line chemotherapy.

For patients with an isolated recurrence in the pelvis, radiotherapy can be useful. Ackerman and coworkers treated 21 patients with pelvic relapse and found radiation achieved pelvic control of disease in 14 (67%) (Ackerman, 1996). The best

results were with recurrences in the vaginal mucosa. Similarly, Sears and colleagues treated 45 patients with vaginal recurrence of endometrial cancer with radiation and achieved a 44% 5-year survival rate (Sears, 1994). Carey and associates salvaged 15 of 17 patients with vaginal recurrence initially treated by operation alone. The addition of chemotherapy at the time of radiation is currently being evaluated. In patients who have had previous irradiation, pelvic exenteration can be considered for those with an isolated central recurrence.

Chemotherapy for Advanced and Recurrent Uterine Serous Carcinoma

The majority of information available for patients with USC is from retrospective, nonrandomized case series. In addition, response rates to therapy often come from subset analysis of studies of all types of advanced or recurrent endometrial cancer, including phase III GOG studies. Levenback and associates reported 20 patients with recurrent or advanced USC treated with cyclophosphamide, doxorubicin, and cisplatin. Fifty-eight percent of the patients were alive without disease after 24 months. However, this regimen was highly toxic. Price and coworkers also evaluated cyclophosphamide, doxorubicin, and cisplatin in 19 patients with advanced disease and 11 patients with recurrent disease. Of the patients treated in the adjuvant setting for advanced disease, 58% were alive without evidence of disease with a median follow-up of 24 months. In the patients with recurrent disease, the response rate was 27%. In addition, all the patients developed treatment-related toxicities.

More favorable results using paclitaxel with and without carboplatin have been demonstrated. In a phase II study evaluating carboplatin and paclitaxel, the response rate was 60% in 20 patients with high-stage USC. The progression-free survival time was 18 months, and the 3-year overall survival rate was 39%. Two of four patients with recurrent USC demonstrated a response to carboplatin and paclitaxel. Zanotti and colleagues evaluated 24 patients with measurable disease (either progressive disease after initial surgery or recurrent disease). There was an 89% response rate in patients treated after initial surgery and a 64% response rate for patients with recurrent disease. At the University of Texas MD Anderson Cancer Center, single-agent paclitaxel demonstrated a 77% response rate in patients with recurrent disease. Despite this activity, the duration of response in these studies is less than 1 year (Ramondetta, 2001). Other agents are under investigation for the treatment of USC.

HORMONE THERAPY

Progestins for Advanced or Recurrent Disease

Since the 1960s, progestational agents have been valuable in the armamentarium against endometrial cancer, particularly in patients with recurrent disease. Progestins are generally well tolerated. Side effects are usually minor and include weight gain, edema, thrombophlebitis, headache, and occasional hypertension. In patients with medical comorbidities, use of hormonal agents may be preferable to cytotoxic chemotherapy. Initial clinical trials in patients with advanced or recurrent endometrial cancer demonstrated response rates of 30% to 50%. Larger studies with more specific response criteria demonstrate more modest response rates, usually between 11% and 24%. Podratz

and colleagues treated 155 patients with advanced or recurrent endometrial cancer with progesterone. The objective response rate was 11%. Overall, survival after initiation of hormone therapy was 40% at 1 year, 19% at 2 years, and 8% at 5 years. In a GOG phase II study, patients who had no previous exposure to chemotherapy or hormonal agents were treated with megestrol acetate (800 mg/day) (Lentz, 1996). The overall response rate was 24%. The progression-free survival and overall survival were 2.5 months and 7.6 months, respectively.

Current recommendations for progestin therapy include oral medroxyprogesterone acetate (Provera), intramuscular medroxyprogesterone acetate (Depo-Provera), and megestrol acetate (Megace). Although there are no randomized studies that have directly compared different formulations of progestins, response rates are similar. In addition, although a dose-response effect of progestin therapy has been reported in breast cancer, there is no evidence of this effect in patients with endometrial cancer. In a randomized trial of oral medroxyprogesterone acetate, patients receiving the low-dose regimen (200 mg/day) had a higher response to therapy than those receiving the high-dose regimen (1000 mg/day).

There are a number of tumor characteristics that increase the likelihood of response to hormone therapy. These include low-grade tumors, the presence of steroid hormone receptors (i.e., progesterone-receptor [PR] and estrogen-receptor [ER]-positive), and a longer disease-free interval. The GOG demonstrated a response rate of 8% in women whose tumors were PR negative and 37% for women whose tumors were PR positive. In addition, there was a 7% response rate in women with ER-negative tumors compared with a 26% response rate in women with ER-positive tumors. Patients with poorly differentiated tumors or hormone-receptor-negative tumors have significantly lower response rates to progestin therapy.

Because of the low toxicity profile and modest efficacy, progestins should be considered in patients with recurrent endometrial cancer. In particular, all patients not eligible for clinical trials with well-differentiated hormone receptor positive recurrent or advanced disease can be given a trial of progestin therapy. If the patient has an objective response, the progestin may be continued indefinitely until there is disease progression.

Selective Estrogen Receptor Modulators and Aromatase Inhibitors

Selective estrogen receptor modulators (SERMs) with antiestrogenic effects in the uterus have been used to treat women with recurrent endometrial cancer. First-generation SERMs such as tamoxifen have mixed estrogenic agonist and antagonist activity. Early response rates for tamoxifen in advanced or recurrent endometrial cancer were between 20% and 36%. However, in a GOG phase II study of tamoxifen given at a dose of 20 mg twice daily, only 10% of patients demonstrated an objective response. Grade 1 and 2 tumors were more likely to respond to tamoxifen than grade 3 tumors.

Short-term administration of tamoxifen can cause an increase in the progesterone receptor levels in postmenopausal women with endometrial cancer. Studies with alternating tamoxifen and progestins have been performed to determine whether this up-regulation increases the response to progestin therapy. Phase II trials of tamoxifen plus alternating cycles of progestin demonstrated a 27% to 33% response rate (Whitney, 2004). The

Eastern Cooperative Oncology Group found no difference in response rates between patients treated with progestin alone and those treated with progestin in combination with tamoxifen (Pandya, 2001).

The U.S. Food and Drug Administration has approved anastrozole, an oral nonsteroidal aromatase inhibitor, for postmenopausal women with progressive breast cancer following tamoxifen therapy. Aromatase is elevated in the stroma of endometrial cancer. In a phase II trial by the GOG, anastrozole was found to have minimal activity (9% response rate) in an unselected population of patients with advanced or recurrent endometrial cancer. More than 25% of the patients in this study had nonendometrioid histologic subtypes, and only 22% of the patients had ER- and PR-positive tumors or demonstrated a response to previous therapy. In the subset of women with FIGO grade 1 and 2 tumors with endometrioid histology, the response rate was 30%.

TARGETED THERAPY

There are a number of molecular aberrations commonly seen in endometrioid adenocarcinomas, the most common being abnormalities in the PTEN/AKT pathway. A number of clinical trials exploiting this pathway have shown promising results in women with recurrent endometrial cancer. Several studies have shown efficacy of mTOR inhibitors including temsirolimus, everolimus, and ridaforolimus in endometrial cancer recurrence (Slomovitz, 2010). In the first-line setting, response rates have been 9% to 24% with clinical benefit rates up to 90%. Combining agents such as everolimus and letrozole have a reported response rate of 31% with a median duration of response of 12.5 months. The GOG has an ongoing study comparing this combination to tamoxifen alternating with Megace, which is considered the standard hormonal regimen.

SARCOMAS

Sarcomas account for less than 5% of uterine malignancies and are much less frequent than endometrial carcinomas, particularly in Western countries. Numerous terms have been used to describe the many histologic types. One useful classification is based on determination of the resemblance of the sarcomatous elements to mesenchymal tissue normally found in the uterus (homologous sarcomas) in contrast to tissues foreign to the uterus (heterologous sarcomas). Homologous types include leiomyosarcoma, endometrial stromal sarcoma (ESS), and, rarely, angiosarcoma. Heterologous types include rhabdomyosarcoma, chondrosarcoma, osteosarcoma, and liposarcoma. These sarcomas may exist exclusively or may be admixed with epithelial adenocarcinoma, in which case the term *carcinosarcoma* (malignant mixed müllerian tumor) is applied. Box 32.3 shows a morphologic classification for uterine sarcomas. A study by Zelmanowicz and colleagues suggests risk factors for these tumors are similar to those of endometrial carcinoma—that is, estrogens and obesity increase the risk and oral contraceptive use decreases the risk. No uniformly defined staging criteria exist for these tumors, and the most widely used definitions are similar to those for endometrial carcinoma: stage I, confined to the corpus; stage II, corpus and cervix involved;

Box 32.3 Modified Classification of Uterine Sarcomas

- I. Pure sarcoma
 - A. Homologous
 - 1. Smooth muscle tumors
 - a. Leiomyosarcoma
 - b. Leiomyoblastoma
 - c. Metastasizing tumors with benign histologic appearance
 - i. Intravenous leiomyomatosis
 - ii. Metastasizing uterine leiomyoma
 - iii. Leiomyomatosis peritonealis disseminata
 - 2. Endometrial stromal sarcomas
 - a. Low grade: endolymphatic stromal myosis
 - b. High grade: endometrial stromal sarcoma
 - B. Heterologous
 - 1. Rhabdomyosarcoma
 - 2. Chondrosarcoma
 - 3. Osteosarcoma
 - 4. Liposarcoma
 - C. Other sarcomas
- II. Carcinosarcoma: malignant mixed müllerian tumors
 - A. Homologous (carcinosarcoma): carcinoma + homologous sarcoma
 - B. Heterologous: carcinoma + heterologous sarcoma
- III. Müllerian adenosarcoma
- IV. Lymphoma

Modified from Clemet P, Scully RE. Pathology of uterine sarcomas. In: Coppleson M, ed. *Gynecologic Oncology*. New York: Churchill Livingstone; 1981:591.

stage III, spread outside the uterus but confined to the pelvis or retroperitoneal lymph nodes; and stage IV, spread outside the true pelvis or into the mucosa of the bladder or rectum. Similar to endometrial adenocarcinoma, operative stage is the most important predictor of survival (Zelmanowicz, 1998).

LEIOMYOSARCOMA

Leiomyosarcomas represent 1% to 2% of uterine malignancies and approximately one third of uterine sarcomas (Fig. 32.11). Although the exact cause is unknown, leiomyosarcomas are not thought to arise from benign leiomyomas. Leibsohn and coworkers noted that among 1423 patients who had hysterectomies for presumed leiomyomas with a uterine size comparable with a 12-week pregnancy or larger, the risk of sarcoma increased with age, from 0.4% for those in their 30s to 1.4% for those in their 50s. The determination of malignancy is made in part by ascertaining the number of mitoses in 10 hpf as well as the presence of cytologic atypia, abnormal mitotic figures, and nuclear pleomorphism (see Fig. 32.11). Vascular invasion and extrauterine spread of tumor are associated with worse prognoses. A finding of more than 5 mitoses per 10 hpf with cytologic atypia leads to a diagnosis of leiomyosarcoma; when there are four or fewer mitoses per 10 hpf, the tumors usually have a more benign clinical course. The prognosis worsens for tumors with more than 10 mitoses per 10 hpf. The presence of bizarre cells may not necessarily establish the diagnosis because they can occasionally be seen in benign leiomyomas and in patients receiving progestational agents. Furthermore, it is important to note that an increase in mitotic

Figure 32.11 Leiomyosarcoma. Nuclear hyperchromatism and mitotic figures are present ($\times 660$). (From Clement PB, Scully RE. Pathology of uterine sarcomas. In: Coppleson M, ed. *Gynecologic Oncology*. Edinburgh: Churchill Livingstone; 1981.)

count in leiomyomas occurs in pregnancy, as well as during oral contraceptive use. This can occasionally cause confusion in the histologic diagnosis.

Usually, the patient has an enlarged pelvic mass, occasionally accompanied by pain or vaginal bleeding. Leiomyosarcomas are suspected if the uterus undergoes rapid enlargement, particularly in patients in the perimenopausal or postmenopausal age group. Approximately 85% of women diagnosed with a leiomyosarcoma have clinical stage I or II disease (i.e., disease that is limited to the uterus and cervix). The risk of lymph node involvement is very low. Primary treatment includes total hysterectomy, bilateral salpingo-oophorectomy, and staging. Despite the low incidence of high-stage disease, approximately 50% of patients will have a recurrence within 2 years. The recurrence in most of these patients is outside the pelvis.

The GOG evaluated the role of adjuvant radiation therapy in patients ($N = 48$) with clinical stage I and II disease (see Table 32.9). There was no difference in the progression-free interval, absolute 2-year survival rate, or site of first recurrence between patients who received pelvic radiation ($N = 11$) and those who did not ($N = 37$). This is not surprising because most recurrences were outside the pelvis (83%). There was recurrence in 48% of the patients, and most of these patients had a recurrence within 17 months of diagnosis. In the adjuvant chemotherapy trial by the GOG, patients treated with Adriamycin had a recurrence less frequently than those in the observation arm (44% versus 61%); however, this difference was not statistically significant. There is no known benefit to adjuvant radiation or chemotherapy in women with leiomyosarcoma limited to the uterus.

Several studies have evaluated treatment of advanced or recurrent leiomyosarcoma. Hannigan and colleagues used vincristine, actinomycin D, and cyclophosphamide (Cytoxan) and noted a 13% complete response rate and 16% partial response rate in 74 patients with advanced metastatic uterine sarcomas. A large collaborative trial was conducted by the GOG and reported by Omura and associates. The best responses were obtained for patients with lung metastases

who received doxorubicin and dacarbazine (DTIC). Current evidence suggests that a multidrug program offers the greatest response for these patients. Cisplatin, Adriamycin, paclitaxel (Taxol), ifosfamide, and etoposide (VP-16) all appear to have some effectiveness. Gemcitabine and docetaxel have been evaluated in a phase II study for patients with recurrent leiomyosarcoma (Hensley, 2002). In this study, 34 patients with leiomyosarcoma were treated. Overall response rate was 53%; however, the duration of response was only 5.6 months. This regimen is used commonly for advanced and recurrent disease. A phase III study completed by the GOG failed to show any additional benefit to the addition of bevacizumab to gemcitabine and docetaxel in the treatment of this disease (Hensley, 2014).

ENDOMETRIAL STROMAL SARCOMA

Overall, stromal tumors comprise approximately 10% of uterine sarcomas. Their behavior correlates primarily with the mitotic rate. Although these tumors were once divided into low grade and high grade, more recently all ESSs are considered low grade. If high-grade elements are present, these tumors would be classified as undifferentiated high-grade sarcomas. Undifferentiated sarcomas have a greater degree of anaplasia and lack the branching vasculature characteristic of ESSs. ESSs have a peak incidence in the fifth decade of life. There is no association with previous radiation nor are risk factors of endometrial carcinoma associated with the development of ESS. Histologically, ESS most resembles proliferative endometrial stroma. Prognosis depends on the extent of disease and ability to remove the entire tumor at the time of surgery. In general, ESSs are indolent, slowly progressing tumors.

Recurrent disease may be diagnosed as many as 30 years after diagnosis. ESS tends to recur locally in the pelvis or peritoneal cavity and frequently spreads to the lungs. In treating metastatic disease, it should be remembered that these tumors contain estrogen and progesterin steroid hormone receptors and are often sensitive to hormone therapy. Complete resolution has been reported with megestrol acetate (Megace), medroxyprogesterone (Provera), letrozole (Femara), tamoxifen, and 17 α -hydroxyprogesterone caproate (Delalutin).

There are reports of radiation in the treatment of pelvic recurrence, with resolution of all residual tumors, but extensive experience with radiation therapy is not available. Systemic chemotherapy with cytotoxic agents has not been reported to be effective, although good responses to doxorubicin (Adriamycin) have been reported.

UNDIFFERENTIATED SARCOMAS

These high-grade tumors behave aggressively and have a poor prognosis. These tumors must be evaluated carefully as they are often confused with other large cell undifferentiated tumors (lymphoma, leukemia, high-grade endometrial cancer, carcinosarcoma).

Microscopically, more than 10 mitoses per 10 hpf are present, and frequently 20 or more mitoses per 10 hpf are present. Some series have reported 100% fatalities, although Vongtama and coworkers reported survival of more than 60% for 24 patients with stage I and 1 patient with stage II disease.

Recurrences are common in the pelvis, lung, and abdomen. If there has not been previous radiation treatment and the recurrence is confined to the pelvis, usually pelvic irradiation is prescribed. If there is disseminated disease, multiple-agent chemotherapy is used.

CARCINOSARCOMA (MALIGNANT MIXED MÜLLERIAN TUMORS)

As shown in Box 32.3, these tumors consist of both carcinoma and sarcoma elements native to the uterus that may resemble the endometrial stroma of smooth muscle (homologous) or of sarcomatous tissues foreign to the uterus (heterologous). Spanos and colleagues reviewed 188 patients with mixed mesodermal tumor and found both the prognosis and the pattern of survival to be similar for both homologous and heterologous tumors. The study of George and coworkers showed that patients with these tumors had a markedly worse prognosis than patients with high-grade endometrial carcinomas. Unlike patients with endometrial stromal sarcoma or leiomyosarcoma, those with carcinosarcoma tend to be older and primarily postmenopausal, usually beyond the age of 62 years. Previous pelvic irradiation has been identified as an occasional predisposing factor and was experienced by 17 of the 136 patients reviewed by Norris and Taylor. The heterologous and homologous tumors occur with approximately equivalent frequency. These tumors can spread locally into the myometrium and pelvis, or distally to the abdominal cavity, lungs, and pleura, a pattern similar to the spread of endometrial carcinoma.

A common symptom is postmenopausal bleeding, often accompanied by an enlarged uterus. Occasionally, the diagnosis is made in tissue removed with D&C, and the tumor may appear to be a polypoid excrescence from the cervix; diagnosis may be made also by vaginal ultrasound examination.

As is true for other sarcomas, the primary treatment is surgical removal of the uterus. The extent of the tumor and the depth of myometrial invasion are important prognostic factors. Those with deep myometrial invasion are more likely to have spread to pelvic or paraaortic nodes. Patients with tumors confined to the uterus and little or no myometrial spread have the best prognosis. A comprehensive surgical staging procedure is recommended for all patients with this diagnosis. Nielsen and coworkers reported a 5-year survival rate of 58% for these patients when the disease was confined to the uterus.

In a phase I/II study of ifosfamide and cisplatin as adjuvant therapy in patients with high-stage carcinosarcoma, the GOG found this combination to be tolerable (Sutton, 2000). Progression-free and overall survival rates at 2 years were 69% and 82%, respectively. This study lacked appropriate controls, so the impact of this regimen on improving survival could not be evaluated. For patients with advanced or recurrent disease, the GOG evaluated ifosfamide versus ifosfamide and cisplatin in a phase III randomized study (Sutton, 2005). The response rate to the combination therapy was superior (54% versus 36%); however, the toxicity was significantly higher. In addition, no significant difference in overall survival was seen. A follow-up study compared ifosfamide to ifosfamide and paclitaxel in a phase III randomized study. Response rates in the combination

arm were superior (45% versus 29%), but importantly there was a significant difference in overall survival (13 months versus 8 months) (Homesley, 2006). Finally, a phase II study showed efficacy of paclitaxel and carboplatin in women with advanced or recurrent carcinosarcoma with an overall response rate of 54% using this well-tolerated regimen (Powell, 2010). Paclitaxel and carboplatin are the current standard treatments for women with carcinosarcoma.

MÜLLERIAN ADENOSARCOMA

Müllerian adenosarcoma is a rare low-grade malignancy composed of both a sarcomatous stroma (homologous) and a proliferation of benign glandular elements that are intimately associated. It occurs predominantly in women older than 60 years. Total abdominal hysterectomy with bilateral salpingo-oophorectomy is the treatment of choice. Mitotic index and sarcomatous overgrowth are related to prognosis.

KEY POINTS

- Endometrial carcinoma is the most common malignancy of the female genital tract. In the United States, the lifetime risk of endometrial cancer is 3%.
- Most women who develop endometrial cancer are between 50 and 65 years of age.
- Women with Lynch syndrome (hereditary nonpolyposis colorectal cancer syndrome) have a 40% to 60% lifetime risk of endometrial cancer, which is similar to their lifetime risk of colon cancer.
- Chronic unopposed estrogen stimulation of the endometrium leads to endometrial hyperplasia and in some cases adenocarcinoma. Other important predisposing factors include obesity, nulliparity, late menopause, and diabetes.
- The risk of a woman developing endometrial carcinoma increases three times if her body mass index is greater than 30 kg/m².
- Tamoxifen use increases the risk of endometrial neoplasia two- to threefold.
- The primary symptom of endometrial carcinoma is postmenopausal bleeding. Women with abnormal bleeding should undergo an endometrial sampling to rule out endometrial pathology.
- Cytologic atypia in endometrial hyperplasia is the most important factor in determining malignant potential.
- Simple hyperplasia will develop into endometrial cancer in 1% of patients, whereas complex hyperplasia will develop into cancer in 29% of patients.
- Studies have found that there is a 40% concurrent rate of endometrial cancer in patients with a preoperative diagnosis of complex atypical hyperplasia.
- Prognosis in endometrial carcinoma is related to tumor grade, tumor stage, histologic type, and degree of myometrial invasion.
- Older patients with atypical hyperplasia are at increased risk of malignant progression compared with younger patients.
- A key determinant of the risk of nodal spread of endometrial carcinoma is depth of myometrial invasion, which is often related to tumor grade.
- Well-differentiated (grade 1) endometrial carcinomas usually express steroid hormone receptors, whereas poorly differentiated (grade 3) tumors usually do not express receptors.
- Uterine serous carcinoma is an aggressive histologic subtype associated with metastatic disease even in the absence of myometrial invasion.
- Ninety percent of recurrences of adenocarcinoma of the endometrium occur within 5 years.
- Overall survival rates for patients with adenocarcinoma of the endometrium by stage are as follows: stage I, 86%; stage II, 66%; stage III, 44%; stage IV, 16% (overall there is a 72.7% 5-year survival rate combining clinical and operative staging systems).
- Histologic variants of endometrial carcinoma with a poor prognosis include uterine serous carcinoma and clear-cell carcinoma.
- Patients with uterine serous or clear-cell carcinoma of the endometrium should have a full staging laparotomy similar to that for ovarian carcinoma.
- The most frequent sites of distant metastasis of adenocarcinoma of the endometrium are the lung, retroperitoneal nodes, and abdomen.
- Primary treatment of endometrial cancer includes hysterectomy, bilateral salpingo-oophorectomy, pelvic cytology, bilateral pelvic and paraaortic lymphadenectomy, and resection of all disease. The exceptions include young premenopausal women with stage I and grade 1 endometrial carcinoma associated with endometrial hyperplasia, and women with increased risk of mortality secondary to medical comorbidities.
- Postoperative adjuvant radiation has not been shown to improve overall survival.
- Patients with high-stage or recurrent disease should be treated in a multimodality approach including chemotherapy, radiation, or hormone therapy.
- Uterine sarcomas make up less than 5% of uterine malignancies.
- Uterine sarcomas are treated primarily by operation including removal of the uterus, tubes, and ovaries.
- Endometrial stromal sarcomas are low-grade sarcomas with an indolent course.
- Multiagent chemotherapeutic regimens are usually prescribed for metastatic sarcomas; complete responses are rare and usually temporary.

Neoplastic Diseases of the Ovary Screening, Benign and Malignant Epithelial and Germ Cell Neoplasms, Sex-Cord Stromal Tumors

Robert L. Coleman, Pedro T. Ramirez, David M. Gershenson

Ovarian cancer is the second most common malignancy of the lower part of the female genital tract, occurring less frequently than cancers of the endometrium but more frequently than cancers of the cervix. However, it is the most frequent cause of death from gynecologic neoplasms in the United States. Cancer Statistics 2015 has reported that approximately 21,290 new cases of ovarian cancer will be diagnosed yearly in the United States, and there will be 14,180 deaths. A major contributing factor to the high death rate from the relatively few cases stems from the frequent detection of the disease after metastatic spread when symptoms direct clinical investigation or raise clinical concern. Surprisingly, most women diagnosed with ovarian cancer do report symptoms for months before diagnosis. As detailed later, only the severity and duration of symptoms differentially segregate cancer patients from noncancer patients. The incidence of ovarian cancer (Fig. 33.1) increases with age, becoming most marked beyond 50 years, with a gradual increase continuing to age 70 years followed by a decrease for those older than 80. Moreover, Yancik and associates noted that those older than 65

are more likely to have their cancers diagnosed at an advanced stage, leading to a worse prognosis and poorer survival compared with those younger than 65 years.

Despite numerous epidemiologic investigations, a clear-cut cause of ovarian cancer has not been defined. A number of theories have been advanced. It is thought that these malignancies are related to frequent ovulation, and therefore women who ovulate regularly appear to be at higher risk. Included are those with a late menopause, history of nulliparity, or late childbearing. Conversely, women who have had several pregnancies or who have used oral contraceptives appear to have some protection against ovarian cancer. Casagrande and colleagues related the development of ovarian cancer to ovulatory age—that is, the number of years during which the woman has ovulated. This number would be reduced by pregnancy, breast-feeding, or oral contraceptive use. Schildkraut and associates correlated overexpression of mutant p53 protein in ovarian cancers with reproductive histories and found that overexpression was more likely in those who had high ovulatory cycle histories. In addition, talcum powder used on the perineum has been postulated to increase the risk but, as noted by Cramer and coworkers, it is a weak association. The use of oral contraceptives decreases the risk by approximately 50% after 5 years of use (approximately 10% to 12%/year). The protection increases with duration of use to 10 years and appears to last for approximately 15 years after discontinuation of use. Schlesselman has calculated a decrease of 369 ovarian cancer cases/100,000 women for 8 years of use. Given that the approximate occurrence of ovarian cancer cases in this group would be expected to be 1400, such a decrease approximates 25%. Breast-feeding, pregnancy, tubal ligation, and, to a lesser extent, hysterectomy with ovarian preservation also lower the risk of ovarian cancer. It has been suggested that ovulation-inducing drugs such as clomiphene citrate increase the risk of ovarian cancer, as noted by Whittemore and colleagues. Rossing and coworkers reported an increase in risk from a population-based study that suggested that the risk is associated with prolonged use of clomiphene insofar as no association was noted with less than 1 year of use. The study was significant but had wide 95% confidence limits, and only 11 cancer cases occurred in the clomiphene group among 3837 women studied in the infertility clinic. However, Venn and

Figure 33.1 Ovarian cancer incidence rates by age, 1973 to 1982. (From Yancik R, Ries LG, Yates JW. Ovarian cancer in the elderly: an analysis of Surveillance, Epidemiology, and End Results Program data. *Am J Obstet Gynecol.* 1986;154[3]:639-647.)

associates from Australia have not demonstrated an increase in ovarian cancer for those using fertility drugs for in vitro fertilization. Mahdavi and colleagues assembled a review of cohort and case-control studies evaluating the relationship of fertility agents to ovarian cancer. In this report, little evidence supported the hypothesis that ovulation induction substantially increases cancer risk. Furthermore, a large population-based Danish cohort study also failed to demonstrate any increased risk of ovarian cancer among 54,362 women seeking consultation relating to fertility problems. Agents evaluated in this study were gonadotropins, clomiphene citrate, human chorionic gonadotropin, and gonadotropin-releasing hormone. Additionally, no associations were found between these agents and the number of cycles of use, parity, or length of follow-up. However, three reports specifically evaluating the association of these agents and the development of borderline tumor or low malignant potential tumors have suggested that a relationship may exist. The frequent presence of hormone receptors in these lesions, as well as the hyperestrogenic microenvironment, may support this observation.

Cramer and coworkers found women with ovarian cancer to have a diet high in animal fat in compared with control subjects, and studies of Risch and associates suggested that saturated fat increases the risk of ovarian cancer, whereas vegetable fiber may reduce it. Table 33.1 shows the various factors that alter the risk of ovarian cancer. The familial or inherited aspects of the disease are considered subsequently.

There are geographic and racial differences in the distribution of ovarian cancers. These cancers occur most frequently in industrialized and affluent countries such as the United States and Western Europe and less frequently in Asia and Africa. The disease is more frequent among white than black women. Finally, patients with ovarian carcinoma have an increased risk of developing breast and endometrial cancer. Notwithstanding the familial syndromes, major factors appear to be related to the frequency of ovulation and residence in an industrialized country.

FAMILIAL OVARIAN CANCER

In a case-control study, Hartge and colleagues showed that a familial history of breast cancer and a personal history of breast cancer are ovarian cancer risk factors. Lynch and associates reported on families with these hereditary ovarian cancers and

noted that they tend to occur at a younger age than in the general population. It appears that germline mutations of the *BRCA* tumor suppressor gene on chromosome 17q are responsible for a large proportion of hereditary cancers (discussed later). However, these are a small proportion of all ovarian carcinomas. Risk alteration in these patients through oral contraceptive use is of uncertain impact. Narod and coworkers suggested that it might be possible to reduce incident risk by their administration. However, Modan and colleagues conducted a case-control study of Jewish women in whom *BRCA* founder mutational analysis was performed; they evaluated the risk of cancer development based by parity and oral contraceptive use. They were able to establish a protective effect by oral contraceptive use in the cohort, but subanalysis by carrier status demonstrated no effect in those harboring a *BRCA* founder mutation (odds ratio [OR], 1.07; 95% confidence interval [CI], 0.63-1.83). Further studies are needed.

Hereditary ovarian cancers are uncommon, accounting for approximately 10% to 15% of all incident cases. However, identification of affected or unaffected women with significant familial risk is important, given their accelerated risk of ovarian and other cancers. In addition, these patients are frequently diagnosed at a younger age (median, 50 years), and unaffected individuals are able to consider prophylactic procedures that can affect their lifetime risk. The term *familial ovarian cancer* denotes an inherited trait that predisposes to ovarian cancer development. It has been widely studied and two definitions are important:

- 1. A first-degree relative is a mother, sister, or daughter of an affected individual.
- 2. A second-degree relative is a maternal or paternal aunt or grandmother.

As noted in the review by Kerlikowske and colleagues, previous studies suggested an increase from approximately 1.5% to 5% in the lifetime risk of ovarian cancer with one first-degree relative; with two or more, the risk reaches may exceed 7% to 12%. Because contemporary family size may preclude disease penetrance, careful attention to *BRCA*-associated cancers in either gender should be performed in a multigenerational history. Furthermore, the high association of fallopian tube cancer and underlying *BRCA* mutation has prompted some to call for routine *BRCA* testing in all such cases.

Most ovarian cancers develop sporadically. For the woman with a familial history of ovarian cancer (not the dominant genetic hereditary type), periodic surveillance with transvaginal ultrasonography 6 months after the age of 35 years has been suggested (see the ultrasonography discussion presented later in this chapter). Unfortunately, such a strategy has not been shown to be worthwhile or cost effective in disease prevention and may, on occasion, lead to additional tests or unnecessary procedures when a questionable ultrasound result is. The use of prophylactic oophorectomy in patients whose mothers had ovarian cancer has been a controversial topic. Kerlikowske and colleagues and Herbst have provided reasons opposing the widespread use of this practice. However, the use of prophylactic oophorectomy to reduce the risk of ovarian or peritoneal cancer in mutation carriers may have validity. Finch and associates studied 1828 women enrolled in an international registry over an 11-year period ending in 2003. In this cohort, 575 (30%) had undergone oophorectomy before enrollment, 490 (27%) underwent the procedure after

Table 33.1 Putative Associations of Increasing and Decreasing Risks of Ovarian Epithelial Carcinoma

study entry, and 783 (43%) did not undergo the procedure. After a median follow-up of 3.5 years, 50 incident cases were identified, 18 in women undergoing oophorectomy and 32 in women with intact ovaries. The protective effect was 80% (hazard ratio [HR], 0.2; 95% CI, 0.02-0.58; $P = .003$). It is reasonable that for patients with a significant family history in whom an operation such as hysterectomy is required, removal of both tubes and ovaries at the time of operation is appropriate. Similarly, mutation carriers who have finished childbearing may reduce their subsequent cancer risk by salpingo-oophorectomy. The recommendation for hysterectomy at this time is controversial but has been advocated by some to ensure complete removal of the fallopian tube (cornual segment). The woman must be aware that peritoneal carcinomatosis, a process resembling serous carcinoma of the ovary, can develop (rarely) despite the removal of both ovaries.

Because evidence has suggested a significant proportion of ovarian carcinomas arise for preinvasive intraepithelial carcinomas in the fallopian tube, interest in a two-step approach to removal of the adnexa has arisen. Preserving ovarian function in high-risk women while mitigating risk via removal of the fallopian tubes has appeal for maintaining quality of life and avoidance of the risks from premature castration. Nevertheless, much is unknown regarding the efficacy and safety of this approach, including how strong is the risk mitigation and to what degree does retaining the ovary increase risk of breast cancer in these at-risk women. Finally, the timing for oophorectomy is unknown. Fortunately, several prospective clinical trials are under way to address this novel approach to risk reduction surgery (Daly, 2015).

The following describes the classification and histology of the major ovarian neoplasms. Pertinent microscopic findings, clinical behavior, and appropriate therapy are presented.

CLASSIFICATION OF OVARIAN NEOPLASMS

The most widely used classification of ovarian neoplasms is that of the World Health Organization (WHO). This classification, along with frequency of occurrence of the primary ovarian neoplasms, is shown in Table 33.2.

Epithelial stromal tumors (common epithelial tumors) are the most frequent ovarian neoplasms. They are believed to arise

Table 33.2 World Health Organization Classification: Frequency of Ovarian Neoplasms

Class	Approximate Frequency (%)
Epithelial stromal (common epithelial) tumors	65
Germ cell tumors	20-25
Sex cord-stromal tumors	6
Lipid (lipoid) cell tumors	<0.1
Gonadoblastoma	<0.1
Soft tissue tumors (not specific to ovary)	
Unclassified tumors	
Secondary (metastatic) tumors	
Tumor-like conditions (not true neoplasm)	

from the surface (coelomic) epithelium. Germ cell tumors are the second most frequent and are the most common among young women. Histologically, they may be composed of extraembryonic elements or may have features that resemble any or all of the three embryonic layers (ectoderm, mesoderm, or endoderm). Germ cell tumors are the main cause of ovarian malignancy in young women, particularly those in their teens and early 20s. Sex cord-stromal tumors are the third most frequent and contain elements that recapitulate the constituents of the ovary or testis. These tumors may secrete sex steroid hormones or may be hormonally inactive. Lipid (lipoid) cell tumors are extremely rare and histologically resemble the adrenal gland. Gonadoblastomas consist of germ cells and sex cord-stromal elements. They occur in individuals with dysgenetic gonads, particularly when a Y chromosome is present. All these ovarian neoplasms are discussed later in this chapter.

Soft tissue tumors not specific to the ovary, such as a hemangioma or lipoma, are extremely rare and are categorized according to the criteria for soft tissue tumors arising elsewhere in the body. Unclassified tumors, as the name implies, cannot be placed in any of the preceding categories. One example is small cell carcinoma, which is a highly virulent cancer affecting primarily young women (discussed later). Metastatic tumors to the ovary may arise elsewhere in the reproductive tract or from distant sites such as the bowel or stomach (Krukenberg tumors). Tumor-like conditions refer to enlargements of the ovary, such as extensive edema, pregnancy luteoma, endometriomas, and follicular or luteal cysts, none of which are true neoplasms. With the exceptions of metastatic tumors and small cell carcinoma of the ovary, none of these are considered further in this chapter.

EPITHELIAL OVARIAN NEOPLASMS

According to Scully, two thirds of ovarian neoplasms are epithelial tumors; malignant epithelial tumors account for approximately 85% of ovarian cancers, probably arising from inclusion cysts lined with surface (coelomic) epithelium within the adjacent ovarian stroma. Table 33.3 summarizes the five cell types that most commonly constitute epithelial ovarian tumors, indicating their relative frequency.

Epithelial tumors can be categorized as benign (adenoma), malignant (adenocarcinoma), or of an intermediate form, known as borderline tumor or tumor of low malignant potential. The term *papillary* or the prefix *cyst-* (as in cystadenoma) is used when the tumor has, respectively, papillae or cystic

Table 33.3 Epithelial Ovarian Tumor Cell Types

Cell Type	APPROXIMATE FREQUENCY (%)	
	All Ovarian Neoplasms	Ovarian Cancers
Serous	20-50	35-40
Mucinous	15-25	6-10
Endometrioid	5	15-25
Clear cell (mesonephroid)	<5	5
Brenner	2-3	Rare

Modified from Scully RE. Tumors of the ovary and maldeveloped gonads. In Scully RE. *Atlas of Tumor Pathology*. Fascicle 16. Series 2. Washington, DC: Armed Forces Institute of Pathology; 1979.

Figure 33.2 **A**, Ciliated epithelium of a well-differentiated serous tumor ($\times 800$). **B**, Serous papillary cystadenoma of borderline malignancy. The epithelium resembles that of the fallopian tube, and a well-developed papillary pattern is present ($\times 80$). **C**, Serous papillary adenocarcinoma ($\times 50$). The neoplastic epithelium invades the stroma. (**A** and **C**, From Serov SF, Scully RE, Sobin LH. *Histologic Typing of Ovarian Tumors*. Geneva: World Health Organization; 1973. **B**, Courtesy of Dr. R. E. Scully.)

structures. The suffix *-fibroma* (as in adenofibroma) is added when the ovarian stroma predominates, with the exception of a Brenner tumor, which normally contains a large amount of ovarian stroma.

Low-grade (formerly well-differentiated) serous tumors (Fig. 33.2, **A** and **B**) consist of ciliated epithelial cells that resemble those of the fallopian tube. Serous tumors (Fig. 33.2, **C**) are the most frequent ovarian epithelial tumors. The malignant forms account for 40% or more of ovarian cancers, benign forms (serous cystadenomas) occur primarily during the reproductive years, borderline tumors occur in women 30 to 50 years of age, and carcinomas typically occur in women older than 40 years. Molecular investigation of genetic changes associated with low-grade serous tumors support the reclassification of serous ovarian cancers into low- or high-grade binaries. Currently, a popular theory hypothesizes that high-grade serous carcinoma may arise from fallopian tube epithelium.

Mucinous tumors (Fig. 33.3, **A** and **B**) consist of epithelial cells filled with mucin; most are benign. These cells resemble cells of the endocervix or may mimic intestinal cells, which

can pose a problem in the differential diagnosis of tumors that appear to originate from the ovary or intestine. Benign mucinous tumors are found primarily during the reproductive years, and mucinous carcinomas (Fig. 33.3, **C**) usually occur in those in the 30- to 60-year age range. Overall, they can account for approximately 25% of ovarian tumors and as many as 10% of ovarian cancers.

Endometrioid tumors (Fig. 33.4), as the name implies, consist of epithelial cells resembling those of the endometrium. In the ovary, these neoplasms are less frequent (approximately 5%) than serous or mucinous tumors, but the malignant variety accounts for approximately 20% of ovarian carcinomas. Endometrioid carcinomas usually occur in women in their 40s and 50s. They may be seen in conjunction with endometriosis and ovarian endometriomas, although an origin from endometriosis is rarely demonstrated. Most endometrioid carcinomas arise directly from the surface epithelium of the ovary, as do the other epithelial tumors.

Clear cell tumors (mesonephromas) contain cells with abundant glycogen (Fig. 33.5, **A**) and so-called *hobnail cells* (Fig. 33.5, **B**),

Figure 33.3 **A**, Mucinous cystadenoma ($\times 800$). **B**, Mucinous borderline tumor. Epithelium resembles that of the endocervix. **C**, Mucinous carcinoma ($\times 120$). Incomplete stratification of cells, and atypicity is present. (**A** and **C**, From Serov SF, Scully RE, Sobin LH. *Histologic Typing of Ovarian Tumors*. Geneva: World Health Organization; 1973. **B**, Courtesy of Dr. R. E. Scully.)

Figure 33.4 Endometrioid carcinoma. Tubular glands are lined by stratified endometrium ($\times 80$). (Courtesy of Dr. R.E. Scully.)

in which the nuclei of the cells protrude into the glandular lumen. Tumors with identical histologic features are found in the endometrium, cervix, and vagina, the latter two often associated with intrauterine diethylstilbestrol (DES) exposure. Molecular evaluation of these tumors suggests a homology to similar

pathology occurring in the kidney, which may have therapeutic implications. Clear cell ovarian tumors are not related to DES exposure and comprise approximately 5% of ovarian cancers. They occur primarily in women 40 to 70 years of age and are highly aggressive.

The major cell types of ovarian epithelial tumors recapitulate the müllerian duct–derived epithelium of the female reproductive system (serous-endosalpinx, mucinous-endocervix, endometrioid-endometrium). This differentiation occurs even though the ovary is not derived directly from the müllerian ducts (see [Chapter 2](#)). The clear cell tumors also mimic this müllerian tendency, frequently being admixed with endometrioid carcinomas and with ovarian endometriomas.

Brenner tumors ([Fig. 33.6](#)) consist of cells that resemble the transitional epithelium of the bladder and Walthard nests of the ovary. There is abundant stroma. These tumors constitute only 2% to 3% of all ovarian tumors.

In addition to the cell types shown in [Table 33.3](#), epithelial tumors may be classified as undifferentiated if the tumor consists of poorly differentiated epithelial cells that are not characteristic of any particular cell type. They may be considered unclassifiable if they cannot be placed in any of the categories shown in this table.

Figure 33.5 A, Clear cell adenocarcinoma ($\times 200$). A solid pattern of abundant polyhedral tumor cells containing abundant clear cytoplasm is present. B, Clear cell adenocarcinoma ($\times 200$). Left: Hobnail cells with scant cytoplasm; protruding nuclei line shows tubules. Right: Cysts lined by flattened tumor cells. (A, From Barlow JF, Scully RE. “Mesonephroma” of ovary: tumor of müllerian nature related to the endometrioid carcinoma. *Cancer*. 1967;20[9]:1405-1417. B, Courtesy of Dr. R.E. Scully.)

Figure 33.6 Brenner tumor ($\times 350$). Note the nest of transition-like epithelium containing spaces with eosinophilic material. (From Scully RE. *Atlas of Tumor Pathology*, fascicle 16, series 2. Washington, DC: Armed Forces Institute of Pathology; 1979.)

Many epithelial ovarian tumors can be bilateral, and the risk of bilaterality is an important consideration in therapy, particularly when an ovarian tumor is discovered in a young woman of reproductive age. Widely varying percentages have been reported for bilaterality in ovarian tumors; the most widely quoted are summarized in Table 33.4. Malignant epithelial tumors tend to involve both ovaries more frequently than benign epithelial tumors. Serous tumors also tend to be bilateral more frequently than mucinous tumors.

BENIGN EPITHELIAL OVARIAN TUMORS: THE ADNEXAL MASS

As noted in Chapter 7, enlargement of the ovary beyond 5 cm is considered abnormal. However, age and menstrual status must

Table 33.4 Bilaterality of Ovarian Tumors

Type of Tumor	Occurrence (%)
Epithelial Tumors	
Serous cystadenoma	10
Serous cystadenocarcinoma	33-66
Mucinous cystadenoma	5
Mucinous cystadenocarcinoma	10-20
Endometrioid carcinoma	13-30
Benign Brenner tumor	6
Germ Cell Tumors	
Benign cystic teratoma (dermoid)	12
Immature teratoma (malignant)	2-5
Dysgerminoma	5-10
Other malignant germ cell tumors	Rare
Sex Cord-Stromal Tumors	
Thecoma	Rare
Sertoli-Leydig cell tumor	Rare
Granulosa-theca cell tumor	Rare

also be considered before the appropriate course of action is chosen. A 5- to 8-cm ovarian mass in a woman with regular menses, even if she is in her 40s, is frequently a functioning ovarian cyst, such as a follicular or corpus luteum cyst. It will usually regress spontaneously during a subsequent menstrual cycle. Enlargements of this type in young patients in their 20s or early 30s do not automatically require immediate operative intervention and can be observed for two menstrual cycles. A potential exception would be a mass in a woman who is taking oral contraceptives. Because the principal mechanism of contraception is anovulation, the index of suspicion for neoplastic growth should be raised. However, contemporary oral contraceptives have lower sex steroid levels and may permit follicular development. Careful observation or immediate evaluation (discussed earlier) is warranted. Shushan and colleagues reported on ovarian cysts detected by ultrasonography in pre- and postmenopausal women

taking tamoxifen for breast cancer. Unilocular 5- to 8-cm cysts are likely to be functional (see [Chapter 18](#)), whereas multilocular or partially solid tumors are more likely to be neoplastic. After the age of 40, the risk of malignancy rises. The ovary shrinks during menopause and is approximately 1.5 to 2 cm in size. A transvaginal ultrasound scan can reliably detect an ovary larger than 1 cm in diameter. Higgins and associates estimated the upper limit of the volume of a postmenopausal ovary to be approximately 8 cm³ compared with 18 cm³ for the premenopausal ovary. Ten of their patients who exceeded these criteria and had solid or complex echo patterns had neoplastic tumors, and one carcinoma was discovered. An ultrasound examination, preferably with a vaginal probe, helps differentiate these adnexal masses (discussed later).

Occasionally, it is discovered that the adnexal mass is paraovarian. In a study of 168 paraovarian tumors, Stein and coworkers noted that only three (2%) were malignant. The three cysts all had solid components; the cysts were 8 to 12 cm size in patients 19 to 48 years of age.

Adnexal Mass and Ovarian Cancer

Cancer antigen 125 (CA-125) was described by Bast and colleagues in the 1980s. It is expressed by approximately 80% of ovarian epithelial carcinomas but less frequently by mucinous tumors. The marker is increased in endometrial and tubal carcinoma, in addition to ovarian carcinoma, and in other malignancies, including those originating in the lung, breast, and pancreas. A level higher than 35 U/mL is generally considered to be increased. [Box 33.1](#) lists some of the benign conditions for which the CA-125 level also has frequently been found to be increased.

As can be seen, many of these are frequently found in women of childbearing age. This lack of specificity must be remembered when one is interpreting increased CA-125 levels in younger women with adnexal masses or when screening is being considered (discussed later). In addition, there are rare individuals who have no disease but are found to have levels of CA-125 as high as 200 to 300 U/mL as a consequence of developing idiopathic antibodies to mouse IgG.

One must also be cautious in the interpretation of an increased CA-125 level, particularly in a premenopausal woman with an adnexal mass. The specificity appears to be better for increased

values in the postmenopausal woman. In a study of 182 patients, [Vasilev and coworkers \(1988\)](#) have noted that the CA-125 level is increased in 22% of cases of benign masses, but for postmenopausal patients an increased level usually indicates malignancy. This was also shown in the CA-125 vaginal ultrasound study of 290 postmenopausal patients by Maggino and colleagues.

In addition to CA125 and transvaginal ultrasound, other biomarkers have been evaluated for their ability to preoperatively discriminate between benign disease and cancer. Currently, one test, OVA1, has been approved to aid this decision by providing a probability estimate of cancer based on a proprietary mathematical algorithm of five independent biomarkers: CA-125, β_2 -microglobulin, transferrin, apolipoprotein A1, and transthyretin. OVA1 was the first blood test cleared by the U.S. Food and Drug Administration (FDA) to help evaluate the likelihood that a woman's ovarian mass is malignant or benign prior to a planned surgery. The OVA1 test, when performed in 516 women with adnexal masses deemed appropriate for surgical excision, improved the sensitivity of cancer versus noncancer discrimination in a double-blind clinical study from 72% to 92% when using the biomarker panel. Among gynecologic oncologists, the sensitivity increased from 86% to 99%. Although not approved for surveillance or diagnosis, the test may complement clinical decision making, particularly if a gynecologic oncologist is not available to perform appropriate staging should cancer be identified.

Evaluation of the Adnexal Mass

Ultrasound has helped define criteria to allow conservative follow-up and the risk of malignancy of some adnexal masses. Goldstein and associates studied 42 postmenopausal patients whose ultrasound scans have shown unilocular cysts smaller than 5 cm in diameter; 28 were explored, and none had malignancy, and 14 were followed for as long as 6 years, with no change in ultrasound appearance. Finkler and colleagues noted that the addition of a CA-125 serum assay to their ultrasound criteria in postmenopausal women increases the accuracy of preoperative evaluation. In a clinicopathologic study to define ultrasound criteria of malignancy, [Granberg and associates \(1989\)](#) studied the ovarian tumors in 1017 women. Of 296 with unilocular cysts, only one was malignant and had visible papillary formations on the cyst wall; 60% of these women were older than 40 years. In contrast, malignancy rates were 8% (20 of 229) for multilocular cysts, 65% (147 of 201) for multilocular solid tumors, and 39% (31 of 80) for solid ovarian masses. In a follow-up study of 180 women, the authors noted that 45 of 45 unilocular cysts were benign. In an ultrasound study of cystic ovarian masses in women older than 50 years, Bailey and coworkers noted that unilocular cysts smaller than 10 cm in diameter are rarely malignant, whereas complex cysts or those with solid areas are at high risk of malignancy.

Several scoring systems have been proposed to try to determine the risk of an ovarian mass being malignant. They usually include the following:

1. Is the finding a simple (unilocular) or complex (multicystic or multilocular with solid components) cyst?
2. Are there papillary projections?
3. Are the cystic walls or septa regular and smooth?
4. What is the echogenicity (tissue characterization)?

These terms, definitions, and measurements have been standardized under a consensus opinion from the International

Ovarian Tumor Analysis (IOTA) group and help refine the likelihood of malignancy. Shalev and coworkers combined transvaginal ultrasonography and normal CA-125 values in 55 postmenopausal women with simple cystic or septate cystic ovarian masses; all 55 had benign disease. Although this was a small study, it suggests the potential of applying stringent ultrasound criteria with CA-125 evaluation of ovarian masses in postmenopausal women.

Others have advocated using transvaginal pulsed Doppler color-enhanced flow studies to differentiate benign from malignant masses. The resistance index, which measures resistance to flow in the vessels, has been used and presumably is low in the presence of neovascularization that is seen with malignant tumors. The vessels of neoangiogenesis are abnormal in their distribution, with disorganized branching and a loss of the muscularis layer, all of which contribute to the decreased resistance to flow. A resistance of 0.40 or less was found useful by Kurjak and coworkers in a study of 254 women. In contrast, Bromley and colleagues, in a study of 33 postmenopausal women, used a cutoff of 0.6, which did not greatly add to their specificities; they relied on morphologic criteria (e.g., solid elements, papillary projections) to diagnose malignancy.

Valentin and associates evaluated the characteristics of 1066 adnexal masses; 266 were malignant (55 borderline ovarian tumors, 144 primary invasive epithelial cancers, 25 nonepithelial ovarian cancers, 42 metastatic cancers). A scoring system was used as well as information from color Doppler studies. They reported that borderline and stage I ovarian cancers shared similar morphology but had different characteristics from more advanced-stage tumors. They were larger, contained more papillary projections, and were more often multilocular, without solid components, but were less often purely solid and less likely to be associated with ascites. Significant variation was noted, however. Similarly, Twickler and colleagues described a scoring model to create an ovarian tumor index for women with adnexal disease. Of 244 women with follow-up, 214 had nonmalignant findings and 30 had cancer. In addition to age, transvaginal ultrasound variables, including ovarian volume, the Sassone morphology scale, and Doppler determination of angle-corrected systole, diastole, and time-averaged velocity, were evaluated. An ovarian tumor index was created from discriminant variables (continuous and weighted) correctly classifying the two cohorts. The area under the receiver operator characteristic curve (AUC) was highly significant (AUC = 0.91). Unfortunately, scoring systems such as these, developed from data produced by highly skilled and proficient sonographers, are difficult to generalize and, although promising, are highly operator dependent. The IOTA group has temporally and externally validated the diagnostic performance of two logistic regression models containing clinical and ultrasound variables for malignancy identification. In this study, the prevalence of invasive cancer was 3%. The likelihood of cancer from a positive screen exceeded 6 for both models; a negative likelihood ratio was under 0.1, suggesting that the criteria may be of use for evaluating women with an adnexal masses.

It should be noted that there is a difference in using ultrasonography to screen for ovarian cancer as opposed to using different modalities of ultrasonography to characterize an ovarian mass as benign or malignant. For example, the addition of color Doppler sonography, which measures blood flow and direction of flow, and power Doppler sonography, which

can detect slow flow in small vessels, can add useful information. These permit visualization of flow location (peripheral, central, or within a septum). Most malignant tumors have a central flow (75% to 100%) compared with only 5% to 40% of benign ovarian tumors. Schelling and colleagues studied transvaginal B-mode and color Doppler sonography for the diagnosis of malignancy in 257 adnexal masses with unclear malignant status. They achieved 92% sensitivity and 94% specificity. The development of three-dimensional ultrasonography may allow more accurate volume assessments. In addition, color Doppler with three-dimensional ultrasonography may permit better detection of vessel irregularity, coiling, and branching. Another possibility is the use of contrast media to quantify and permit earlier detection of abnormal angiogenesis, as noted by Abramowicz. Contrast-enhanced (microbubble) power three-dimensional Doppler sonography has been investigated to evaluate the efficacy of antiangiogenic biologic in serial scanning.

Ovarian Cancer Screening

Although ovarian cancer is characterized by advanced-stage disease at diagnosis and high mortality, early-stage disease is often curable. The greatest impact on these statistics, other than prevention, would be screening to identify early-stage disease. Three modalities, used individually or in combination, have been the common theme of this effort: physical examination, biomarkers (e.g., CA-125), proteomics-genomics (experimental) and sonography. For a disease to be amenable to screening, it should be sufficiently severe (high mortality) and have a natural history from latency to overt disease that is well characterized, and there should be a successful outcome if early disease is treated. The screening modality should have high positive and negative predictive values, and high sensitivity and specificity, and be acceptable to the population, cost-effective, and widely available. The screening population should be identifiable and, for those in whom early disease is identified, effective therapy should be available. Although ovarian cancer satisfies many of these mandates, it is rare in the general population and not readily characterized by an identifiable precursor, thus producing a high bar for any modality.

Of the three most commonly used modalities, the least sensitive and specific is physical examination. It is estimated that just one early ovarian cancer will be identified in 10,000 physical examinations. Although the easiest to implement, poor sensitivity limits this intervention as an effective strategy.

Biomarkers such as CA-125 are of great interest because they are easy to obtain and serial evaluation can be tracked. CA-125 has been used most consistently since being discovered as a reliable biomarker for epithelial nonmucinous ovarian cancer. Early, large, population-based studies highlighted its limitation as a sole strategy for ovarian cancer screening. Einhorn and associates screened 5550 women and, in 1992, reported that only two stage I cancers in 175 women with elevated CA-125 values were identified. As noted, a differential effect would be expected between pre- and postmenopausal women. Using the modality in women with a pelvic mass (in whom prevalence is increased) has substantial effects on test characteristics but overlooks the obvious need for cancer identification before gross ovarian enlargement. This has led to the development of combined evaluation (sonography) described here.

Ultrasonography as an isolated modality has also been advocated for screening. Although more expensive and less amenable to population screening, it has become increasingly accurate in identifying early changes within the ovary, as noted. Campbell and coworkers screened 5479 patients and obtained 338 abnormal scans. Five early-stage ovarian cancers were identified. The positive predictive value was only 1.5%. Similarly, van Nagell screened 1300 patients and obtained 33 abnormal scans. Two early-stage ovarian cancers were identified. As with single-modality testing, sonography is too insensitive to be widely used for screening.

Population-based ovarian cancer screening programs have been difficult to recommend and implement because poor sensitivity and positive predictive value characteristics accompany expensive and inefficient testing methodology and triage algorithms. Menon and colleagues approached this problem by evaluating a prospectively based algorithm in a population-based screening program in the United Kingdom. The population cohort used to evaluate this screening strategy involved 13,582 menopausal women 50 years or older with at least one ovary, of whom 6532 randomized women completed a first screen; the remainder served as controls. The screening strategy was a staged process in which each CA-125 sample drawn underwent a calculation for risk of ovarian cancer (ROCA). The calculation was based on the woman's age and CA-125 value relative to her personal baseline. In this trial, an estimated risk of less than 1 in 2000 was considered normal, whereas a risk of more than 1 in 500 was considered increased; those in between were considered intermediate and required repeat testing. Those not considered normal were referred for a second stage of screening that incorporated a transvaginal ultrasound scan and repeat CA-125 testing. A transvaginal ultrasound scan was considered normal, abnormal, or equivocal based on ovarian volume and morphology. From the combination of CA-125 risk estimation and transvaginal ultrasound scan, a follow-up recommendation was made that could be a gynecologic oncology referral, repeat CA-125 testing, or transvaginal ultrasound scan or annual screening. In the screened group, almost 80% continued with annual screening; 91 (1.4%) were considered at increased risk. Among the intermediate group, repeat testing was normal in 92%, leaving 188 (2.9% of the initial population) to undergo second-stage evaluation. Of the 144 who stayed in the program, 95 were returned to annual screening based on CA-125 and transvaginal ultrasound scan findings, 6 were found to have nongynecologic malignancies, 43 were referred to a gynecologic oncologist, of whom 27 were returned to annual screening, and 16 women underwent surgery. From this group, five ovarian cancers were identified (four malignant epithelial and one borderline); the 11 remaining women had benign ovarian neoplasms. Compared with the authors' previous algorithm based on flat CA-125 values (normal = 30 U/mL), the new process referred less than 50% to secondary screening. It was concluded that this algorithm increases screening precision.

Two other prospective trials of general population screening deserve mention: the Prostate, Lung, Colorectal and Ovarian (PLCO) study and the United Kingdom Collaborative Trial of Ovarian Cancer Screening (UKCTOCS). The primary objective of the PLCO study is to evaluate the impact of annual screening with transvaginal ultrasound (TVUS) and CA-125 on ovarian cancer mortality. The study is following a

cohort of more than 34,000 largely postmenopausal women with intact ovaries prospectively with an algorithm indicating that an abnormal CA-125 level (≥ 35 U/mL) or an abnormality on TVUS is considered a positive screen. Follow-up procedures of a positive screen are not prespecified but have been tracked, as well as any surgical interventions resulting from these findings. Compliance over four rounds of screening decreased slightly over the 3 years of postbaseline evaluation but remained above 75%. In contrast to CA-125, screen-positive TVUS decreased over the interval from 4.6% at baseline to 3.4% at year 3. Almost 90 ovarian cancers have been diagnosed so far; 60 were identified by screening abnormalities. Overall, the ratio of screen-positive ovarian cancers relative to benign disease decreased from 30:1 to almost 20:1. Of the ovarian cancers identified, 72% were advanced stage. The study continues to mature, with relatively good compliance. However, the impact of screening on the primary end point (mortality) is unknown.

The UKCTOCS was designed to assess the effect of ovarian cancer screening on mortality definitively, as well as comprehensively address the cost, acceptance, physical and psychosocial morbidity, and performance characteristics of multimodal screening and ultrasound-based screening. Between 2001 and 2005, a total of 202,638 postmenopausal women 50 to 74 years of age were randomly assigned to control (no screening), annual CA-125 screening (based on risk of ovarian cancer [ROC] algorithm), and second-line ultrasound testing (multimodal screening [MMS]) or annual transvaginal ultrasound (USS) alone in a 2:1:1 ratio. In the prevalence screen, 50,078 women (98.9%) underwent MMS and 48,230 (95.2%) underwent USS. Overall, 9% of the MMS cohort and 12% of the USS cohort required repeat testing. Surgery was undertaken in a small proportion of both cohorts but was significantly more likely following USS. Ovarian neoplasms, benign and malignant, were identified in both screening cohorts. The proportion of stage I and II cases was 48.3% and was balanced between the two screening algorithms. However, specificity was significantly higher for the MMS strategy (99.8%) relative to USS (98.2%). The performance of both screening modalities is encouraging and establishes feasibility (Table 33.5). The impact of stage migration following screening, as reflected in disease-specific mortality, is pending study completion, expected in 2014.

Successful prediction of cancer in the general public is limited by the low prevalence of disease. Creasman and DiSaia have estimated that if vaginal ultrasound scanning and CA-125 testing were performed annually on all women older than 45 years in the United States, the cost would exceed \$10 billion annually.

One strategy to improve the predictive index is to address a population in which prevalence is increased. A number of studies have been undertaken using transvaginal ultrasonography to screen for ovarian malignancy in higher risk women. Bourne and colleagues screened 775 women who had at least one first-degree ($n = 677$) or second-degree ($n = 98$) relative with ovarian cancer. Overall, 43 women were referred for surgery with abnormal-appearing ovaries and 39 underwent surgery, with three stage IA ovarian carcinomas discovered (3.9 of 1000 screened); one of these was a borderline tumor. One screened patient was found to have peritoneal carcinomatosis 11 months after a normal screening study. The remainder had

Table 33.5 Screening Performance of Multimodal and Transvaginal Ultrasound in the United Kingdom Collaborative Trial of Ovarian Cancer Screening Prevalence Study

Parameter	SCREENING MODALITY	
	Multimodal Screening	Transvaginal Ultrasound
Repeat testing	9%	12%
Clinical evaluation	0.3%	3.9%
Surgery	0.2%	1.8%
Number of ovarian cancers	42	45
Borderline cancers	8	20
Stage I and II cancers (48.3% of cancers identified)	16	12
Sensitivity	89.5%	75%
Specificity	99.8%	98.2%
Positive predictive value	35.1%	2.8%

nonmalignant findings. DePriest and associates screened 6470 asymptomatic postmenopausal women and defined abnormality as an ovary with a volume larger than 10 cm³ or papillary projections in a cystic ovarian tumor. Ninety patients who had persistent findings by repeat ultrasound scanning at 4 to 6 weeks had an operation, with the finding of five early (stage IA; see later) and one advanced (stage IIIB) carcinomas. There were 37 serous cystadenomas and 20 assorted benign ovarian conditions. One woman with a normal scan was found to have peritoneal carcinomatosis 11 months later. These investigators noted that normal ovarian volume in a postmenopausal woman is smaller than 10 cm³ and, in a premenopausal woman it is as much as 20 cm³, as reported by Pavlik and colleagues.

Clinicopathologic studies of Bell and Scully, as well as ultrasound screening trials by Crayford and colleagues, have provided an explanation for the lack of success with ultrasound screening for detecting low-stage ovarian carcinomas. Bell and Scully proposed the term *early de novo carcinoma* to explain their findings of 14 carefully studied cases. None of these patients had clinical evidence of ovarian carcinoma at the time of operation. All had microscopic foci of carcinoma in their ovaries, and three cases were detected only years later postoperatively, when the patients were discovered to have widespread carcinoma consistent with what was found in their ovaries on retrospective study. Crayford and colleagues screened 5479 self-referred asymptomatic women by vaginal ultrasonography and removed all persistent ovarian cysts in an attempt to reduce the frequency of ovarian cancer. Of these, 88 patients had cysts removed. A slight nonsignificant increase in ovarian cancer deaths for this group was found 12 years after the conclusion of the study. Therefore it appears that most ovarian carcinomas (particularly serous) arise from a tiny cancer of the surface of the ovary, from which it can spread rapidly before the ovary enlarges. Some ovarian tumors, such as endometrioid carcinoma, may have their origin in endometriosis. These carcinomas, as well as mucinous, tend to be detected more frequently at earlier stages. Therefore they appear more likely to have a cystic rather than a de novo origin. These observations strongly suggest that current strategies to use vaginal

ultrasound screening to detect early ovarian carcinoma will have only limited success, as noted by Herbst.

Nonmalignant Neoplasms

Most nonmalignant epithelial ovarian tumors are asymptomatic unilateral adnexal masses that can be treated by oophorectomy or occasionally cystectomy (see Benign Cystic Teratomas [Dermoids,] presented later). In the past, some recommended bisecting the opposite ovary to rule out bilaterality in the case of benign epithelial ovarian tumors (see Table 33.4), but in view of the risk of adhesions and infertility as well as the availability of vaginal ultrasonography, this is no longer done. In a woman beyond her reproductive years, especially in the presence of a serous cystadenoma, which tends to be bilateral, hysterectomy and bilateral salpingo-oophorectomy are usually performed.

Mucinous tumors can become particularly large and reach sizes of 30 cm or larger. Possible complications of mucinous cystadenoma are perforation and rupture, which can lead to the deposit and growth of mucin-secreting epithelium in the peritoneal cavity (pseudomyxoma peritonei; discussed later).

Adenofibromas consist of fibrous and epithelial elements. The epithelial component may be serous, mucinous, clear cell, or endometrioid, the architectural subtypes of these benign ovarian tumors. Their appearance will depend on the predominant histologic features, epithelial or fibrous. These tumors are also managed by simple excision. Endometriomas are considered in Chapter 19.

Brenner tumors (see Fig. 33.6) are rare and often incidental findings when oophorectomy is performed for an indication other than ovarian enlargement. Usually these tumors occur in women in their 40s and 50s, but younger and older patients have been found to have them. Brenner tumors are almost always benign and can usually be managed by oophorectomy. When the ovary is palpably enlarged, approximately 5% of Brenner tumors will prove to be malignant. These tumors often occur in perimenopausal and postmenopausal women, in which case, hysterectomy and bilateral salpingo-oophorectomy are indicated. Unfortunately, malignant Brenner tumors appear to have a poor prognosis despite this operative therapy, and an effective program of chemotherapy has not been developed.

The differential diagnosis for and approach to an adnexal mass in women of various ages are discussed in Chapter 7. Ovarian enlargement in the premenarchal female is usually the result of a germ cell tumor, which may be malignant but is usually benign (discussed later). During the reproductive years, ovarian neoplasms are usually benign. For the woman in her 20s or 30s, most ovarian enlargements can be approached surgically through a lower abdominal transverse (Pfannenstiel) incision or by laparoscopy. However, contingency plans in the setting of an unanticipated malignancy should be considered preoperatively and discussed with the woman. Larger masses usually require a vertical skin incision to ensure intact removal and safe dissection. Although the diagnosis of cancer can only be verified in tissue, patient characteristics (e.g., age, family history), preoperative ovarian morphology (e.g., exophytic or endophytic masses, masses with large solid components, size), and biomarker studies (e.g., CA-125, HE4) may modulate risk assessment and thus the surgical approach.

The liberal use of intraoperative frozen-section assessment should be exercised, particularly in menopausal women. For women of reproductive age desiring fertility, if the diagnosis of malignancy is suspected but uncertain even after a frozen section is obtained, the operation should be terminated after removal of the ovarian tumor. A second procedure can be performed if malignancy is confirmed after detailed histologic study of the permanent sections. This is preferable to risking an unnecessary hysterectomy or bilateral salpingo-oophorectomy in a woman who desires to preserve childbearing function. Women who do not desire childbearing should undergo careful counseling to describe the potential need for a staging procedure in case a documented or suspected malignancy is identified from the frozen section.

CARCINOMAS

Diagnosis, Staging, Spread, Preoperative Evaluation, and Prognostic Factors

Ovarian carcinomas are usually diagnosed by detection of an adnexal mass on pelvic or abdominal examination. Occasionally, the diagnosis is made from a radiographic survey carried out for the evaluation of nonspecific gastrointestinal symptoms. Unfortunately, the diagnosis is frequently made only after the disease has spread beyond the ovary, as noted earlier when we described the *de novo* origin of these tumors. Scully has estimated that the risk of malignancy in a primary ovarian tumor increases to approximately 33% in a woman older than 45, whereas it is less than 1 in 15 for women who are 20 to 45 years of age. In general, more than 50% of ovarian carcinomas occur in women older than 50. In a hospital-based study of ovarian neoplasms in 861 women, Koonings and associates noted that the risk of malignancy was 13% in premenopausal women but rose to 45% in postmenopausal women. In their study, benign ovarian neoplasms were most common in those 20 to 29 years of age.

More than 90% of women diagnosed with ovarian cancer report symptoms before diagnosis. Unfortunately, these symptoms are vague and not specific for early-stage disease or even ovarian cancer. Goff and colleagues conducted a prospective survey of women seeking medical care. The case patients were those about to undergo surgery for a known or suspected pelvic or ovarian mass; the controls were women presenting to one of two primary care clinics, in which approximately two thirds were being seen for a specific problem. The voluntary questionnaire instrument administered to both cohorts asked the respondents to score the severity, frequency, and duration of 20 symptoms generally reported by ovarian cancer patients. In both groups, recurring symptoms were common and non-specific. Symptomatology in control patients was related to the purpose of their visit (general checkup vs. specific complaint), underlying disease comorbidities, and menopausal status. Not surprisingly, women with the final diagnosis of ovarian cancer generally reported numerically more symptoms and of greater severity but of shorter duration of onset compared with the clinic controls or patients with benign ovarian tumors. Ovarian cancer patients were also statistically more likely to report increased abdominal size, bloating, urinary urgency, and pelvic pain. Because the combination of increased abdominal size, bloating, and urinary urgency was reported five times

more often and had greater severity in cancer patients than in controls, the authors recommended further clinical investigation when identified. The diagnosis is established by histologic examination of tumor tissue removed at operation. Occasionally, the initial diagnosis is suggested by malignant cells found in ascitic or pleural fluid obtained at paracentesis or thoracentesis, respectively.

The staging of ovarian cancer (Table 33.6) is designed according to the criteria of the International Federation of Gynecology and Obstetrics (FIGO). It is based on the results of operative exploration. Before surgical exploration for suspected ovarian carcinoma, the woman has a preoperative workup that is standard for a major abdominal operation (see Chapter 24). Additional diagnostic studies may include a computed tomography (CT) scan of the abdomen to search for disease that would preclude a surgical intervention. Involvement of certain sites in the abdominal or pelvic cavity would be considered inoperable to achieve an optimal cytoreduction (<1 cm residual disease). These sites include retroperitoneal suprarenal lymph node enlargement, mesenteric disease, porta hepatis disease, or bilateral parenchymal liver metastases.

A few studies have evaluated the role of combined positron emission tomography (PET) and CT in the treatment of primary epithelial ovarian cancer. Risum and associates prospectively analyzed the diagnostic value of PET-CT for detecting a malignant tumor in 97 patients with no previous cancer history who presented with a pelvic mass. All the patients included in the study had PET-CT scans prior to surgery; the average serum CA-125 level was 784 U/mL. The sensitivity and specificity of PET-CT in diagnosing a malignant pelvic tumor were 100% and 92.5%, respectively.

Occasionally, a barium enema or colonoscopy is performed to evaluate pelvic or gastrointestinal symptoms. Consideration of gastrointestinal pathology is of importance for the potential of a primary colon carcinoma, which may present initially as an adnexal mass in the older woman. Approximately 4% of colon cancers have metastatic involvement of the ovary at diagnosis. Determination of the serum carcinoembryonic antigen level may be useful in this setting and is recommended as part of the preoperative evaluation of a pelvic mass. An endoscopic or gastrointestinal radiographic examination is performed if there is evidence of gastrointestinal bleeding or the suggestion of any gastrointestinal pathology.

A CA-125 sample is obtained and, if the level increased at the time of operation, is useful for following the progress of the woman during and after treatment and for demonstrating the response to therapy or detecting tumor progression. Buller and associates studied the regression slope for CA-125 during chemotherapy and found the slope of the regression curve to be predictive of therapeutic outcome. Other investigators have shown that patients whose CA-125 values decrease from increased to normal rapidly while undergoing primary chemotherapy have an improved prognosis over those whose values decrease more slowly. Markman has evaluated the survival impact of CA-125 levels reaching 50% of pretreatment baseline at 8 weeks after surgery and cisplatin-based chemotherapy. Survival was 21 months for those achieving this decrease versus only 10 months for those not achieving a 50% decrease. Clearly, this imperfect marker has prognostic significance in many situations. The serum inhibin level

Table 33.6 Staging of Ovarian Carcinomas*

Stage	Characteristics
I	Tumor confined to the ovaries
IA	Growth limited to one ovary (capsule intact); no tumor on ovarian surface; no malignant cells in the ascites or peritoneal washings
IB	Tumor limited to both ovaries (capsule intact); no tumor on ovarian surface; no malignant cells in the ascites or peritoneal washings
IC	Tumor limited to one or both ovaries
1C1	Surgical spill
1C2	Capsule ruptured before surgery or tumor on ovarian surface
1C3	Malignant cells in the ascites or peritoneal washings
II	Tumor involves one or both ovaries with pelvic extension
IIA	Extension or metastases to the uterus or fallopian tubes
IIB	Extension to other pelvic intraperitoneal tissues
III	Tumor involving one or both ovaries with cytologically or histologically confirmed spread to the peritoneum outside the pelvis or metastasis to the retroperitoneal lymph nodes
IIIA1	Positive retroperitoneal lymph nodes only (cytologically or histologically proved)
IIIA1 (i)	Metastasis up to 10 mm in greatest dimension
IIIA1 (ii)	Metastasis more than 10 mm in greatest dimension
IIIA2	Microscopic extrapelvic (above the pelvic brim) peritoneal involvement with or without positive retroperitoneal lymph nodes
IIB	Macroscopic peritoneal metastasis beyond the pelvis up to 2 cm in greatest dimension, with or without metastasis to the retroperitoneal lymph nodes
IIIC	Macroscopic peritoneal metastasis beyond the pelvis more than 2 cm in greatest dimension, with or without metastasis to the retroperitoneal lymph nodes (includes extension of tumor to capsule of liver and spleen without parenchymal involvement of either organ)
IV	Distant metastases excluding peritoneal metastases
IVA	Pleural effusion with positive cytology
IVB	Parenchymal metastases and metastases to extra-abdominal organs (including inguinal lymph nodes and lymph nodes outside of the abdominal cavity)

*According to the International Federation of Gynecology and Obstetrics (FIGO), 2014.

has been reported to be elevated in mucinous carcinomas and may serve as a marker, according to the studies of Healy and associates. Frias and coworkers reported pretreatment levels of inhibin A to be a prognostic factor for survival in postmenopausal women with ovarian cancer. However, inhibin levels are not routinely determined in the woman with an epithelial ovarian malignancy.

Preoperatively, the use of routine bowel preparation prior to major abdominal surgery for advanced ovarian cancer is no longer considered routine standard of care. In fact, this practice has been shown to increase patient dissatisfaction and may cause dehydration. In a systematic review of 18 randomized clinical trials (5805 patients), Guenaga and colleagues found no statically significant evidence that patients benefit from either bowel preparation or rectal enemas; specifically, the infection and anastomotic leak rates in patients with a bowel preparation was 9.6% and 4.4%; respectively, compared with 8.5% and 4.5% for those without. Venous thromboembolism prophylaxis is of particular importance in patients with ovarian cancer because a large tumor burden is associated with venous stasis and prolonged operation times. Treatment with variable compression leg support stockings and heparin (fractionated and unfractionated) appears to reduce the risk of thromboembolism in gynecologic oncology patients undergoing surgical tumor extirpation. A study by Einstein and colleagues evaluated the usefulness of a dual prophylaxis protocol using sequential compression devices and heparin three times daily (or daily low-molecular-weight heparin) until discharge for patients with gynecologic malignancies. A dual prophylaxis protocol was shown to be associated with a significant reduction in the rate of venous thromboembolism without increasing bleeding complications.

Ovarian carcinomas infiltrate the peritoneal surfaces of the parietal and intestinal areas, as well as the undersurface of the diaphragm, particularly on the right side (Fig. 33.7). This is particularly important because tumors that appear at operation to be confined to the ovary may have small areas of diaphragmatic involvement as the sole site of extraovarian spread. As noted earlier, most ovarian carcinomas, particularly the serous type, appear to arise from microscopic ovarian sites and do not become clinically evident until there is widespread metastatic disease. Lymphatic dissemination is also a prominent part of disease spread (Fig. 33.8), and it is particularly important to note that the para-aortic nodes are at risk through lymphatics that run parallel to the ovarian vessels. Knapp and Friedman have noted that of 26 patients with ovarian cancer apparently limited to the ovary, 19% had para-aortic involvement, and all had poorly differentiated tumors. In a study of 180 patients, Burghardt and coworkers observed that the proportion of positive nodes increases with higher-stage tumors—24% in stage I, 50% in stage II, and 73.5% in stages III and IV. A study conducted by Schmeler and colleagues has evaluated the prevalence of lymph node involvement in women with primary mucinous ovarian carcinomas. A total of 107 patients were identified. Of the patients with tumor grossly confined to the ovary at surgical exploration who underwent lymphadenectomy, none had metastatic disease to the pelvic or para-aortic lymph nodes. In addition, the authors found no significant differences in progression-free survival or overall survival between patients who underwent lymphadenectomy and those who did not.

The prognosis for patients with ovarian carcinoma is related to tumor stage, tumor grade, cell type, and amount of residual tumor after resection. Worldwide results for patients treated from 1990 to 1992 are summarized in Table 33.7. Data from

Figure 33.7 Peritoneal spread of ovarian cancer. Portions of the omentum, small intestine, and transverse colon have been resected. (From Knapp RC, Berkowitz RS, Leavitt T Jr. Natural history and detection of ovarian cancer. In: *Gynecology and Obstetrics*. vol 4. Philadelphia: JB Lippincott; 1986.)

Figure 33.8 Lymph nodes draining ovaries. Primary routes of spread to the pelvic and para-aortic nodes are illustrated. (Modified from Musumeci R, Banfi A, Bolis G, et al. Lymphangiography in patients with ovarian epithelial cancer: an evaluation of 289 consecutive cases. *Cancer*. 1977;40[4]:1444-1449.)

the Survey Epidemiology and End Results (SEER) database are presented in [Table 33.8](#).

Cell type has been reported to be an important factor in prognosis, as shown in [Figure 33.9](#), which summarizes the 20-year survival rate of a group of patients. The most common invasive epithelial cancers, serous carcinomas, have the worst prognosis; prognosis may be better for mucinous and endometrioid tumors. A variant of papillary serous carcinoma termed *transitional cell carcinoma* is thought by some to be a rare but more chemosensitive tumor. However, this has not been established in multi-institutional studies. Endometrioid carcinoma may be associated with endometriosis and, according to McMeekin and colleagues, such cases more commonly occur in younger women and have a better prognosis than typical endometrioid carcinomas of the ovary. Clear cell cancers have a worse prognosis, but Kennedy and associates noted that mitotic activity and tumor stage are important prognostic features of this tumor in their series. Tubulocystic pattern did not appear to affect prognosis, as earlier studies by Aure and colleagues had suggested (see [Fig. 33.9](#)). Nonetheless, these are aggressive tumors with a propensity for recurrence, even in stage I. In a follow-up analysis, Kennedy and associates noted a survival probability of only 50% for stages I and II. It should be noted that stage and grade affect these observations. Serous tumors tend to be more poorly differentiated and discovered at a higher-stage than mucinous tumors.

In some cases, patients are found to have small ovaries (<4 cm in diameter) and widespread papillary serous carcinoma in the abdomen. In such cases, the term *serous surface papillary carcinoma of the ovary* is applied. Fromm and coworkers reported

on 74 patients and found that survival improves if the patients were treated postoperatively with combination chemotherapy (discussed later).

Another variety of serous carcinoma is primary peritoneal carcinoma. In these cases, the ovaries may be of normal size with surface metastatic tumor deposits. There is widespread intra-abdominal spread of carcinoma of serous histology. These cases can be associated with *BRCA1* and *BRCA2* mutations, as shown by the studies of Karlan and colleagues. The cloning of the *BRCA1* gene has advanced our knowledge of the molecular genetics of ovarian cancer, but the role of this gene, which resides on chromosome 17q21, is not clear. It appears to be a tumor suppressor gene that is highly expressed in ovarian borderline carcinoma. Mutations in *BRCA1* are strongly associated with an increased risk of breast and ovarian cancer, and a similar increase in risk occurs with mutations in *BRCA2*. These mutations are seen in approximately 2% to 2.5% of Ashkenazi Jewish women, who appear to be an appropriate target group for testing whether breast cancer is diagnosed before age 50 in the woman or a close relative, according to Warner and associates. Prophylactic oophorectomy reduces the risk of ovarian cancer in those with a mutation but does not eliminate the problem because of the potential for primary peritoneal carcinoma. The study of Rebbeck and colleagues of *BRCA1* mutation carriers has suggested that prophylactic oophorectomy may also reduce the subsequent risk of breast cancer. Boyd and coworkers reported that stage for stage, the hereditary ovarian cancer group may have a better prognosis than those with spontaneously occurring tumors. Lu and associates noted a high proportion of microscopic carcinomas in apparently normal ovaries removed from patients with *BRCA* mutations, an observation consistent with the de novo origin of serous and poorly differentiated carcinomas.

In addition to stage, the grade of the tumor is a major determinant of patient prognosis. [Figure 33.10](#) demonstrates the survival of 442 patients with ovarian carcinoma by grade, with a markedly worse prognosis for poorly differentiated tumors (grade 3). The relationship between grade and survival also exists when the results are examined separately for each stage of disease.

The development of gene expression profiling has enabled a more precise evaluation of clinical behavior in some tumors. Bonome and coworkers studied the gene expression of low malignant potential (LMP) serous neoplasms and invasive low-grade and high-grade serous tumors. A distinct and separate clustering was observed between LMP tumors and high-grade cancers. Low-grade serous tumors generally clustered with LMP neoplasms. High-grade tumors differentially expressed genes

Table 33.7 Carcinoma of the Ovary: Survival by International Federation of Gynecology and Obstetrics (FIGO) Stage*

Stage	5-Year Survival (%)
IA	94%
IB	92%
IC	85%

Figure 33.9 Survival rates for 983 patients with all stages of ovarian cancer by histologic type. 1b, Serous, low malignant potential (74 cases); 2b, mucinous, low malignant potential (80 cases); 1c, serous carcinoma (283 cases); 2c, mucinous carcinoma (123 cases); 3c, endometrioid carcinoma (205 cases); 4C, clear cell (36 cases); 4T, tubulocystic pattern of clear cell (27 cases); 5, undifferentiated (155 cases). (Modified from Aure JC, Hoeg K, Kolstad P. Clinical and histologic studies of ovarian carcinoma: long-term follow-up of 990 cases. *Obstet Gynecol.* 37[1]:1-9, 1971.)

Figure 33.10 Survival rates for patients with ovarian cancer by tumor grade. Survival curves for the complete series according to the histologic degree of differentiation. All differences between curves are highly significant. (From Kosary CL. Ovarian carcinoma clinical trial. *Semin Surg Oncol.* 1994;10[1]:31-46.)

linked to cell proliferation, chromosomal instability, and epigenetic silencing. Based on these findings, high-grade epithelial cancers appear to have a distinct profile relative to LMP neoplasms. Low-grade serous tumors are remarkably similar to LMP serous neoplasms. These observations have ushered in the consideration of reclassifying invasive malignant cancers into two categories, low grade and high grade.

Studies of flow cytometry have indicated that the ploidy of the tumor is also prognostic, with aneuploidy being a negative prognostic factor. Kleimi and colleagues noted an independent prognostic association with the DNA index and S-phase fraction. A better prognosis was observed if the proportion of S-phase cells was less than 11% or if the DNA index (the relative DNA content of aneuploid cells compared with diploid) was less than 1.3. Genetic studies by Slamon and coworkers showed that the *HER2/neu* oncogene is amplified in ovarian and breast cancers. As noted in a review by Berchuck and associates, the overexpression of *HER2/neu* was suspected to occur in approximately 30% of epithelial ovarian cancers and appears to be associated with a worse prognosis. However, a Gynecologic Oncology Group (GOG) study of trastuzumab (a monoclonal antibody to the extracellular domain of *HER2*) in patients with recurrent ovarian cancer has suggested that the incident overexpression by fluorescence in situ hybridization is much lower. In this study, 837 samples were screened for immunohistochemistry overexpression (2+ or 3+) or fluorescence in situ hybridization positivity. Only 95 patients (11.4%) met criteria for therapy. It is likely that this prospective trial more accurately represents the incidence of this factor in ovarian cancer. The *p53* tumor suppressor gene is mutated in approximately 50% of ovarian epithelial

cancers studied, whereas the *C-myc* oncogene is overexpressed more commonly in serous cases and the *K-ras* oncogene has been identified more frequently in borderline ovarian cancers. The molecular genetic events surrounding ovarian carcinoma development and biologic behavior are incompletely understood.

The size of residual nodules and presence or absence of tumor after surgery has been related to the survival of patients treated for ovarian carcinoma. Chi and colleagues analyzed survival by diameter of residual disease (grouped in five categories) to determine the optimal goal of primary cytoreduction for patients with stage IIIC epithelial ovarian cancer. The median overall survival (OS) by diameter of residual disease were as follows: 106 months for no gross residual disease, 66 months for 0.5 cm or less, 48 months for 0.6 to 1 cm, 33 months for 1 to 2 cm, and 34 months for larger than 2 cm. Aure and colleagues noted a 5-year survival rate of more than 30% for stage III tumors that were completely resected compared with 10% when resection was incomplete. The impact of cytoreduction for advanced-stage disease is discussed next.

TREATMENT

Borderline Ovarian Tumors: Ovarian Carcinomas of Low Malignant Potential

Approximately 20% of ovarian epithelial cancers are tumors of LMP and usually have an excellent prognosis, regardless of stage. Most studies have been confined to borderline tumors of the serous (see Fig. 33.2B) and mucinous (see Fig. 33.3B) varieties, which are the most common histologies; however, other epithelial types (see Table 33.3) can occur. The cells of these epithelial tumors do not invade the stroma of the ovary. It is extremely important that the ovarian tumor be thoroughly sampled by the pathologist to ensure that a borderline tumor is not mixed with invasive elements. Numerous studies have confirmed that borderline tumors have a slower growth rate than invasive ovarian carcinomas, manifested by prolonged survival (see Fig. 33.9).

Surgery is the primary treatment for women with borderline ovarian tumors. The principal objectives of surgery are as follows: (1) diagnosis, (2) fertility-sparing surgery for patients who have not completed childbearing or who are young and have only unilateral ovarian involvement, (3) surgical staging for apparent early-stage disease, and (4) cytoreductive surgery for the minority of patients who have obvious advanced-stage disease.

The typical scenario is surgery for an adnexal mass of unknown type. One of the initial considerations in planning surgery for a pelvic mass is the surgical approach—minimally invasive or open technique. Factors to be considered in the selection of minimally invasive surgery (laparoscopic or robotic) include size of the ovarian mass(es), extent of tumor metastasis, number and type of previous operations, and body habitus. Several reports have documented the feasibility and safety of the minimally invasive approach when appropriately used (Romagnolo, 2006).

Once the mass is excised, frozen-section examination is a key element in assuring appropriate decision making. If the frozen section suggests a borderline ovarian tumor, considerations for fertility-sparing surgery include the woman's age, her desire for future childbearing, and the degree of involvement of the ovaries—unilateral versus bilateral disease. Options for fertility-sparing surgery include ovarian cystectomy and unilateral adnexectomy. Even with bilateral borderline ovarian tumors,

bilateral ovarian cystectomies may be performed, depending on the extent of ovarian disease. Lim-Tan and associates reported on 33 cases of stage I serous borderline tumors initially treated by cystectomy. Only 3 of 33 patients undergoing cystectomy had recurrence or persistence of borderline tumor, and these patients had positive resection margins or multiple cysts present in the ovary, emphasizing the effectiveness of conservative operation. However, for most stage IA cases, unilateral adnexectomy is performed and, if the opposite ovary looks normal, no biopsy or wedge resection is done.

Surgical staging for borderline ovarian tumors remains somewhat controversial. The most compelling reason for surgical staging in a woman with borderline tumor on frozen-section examination is the risk of invasive carcinoma on final pathology. For women with pathologically confirmed borderline tumors, the incidence of lymph node involvement is only approximately 5%. Therefore most investigators have recommended against routine pelvic and para-aortic lymphadenectomy. However, omental and peritoneal biopsies are recommended because peritoneal implants are usually small or microscopic (Harter, 2014).

For stage I serous borderline tumors, surgery alone is the standard of care because the cure rate associated with this treatment approaches 100% (see Fig. 33.9). On the other hand, approximately 30% of women will have peritoneal implants, which are classified as noninvasive (Fig. 33.11) or invasive (Fig. 33.12). For these women, the recurrence rate associated with noninvasive implants is 20% to 40% and the recurrence rate with invasive implants is 50% to 70%. Unfortunately, no studies to date have convincingly demonstrated any benefit to postoperative therapy for women with stages II to IV disease. Although no standard exists, some oncologists recommend postoperative treatment—paclitaxel-carboplatin chemotherapy or hormonal therapy—only for patients with invasive implants based on the very high risk of relapse.

Outcome is influenced by several factors, including pathologic and clinical factors. Pathologic factors that may be associated with an increased risk of relapse include the presence of

Figure 33.11 Noninvasive implant, epithelial type. Branching papillae and detached clusters of polygonal cells showing moderate cytologic atypicity are present (H&E, $\times 313$). (From Bell DA, Weinstock MA, Scully RE. Peritoneal implants of ovarian serous borderline tumors: histologic features and prognosis. *Cancer*. 1988;62[10]:2212-2222.)

the micropapillary/cribriform pattern or microinvasion in the primary ovarian serous LMP tumor or the presence of peritoneal implants (Longacre, 2005).

Mucinous borderline tumors also are associated with an excellent prognosis (see Fig. 33.9). Hart and Norris reviewed 97 patients with stage I tumors who were 9 to 70 years of age (median, 35 years). More than 10% of the tumors were discovered during pregnancy or in the immediate postpartum period. Follow-up data were available on 87 of the patients, and there were only three tumor-related deaths during the 5- to 10-year follow-up. The actuarial survival was 98% at 5 years and 96% at 10 years. This was also noted by Bostwick and colleagues, who reported on 109 borderline tumors, 33 of which were mucinous and all of which were stage I, contributing to the good prognosis.

Mucinous borderline tumors include two distinct subtypes, gastrointestinal and seromucinous or endocervical. In the seromucinous type, the association of endometriosis is high ($\approx 40\%$). They also may have associated microinvasion and lymph node involvement. The prognosis associated with the seromucinous type is excellent. Conversely, the gastrointestinal type may rarely be associated with the condition known as *pseudomyxoma peritonei*, consisting of widespread growth of mucin-producing cells in the peritoneum. The result may be the accumulation of large amounts of mucinous material, which is sometimes associated with recurrent episodes of bowel obstruction. Studies by Young and coworkers suggested that pseudomyxoma peritonei usually arises in the appendix. The review of Ronnett and coworkers supports a primary appendiceal origin for these tumors and, therefore, appendectomy is indicated for women with an intraoperative diagnosis of a mucinous ovarian tumor. The disease tends to recur and is frequently characterized by repeated laparotomy to relieve bowel obstruction. Chemotherapy and mucolytic agents have been tried but are usually not successful.

Invasive Epithelial Carcinomas

The primary treatment of ovarian epithelial carcinoma is removal of all resectable gross disease. The woman's abdomen

is explored through a vertical incision. If ascitic fluid is present, it is sent for cytologic evaluation; if ascites is not present, 200 to 400 mL of normal saline solution is used to obtain cytologic samples from the peritoneum by irrigating at least the pelvis, upper abdomen, and right and left paracolic gutters before any resection is done. The diaphragm can be cytologically sampled by scraping the undersurface with a sterile tongue depressor and the sample placed on a glass slide and sprayed with a fixative. Biopsy or, preferably, excision of any suspicious nodules is performed. A total abdominal hysterectomy, bilateral salpingo-oophorectomy, and infracolic omentectomy are performed if technically possible. When there is no gross disease outside the pelvis, para-aortic and pelvic lymph node sampling is recommended, with care taken to remove enlarged nodes. Although the impact of systematic lymphadenectomy has been addressed in one randomized clinical trial by Benedetti-Panici and associates, without significant effect on overall survival, it is reasonable to explore these areas because inspection by palpation is notoriously inaccurate. Evidence suggests that if all gross disease can be resected, the duration of patient survival is enhanced. Although randomized clinical trials have not been performed to document this effect, a meta-analysis of 6885 patients gathered from 81 cohorts has suggested a linear relationship between the degree of cytoreduction and overall survival. In this report, Bristow and colleagues noted that for each 10% increase in cytoreduction, a 5.5% increase in survival was observed. The surgical procedures required to achieve maximal cytoreduction may be extensive and involve splenectomy, diaphragmatic stripping-resection, and posterior exenteration. It may occasionally be necessary to resect bowel to relieve impending obstruction or remove a tumor nodule, thereby eliminating all gross disease from the peritoneal cavity. Heintz and coworkers noted that prognosis is improved for younger patients (<50 years), those with good initial performance status (Karnofsky score >80), and those whose disease could be cytoreduced to less than 1.5 cm. Adverse factors were large before initial operation, ascites, and peritoneal carcinomatosis. In a small collaborative GOG study, Hoskins and colleagues found that those who started with large-volume disease did worse than those who initially had small-volume disease; no survival advantage could be demonstrated for the debulking operation in the large-volume disease group. Chi and associates noted that those with advanced disease and a preoperative CA-125 level higher than 500 U/mL had less than a 20% chance of an optimal surgical debulking (discussed later).

One exception to the required removal of the uterus and opposite ovary occurs in the case of well-differentiated (grade 1) ovarian tumors confined to one ovary (stage IA). DiSaia and coworkers outlined criteria for preserving childbearing function in a young woman with stage IA, grade 1 ovarian epithelial carcinoma, as follows:

1. Tumor confined to one ovary
2. Tumor well differentiated (grade 1), with no invasion of capsule, lymphatics, or mesovarium
3. Peritoneal washings negative
4. Omental biopsy specimen negative
5. Young woman of childbearing years with a strong desire to preserve reproductive function

These criteria can be applied to all types of epithelial ovarian tumors but are more likely to be satisfied in the case of

Figure 33.12 Invasive implant. Glands with an irregular contour lined by severely atypical epithelial cells with extensive intraglandular bridging are present (H&E, $\times 313$). (From Bell DA, Weinstock MA, Scully RE. Peritoneal implants of ovarian serous borderline tumors: histologic features and prognosis. *Cancer*. 1988;62[10]:2212-2222.)

mucinous tumors, which are more frequently well differentiated and unilateral than serous carcinomas. Wedge resection of a normal-appearing contralateral ovary is unlikely to uncover an occult tumor. In these cases, it is reasonable to follow the woman closely with vaginal ultrasonography for any evidence of future ovarian enlargement.

Early-Stage Ovarian Carcinomas

Stage I

The standard therapy for all patients with early-stage ovarian cancer (EOC) includes hysterectomy (usually performed via celiotomy) with bilateral salpingo-oophorectomy. In patients interested in preserving fertility, unilateral salpingo-oophorectomy with preservation of the contralateral ovary and uterus is often feasible. In addition, all patients with early-stage disease should undergo pelvic washings, omental biopsy, cytologic sampling of the surface of the diaphragm, complete bilateral pelvic and para-aortic lymphadenectomy or lymph node sampling, and bilateral biopsies of the paracolic gutters and pelvic peritoneal surfaces. It is important to emphasize that careful assessment of the subdiaphragmatic areas and inspection of the entire peritoneum and the retroperitoneal para-aortic and pelvic nodes are important, particularly in view of the risk of diaphragmatic and nodal spread in higher-grade tumors that initially appear to be at stage I, particularly those on frozen section that appear to be less well differentiated than grade 1.

Le and colleagues compared a group of patients who underwent minimal staging performed by a general gynecologist with a group of patients who underwent comprehensive staging performed by a gynecologic oncologist. They found the risk of recurrence to be increased for patients operated on by the general gynecologist. Another study by Mayer and associates showed that patients operated on by a gynecologic oncologist had a 24% improvement in 5-year overall survival.

Rupture of Ovary

Occasionally, during removal, a stage I ovarian carcinoma is inadvertently ruptured (stage IC, see [Table 33.6](#)). There are conflicting opinions as to the potential adverse effects on prognosis. In an analysis of 394 patients, Sjövall and associates found that rupture during surgery did not affect survival, whereas there was marked reduction in survival in that study among those whose ovarian rupture occurred *before* the operation. In general, the spilled fluid and all residual tumor should be removed promptly from the operative field after a rupture (discussed later). Presumably higher-grade and larger tumors are most prone to rupture.

A study by Dembo and colleagues of 519 stage I patients found that adverse factors were grade of tumor, dense pelvic adherence (no invasion but adhesion), or more than 250 mL of ascites. Patients without these features had a 98% 5-year survival rate. It appears that patients with stage I grade 3 tumors should have postoperative therapy, but data are unclear for stage I grade 2 patients.

Minimally Invasive Surgical Staging of Early-Stage Ovarian Cancer

An estimated 15% of women with EOC have early-stage disease at diagnosis. In these patients, comprehensive surgical staging is required to provide accurate prognostic information and plan treatment options. Frequently, the diagnosis of EOC is made incidentally during adnexal surgery for other indications. Because minimally invasive surgical procedures are becoming more

common in gynecology and more in demand by the public at large, determining the feasibility and safety of these procedures for the staging of presumed early-stage EOC has become a necessity.

Laparoscopy often leads to a shorter hospital stay, less intraoperative blood loss, and a shorter recovery period than laparotomy. However, surgical staging for EOC requires meticulous inspection of the peritoneal cavity and careful dissection of lymph nodes, vessels, and other abdominal and pelvic structures. Thus to assess the feasibility of minimally invasive surgical staging, several issues must be considered, such as the frequency of complications, frequency of conversion to laparotomy, and recurrence rate following laparoscopic staging.

Nezhat and associates performed a retrospective review of 36 patients who underwent laparoscopic staging for presumed early-stage ovarian and fallopian tube carcinoma from 1995 to 2007. Of the 36 patients, 20 were diagnosed with invasive EOC, 11 with borderline ovarian tumors (BOT), and 5 with nonepithelial tumors. There were no intraoperative complications, but there were four postoperative complications (one partial small bowel obstruction managed conservatively, two lymphoceles, and one lymphocele cyst requiring drainage). The mean number of pelvic lymph nodes obtained was 14.8, and the mean number of para-aortic lymph nodes obtained was 12.2. Of the 9 patients who underwent completion staging, 7 (77.8%) had their disease upstaged. During a mean follow-up of 55.9 months, there were three recurrences in patients who underwent conservative surgery, and the overall survival rate was 100%. Jung and coworkers conducted a retrospective review to evaluate the feasibility and efficacy of laparoscopically assisted staging surgery for ovarian cancer in 24 patients with ovarian or fallopian tube cancer. There were no conversions to laparotomy and no intraoperative complications. The only postoperative complication was a port site metastasis. Ten patients (41.7%) had their disease upstaged. The mean number of pelvic lymph nodes obtained was 22.5 and the mean number of para-aortic lymph nodes obtained was 11. Interestingly, the mean hospital stay was 10.6 days, which was attributed to differences in practice patterns in Korea.

In a study by Gallota and colleagues, the authors evaluated the safety and perioperative outcomes of laparoscopic staging of patients with apparent early stage ovarian cancer ([Gallota, 2014](#)). A total of 300 patients were selected: 150 had been submitted to immediate laparoscopic staging (group 1), whereas 150 had undergone delayed laparoscopic staging (group 2). No significant differences of postoperative complications were observed between the two groups. Histologic data revealed more frequently serous tumors (0.06), grade 3 ($P = .0007$) and final up-staging ($P = .001$) in group 1. Recurrence and death of disease were documented in 25 (8.3%), and 10 patients (3.3%), respectively. The 3-year disease-free survival (DFS) and overall survival (OS) rates were 85.1%, and 93.6%, respectively, in the whole series. There was no difference between group 1 and group 2 in terms of DFS (P value = 0.39) and OS (P value = 0.27). The authors concluded that laparoscopic management of early ovarian cancer is safe and feasible.

In summary, it appears that minimally invasive surgical staging of presumed EOC is safe and effective when performed by a trained gynecologic oncologist.

Adequacy of Minimally Invasive Surgery Compared with Laparotomy for Staging of Ovarian Neoplasms

Important concerns have been raised about laparoscopic staging for ovarian neoplasms, including concerns about the adequacy

of the lymph node dissection, differences between laparoscopy and laparotomy in operative time, postoperative complications, and postoperative recovery. In one meta-analysis of laparoscopic staging surgery in patients with presumed early-stage ovarian cancer, Park and colleagues identified 11 observational studies (Park, 2013). The combined results of three retrospective studies showed that the estimated blood loss in laparoscopy was significantly lower than that for laparotomy ($P < .001$). The overall upstaging rate after laparoscopic surgery was 22.6% (95% CI, 18.1-27.9) without significant heterogeneity among all study results. The overall incidence of conversion from laparoscopy to laparotomy was 3.7% (95% CI, 2.0-6.9). The overall rate of recurrence in studies with a median follow-up period of ≥ 19 months was 9.9% (95% CI, 6.7-14.4). The authors concluded that the operative outcomes of a laparoscopic approach in patients with early-stage ovarian cancer could be compatible with those of laparotomy.

Data on the application of robotic surgery for ovarian cancer staging are scant. In a study by Brown and associates, the authors evaluated the safety and feasibility of robotic-assisted systematic lymph node staging in the management of early-stage ovarian cancer. A total of 26 early-stage ovarian cancer patients were identified. The mean operating time was 2.90 hours, and the estimated blood loss was 63 mL; there were no intraoperative complications, although one patient's surgery was significantly prolonged due to pelvic adhesions. The mean number of pelvic and para-aortic lymph nodes removed was 14.6 (2.3% incidence of pelvic lymph node metastases) and 5.8 (3.3% incidence of para-aortic lymph node metastases), respectively. The patients' mean duration of hospital stay was 18.4 hours, and 2 patients were readmitted for either a postoperative wound infection or vaginal dehiscence. The authors concluded that robotic-assisted surgical staging was feasible and safe; however, there was a low incidence of lymph node metastasis (2.3%) and the authors stressed the value of a systematic lymph node dissection.

Stage II

Stage II ovarian cancer is initially treated by removal of all gross disease, including the uterus, tubes, and ovaries, and an omentectomy (infracolic) is performed. The pelvic and para-aortic nodes are sampled.

Postoperative Management for Stages I and II

Recommendations for postoperative or adjuvant therapy generally have evolved around the identification of patients in whom a sufficient risk of recurrence is observed. The precision to make this assessment is low and has been based on morphologic features such as grade, histology, and presence of rupture and residuum. Historically, several modalities have been evaluated alone and in combination by prospective studies of unselected patients, including chemotherapy, radiation therapy, intraperitoneal (IP) radiocolloids, and immunotherapy. Guthrie and coworkers evaluated 656 patients treated for epithelial ovarian carcinomas that had been totally excised. Most carcinomas were stage I or II, and patients were randomly assigned to receive postoperative treatment of radiation therapy alone, chemotherapy alone, radiation therapy and chemotherapy, or no postoperative therapy. Follow-up was for at least 2 years. Approximately 20% of the tumors were borderline malignancies and the rest were invasive carcinomas. Perhaps surprisingly, the lowest frequency of death or

recurrence was noted in the group receiving no postoperative therapy (2%), whereas in the other groups, the death or recurrence incidence was 14% to 17%. Thus this study has shown no benefit for adjuvant therapy and highlights the need for careful case selection and pathologic review. In addition, because survivorship of low-stage cancer is better, long-term follow-up is necessary to tease out the merits of intervention.

Two large multicenter trials have been conducted and were combined for analytic purposes to address this issue. The International Collaborative Ovarian Neoplasm 1 (ICON1) and Adjuvant ChemoTherapy in Ovarian Neoplasm (ACTION) trials compared platinum-based chemotherapy with observation in patients after surgery with EOC. The two trials differed somewhat in patient eligibility with ICON1 predominantly enrolling postoperative stages I and II patients with limited staging and ACTION enrolling postoperative stage IA and IB, grades 2 and 3, stages IC to IIA, all grades, and clear cell tumor patients. Overall, 925 patients were collectively enrolled (477 in ICON1 and 448 in ACTION) and followed for a median 4 years. The overall survival rate at 5 years was 82% in the chemotherapy arm and 74% in the observation arm (HR, 0.67; 95% CI, 0.5-0.9; $P = .001$). Recurrence-free survival at 5 years was also significantly higher in the chemotherapy arm compared with observation (HR, 0.64; 95% CI, 0.5-0.82). In select patients, platinum-based therapy appears to improve survival and lower recurrence at 5 years over observation. In all, three randomized clinical trials have addressed platinum-based chemotherapy versus observation in EOC. These three trials were evaluated via meta-analysis to assess the role of adjuvant chemotherapy. As expected, the combined data mirror the results of the two larger studies with regard to the impact of adjuvant chemotherapy (HR, 0.71; 95% CI, 0.53-0.93) on 5-year survival. However, when subcategorized by surgical staging, this benefit retained significance only in the group in whom nonoptimal staging was performed. An update from ICON1 with a median follow-up of 10 years confirmed the impact of adjuvant chemotherapy in this cohort (Collinson, 2014). These data highlight the importance of accurate surgical staging information when devising an appropriate postoperative treatment plan.

Young and colleagues conducted two randomized studies of adjuvant therapy for patients with stage I disease. The first study showed that those with stage IA, grades 1 and 2, had 5-year survival rates more than 90% and did not benefit from adjuvant alkylating agent chemotherapy. The second study showed comparable results for adjuvant ^{32}P and platinum-based therapy for a higher risk cohort, including stage I, grade 3, as well as completely resected stage II cases. The assessable cohort included 229 randomized patients. The cumulative incidence of recurrence at 10 years was 29% lower for those receiving chemotherapy compared with ^{32}P (28% vs. 35%; $P = .15$) but was not statistically significant. The recurrence risk in this cohort of patients was substantial—all stage I, 27%, and stage II, 44%. Inadequate distribution and small bowel perforation are cited as reasons that ^{32}P is less desirable as adjuvant therapy. Piver and associates reported 93% 5-year survival for stage IC or stage I, grade 3, patients who received multiagent chemotherapy containing cisplatin. Vergote and coworkers analyzed 313 patients treated with ^{32}P after the primary operation or second-look operation (discussed later). Bowel complications occurred in 22 (7%) and 13 required operation. Bolis and colleagues reported on two randomized trials

comparing ^{32}P and chemotherapy with cisplatin, 50 mg/m², for six cycles. Stages IA and IB grades 2 to 3 and stages IC showed significantly reduced relapse rates in the cisplatin arms. Unfortunately, a survival advantage was not demonstrated, and those who had a recurrence after receiving chemotherapy did worse than those who received ^{32}P .

When indicated, the most frequently used modality is now chemotherapy, although the ideal regimen and number of courses needed are still debated. Bell and associates reported the results of a GOG randomized study comparing three and six cycles of adjuvant paclitaxel and carboplatin for women with stages IA and IB, grade 3, all stage IC, clear cell tumor, and completely resected stage II epithelial ovarian cancer. The study was powered for a 50% or greater decrease in recurrence for six cycles of therapy. A total of 457 patients were recruited; 344 were alive a median of 6.8 years since entry. The overall treatment effect is a nonsignificant 24% reduction in recurrence for the six-cycle arm (HR, 0.76; 95% CI, 0.51-1.13; $P = .18$). The improved impact on estimated recurrence at 5 years was 5%, and there was no difference in overall survival between the arms. Approximately one third of patients in both arms had stage II disease. Forest plot analysis by stage did not demonstrate any alteration in the study's conclusions in this cohort. Although no difference was observed in this trial, many investigators have questioned the pretreatment statistical goals and have continued to recommend six cycles of therapy in patients with early-stage disease requiring treatment. A post hoc analysis of the survival results by histology raises the hypothesis that six cycles of therapy may benefit patients with serous histology to a different degree than the others included in the trial. It also should be noted that the carboplatin dose used in this trial was AUC 7.5.

A follow-up study by the GOG (protocol, 0175) addressed the role of maintenance therapy in this setting. Women with the same eligibility as GOG 157 were randomized to three cycles of paclitaxel and carboplatin (AUC 6) followed by normal surveillance or 24 infusions of low-dose (40 mg/m²) weekly paclitaxel. The study was powered to address a 43% reduction in the risk of recurrence and enrolled 542 patients. The stage distribution was 71% stage I; 80% of patients randomized to the maintenance arm received all assigned therapy. Toxicity was similar between the two arms. The HRs for progression-free survival (PFS) and OS were 0.81 (95% CI, 0.56-1.15) and 0.78 (95% CI, 0.52-1.17), respectively. Subgroup analysis demonstrated no effect by stage, histology, or grade. There was remarkable consistency between the two GOG studies in the 5-year survival recorded by the three-cycle cohort. Although the optimal treatment is still not known, high-risk, early-stage patients clearly benefit from therapy.

Primary Cytoreductive Surgery

Most patients with ovarian cancer present with disease that has spread beyond the pelvis and into the upper abdomen. The routine recommendation for patients with advanced disease who are surgical candidates is to perform a total abdominal hysterectomy, bilateral salpingo-oophorectomy, complete omentectomy, and resection of all visible tumor. Bristow and colleagues performed a retrospective population-based study of consecutive patients diagnosed with epithelial ovarian cancer (Bristow, 2015). A total of 9933 patients were identified (stage I, 22.8%; stage II, 7.9%; stage III, 45.1%; stage IV, 24.2%), and 8.1% of patients

were treated at comprehensive cancer centers (National Cancer Institute Comprehensive Cancer Center [NCI-CCC]). Overall, 35.7% of patients received National Comprehensive Cancer Network (NCCN) guideline adherent care, and NCI-CCC status (odds ratio [OR] 1.00) was an independent predictor of adherence to treatment guidelines compared with high-volume hospitals (HVHs) (OR, 0.83; 95% CI, 0.70-0.99) and low-volume hospitals (LVHs) (OR, 0.56; 95% CI, 0.47-0.67). The median ovarian cancer-specific survivals according to hospital type were NCI-CCC 77.9 (95% CI, 61.4-92.9) months, HVH 51.9 (95% CI, 49.2-55.7) months, and LVH 43.4 (95% CI, 39.9-47.2) months ($P < .0001$). National Cancer Institute Comprehensive Cancer Center status (hazard ratio [HR] 1.00) was a statistically significant and independent predictor of improved survival compared with HVH (HR 1.18; 95% CI, 1.04-1.33) and LVH (HR 1.30; 95% CI, 1.15-1.47).

Aletti and associates sought to estimate the effect of aggressive surgical resection on the survival of epithelial ovarian cancer patients. They found that the 5-year disease-specific survival rate was markedly better for patients operated on by surgeons who were most likely to use radical procedures than for patients operated on by surgeons who were least likely to use radical procedures (44% vs. 17%; $P < .001$). Also, the rate of optimal resection was 84% for the surgeons most likely to use radical procedures compared with 51% for the surgeons least likely to use radical procedures, highlighting the value of extensive surgical effort.

Zivanovic and colleagues evaluated the impact of upper abdominal disease (UAD) cephalad to the greater omentum on surgical outcomes for 490 patients with stage IIIC ovarian, fallopian tube, and primary peritoneal cancers. Patients were divided into three groups according to the amount of disease in the upper abdomen. Group 1 was defined as no disease in the upper abdomen, group 2 as having tumors smaller than 1 cm, and group 3 as having bulky disease, larger than 1 cm. The authors found that optimal cytoreduction was achieved in 81%, 63%, and 39% of patients in groups 1, 2, and 3, respectively. In the largest study of postoperative tumor residuum and outcome, resection to no visible intraperitoneal disease was substantially related to progression-free and overall survival. The study population ($n = 3126$) was generated from three randomized phase III trials assessing primary chemotherapy regimens in advanced stage disease patients. Median overall survival was 99.1 months for patients with no postoperative tumor residua compared with 36.2 months for those with visible disease 1 cm or smaller and 29.6 months in those with more than 1 cm of tumor residua.

Chang and associates sought to quantify the impact of complete cytoreduction to no gross residual disease on overall survival among patients with advanced-stage ovarian cancer treated during the platinum-taxane era (Chang, 2013). A total of 18 relevant studies (13,257 patients) were identified for analysis. After controlling for other factors on multiple linear regression analysis, each 10% increase in the proportion of patients undergoing complete cytoreduction to no gross residual disease was associated with a significant and independent 2.3-month increase (95% CI, 0.6-4.0, $P = .011$) in cohort median survival compared with a 1.8-month increase (95% CI, 0.6-3.0, $P = .004$) in cohort median survival for optimal cytoreduction (residual disease ≤ 1 cm). Each 10% increase in the proportion of patients receiving intraperitoneal chemotherapy was associated

with a significant and independent 3.9-month increase (95% CI, 1.1-6.8, $P = .008$) in median cohort survival time. The authors found that the proportions of patients left with no gross residual disease and receiving intraperitoneal chemotherapy are independently significant factors associated with the most favorable cohort survival time.

Role of Laparoscopy in Assessing Resectability to R0 in Advanced Ovarian Cancer

A number of studies have evaluated the use of serologic markers, such as CA-125, and imaging modalities, such as computed tomography (CT) or positron emission tomography/CT (PET/CT), to determine which patients are ideal candidates for primary cytoreductive surgery. More recently, laparoscopy has been proposed as a reliable predictor of R0 resection. In this chapter, we review the existing literature on the proposed criteria to predict the outcome of cytoreductive surgery and the role of laparoscopy-based scores in the management of advanced ovarian cancer.

Gómez-Hidalgo and colleagues published a comprehensive review of the evolution of laparoscopy as a tool to help identify ideal patients with advanced ovarian cancer for optimal cytoreduction (R0) (Gómez-Hidalgo, 2015). The authors concluded that existing studies point to a highly valuable role for laparoscopy for objectively assessing the feasibility of optimal primary and interval cytoreductive surgery for patients with advanced-stage ovarian cancer (FIGO stages III and IV). They went on to suggest that the Fagotti laparoscopy-based score is a useful predictor of optimal cytoreduction.

Nick and colleagues published an algorithm that identifies patients in whom complete gross resection at primary surgery is likely to be achieved (Nick, 2015). Such an algorithm is currently being used to ensure that the rate of optimal cytoreduction (R0) increases and the rate of patients unnecessarily undergoing neoadjuvant chemotherapy decreases. In addition, the algorithm allows surgeon to obtain tissue prior to the initiation of therapy, thus targeting molecular pathways in a much more precise and personalized strategy.

Utility of Video-Assisted Thoracoscopy

Unfortunately, no tools are available that allow surgeons to predict with high confidence whether there is disease in the pleural cavity. Video-assisted thoracoscopic surgery (VATS) allows surgeons, through a minimally invasive approach, to not only drain the pleural cavity of fluid but also evaluate whether pleural disease is present.

In 2010, Diaz and coworkers published on a total of 42 patients who underwent VATS prior to cytoreduction. VATS was performed for right-sided effusions in 30 patients (71%). Macroscopic pleural disease was found in 29 patients (69%); the other 13 patients (31%) had no evidence of intrathoracic disease. Of the 29 patients with macroscopic disease, 17 underwent primary abdominal cytoreduction, and 12 went on to receive neoadjuvant chemotherapy. Eighteen patients (62%) had nodules larger than 1 cm. Twelve of these patients went on to receive neoadjuvant chemotherapy, and 6 patients underwent intrathoracic cytoreduction. Of the 27 patients with positive pleural cytology, 12 had macroscopic disease larger than 1 cm, 9 had macroscopic disease smaller than 1 cm, and 6 had no macroscopic disease. Of the 11 patients with negative pleural cytology,

4 had macroscopic disease (larger than 1 cm in 2 patients), and 7 had no macroscopic disease. The authors concluded that 31% of all patients who met the inclusion criteria and underwent VATS had no evidence of intrathoracic disease and that VATS altered primary management in 43% of patients.

Diaphragmatic Stripping or Resection

At initial surgical exploration, diaphragmatic disease may be the largest volume metastatic disease. Unfortunately, the presence of diaphragmatic disease is one of the most common factors precluding optimal tumor reduction surgery. Large diaphragmatic metastases were cited as a significant barrier to optimal tumor-reductive surgery by 76% of the members of the Society of Gynecologic Oncologists in a study reported by Eisenkop and associates. In that same study, only 24% of those surveyed used diaphragm resection and 30% reported not being experienced with the procedure. Aletti and coworkers evaluated the therapeutic value of diaphragmatic surgery in patients with advanced ovarian cancer and found that patients who underwent diaphragmatic surgery (stripping of the diaphragm peritoneum, full- or partial-thickness diaphragm resection, or excision of nodules) had an improved 5-year overall survival rate relative to patients who did not undergo diaphragmatic surgery (53% vs. 15%, $P < .0001$).

A study by Pathiraja and colleagues compared the surgical morbidity of diaphragmatic peritonectomy versus full-thickness diaphragmatic resection with pleurectomy at radical debulking. A total of 42 patients were eligible for the study; 21 underwent diaphragmatic peritonectomy (DP, group 1) and 21 underwent diaphragmatic full thickness resection (DR, group 2). Forty patients out of 42 (93%) had complete tumor resection with no residual disease. Histology confirmed the presence of cancer in the diaphragmatic peritoneum of 19 patients out of 21 in group 1 and all 21 patients of group 2. The overall complications rate was 19% in group 1 versus 33% in group 2. The pleural effusion rate was 9.5% versus 14.5%, and the pneumothorax rate was 14.5% only in group 2. Two patients in each group required postoperative chest drains (9.5%). The authors concluded that patients in the pleurectomy group experienced pneumothorax and a higher rate of pleural effusion, but none had long-term morbidity or additional surgical interventions.

Splenectomy

For optimal cytoreductive surgery, a splenectomy may be required if there is disease involving the hilum, capsule, or parenchyma of the spleen. Magtibay and colleagues evaluated 112 patients who underwent splenectomy as part of primary or secondary cytoreductive surgery. They found that the most common indications for splenectomy were direct metastatic involvement (46%), facilitation of an en bloc resection of perisplenic disease (41%), and intraoperative trauma (13%). In that same study, the authors found that 65% of patients had hilar involvement, 52% capsular involvement, and 16% parenchymal metastases. Interestingly, patients with disease directly involving the splenic parenchyma did not have a worse prognosis than patients with disease involving the splenic hilum or capsule.

Hepatic Resection

The clinical significance of hepatic parenchymal metastasis on survival in patients with advanced ovarian cancer has been

studied. Lim and coworkers reported on a series of patients with hepatic parenchymal metastases. In this series, patients underwent wedge resection, segmentectomy, or hemihepatectomy as part of their tumor reductive surgery. The 5-year PFS and OS rates for patients with stage IIIC disease and patients with stage IV disease and hepatic parenchymal metastasis from peritoneal seeding were 25% and 23% and 55% and 51%, respectively. The authors advocated that complete hepatic resection should be attempted for patients with hepatic parenchymal metastasis.

Bowel Resection

Because ovarian cancer often presents with confluent tumor in the cul de sac, rectosigmoid resection—along with or en bloc with hysterectomy and bilateral salpingo-oophorectomy—is often necessary to achieve complete tumor resection in the pelvis. This results in high rates of optimal cytoreduction, with acceptable morbidity. An average of 26% of women with ovarian cancer undergo colon resection as part of their primary cytoreductive operation according to a study by Aletti and colleagues. Peiretti and associates aimed to determine the impact of rectosigmoid resection, at the time of primary cytoreductive surgery, on morbidity and survival of patients with advanced ovarian cancer. A total of 238 patients were identified; 180 (75%) had stages IIC to IIIC and 58 (25%) had stage IV. Complete cytoreduction was achieved in 41% of the cases. Stapled coloproctostomy was performed in 98%, whereas hand-sewn coloproctostomy was performed in only 2%; a protective ileostomy and colostomy were necessary (constructed) in 2 (0.8%) and 5 (2%) cases, respectively. The complications associated to rectosigmoid resection were anastomotic leakage in 7 (3%) patients and pelvic abscess in 9 (3.7%). Fifty percent of patients recurred during the study period, but only 5% of them showed a relapse at the level of the pelvis, whereas 8% presented with abdominal recurrence associated with pelvic disease as well. The median overall survival time among patients with complete cytoreduction was 72 months compared with 42 months among the rest of patients ($P = .002$). The authors concluded that rectosigmoid colectomy may significantly contribute to a complete primary cytoreduction for advanced stage ovarian, tubal, and peritoneal cancers and that pelvic complete debulking accomplished by rectosigmoid resection could be associated with a lower rate of pelvic recurrence as well.

Retroperitoneal Lymphadenectomy

Whether systematic removal of retroperitoneal lymph nodes should be part of optimal cytoreductive surgery had been a topic of debate for many years. We now have evidence that systematic lymphadenectomy in patients with grossly uninvolved lymph nodes provides no benefit to the woman. A prospective randomized trial by Benedetti-Panici and colleagues showed that systematic lymphadenectomy improves PFS but not OS in women with optimally debulked advanced ovarian cancer. In addition, the median operating time was longer (300 vs. 210 minutes; $P < .001$) and the percentage of patients requiring blood transfusions was higher (72% vs. 59%; $P = .006$) in the systematic lymphadenectomy arm. An ongoing randomized trial of systematic lymphadenectomy versus no further dissection is being conducted in stages II to IV patients in whom complete cytoreduction has been otherwise achieved at the point of primary cytoreduction. The primary end points of the LION

(Lymphadenectomy in Ovarian Neoplasms) study are OS, PFS, and quality of life.

Postoperative Therapy for Advanced Epithelial Carcinomas (Stages III and IV)

For historical interest, early adjuvant therapy attempts in advanced disease included single-agent and combination chemotherapy regimens based on the alkylating agents. A limited number of responses were observed, and treatment frequently continued for 1 to 3 years. With the discovery of cisplatin (and carboplatin, subsequently), several randomized trials were conducted comparing platinum and platinum combinations with nonplatinum regimens. These pivotal trials secured platinum as the agent of choice in primary adjuvant therapy, which continues to this day. In addition, several clinical trials have established that little additional benefit to treatment is observed beyond four cycles of therapy. Most recently, the development of the taxanes has documented the importance of this agent (discussed later). By convention, six to eight cycles of combination platinum- and taxane-based therapy are now recommended as adjuvant therapy for most patients with advanced disease.

The pivotal trial establishing the importance of paclitaxel in primary ovarian cancer management was reported by McGuire and associates on behalf of the GOG. They conducted a randomized trial comparing cisplatin, 75 mg/m², with cyclophosphamide, 750 mg/m², or paclitaxel, 135 mg/m², over 24 hours and demonstrated a survival advantage in the paclitaxel arm. All patients had residual tumors larger than 1 cm after the primary operation. Response rates improved with paclitaxel relative to control in patients with measurable disease (73% vs. 60%). The median PFS was 18 months in the paclitaxel arm compared with 13 months in the platinum arm ($P < .001$). OS was similarly improved (38 vs. 24 months; HR = 0.6; 95% CI, 0.5-0.8; $P < .001$).

The results of this study were confirmed in similar randomized clinical trials conducted worldwide. The taxane-platinum combination was generally considered to be the recommended first-line therapy for ovarian cancer. The platinum analogue carboplatin was found to be less nephrotoxic and neurotoxic and easily administered without prehydration, thus shortening the time of infusion. After several randomized clinical studies demonstrating the equivalence of this agent to cisplatin in ovarian cancer, carboplatin was substituted for cisplatin in taxane-based regimens. In addition, paclitaxel infused over 3 hours was found likely to be equivalent to paclitaxel infused over 24 hours and, in combination with carboplatin, enabled the combination to be given on an outpatient basis. Phase III studies by Ozols and coworkers showed that paclitaxel-carboplatin is a feasible outpatient regimen with less toxicity than paclitaxel-cisplatin and is associated with equivalent survival.

It should be noted that carboplatin is quantitatively excreted by the kidney and its effective serum concentration can be calculated from a formula based on the woman's glomerular filtration rate (GFR). This can be determined by various methods but is generally estimated by calculating the creatinine clearance. The Calvert formula is most commonly used and determines a total dose by this formula:

$$\text{Carboplatin, total dose} = \text{Desired AUC} \times (\text{GFR} + 25)$$

AUC-based dosing is preferred for carboplatin because the AUC most accurately reflects observed dose-specific toxicity and is

more reliable across patients than dosing based on the body mass index. A usual dose for carboplatin is calculated for AUC values of 5 to 7.5. Both paclitaxel and platinum compounds are neurotoxic, as noted by Warner, and this is often the dose-limiting toxicity. The taxane, docetaxel, was found to be potentially less neurotoxic than paclitaxel. Vasey and colleagues reported on a large phase III study comparing docetaxel and carboplatin with paclitaxel and carboplatin in patients with stages IC to IV ovarian cancer. Almost identical survival parameters were observed between the two agents. The docetaxel arm was significantly less neurotoxic; however, it was associated with more myelosuppression. Neurotoxicity, as evaluated by several objective measures, returned to parity several months after treatment. Granulocyte colony-stimulating factor is occasionally needed to reduce the duration of significant neutropenia in these regimens. A commonly used regimen is paclitaxel, 175 mg/m² over 3 hours, or docetaxel, 75 mg/m² over 1 hour, and carboplatin (AUC = 5 to 6) given as a 1-hour infusion every 3 weeks. Premedication is required for both taxanes to combat hypersensitivity reactions, which have been attributed to the taxane itself and the carrier vehicle required to make these agents water soluble. In addition, steroid administration is necessary after treatment for docetaxel to combat fluid retention and effusion, a complication that may occur in as many as 25% of patients without prophylaxis.

Alterations in Frontline Treatment Strategies

Although the preferred sequence in primary advanced ovarian cancer management is surgery followed by chemotherapy, several authors have attempted to take advantage of the disease's intrinsic chemosensitivity to improve outcomes in patients with extensive disease. Two avenues have been pursued:

- Neoadjuvant chemotherapy, in which, following biopsy or limited surgery, chemotherapy is administered for a reduced number of cycles (usually three to four) and an operation is planned for removal of the primary tumor (if present) and residual metastases
- Interval cytoreduction, when an unsuccessful maximal attempt at cytoreduction is followed by a reduced number of chemotherapy cycles (usually three to four), followed by a second cytoreduction attempt

Both strategies are followed by three to four cycles of chemotherapy after surgery. This latter strategy has been evaluated in randomized clinical trials with conflicting results; the former was evaluated in a randomized evaluation.

Neoadjuvant Chemotherapy

Neoadjuvant chemotherapy is practiced as an alternative for patients thought to have substantial operative risk or preoperative disease distribution that could preclude optimal cytoreduction. Several authors have noted the potential benefits to this strategy, including the opportunity to allow for an improvement in performance status, decreasing operative morbidity through less extensive surgery, and increasing the opportunity to achieve an optimal result. Each of these goals has been demonstrated in small, single-institution retrospective and prospective studies. For example, in a series of 85 women treated with either neoadjuvant chemotherapy ($n = 57$) or primary cytoreduction ($n = 28$), Morice and associates reported a significant decrease in major morbidity, defined as morbidity requiring a second

operation (7% vs. 36%; $P = .01$). Survival in this trial was similar between the cohorts, although with wide confidence limits.

Schwartz and colleagues reported on 59 women undergoing neoadjuvant chemotherapy and compared their surgical morbidity with 206 patients treated in the same time period by a standard approach. They found that patients in the former group had a shorter intensive care unit stay and postoperative hospital stay compared with conventional patients. Both groups received platinum-based chemotherapy. Because patients in these small trials are selected for treatment based on presenting disease volumes or medical status, it has been difficult to determine whether there is a detriment to survival by this approach. Clearly, patients too infirm to be operated on gain from this approach because if they have chemoresistant disease, surgery would have little value and likely would hasten an adverse outcome. Conversely, patients able to undergo the procedure could have a poorer outcome because there could be further expansion of a large population of resistant clones by delaying cytoreductive disease.

Loizzi and coworkers reported a case-control study of neoadjuvant chemotherapy in 60 patients (30 in each group). Patients were matched 1:1 based on date of diagnosis, histology, and stage. They documented that although the neoadjuvant cohort was older and represented a poorer performance status, these patients underwent optimal cytoreduction at a favorable rate (76% vs. 60%) and, following platinum-based chemotherapy, had similar PFS and OS compared with the control cohort. A critical question to be answered in this methodology is one of biology, which can only be addressed in a prospective clinical study of potentially operable patients. Fortunately, two trials are ongoing to address this question, one of which was recently reported. In this prospective multi-institutional study, 668 evaluable patients were randomized to primary cytoreduction followed by six cycles of platinum-taxane chemotherapy or three cycles of neoadjuvant platinum-based therapy followed by interval cytoreduction and three additional cycles of therapy. Patients were diagnosed by biopsy before randomization. Only 10% of patients randomized to interval surgery did not undergo the procedure because of the uncommon event of primary platinum and taxane resistance. Optimal cytoreduction (to <1 cm or to no visible disease) was statistically higher in the neoadjuvant therapy arm. This arm was also associated with lower postoperative morbidity. However, no difference was observed in PFS (HR, 0.99; 95% CI, 0.87-1.13) or OS (HR, 0.98; 95% CI, 0.85-1.14). Low rates of primary optimal cytoreduction and relatively low absolute median survivals observed in this study have been raised as criticisms. In 2010, Vergote and colleagues published a prospective trial randomizing patients with stage IIIC or IV epithelial ovarian carcinoma, fallopian tube carcinoma, or primary peritoneal carcinoma to primary debulking surgery followed by platinum-based chemotherapy or to neoadjuvant platinum-based chemotherapy followed by debulking surgery (Vergote, 2010). Of the 670 patients randomly assigned to a study treatment, 632 (94.3%) were eligible and started the treatment. The majority of these patients had extensive stage IIIC or IV disease at primary debulking surgery (metastatic lesions that were larger than 5 cm in diameter in 74.5% of patients and larger than 10 cm in 61.6%). The largest residual tumor was 1 cm or less in diameter in 41.6% of patients after primary debulking and in 80.6% of patients after interval debulking. Postoperative rates of adverse effects and mortality tended to be higher after primary debulking than after interval debulking. The hazard ratio for

death (intention/treat analysis) in the group assigned to neoadjuvant chemotherapy followed by interval debulking, as compared with the group assigned to primary debulking surgery followed by chemotherapy, was 0.98 (90% CI, 0.84-1.13; $P = .01$ for non-inferiority), and the hazard ratio for progressive disease was 1.01 (90% CI, 0.89-1.15). Complete resection of all macroscopic disease (at primary or interval surgery) was the strongest independent variable in predicting overall survival. The authors concluded that neoadjuvant chemotherapy followed by interval debulking surgery was not inferior to primary debulking surgery followed by chemotherapy as a treatment option for patients with bulky stage IIIC or IV ovarian carcinoma in this study. They went on to suggest that complete resection of all macroscopic disease, whether performed as primary treatment or after neoadjuvant chemotherapy, remains the objective whenever cytoreductive surgery is performed.

An additional phase III trial comparing primary cytoreduction to the neoadjuvant chemotherapy (NACT) approach has been published (Kehoe, 2015). In this trial 552 women with stage III or IV ovarian cancer were randomized 1:1 to either primary surgery followed by six 3-week cycles of a carboplatin regimen (usually in combination with paclitaxel) or to 3 induction cycles of chemotherapy followed by surgery followed by 3 adjuvant cycles of chemotherapy. The primary end point was OS, which was similar (primary debulking surgery [PDS]: 22.6 months vs. NACT: 24.1 months, upper bound of the one-sided 90% CI, 0.98), favored the NACT arm. High-grade adverse events related to surgery, including mortality, were higher in the PDS arm. However, like the European Organization for Research and Treatment of Cancer (EORTC) trial, overall survival in the trial (both cohorts) was much lower than expected, reflecting low rates of complete cytoreduction (PDS: 17%, NACT: 39%) and heterogeneity in treatment care (76% of both arms receiving paclitaxel and carboplatin). Criticisms for both trials lie in patient selection and surgical effort potentially confounding the interpretation of contemporary management.

Interval Cytoreduction

Cytoreductive surgery performed after an initial failed attempt or in patients who were initially not considered candidates for

cytoreductive surgery is referred to as interval cytoreductive surgery. Rose and colleagues published a prospective trial in 2004 evaluating the role of interval cytoreduction. In this trial, GOG conducted a randomized phase III study involving 550 patients with stage III and IV EOC who had residual disease of more than 1 cm after an initial attempt at primary cytoreductive surgery. All patients received three cycles of initial chemotherapy in the form of cisplatin and paclitaxel. Eligible patients were randomly assigned to undergo interval cytoreductive surgery followed by chemotherapy ($n = 216$) or chemotherapy alone ($n = 208$). Protocol compliance was good; only 7% of the patients who were randomly assigned to undergo interval cytoreductive surgery did not undergo surgery. Among patients who were randomly assigned to receive chemotherapy alone, 3% had interval cytoreductive surgery. It was found that PFS did not significantly differ between the two groups (HR, 1.07; 95% CI, 0.87-1.31; $P = .54$). In addition, there was no significant difference in the relative risk (RR) of death for patients undergoing interval cytoreductive surgery compared with chemotherapy alone (RR, 0.99; 95% CI, 0.79-1.24; $P = .92$).

Additions to the Paclitaxel and Carboplatin Backbone

It has been postulated that agents with nonoverlapping cross resistance mechanisms or alternative mechanisms of action may be complementary opportunities in primary ovarian cancer patients to improve the therapeutic index. Several trials have been completed, with mixed results. The prevalent strategy has been to add to platinum and taxane therapy or substitute another agent for paclitaxel. The largest trial reported to date is GOG-182, which randomized 4312 patients to one of four experimental arms against paclitaxel and carboplatin (Bookman, 2009). Two of the experimental arms involved a three-drug strategy (adding gemcitabine or pegylated liposomal doxorubicin to paclitaxel and carboplatin, with the latter triplet given every other course) and two others substituted topotecan or gemcitabine for paclitaxel for four of the eight planned cycles in a sequential administration design (Fig. 33.13).

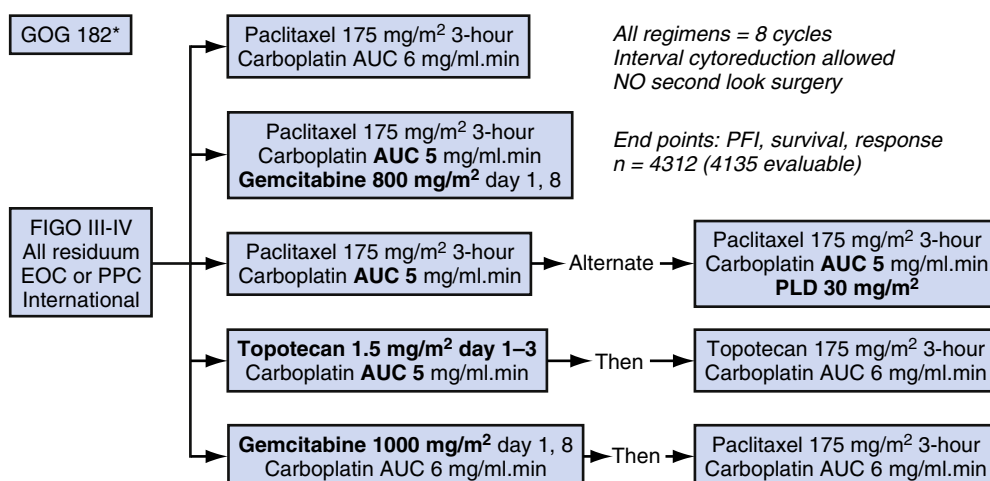

Figure 33.13 GOG-182 trial that randomized 4312 patients to one of four experimental arms against paclitaxel and carboplatin. (Modified from Bookman MA, Brady MF, McGuire WP, et al. Evaluation of new platinum-based treatment regimens in advanced-stage ovarian cancer: a phase III trial of the Gynecologic Cancer InterGroup. *J Clin Oncol.* 2009;27[9]:1419-1425.)

Although considered a highly successful trial in terms of global participation and recruitment, the trial failed to improve outcomes by any parameter (response, PFS, or OS). However, as anticipated, the three-drug regimens were more toxic. Two other trials, the MITO-2, which randomized patients to an experimental regimen with carboplatin and pegylated liposomal doxorubicin, and OVAR9, which randomized patients to an experimental arm of paclitaxel, carboplatin, and gemcitabine, also failed to demonstrate superiority to this strategy. It is unclear whether the addition or substitution of available cytotoxic agents in this setting will improve outcomes in primary disease, given the probability for overlapping toxicities.

Based on emerging efficacy data regarding angiogenesis inhibition on ovarian cancer response and prevention of progression, several trials were launched with the agent bevacizumab. GOG 218 included two experimental arms with bevacizumab—one arm also administered bevacizumab as a maintenance agent for 16 21-day cycles following primary therapy and the other experimental arm administered only placebo in maintenance (Burger, 2011). ICON7 is a two-armed trial in which bevacizumab is administered with chemotherapy at half the dose of GOG 218 (7.5 mg/kg), but for 12 cycles in maintenance after administration with paclitaxel and carboplatin for five or six cycles (Perren, 2013). The trials have important differences (Table 33.9). Both have reported meeting their primary end point, PFS, but OS data are immature. In GOG 218, the improvement in PFS over controlled paclitaxel and carboplatin was seen only for arm 3, in which bevacizumab was administered with chemotherapy and in the maintenance setting. There was no difference in PFS for arm 2 compared with the control. The HR for PFS arm 3 versus arm 1 was 0.717 ($P < .001$); the HR for PFS, arm 2 versus arm 1, was 0.908 ($P = .16$) and corresponded to median durations of 10.3, 11.2, and 14.1 months, respectively. The anticipated HR for ICON7 was 0.78, which was observed, but details of this study have not been released.

Additional studies of other molecules targeting one or more processes of angiogenesis as well as novel targets, such as the folate receptor, are being pursued in this setting.

Intraperitoneal Therapy

One promising but relatively old strategy that has been investigated is chemotherapy given by the IP route. Ovarian cancer appears to be IP-friendly because the distribution of disease is largely confined to this space, the pharmacokinetics of drug

delivery are favorable, and the tumor is considered chemosensitive. Early experience with IP administration of chemotherapy has documented that it could be used to control ascites. Pharmacologic studies in the 1970s and 1980s demonstrated favorable profiles of relatively high direct drug exposure (high C_{max} and AUC) for a number of agents subsequently identified to be important for ovarian cancer treatment. In this regard, platinum (cisplatin and carboplatin) and taxanes (paclitaxel and docetaxel) have been shown to have superior pharmacokinetic profiles when delivered into the peritoneum directly compared with IV administration.

Currently, administration is done principally via an implantable vascular access device placed during surgery or subsequent minilaparotomy (Fig. 33.14). A number of phase I and II clinical studies have been performed since the 1980s to document the safety of the strategy and to suggest efficacy. This has led to the performance and reporting of more than eight randomized clinical studies formally evaluating the efficacy of IP-based chemotherapy compared with IV-based chemotherapy in patients with advanced-stage ovarian cancer. A meta-analysis of these studies has been published and concluded that the route of administration “has the potential to improve cure rates from ovarian cancer.” Similarly, the National Cancer Institute has issued a clinical announcement accompanying the publication of a large GOG study stating that the IV and IP regimen “conveys a significant survival benefit among women with optimally debulked epithelial ovarian cancer, compared with intravenous administration alone.” In this latter study, patients with stage III epithelial ovarian cancer rendered optimal (defined as postsurgical disease residual <1 cm) were eligible for randomization to standard IV cisplatin and paclitaxel (24-hour infusion) or to IV paclitaxel (135 mg/m² on day 1), IP cisplatin (100 mg/m² on day 2), and IP paclitaxel (60 mg/m² on day 8) (Armstrong, 2006). This was the first phase III study to include IP paclitaxel in primary ovarian cancer therapy. Both cohorts were to undergo repeat cycles every 21 days for six total infusions. The primary end points were PFS and OS, and reassessment operations, if planned, were indicated at randomization.

This study was also the first to evaluate formally the impact of treatment on health-related quality of life. Assessment was made at baseline after the third cycle, after treatment completion, and 12 months after treatment completion. Overall, 415 eligible patients made up the study population. Both PFS and OS were significantly improved in the intent to treat the IP

Table 33.9 Comparison of Gynecologic Oncology Group (GOG)-0218 and International Collaborative Ovarian Neoplasm (ICON)7 Study Characteristics

Parameter	TRIAL	
	GOG-0218	ICON7
Setting and design	Double blinded, placebo controlled Three-arm study	Open label Two-arm study
Patient population	Bevacizumab for 16 cycles (maintenance)	Bevacizumab for 12 cycles
	Bevacizumab dose, 15 mg/kg/3 wk	Bevacizumab dose, 7.5 mg/kg/3 wk
	Stage III (suboptimal)	Stage I or IIA (grade 3/clear cell histology)
	Stage III (optimal, visual or palpable)	Stages IIB-IV (all)
Additional end point	Stage IV	
	OS analysis (formal testing at time of PFS)	Defined final OS analysis (end, 2012)
	IRC	No IRC

IRC, Independent radiology review; OS, overall survival; PFS, progression-free survival.

Figure 33.14 Peritoneal catheter with access port for infusion of drugs. (Port-A-Cath, Pharmacia Deltec, St. Paul, MN.)

cohort ($HR_{PFS} = 0.80$; 95% CI, 0.64-1.00; $HR_{Death} = 0.75$; 95% CI, 0.58-0.97, respectively). The recorded median overall survival of 65.6 months is among the longest ever observed in an adjuvant therapy phase III ovarian cancer study. The results are even more impressive given that most (58%) randomized IP patients did not complete all six cycles of their assigned therapy via IP administration. This was largely because of significant differences in hematologic and nonhematologic toxicities associated with the IP regimen. Leukopenia and thrombocytopenia were significantly more common in the IP arm, as were pain (11-fold increase), fatigue (fourfold increase), fever (2.5-fold increase), and metabolic (fourfold increase), renal (threefold increase), infection (2.5-fold increase), neurologic (twofold increase), and gastrointestinal (twofold increase) events, among others. In addition, almost one in five (40 of 205 patients) randomized IP patients experienced a catheter failure necessitating treatment discontinuation. A detailed assessment of IP catheter complications in this trial has been published. A clear profile for catheter malfunction risk was not identified, although timing and accompanying surgical procedures were closely scrutinized. In a reflection of these observed adverse events, health-related quality-of-life assessments were significantly lower throughout the trial but returned to parity 12 months after therapy. It was concluded that the IP regimen provides superior survival efficacy and is associated with significant but manageable toxicity. The authors encouraged the use of IP therapy in clinical practice.

Lesnock and colleagues reported on the impact of somatic or germline *BRCA* mutation status relative to IP (vs. IV) therapy (Lesnock, 2013). In this trial just under half (48%) of the population had aberrant *BRCA* expression in the tumor. Patients with tumors harboring aberrant *BRCA* expression who received IP therapy had substantially longer PFS and OS relative to patients with aberrant *BRCA* expression receiving IV chemotherapy. This highlights the important role *BRCA* alterations have on outcomes, particularly in those receiving IP therapy. Unfortunately, toxicity concerns and a number of unanswered fundamental questions regarding efficacy (e.g., optimal agent, schedule, future trial designs) and the impact of alternative agents such as biologic therapies (e.g., vascular endothelial growth factor and epidermal growth factor targeting) have limited the general acceptance of this strategy in the clinical community without subsequent information. Clinical investigation with alternative

agents such as docetaxel and carboplatin have completed phase I feasibility studies; phase III studies with the antiangiogenesis agent bevacizumab are ongoing.

Dose-Dense Chemotherapy

One additional strategy, dose-dense and dose-intense chemotherapy, has received attention based on positive results reported in primary ovarian cancer patients (Katsumata, 2009). The trial, conducted by the Japanese Gynecologic Oncology Group (JGOG) and published in 2009, randomized 631 patients to standard paclitaxel (180 mg/m^2) and carboplatin (AUC 6), or weekly paclitaxel ($80 \text{ mg/m}^2/\text{wk}$) and carboplatin (AUC 6), for six to nine cycles. The dose density (measured in $\text{mg/m}^2/\text{wk}$) was 33% greater in the experimental arm. Despite just 62% of patients receiving six or more cycles of the dose-dense strategy (vs. 73% in the control arm), the median PFS was 28 versus 17.2 months (HR , 0.714; $P = .0015$). OS, although early, also demonstrated a significant difference, with 3-year OS in the experimental arm at 72.1% versus 65.1% in the control arm (HR , 0.75; $P = .03$). Another trial evaluating dose dense strategy was GOG-262, which was conducted in women with suboptimal (defined as postoperative tumor residuum of greater than 1 cm) cytoreduction or undergoing NACT (Chan, 2014). In this phase III trial, 692 women were randomized 1:1 to dose dense paclitaxel (80 mg/m^2 , weekly) plus carboplatin AUC 6 or standard 3-weekly paclitaxel/carboplatin. Bevacizumab could be added at the discretion of the physician and, if chosen, was to be administered in maintenance until progression. Overall, 84% of patients received bevacizumab and over 87% underwent a primary debulking attempt. In contrast to the JGOG trial, no significant difference was observed between the arms for PFS or OS. However, looking at just the cohort who opted not to receive bevacizumab, the dose-dense strategy was more effective on PFS. When bevacizumab was added, this effect was lost. This strategy is the subject of ongoing phase III studies with similar designs, addressing IP infusion, and with the addition of bevacizumab (e.g., IPocc, GOG-252).

Evaluation of Chemotherapy Results

Chemotherapy is usually administered every 3 weeks. The patient is monitored with careful physical examination; blood tests to measure hematologic, liver, and kidney function; and radiographic studies, such as chest radiography, ultrasound, or, usually, CT of the abdomen and pelvis. Granulocyte colony-stimulating factor is added as needed to combat neutropenia. Mild neutropenia after chemotherapy can be managed expectantly, but for the patient who develops severe neutropenia with fever and an absolute neutrophil count of less than 500 cells/mL, antibiotics are prescribed to prevent septic complications.

If tumor is suspected on CT scan, fine-needle biopsy can frequently document the presence of persistent or recurrent disease. A negative CT scan, however, does not guarantee complete clinical response. Goldhirsch and coworkers noted that 5 of 26 patients with tumor nodules larger than 1 cm have negative CT scans, and the examination is most effective (80%) for detecting metastasis in retroperitoneal nodes. In 1989, Reuter and colleagues reported improved results of 8% false-negatives using newer equipment, with CT slices at 10- to 15-mm intervals. Patsner has reported that 24 of 60 patients with negative CT scans have a positive second-look operation, calling into

question the value of this imaging study. Vaginal ultrasonography is particularly useful to assess the pelvis. CA-125 levels are used to monitor the course of the woman with carcinoma. As noted, Buller and colleagues calculated that the CA-125 level follows an exponential regression curve in successfully treated patients. This provides the possibility of mathematically estimating the patient's response to chemotherapy early in treatment. Bridgewater and associates reported that a greater than 50% decrease in the CA-125 level is a good sign of clinical response.

Second-Look Procedures

Second-look laparotomy was introduced in the late 1940s as a method of assessing disease status after primary therapy in patients with colon cancer. In the 1970s, the same procedure was introduced for the treatment of epithelial ovarian cancer. In the field of gynecologic oncology, the rationale for using second-look surgery was that the optimal duration of chemotherapy was unknown (at the time) and the second-look procedure allowed surgeons to decide the optimal duration of exposure to alkylating agents for their patients. The primary concern with prolonged exposure to alkylating agents was the potential for secondary malignancies. Ideally, a second-look procedure would be able to identify the presence or absence of disease, which would help guide subsequent management.

Greer and coworkers performed a nonrandomized comparison in patients undergoing second-look laparotomy or clinical follow-up after receiving six cycles of combination chemotherapy with paclitaxel plus cisplatin or carboplatin. In that study, all patients were required to undergo optimal cytoreduction surgery prior to trial entry. The researchers demonstrated that second-look surgery was not associated with longer survival (in the context of a nonrandomized study). Therefore second-look surgery should only be performed in the setting of a clinical trial. If a second-look laparotomy is performed, it is important to extensively sample the peritoneal surfaces and lymph nodes. Particular attention is paid to areas that contained residual disease at the conclusion of the initial surgical procedure.

Maintenance Therapy

Unfortunately, many patients develop recurrent disease, even after a negative second-look operation. Rubin and associates noted a high rate of recurrence (45%) in patients with a negative second-look laparotomy. Those who initially have higher-stage and higher-grade tumors are more likely to have a recurrence after a negative second-look operation. However, those who were disease free at 5 years are likely to remain disease free by the subsequent follow-up period. Nonetheless, this high recurrence risk has prompted several authors to consider additional treatment at the identification of a complete response to primary treatment. This is often termed *maintenance* or *consolidation therapy*, although the former term is favored, given that the decision for treatment is based on the effect of primary therapy. Several randomized and nonrandomized clinical trials have been conducted in this arena, including hormones, vitamins, radiation therapy, chemotherapy, radioimmunoconjugates, immunotherapy, vaccines, gene therapy, biologic therapy, complementary medicines, and holistic approaches. Unfortunately, all have been negative in regard to improving overall survival. However, one randomized study did show an improvement in PFS. Markman and coworkers studied whether 3 or 12 additional months of paclitaxel could influence the time until progression in women who

had achieved a complete clinical remission after primary treatment. The trial was designed to accrue 450 patients; however, at a planned interim analysis (after 277 patients were randomized), a statistically significant benefit for the longer treatment was demonstrated, which closed the trial to further accrual. The initial report demonstrated a 7-month improvement in median PFS (28 vs. 21 months; $P = .0035$); a later report with a long follow-up confirmed these earlier results (median PFS, 21 vs. 14 months; $P = .006$). No effect on survival was demonstrated, however. As noted, the addition of a maintenance biologic agent such as bevacizumab improved PFS relative to placebo, but the effect on overall survival remains to be seen.

Several additional biologic agents have entered phase III in this setting with mixed results. Pazopanib, an oral tyrosine kinase inhibitor (TKI) of vascular endothelial growth factor receptor (VEGFR), platelet-derived growth factor receptor (PDGFR) c-Kit, and fibroblast growth factor receptor (FGFR), was studied in women without evidence of progression on primary chemotherapy (du Bois, 2014). In all, 940 women were randomized and given either placebo or pazopanib for up to 24 months. The primary end point was PFS, which was extended by 5.6 months on the median (HR: 0.77; 95% CI, 0.64-0.91, $P = .0021$). Unfortunately, no difference was seen in OS, and the regimen was associated higher rates of hepatotoxicity, hypertension, and gastrointestinal adverse events. Further, among Asians, much lower dosages were required radioimmunoconjugates and there was a potential survival detriment in that cohort for patients taking pazopanib. Another TKI targeting the epidermal growth factor receptor (EGFR) pathway, erlotinib, was studied as a primary maintenance intervention in a phase III randomized trial (Vergote, 2014). In this trial, 835 patients achieving complete clinical response (CR) to six to nine cycles of platinum-based chemotherapy were randomized to either erlotinib (150 mg/day) for 24 months or observation. The primary end point was PFS, which was similar between the two arms (erlotinib: 12.7 months, observation 12.4 months; $P = .91$). Similarly, OS was no different between the arms. Of interest, a mutational analysis of EGFR, Ras, Raf, and PI3K was performed in 318 (38%) patients. The mutational rate in these genes was low ($n = 24$, 8%), and although PFS was significantly better in this cohort (positive prognostic factor), there was no difference in PFS based on mutation status (nonpredictive factor).

Another strategy that has been tried and continues to be of great interest is immunotherapy. Work from the Cancer Genome Atlas (TCGA) has demonstrated that ovarian cancers have a mutational load and thus the possibility for a high degree of expressed neoantigens, making them a prime target for immune targeted therapy (Bell, 2011). Although multiple vaccination strategies such as oregovomab, abagovomab, and agents targeting Muc-1 and Muc-16 have been conducted without direct effects, the appearance of the immune checkpoint inhibitors provides renewed interest in leveraging long-term immunosurveillance for ovarian cancer patients. Given the high stakes for patients at this point in their treatment, the effort to incorporate new knowledge of biology (e.g., poly-ADP [ribose] polymerase [PARP] inhibitors, discussed later) for treatment continues.

Cancer Antigen125 Surveillance after Primary Therapy

Because patients with advanced ovarian cancer frequently have CA-125 values that pace tumor response and progression during

therapy, a common practice for monitoring patients following therapy involves serial CA-125 level determinations. The supposition is that earlier identification of recurrent disease can be better controlled by earlier initiation of therapy. To formally address this hypothesis, the European Organization for Research and Treatment of Cancer (EORTC) has conducted a randomized phase III trial in which women in complete clinical remission following primary surgery and chemotherapy were enrolled into a blinded surveillance program. Follow-up visits were scheduled every 3 months, when an examination was performed and blood was taken for CA-125 level assessment. All registrants were blinded to their CA-125 values during this time. However, when an individual's CA-125 level rose to twice the upper limit of normal, the patient was randomized 1:1 to unblinding of the result (early) or continued blinded surveillance (delayed). In this latter group, intervention was determined by the development of clinical or symptomatic relapse. Postprogression therapy was determined by local standards of care. The primary end point of the study was overall survival. In all, 1442 patients were registered, of whom 529 were randomly assigned to the treatment groups. Patients unblinded and made aware of their rising CA-125 values generally started treatment immediately, 4.8 months (median) before those in the delayed group. After a median follow-up of almost 57 months from randomization and 370 deaths, there was no difference in overall survival between the arms (HR, 0.98; 95% CI, 0.8-1.2). Median survival in the early treatment group was 25.7 months compared with 27.1 months in the delayed group. For patients receiving third-line therapy, the time differential to initiation was almost the same as the time differential to initiation of second-line therapy (median 4.6 months). Interestingly, a first deterioration in Global Health score occurred significantly sooner in the early treatment group. The authors concluded that no benefit in survival is gained by treatment dictated solely by an asymptomatic rise in CA-125 level and challenge the practice of routine biomarker surveillance in this setting.

Although practice standards may individually change on the basis of this new information, counseling patients to watchful waiting is a challenge in the setting of rising CA-125 level without measurable recurrent disease. An alternative approach in this setting has been the use of hormonal therapy, such as tamoxifen. GOG completed a randomized clinical trial (GOG protocol 198) to address the impact of tamoxifen and thalidomide in women with significantly elevated CA-125 levels in the absence of measurable recurrent disease following primary therapy. Eligible patients had stage III or IV histologically confirmed epithelial ovarian, fallopian tube, or peritoneal primary cancer and a posttreatment CA-125 level exceeding twice the upper limit of normal in the absence of Response Evaluation Criteria in Solid Tumors (RECIST) 1.0 measurable disease. The primary end point of the trial was to compare PFS and OS between the two treatment arms and assess toxicity. At study closure, 139 women were randomized to oral thalidomide, 200 mg daily, with escalation to a maximum of 400 mg or tamoxifen, 20 mg orally twice daily. High-grade toxicities (grades 3 and 4) were experienced more frequently in the thalidomide arm (55% vs. 3%), with randomized patients experiencing more constitutional, somnolence, and pulmonary toxicities. There were more venous thromboembolism and gastrointestinal toxicities in the tamoxifen arm, but these were infrequent (<1.5%). The risk for progression was similar between the cohorts (HR, 1.31; 95% CI, 0.92-1.85), but

the risk for death was significantly higher in the thalidomide arm (HR, 1.76; 95% CI, 1.16-2.68). Of interest, the time to measurable progression on tamoxifen was 4.5 months (vs. 3.2 months for thalidomide), which mirrors the lead time to symptomatic progression in patients blinded to their rising CA-125 level observed in the EORTC trial (4.8 months). Appropriate therapy for patients with rising CA-125 levels in the absence of measurable disease has yet to be determined.

Recurrent Ovarian Cancer Management

Unfortunately, as many as 70% of patients who present with advanced staged disease will exhibit recurrent or persistent disease after primary treatment. These women may have prolonged survival despite developing recurrence; however, they are rarely cured. For this reason, treatment is generally considered palliative and must balance efficacy with toxicity. The choice of therapy is largely empirical; the treatment plan usually involves several agents in sequence, depending on treatment history, observed and expected toxicity, and performance status. Surgery, chemotherapy, immunotherapy, radiation therapy, biotherapy, and hormone therapy are options, alone and in combination, in this cohort of patients. It is not uncommon for a woman to undergo five or more different chemotherapy regimens, including cycles of retreatment with one or more agents. This characteristic reflects the increasing number of agents available for use, short duration of response, and general health of those receiving therapy.

Although there are few specific treatment guidelines as to how recurrence should be approached, initial consideration is most often guided by the interval of time until recurrence is identified. Patients are categorized as potentially platinum sensitive, platinum resistant, or platinum refractory based on the length of time from the completion of primary therapy until recurrence is identified. By convention, patients exhibiting a treatment-free interval of 6 months or longer are considered as having potentially platinum-sensitive disease. Those who achieved a complete response and were identified with recurrence under this benchmark are considered platinum resistant, and those who did not achieve a complete response or had disease progression during frontline therapy are considered platinum refractory. In reality, the probability for subsequent chemotherapy response likely represents a continuum based on this interval of time. However, clinically, the arbitrary division is used frequently to make treatment decisions.

Platinum-Refractory Disease

Patients who fall into this designation have a difficult disease to treat because their objective response to almost all available agents is low and the duration of any individual therapy is short. The choice of therapy depends on the woman's wishes and comorbidities. Because expectations for response to standard agents are low, these women are good candidates for investigative clinical studies, in which new agents with alternative mechanisms of action or targets are being evaluated. Under these expectations, some patients may opt to continue active treatment, whereas others may choose supportive care.

Platinum-Resistant Disease

Patients demonstrating an abbreviated initial response to frontline therapy represent cohorts who are unlikely to respond well

to platinum retreatment. This is not to imply that some of these patients would not respond to retreatment with a platinum compound, just that the probability of response would be no greater than with any other agent and potentially lower. A current recommendation for most of these patients is to consider an alternative nonplatinum agent for the first treatment of recurrence. Table 33.10 lists the potential agents for treating these patients, their respective response rates, and significant common toxicities. Patients achieving stable disease or better are usually treated until the agent no longer demonstrates a clinical benefit or toxicity precludes further infusion.

Because expected overall survival is shorter in patients with this phenotype, a number of clinical trials with novel agents have been completed or are ongoing (see “Targeted Therapy,” presented later in the chapter).

Platinum-Sensitive Disease

Patients in whom disease recurrence is identified more than 6 months after the completion of front-line treatment are considered potentially platinum sensitive. These patients are good candidates for retreatment with platinum or a platinum-based combination regimen. In many cases, this combination is similar to that received in front-line treatment, paclitaxel and carboplatin. However, other two-drug and three-drug combinations have been investigated. A limited number of phase III studies have been conducted in this setting, but only one has demonstrated an overall survival advantage for the use of a taxane- and platinum-based regimen. The ICON4-AGO-OVAR 2.2 study randomized 802 women with recurrent ovarian cancer to paclitaxel and platinum or a nontaxane platinum regimen. Objective response was 66% in the taxane arm compared with 54% in the conventional arm ($P = .06$). PFS was significantly improved (12 vs. 9 months; HR, 0.76; 95% CI, 0.66-0.89), as was OS (29 vs. 24 months; HR, 0.82; 95% CI, 0.69-0.97). Approximately 75% of women in both groups had a treatment-free interval of at least 12 months, and 64% were taxane naïve at randomization. These are important factors when considering the study's conclusions. In all, six phase III clinical trials in platinum-sensitive patients have been completed. They differ substantially by agents investigated, sample size, use of measurable patients, prior exposure to paclitaxel and platinum in front-line therapy, and median progress-free interval prior to registration. Each of these factors has important consequences in regard to the data reported, making cross-trial comparisons among experimental groups hazardous.

Table 33.11 summarizes the key features of these trials. It is noteworthy that two of these efforts included the use of nonplatinum agents in potentially platinum-sensitive patients, according to the definition provided earlier. These are important trials to consider given the high rate of drug hypersensitivity (platinum or taxane), intolerance, and lack of a clear benefit between platinum-containing and nonplatinum-containing agents in patients with moderate platinum-sensitive disease, such as those recurring between 6 and 12 months after primary therapy. Currently, only the combination of gemcitabine and carboplatin is approved for use in patients with platinum-sensitive recurrent disease in the United States.

Similar to work being conducted in platinum-resistant disease, investigation into improving the outcomes of these patients continues (see “Targeted Therapy,” presented later in the chapter).

Secondary Cytoreduction

The recurrence rate in patients with advanced epithelial ovarian cancer ranges from 50% to 90%. Therefore secondary cytoreductive surgery might be a viable treatment option for a select group of patients. Because patients with long treatment-free intervals have disease that is considered potentially chemotherapy sensitive, investigators have evaluated the role of surgery in this setting as well. Although there is some inconsistency in the definition of secondary cytoreduction procedures, the specific intent in this setting is resection of disease at recurrence, with the intent of debulking. The treatment of recurrent epithelial ovarian cancer is variable and dependent on a number of important criteria, which are evaluated at the time the recurrence is diagnosed. These include but are not limited to the time from completion of initial adjuvant therapy, site of disease, number of disease sites, and the woman's performance status. Most studies in the literature suggest that patients with platinum-resistant disease (recurrent disease within 6 months of completing platinum-based treatment) do not benefit from secondary cytoreductive surgery. However, others have argued for a role of surgery in this patient population. Musella and colleagues evaluated the role of secondary cytoreductive surgery in platinum-resistant recurrent ovarian cancer patients. Patients considered susceptible of cytoreductive surgery (group A) were compared with a historical series of patients with similar characteristics but not eligible for surgery (group B). Of 122 platinum-resistant patients, 18 met the inclusion criteria for the study and were enrolled. They

Table 33.10 Clinical Efficacy of Cytotoxic Agents in Platinum-Resistant and Platinum-Sensitive Ovarian Cancer Toxicity

Agent	RESPONSE RATE (%)		Principal Toxicity
	Platinum-Resistant	Platinum-Sensitive	
PLD	14-20	28	PPE, mucositis
Topotecan	14-18	33	Myelosuppression
Hexamethylmelamine	10-18	27	Nausea, vomiting
Gemcitabine	16		Myelosuppression
Etoposide	27	35	Myelosuppression, leukemia
Ifosfamide	12		Hemorrhagic cystitis, CNS
Tamoxifen	10-15	10-15	Hot flashes, thromboembolic
Docetaxel	22-25	38	Myelosuppression
Paclitaxel	12-33	20-41	Myelosuppression
Vinorelbine	21	29	Myelosuppression

CNS, Central nervous system neurotoxicity; PLD, pegylated liposomal doxorubicin; PPE, palmar-plantar erythrodysesthesia.

were compared with a historical series of 18 patients not surgically treated with analogous clinical and pathologic features. The most frequent sites of relapse included pelvic and aortic lymph nodes (39%), peritoneum (33%), bowel (28%), and pelvis (22%). A low rate of intraoperative and postoperative complications was reported. No deaths were recorded. Overall survival was significantly longer in the cytoreductive group when compared with the control group ($P = .035$). Median overall survival was 44 months. Estimated 5-year overall survival rates were 57 versus 23.5 % for groups A and B, respectively.

No randomized trials have been conducted to identify a clinical benefit in this setting. However, several prospective and retrospective reports have suggested that only patients with extended treatment-free intervals and those who achieve a complete resection (no visible residual) benefit from the procedure.

In a study by Zang and colleagues, the authors aimed to identify prognostic factors and to develop a risk model predicting survival in patients undergoing secondary cytoreductive surgery (SCR) for recurrent epithelial ovarian cancer (Zang, 2011). Individual data of 1100 patients with recurrent ovarian cancer of a progression-free interval at least 6 months who underwent SCR were pooled and analyzed. Complete SCR was strongly associated with the improvement of survival, with a median survival of 57.7 months, when compared with 27 months in those with

residual disease of 0.1 to 1 cm and 15.6 months in those with residual disease of >1 cm, respectively ($P < .0001$). Progression-free interval (≤ 23.1 months vs. >23.1 months, hazard ratio [HR]: 1.72; score: 2), ascites at recurrence (present vs. absent, HR: 1.27; score: 1), extent of recurrence (multiple vs. localized disease, HR: 1.38; score: 1) as well as residual disease after SCR (R1 vs. R0, HR: 1.90, score: 2; R2 vs. R0, HR: 3.0, score: 4) entered into the risk model.

In the AGO study, researchers also reported their efforts in establishing (DESKTOP I trial) and validating (DESKTOP II trial) a panel of features that would reliably predict optimal (no visible disease) secondary surgical outcomes in women with platinum-sensitive disease. The researchers found, as did others, that only complete surgical cytoreduction was associated with an improved OS and that this could be reliably achieved ($>67\%$ of the time) in patients who had a performance status of 0 or 1, were in the early stage, or had no visible tumor residuum following initial surgical cytoreduction and the absence of ascites.

Al Rawahi and coworkers evaluated the effectiveness and safety of optimal secondary cytoreductive surgery for women with recurrent epithelial ovarian cancer (Al Rawahi, 2013). The authors also aimed to assess the impact of various residual tumor sizes, ranging from 0 cm to 2 cm, on overall survival. The authors found nine nonrandomized studies that reported on

Table 33.11 Phase III Trials in Patients with Platinum-Sensitive Recurrent Disease

Control	Experimental	No. of Patients	TTP/PFS (wk)	P value	OS (wk)	P value	Comments
Carboplatin [†]	Carboplatin Epirubicin	190	65 vs. 78	NS	109 vs. 122	NS	TFI = 17 mo; grade 4 ANC, 45%; T RBC, 30%, Plt, 25%
Platinum [‡]	Platinum Paclitaxel	802	43 vs. 52; HR, 0.76	$<.001$	104 vs. 130 HR, 0.82	.023	TFI = 75% >12 mo; neuro 1% vs. 20%; infection, 17%; hematologic, 46% vs. 29%
Carboplatin [§]	Carboplatin Gemcitabine	356	23 vs. 35 HR, 0.72	$<.001$	75 vs. 78	NS .0016	TFI = 60% >12 mo; RR: 31% vs. 47% ANC, Plt more common in combination
Carboplatin, Paclitaxel	Carboplatin PLD	976	41 vs. 49 HR, 0.82	.001 (noninferiority) .005 (superiority)	30.7 vs 33.0	.94	TFI: Nonhematologic, 37% vs. 29%; HSR, 19% vs. 6%; grade 2-3 PPE, 2% vs. 12%
Topotecan [¶]	Topotecan/ etoposide	502	HR, 0.84	NS	HR, 1.13	NS	TFI 64% >12 mo
	Topotecan- gemcitabine		HR, 0.84	NS	HR, 1.07	NS	More hematologic toxicity, less alopecia in topotecan-gemcitabine arm
PLD**	PLD Trabectedin	672	25 vs. 32 HR, 0.79	0.019	82 vs. 97 HR, 0.86 ($P = .08$)	PLD	TFI (32% >12 mo); effect seen only in PS cohort; PPE less in combination; ANC, LFT

1194 women with comparison of residual disease after secondary cytoreduction using a multivariate analysis that met inclusion criteria. All of the studies included at least 50 women and used statistical adjustment for important prognostic factors. One study compared suboptimal (>1 cm) vs. optimal (<1 cm) cytoreduction and demonstrated benefit to achieving cytoreduction to less than 1 cm, if microscopic disease could not be achieved (HR 3.51; 95% CI, 1.84-6.70). Similarly, one study found that women whose tumor had been cytoreduced to less than 0.5 cm had less risk of death compared with those with residual disease greater than 0.5 cm after surgery (HR not reported; P value < .001). Adverse events, quality of life, and cost effectiveness were not reported in any of the studies. The investigators concluded that in women with platinum-sensitive recurrent ovarian cancer, the ability to achieve surgery with complete cytoreduction (no visible residual disease) is associated with significant improvement in overall survival. However, in the absence of randomized controlled trial evidence, it is not clear whether this is solely due to surgical effect or due to tumor biology.

Two phase III trials are currently under way to address this question in patients with platinum-sensitive disease. GOG protocol 213 is evaluating the role of secondary cytoreductive surgery in patients with recurrent, platinum-sensitive ovarian cancer and the merit of adding an antiangiogenic agent (bevacizumab) to a combination of carboplatin and paclitaxel. In addition, this study will evaluate the usefulness of maintenance bevacizumab until progression relative to control. DESKTOP III is using the triage tool discussed earlier to identify patients likely to undergo complete surgical resection and randomizing them to surgery versus no surgery. Adjuvant therapy is not specified in this trial, but both are focused on overall survival as their primary end point.

Targeted Therapy

The processes that govern cell transformation and immortalization, tumor growth, and metastases for ovarian cancer are complex and nonuniform. Nonetheless, several critical targets have been identified that appear to be differentially expressed in tumors cells relative to normal cells. Novel agents that target disruption or inhibition of these specific processes have been incorporated into the care of ovarian cancer patients. The most

developed of these are agents that disrupt the signals to engender new vessel growth and development or angiogenesis. This process appears critical for a tumor to continue its growth beyond 8 mm³. A number of cytokines have been described that tip the balance to sustained angiogenesis, but the most potent is vascular endothelial growth factor (VEGF). Prognostically, VEGF expression has been documented in all stages of ovarian cancer and has been correlated with impaired survival. VEGF overexpression has also been directly associated with ascites formation. This clinical feature is the result VEGF-induced endothelial hyperpermeability. The compound furthest in development for the treatment for ovarian cancer is bevacizumab, which has been investigated for primary and recurrent ovarian cancers (discussed earlier). However, a number of agents targeting VEGF, its receptors, angiopoietin, the epidermal growth factor receptor family, the phosphatidylinositol-3-kinase (PI3K)/Akt/mTor pathway, and other cellular signaling pathways are also under investigation. In addition, new cytotoxics with alternative mechanisms of action, such as the tubulin poisons, and new topoisomerase inhibitors, agents that bind the minor groove of DNA (trabectedin), have been under phase III investigation. A summary of the outcomes of these trials is provided in Table 33.12. A detailed discussion of these trials is beyond the scope of this chapter; however, one trial deserves mention as it provided the background for the first approval of a biologically targeted agent in platinum-resistant disease. The AURELIA trial was a phase III open-label randomized trial comparing standard chemotherapy (weekly paclitaxel, pegylated liposomal doxorubicin, topotecan) to standard chemotherapy with bevacizumab (Pujade-Lauraine, 2014). The designation of chemotherapy was left to physician's choice, but each cohort was capped to provide equal representation in the randomization strata. The trial's primary end point was PFS. In the overall population, the addition of bevacizumab to chemotherapy significantly improved PFS (median 6.7 months vs. 3.4 months, HR: 0.48; 95% CI, 0.38-0.60, P < .001). The observation was consistent in each chemotherapy stratum; in addition, objective response was significantly improved, both of which may have contributed to the increased frequency of adverse events. However, quality-of-life indicators demonstrated improvement in global symptoms despite these observations. No difference was seen in OS. These data, along with a substantial

database of bevacizumab use in ovarian and other cancers, led to the approval of bevacizumab in combination with chemotherapy for patients with recurrent platinum-resistant disease who have received one or two prior regimens.

Similarly, investigative efforts continue with novel therapies in patients with platinum-sensitive disease. A summary of the outcomes from these trials is presented in Table 33.13. Each of these trials has demonstrated a significant effect in improving PFS, but the impact on OS has been less robust and may directly relate to the opportunities for treatment cross-over and factors associated with long posttreatment survival. This effect is amplified in a woman with a long pretreatment interval. As mentioned previously, patients with a high likelihood for chemosensitivity and recurrent disease amenable to complete cytoreduction are potentially most likely to benefit from the interaction of surgery and novel therapeutic chemotherapy combinations. Although this hypothesis has not been confirmed, it is being prospectively studied in GOG-213.

Poly (ADP-Ribose) Polymerase Inhibitors

Preclinical data have demonstrated the extreme sensitivity of *BRCA*-deficient cells to inhibition of the single-strand repair enzyme poly (ADP-ribose) polymerase (PARP). Inhibition of the PARPs leads to an accumulation of single-strand DNA breaks, which can lead to double-strand breaks at replication forks. Normally, these breaks are repaired through homologous recombination, in which the *BRCA* genes play a major role. However, synthetic lethality occurs when these genes themselves function improperly because of mutation or silencing. This has prompted the clinical development of a new class of novel therapeutics, the PARP inhibitors, which theoretically hold promise for patients whose tumors rely on PARP for continued cell growth.

To test this hypothesis and to evaluate the safety of the first drug in this class, olaparib, a phase I dose escalation clinical trial was conducted to examine the pharmacokinetic and

pharmacodynamic effects in patients with cancers refractory to standard therapy. Given the mechanism of action of olaparib, the population was enriched for patients with *BRCA1* or *BRCA2* mutations. Overall, 60 patients were recruited to the trial, including 22 who carried a *BRCA1* or *BRCA2* mutation and one with a strong family history of *BRCA*-related cancer. The dose of olaparib (capsule formulation) ranged from 10 mg daily, administered for 2 or 3 weeks, to 600 mg twice daily, continuously. At the two highest dose levels, dose-limiting toxicities were observed. This led to a compromised dose of 200 mg twice daily, which was studied in a second cohort of *BRCA1* and *BRCA2* patients only. In general, the agent was well tolerated, with primary toxicities of somnolence, mood alteration, and fatigue. The toxicity profile was not increased in the *BRCA* subpopulation. Analysis of PARP function by pharmacodynamic studies has demonstrated rapid and high-level inhibition within the recommended dosing levels. In support of the hypothesis, objective antitumor activity (63% complete or partial response plus stable disease) was seen only in *BRCA* mutation carriers.

Olaparib has few side effects relative to conventional chemotherapy, inhibits PARP, and has antitumor activity only in patients with *BRCA* germline mutations. A phase II study in *BRCA* carriers has also been conducted, enrolling patients into two consecutive dosing cohorts. Overall, response rates were similar to those observed in the phase I study, with notable activity (>25%) in patients with platinum-resistant disease (Fong, 2009). Rates of discontinuation caused by adverse events were uncommon in both dosing cohorts. This promising degree of clinical activity was confirmed in a larger study of patients with multiple solid tumors including ovarian cancer ($n = 60$) (Kaufman, 2015). Objective responses to single agent olaparib 400 mg twice daily, orally, continuously were observed in 31% (95% CI, 25% to 38%). This is favorably referenced to expected responses from chemotherapy in a similar setting. These data along an extensive safety database led to an accelerated

regulatory approval of olaparib in *BRCA*-mutation carriers with three or more lines of prior therapy. Further perhaps clinical activity has been seen in the secondary maintenance setting. In a large randomized phase II trial of olaparib compared with placebo, PFS was significantly longer when patients with recurrent high-grade serous ovarian cancer were randomized to olaparib (vs. placebo) after achieving a response to platinum-based chemotherapy. In this study, patients taking olaparib (400 mg twice per day, orally continuously capsule formulation) had a median time to treatment progression of 8.4 months versus 4.8 months (HR: 0.35; 95% CI, 0.25-0.49); a post hoc analysis of patient carrying the *BRCA1/2* mutation demonstrated an even greater effect (Ledermann, 2012).

Currently, a number of PARP inhibitors are entering clinical investigation and are expanding eligibility to include patients whose tumors may harbor *BRCA* deficiency (the so-called *BRCA*-like state). Next-generation sequencing studies to identify patients with germline or somatic *BRCA* mutations as well as other alterations promoting a homologous recombination deficient state in tumor tissue are being used in these trials and, if validated, may greatly expand the number of patients for whom PARP inhibitors may be helpful. Another active area of contemporary research are PARP inhibitor combinations, particularly with other biologic agents such as antiangiogenesis inhibitors, immune checkpoint inhibitors, cell cycle checkpoint inhibitors, cyclin dependent kinases, MAPK pathway inhibitors, and PI3K pathway inhibitors (Dalton, 2015; Liu, 2014).

Complications and Other Considerations

Malignant Effusions

Pleural effusions are a common and devastating complication of advanced malignancies. Women with ovarian cancer frequently develop ascites, hydrothorax, or both, requiring repeated drainage by paracentesis or thoracentesis. In the majority of cases, malignant pleural effusion is associated with an incurable disease, with high morbidity and mortality. For the same reason, several studies have argued in favor of a palliative approach, rather than a conventional curative approach for treatment of this condition. Occasionally, sclerosing solutions are used in the thoracic cavity to prevent the reaccumulation of fluid, with resultant adherence of the pleural surfaces. New modalities, such as pleuroscopy and long-term indwelling pleural catheters, offer cost-effective outpatient or minimal hospital stay and less discomfort.

In a review by Musani and associates, it was reported that several mechanisms have been proposed to explain the development of malignant effusion. The inability of the parietal pleura to reabsorb pleural fluid because of the involvement of mediastinal lymph nodes by tumor is likely the most common cause of malignant pleural effusion. Therefore tumors that involve the mediastinal lymph nodes, such as lung cancer, breast cancer, and lymphoma, are responsible for most malignant pleural effusions. Other possible mechanisms include direct tumor invasion, as is sometimes seen in lung cancer, chest wall neoplasms, breast cancer, and ovarian cancer, as well as hematogenous spread to the parietal pleura.

There are several options for therapy, such as thoracentesis, chemical pleurodesis with chest tubes, video-assisted thoracoscopy (VATS), pleuroperitoneal shunts, and chronic indwelling pleural catheters. The advantage of a thoracentesis largely relies

on the rapid relief of symptoms; however, it is unfortunately often associated with reaccumulation of fluid, multiple procedures and hospital visits, and associated complications, such as pneumothorax or reexpansion pulmonary edema. The option of chemical pleurodesis offers the advantage that it is highly effective; however, this treatment may be associated with required hospitalization and high cost. The VATS procedure is also highly effective and can be a diagnostic procedure in addition to a therapeutic procedure. The disadvantages are its cost, invasiveness, and its contraindication for patients who cannot tolerate single-lung ventilation. A pleuroperitoneal shunt may be considered in patients who have recurrent reaccumulation of fluid and those who have failed pleurodesis. However, this approach is not practical for patients with advanced or recurrent ovarian cancer because disease in these patients often also causes significant ascites. The option of a chronic indwelling catheter is ideal for patients who have recurrent episodes of reaccumulation of the pleural effusion. This approach is minimally invasive, cost effective, and successful. One of the major disadvantages is the risk for infection and the fact that the woman must be motivated to learn how to drain; otherwise, a family member or visiting nurse is required for home drainage.

A number of strategies have been studied in prospective trials. Most efficacious for problematic pleural effusion is pleurodesis with a sclerotic agent (e.g., talc slurry, antibiotic), decortication, or placement of an infusion catheter that can be operated by the woman. Tan and coworkers conducted a systematic review. Symptomatic ascites can also be problematic because few sclerodosis or surgical decortication-type procedures are available for long-term care. It is also not uncommon for patients to develop implants of tumor in the subcutaneous tissues after aspiration. Numnum and colleagues reported some success using bevacizumab as an adjuvant for this problem.

Malignant Bowel Obstruction

Intestinal obstruction is a common complication in patients with advanced epithelial ovarian cancer and is estimated to occur in 25% to 50% of patients. The onset of bowel obstruction is rarely an acute event. In cancer patients, compression of the bowel lumen develops slowly and often remains partial. Obstruction can result from partial or total occlusion of the bowel lumen or from alteration of the normal peristaltic motion. The initial symptoms are often abdominal cramps, nausea, vomiting, and abdominal distension that present periodically and resolve spontaneously.

Contrast radiography may help in defining the site and extent of the obstruction. Although barium may provide excellent radiographic definition, it is not absorbed well and may cause severe impaction. Diatrizoate meglumine and diatrizoate sodium solution (Gastrografin) is ideal for this type of contrast radiography because it offers similar radiographic definition and, in certain cases, may restore the intestinal transit. Abdominal CT is usually recommended because it can provide information about the location of the obstruction and the extent of disease. Surgical options may be offered to the woman, depending on a number of factors that dictate the success of surgical management. These include the site of obstruction, number of obstructions along the small or large bowel, number of prior chemotherapy regimens, prior episodes of bowel obstruction, nutritional status of the woman, and her overall functional status.

Pothuri and colleagues reviewed a series of patients undergoing surgery for intestinal obstruction caused by recurrent epithelial ovarian cancer and found that the mean time from original diagnosis of epithelial ovarian cancer to obstruction was 2.8 years. Surgical correction (intestinal surgery performed to relieve the obstruction) was achieved in 84% of cases, and successful palliation (the ability to tolerate a regular or low-residue diet by 60 days after surgery) was achieved in 71% of cases. The median survival in patients with successful palliation was 11.6 versus 3.9 months for all other patients. Major surgical morbidity was documented in 22% of patients. Interestingly, postoperative chemotherapy was administered to 79% of patients for whom surgical correction was possible. The authors noted that with respect to quality of life, it is important to consider that 56% of patients undergoing surgery for bowel obstruction had a colostomy or permanent gastrostomy tube. They also recommended that patients are not ideal surgical candidates if they have bulky carcinomatosis, rapidly progressive disease, multiple sites of obstruction, poor performance status, or heavy pretreatment with chemotherapy and radiation.

In patients who refuse palliative surgery or are considered poor surgical candidates, a percutaneous endoscopic gastrostomy (PEG) tube may offer symptomatic relief without the discomfort or complications of a nasogastric tube. The study by Pothuri and associates has shown that symptomatic relief (defined as the absence of nausea or vomiting) is achieved in 91% of patients with advanced epithelial ovarian cancer and bowel obstruction within 7 days of placement of a PEG tube. Only 13% of patients had resolution of obstruction and removal of the PEG tube after chemotherapy was administered. The median survival from the date of PEG tube placement was 8 weeks. The complication rate was 18%, and the most common complication was leakage. This study also demonstrated that the administration of total parenteral nutrition after PEG tube placement was not associated with a survival benefit. It is important to note that PEG tube placement is feasible for patients with a tumor encasing the stomach, diffuse carcinomatosis, or ascites.

Another potential nonsurgical option for the management of bowel obstruction is the use of metallic stents. These stents are flexible and self-expanding and can be inserted using radiologic or endoscopic techniques. The most important reported complications include local pain, gastric ulceration, gastroesophageal reflux, bleeding, and bowel perforation. Metallic stents are contraindicated in patients with multiple obstructions and peritoneal carcinomatosis. The literature on the usefulness of metallic stents for bowel obstruction in patients with gynecologic cancers is limited.

Immunotherapy

Immunotherapy agents, such as *Corynebacterium parvum* and bacille Calmette–Guérin, have been administered to try to augment the immunologic response and promote tumor resistance in the host. These agents have also been used in combination with cytotoxic chemotherapy; preliminary improved results have been reported. IP immunotherapy approaches have been evaluated with agents such as interferon, lymphokine-activated killer cells, interleukin-2, and tumor necrosis factor. Berek and coworkers conducted a phase I and II trial of IP cisplatin (60 mg/m²) and interferon- α (25 \times 10⁶ IU) given every 4 weeks. Among 18 patients, there were three complete and four partial responses.

Unfortunately, a randomized trial comparing interferon- α with no further treatment in women achieving complete response after primary chemotherapy has shown no benefit. A front-line phase III study of adding interferon- γ to paclitaxel and carboplatin was terminated early when an interim analysis of OS demonstrated a detrimental effect from the intervention.

The use of monoclonal antibodies as a form of site-directed therapy has been investigated. Epenetos and colleagues used tumor-associated antigens linked to ¹³¹I to treat recurrent ovarian carcinoma. After IP administration to 24 patients, responses were noted primarily in those with small-volume disease, with some responses lasting as long as 3 years evaluated by follow-up laparoscopy. Canevari and associates noted responses in 3 of 26 patients treated with autologous T lymphocytes targeted with a bispecific monoclonal antibody. Berek and coworkers reported a phase III study of oregovomab in women achieving a complete clinical response after primary therapy. This novel, murine-derived, immunotherapeutic agent targets the CA-125 antigen. In a placebo-controlled randomized trial, 145 women underwent infusion. The time to relapse was 13.3 months in the treatment arm and 10.3 months in the placebo arm ($P = .71$). Although no benefit was observed, an exploratory analysis suggested that patients with “successful front-line therapy” were designated by patients with less than 2 cm residual postoperative tumor residuum and CA-125 reduction to ≤ 65 U/mL by cycle 3 of platinum and taxane chemotherapy and no clinical evidence of disease following primary therapy. These characteristics served as eligibility criteria for a follow-up phase III trial of oregovomab versus placebo. Unfortunately, this trial failed to meet its primary end point of extending time to progression. A third trial with an anti-idiotypic antibody to OC125 was conducted randomizing 888 patients, 2:1 to abagovomab or placebo (Sabbatini, 2013). The primary end point was relapse-free survival; there was no difference in this end point or in OS with treatment intervention.

Despite the many setbacks of immune-based therapy in ovarian cancer, the field is in a renaissance with the discovery of mechanisms providing immune escape. The development of various immune checkpoint inhibitors has begun to be explored in ovarian cancer, and is summarized in Table 33.14.

Gene Therapy

The therapeutic impact of gene therapy in ovarian cancer has yet to be totally explored. Although the IP nature of this disease makes it well suited for this approach, various gene- or virus-based gene therapy programs have yielded mixed results at best. Several therapeutic models have been used in early investigations, including replacement of a tumor suppressor gene (e.g., *BRCA* and *p53*), suicide gene therapy, and inhibition of growth factor suppressors and regulators. As noted by Berchuck and Bast, there are a number of obstacles to developing this type of therapy to clinical usefulness. However, intensive investigation has been underway in a few centers to develop efficient and efficacious therapeutic programs.

Chemotherapy Sensitivity Assays

A chemotherapy sensitivity and resistance assay (CRSA) is a laboratory algorithm wherein a sample of human tumor is subjected, under experimental conditions, to various chemotherapeutic agents and concentrations to assess response

Study (PD-1/PD-L1)	n	RR	Disease Control Rate	Prior Treatment
Nivolumab				
Cohort 1: 1 mg/kg every 2 weeks	10	1 (PR)/10 (10%)	5/10 (50%)	≥ 2 priors regimens
Cohort 2: 1 mg/kg every 2 weeks	10	2 (CR)/10 (20%)	4/10 (40%)	Platinum-resistant
Avelumab	75	8 (PR)/75 (11%)	41/75 (55%)	No limit on priors (median 4, range 1-11)
10 mg every 2 weeks		2/2 clear cell		Platinum-resistant
Pembrolizumab	26	3 (1 CR, 2PR)/26 (12%)	9/26 (35%)	No limit on priors (>80% ≥4 priors)
10 mg/kg every 2 weeks				PD-L1 IHC positive (49/96, 51%)

(tumor survival). Two broad categories of assay intent separate the available technologies: those that evaluate the inhibition of cell growth and those that address chemotherapy-associated cell death. Although these appear similar, they are different in laboratory protocol and may produce vastly disparate results. In most cases, several agents alone and in combination are evaluated. Theoretically, the most active agent or combination could be picked (sensitivity assay) or eliminated (resistance assay) from an empirical program, offering a more precise decision tool. The hypothesis is that differential selection will improve outcome. Although the concept is simplistic and rational, the effects of chemotherapy response and survival are complex and sometimes counterintuitive. It is frequently noted that a limited sample of tissue obtained from the primary or a metastatic site, at primary diagnosis or in recurrence and after previous chemotherapy or radiation exposure, would not necessarily be representative of active disease at any one time. However, Tewari and colleagues reviewed 119 synchronous and 334 metachronous ovarian primary, metastatic, and recurrent samples and found remarkable consistency in the tumor's drug-resistance profile. However, efficacy requires clinical correlation. Loizzi and coworkers reported a case-control study on 100 recurrent ovarian cancer patients treated by assay or empirical therapy. Overall response (65% vs. 35%; $P = .02$), PFS (15 vs. 7 months; $P = .0002$), and OS (38 vs. 21 months; $P = .005$) were all improved using the assay. Similarly, however, inherent selection bias and treatment overlap necessitate validation by a randomized clinical trial. In 2004, the American Society of Clinical Oncology issued a statement based on an extensive review of global literature; it concluded that this technology needs further investigation before widespread adoption. This was reiterated in 2011, and CRSAs remain an area of active research.

Radiation Therapy

As presented earlier, radiation has been used for curative intent in women with early stage cancer, with some success. At least one report has suggested ovarian clear cell cancer may be responsive to radiotherapy, providing a potential treatment option for patients with this chemoresistant disease (Hoskins, 2012). Treatment planning involves a field that treats the entire abdomen as well as higher doses to the pelvis. Long-term efficacy must be balanced against uncommon toxicities of therapy, which include gastrointestinal stricture and fistulas and compromise of the bone marrow if chemotherapy is needed subsequently. The

modality has also been used to treat recurrent disease. Cmelak and Kapp treated 41 patients with platinum-refractory ovarian cancer who had undergone secondary cytoreduction. They treated the whole abdomen with 28 Gy and a pelvic boost to 48 Gy. For 28 patients with residual disease smaller than 1.5 cm, the 5-year survival rate was 53%, which is better than would be expected with chemotherapy. However, no large-scale trial data are available for this technique and, because of the risk of complications and lack of extensive data regarding its effectiveness, whole abdominal radiation has generally not been used in these cases. However, localized radiation can be of use in select patients with isolated recurrences or persistent disease after chemotherapy or to manage localized symptomatic disease, such as bone metastases. The development of intensity-modulated radiation therapy has widened the therapeutic index by reducing toxicity to surrounding unaffected tissues.

Summary

Therapy for epithelial ovarian carcinoma is based on the removal of all gross disease and sampling of areas at high risk of spread in the peritoneal cavity and retroperitoneal nodes. Postoperative therapy is used according to the stage and grade of the primary tumor. Multiagent platinum- and taxane-based chemotherapy is frequently used as adjunctive treatment for poorly differentiated tumors, such as stage I, grade 3, or for stage II cases without residual tumor.

For high-stage tumors and for patients with residual disease after initial operation, multiagent chemotherapy, usually paclitaxel and carboplatin, is used. It is accompanied by a number of short- and long-term toxic side effects, but initial response rates in stage III cases may exceed 90%. Five-year survival rates decrease to 30% or less. Long-term randomized trials and the development of new agents will be needed to improve rates of salvage and optimize therapy for epithelial ovarian carcinomas. Currently, second-line chemotherapy offers remission to some patients, but the best response rates are achieved with initial chemotherapy.

RARE EPITHELIAL OVARIAN CANCER SUBTYPES

CLEAR CELL CARCINOMA

Clear cell carcinoma is an aggressive subtype and accounts for approximately 5% to 10% of all epithelial ovarian cancers. It appears to be more prevalent in Japan. Over 50% are diagnosed

in the stage I-II category, and outcomes are similar to those of women with high-grade serous carcinoma (Okamoto, 2014). For women with stage III or IV disease, however, the outcomes are worse than those associated with high-grade serous carcinoma (Mackay, 2010). A proportion of clear cell carcinomas appear to arise from endometriosis. The prevailing thought is that clear cell carcinomas are relatively resistant to conventional platinum/taxane chemotherapy. The most frequent alterations include mutations in *ARID1A* and the *PI3K/AKT/mTOR* pathway (Kuo, 2009; Wiegand, 2010). The angiogenesis pathway and *MET* amplification appear to be good potential targets as well (Mabuchi, 2010; Yamashita, 2013).

LOW-GRADE SEROUS CARCINOMA

Low-grade serous carcinoma is a rare subtype constituting approximately 10% of all serous carcinomas. The stage distribution is very similar to that of high-grade serous carcinoma, with over 70% of cases in the stage III or IV category. Compared with high-grade serous carcinoma, low-grade serous carcinoma is characterized by young age at diagnosis, relative chemoresistance, and prolonged survival (Gershenson, 2015). Hormonal therapy has excellent activity for some patients (Gershenson, 2012). Likewise, antiangiogenic therapy appears to be active as well (Grisham, 2014). Translational research investigations have indicated that *K-ras* mutations occur in these tumors with a frequency of 20% to 40%, and *BRAF* mutations occur with a frequency of approximately 5%. MEK inhibitor therapy has demonstrated promising activity in the recurrent setting, and second-generation clinical trials are ongoing (Farley, 2013).

MUCINOUS CARCINOMA

Mucinous carcinoma accounts for approximately 5% of epithelial ovarian cancers and is frequently confused histologically with mucinous tumors of the gastrointestinal tract. It is usually unilateral and is diagnosed in the stage I category in over 50% of cases. Stage I is associated with an excellent prognosis. Women with advanced stage mucinous carcinoma have a worse outcome than those with advanced stage serous carcinoma, and standard platinum/taxane chemotherapy does not appear to be active in this subtype. Consequently, colorectal cancer-type regimens have been administered in some patients; however, no systematic information is yet available. Although information on the biology of mucinous carcinoma is somewhat limited, potential genes or pathways for therapeutic targeting include *HER2/neu* amplification, *KRAS*, *src*, and the angiogenesis pathway.

SMALL CELL CARCINOMA

Dickersin and colleagues described a virulent type of ovarian malignancy that occurs in young women, usually between the ages of 15 and 30 years. Because of its histologic appearance, it has been designated a small cell carcinoma. The tumor is often but not always accompanied by hypercalcemia, as noted by Young and associates in an analysis of 150 cases. Most patients have died, although a few stage I survivors have been reported, some of whom have been treated with adjuvant multiagent

chemotherapy. Reed has reported a patient with stage IC disease treated with cisplatin, etoposide, and bleomycin who survived 5 years. Benrubi and coworkers treated a patient with stage II small cell carcinoma with debulking and multiagent chemotherapy followed by radiation; the woman was disease free for 4 years at the time of the report. Other isolated stage I 5-year survivals have been reported with multiagent chemotherapy programs augmented with subsequent pelvic radiation. However, for advanced-stage disease, and even in most stage I cases, the course of the tumor has been fatal. Harrison and colleagues reported the findings of the combined experience of the Gynecological Cancer Intergroup, which included 17 patients with small cell carcinoma of the ovary, hypercalcemic type. All patients were initially treated with surgery and platinum-based chemotherapy. Seven also received adjuvant radiotherapy with pelvic and para-aortic radiotherapy or pelvic and whole-abdomen radiotherapy. For 10 stage I patients, 6 received adjuvant radiotherapy, and 5 were alive and disease free at the time of the report. All but one of the 7 patients with stage III or unknown stage had died.

The molecular biology of this tumor, small cell carcinoma of the ovary, hypercalcemic type (SCCOHT), has been elucidated. Germline and somatic *SMARCA4* mutations have been identified in a high proportion of these patients, and this information coupled with recent pathology review have led to the conclusion that these neoplasms are actually malignant rhabdoid tumors (Jelincic, 2014).

CARCINOSARCOMA

These are extremely rare ovarian malignancies that histologically resemble comparable tumors in the uterus. Treatment involves operation for cytoreduction, as noted by Muntz and associates, with added therapy, usually in the form of multiagent chemotherapy. Stage is a prognostic factor, and those with advanced stages usually do not survive.

As noted by Hellstrom and coworkers, approximately 500 of these rare tumors have been reported. In their series of 36 of these cases over 20 years, the median survival was 16.6 months, with a 5-year actuarial survival rate of only 18%. Low-stage tumors and those treated with multiagent chemotherapy (cyclophosphamide, doxorubicin [Adriamycin], cisplatin) had an improved survival. Although there remains some question about the efficacy of postoperative platinum-based chemotherapy for treatment of these tumors, as noted by Bicher and colleagues, this approach continues to be the standard. The most commonly used regimens include the combination of cisplatin plus ifosfamide and the combination of paclitaxel and carboplatin. Two reports have suggested that carcinosarcomas have a worse prognosis than high-grade serous carcinomas of the ovary.

GERM CELL TUMORS

These tumors are derived from the germ cells of the ovary. As a group, they are the second most frequent type of ovarian neoplasms and account for approximately 20% to 25% of all ovarian tumors. The classification of germ cell tumors, according to the WHO designation, is shown in [Box 33.2](#).

The most frequent germ cell tumor is the benign cystic teratoma (dermoid); overall, only 2% to 3% of germ cell tumors are malignant. Of the malignant germ cell tumors, the most frequent is the dysgerminoma, which accounts for approximately 45% of malignant germ cell tumors. Next in frequency are immature teratomas and then yolk sac tumors (endodermal sinus tumors). In women younger than 30 years, germ cell tumors are the most frequent ovarian neoplasm, and approximately one third of the germ cell tumors found in those younger than 21 years are malignant.

The histogenesis of germ cell tumors has been extensively studied and summarized by Talerman. [Figure 33.15](#) shows the theoretic histogenesis of these tumors. They are thought to originate from the primitive germ cell and gradually differentiate to mimic the developmental tissues of embryonic origin (ectoderm, mesoderm, or endoderm) and extraembryonic tissues (yolk sac and trophoblast). Germ cell tumors that originate in the ovary have homologous counterparts in the testes—that is, dysgerminoma and seminoma. Germ cell tumors are usually unilateral, except for teratomas and dysgerminomas (see [Table 33.4](#)). The morphologic and clinical aspects of each of the various types of germ cell tumors are considered separately.

TERATOMAS

Teratomas consist of tissues that recapitulate the three layers of the developing embryo (ectoderm, mesoderm, and endoderm). One or more of the layers may be represented, and the tissues can be mature (benign) or immature (malignant). Chromosomal studies indicate that teratomas appear to arise from a single germ and have an XX karyotype. In the older literature, terms such as *malignant teratoma* and *teratocarcinoma* were used to denote the

malignant variety of these tumors, but these terms have been replaced by the nomenclature shown in [Box 33.3](#).

Benign Cystic Teratomas (Dermoids)

Benign cystic teratomas are the most common germ cell tumors and account for 25% of all ovarian neoplasms. They primarily occur during the reproductive years but may occur in postmenopausal women and in children. The risk of malignant transformation (discussed later) is markedly increased if these tumors are found in postmenopausal women. One of the interesting facets of teratomas is their ability to produce adult tissue, including skin, bone, teeth, hair, and dermal tissue. The presence of calcified bone or teeth allows the tumor to be diagnosed preoperatively by ultrasonography or radiography ([Fig. 33.16](#)).

Dermoids are usually unilateral, but 10% to 15% are bilateral. The outside wall of the tumor tends to be smooth, with a yellowish appearance caused by the sebaceous fatty material that fills the tumor. Hair is also a prominent feature once the cyst is opened ([Fig. 33.17](#)). Usually, the tumors are asymptomatic but can cause severe pain if there is torsion or if the sebaceous material perforates the cyst wall, leading to a reactive peritonitis. This rare complication is severe and can occur during pregnancy. Microscopically, a number of adult tissues are seen ([Fig. 33.18](#)).

Treatment of the reproductive-age woman or child consists of cystectomy or unilateral oophorectomy. In most cases, it should be possible to remove only the cyst and preserve normal ovarian tissue. The technique at open laparotomy is demonstrated in [Figure 33.19](#). The opposite ovary should be inspected. If it is grossly normal, nothing further needs to be done. Current treatment involves preservation of the contralateral ovary without any biopsy if it grossly appears normal. In women beyond childbearing years, therapy for a dermoid usually consists of removal of the uterus, both tubes, and the ovaries.

Occasionally, teratomas may be solid and may consist only of adult tissues, leading to the diagnosis of a solid mature teratoma. These benign germ cell tumors are rare.

A cystic teratoma can undergo malignant degeneration, usually after menopause. Generally, it occurs in the squamous

epithelial elements of the dermoid, producing a squamous cell carcinoma. It is a rare complication, estimated to occur in less than 2% of these tumors. If the malignant tissue has spread beyond the confines of the ovary, the prognosis is poor. In such cases, additional therapy for squamous cell carcinoma with radiation therapy, chemotherapy, or both is used.

Immature Teratomas

Immature teratomas are malignant and account for as many as 20% of the malignant ovarian tumors found in women younger than 20 years, but less than 1% of all ovarian cancers. They rarely occur in women after menopause. They consist of immature embryonic structures that can be admixed with mature elements. Approximately one third of immature teratomas express serum α -fetoprotein.

The prognosis for patients with immature teratomas is related to the stage (FIGO) and grade of the tumor. The grade of the tumor is based on the degree of immaturity of the various tissues. Grade 3 tumors consist of the most immature tissues and often have a high proportion of immature neuroepithelium. Figure 33.20 shows the survival of patients with immature teratomas by stage and grade before the advent of modern chemotherapy. Kurman and Norris reported that patients with stage IA immature teratoma have a 10-year actuarial survival rate of 70% after unilateral salpingo-oophorectomy; this rate is comparable with that recorded after bilateral salpingo-oophorectomy.

Dysgerminomas

Dysgerminomas are the most common type of malignant germ cell tumors. They consist of primitive germ cells with stroma infiltrated by lymphocytes (Fig. 33.21). They are analogous to seminoma in the male testis and constitute approximately 1% of ovarian malignancies. Dysgerminomas occur primarily in women younger than 30 years. The tumor can be discovered during pregnancy. Some arise in dysgenetic gonads (discussed later). Unlike other malignant germ cell tumors, dysgerminomas are bilateral in approximately 10% of cases (see Table 33.4). Approximately 15% of dysgerminomas produce human chorionic gonadotropin related to areas of syncytiotrophoblast tissue.

Figure 33.19 Shelling out of teratoma. **A**, Scalpel incision in ovary at intersection of dermoid and normal ovary. **B**, Dermoid being separated. Note how the upper part peels away. **C**, Reconstruction of normal ovary.

Yolk Sac Tumors (Endodermal Sinus Tumors)

The endodermal sinus tumor, or yolk sac tumor, which comprises 10% of malignant germ cell tumors, in part resembles the yolk sac of the rodent placenta, thus recapitulating extraembryonic tissues (see Fig. 33.15). One typical histologic pattern is shown in Figure 33.22. The tumor secretes α -fetoprotein, which is a specific marker useful for identifying and following these tumors clinically. These rapidly growing tumors occur in females between 13 months and 45 years of age. Kurman and Norris noted a median age of 19 years at diagnosis. The yolk sac tumor is the prototype for α -fetoprotein production.

Choriocarcinomas

Nongestational choriocarcinoma is a highly malignant rare germ cell tumor resembling extraembryonic tissues. Like gestational choriocarcinoma (see Chapter 35), it consists of malignant cytotrophoblasts and syncytiotrophoblast; human chorionic gonadotropin is a useful tumor marker. This tumor mostly develops in women younger than 20 years, primarily in the ovary. The disease was usually fatal in the past and did not appear to respond to single-agent chemotherapy (e.g., methotrexate, actinomycin D) with the same frequency as gestational trophoblastic disease. This lack of response may be caused in part by the occurrence of these tumors in combination with other malignant germ cell tumors (mixed germ cell tumor) and, occasionally, the other germ cell elements may not be histologically recognized.

Embryonal Carcinomas

Embryonal carcinoma is a rare malignant germ cell tumor composed of primitive embryonal cells. It occurs in young females between the ages of 4 and 28 years. Kurman and Norris summarized 15 cases. Trophoblastic elements may be present; both human chorionic gonadotropin and α -fetoprotein have also been reported to be present.

Polyembryomas

Polyembryomas are exceedingly rare tumors that are usually found in the testes. They can occur in the ovary and consist of embryonal bodies that resemble early embryos. Trophoblastic elements with human chorionic gonadotropin and placental lactogen secretion have been reported.

Mixed Germ Cell Tumors

Mixed germ cell tumors are combinations of any of the germ cell tumors of the ovary described earlier. They can be bilateral if dysgerminoma elements are involved; otherwise, they are unilateral.

TREATMENT OF MALIGNANT GERM CELL TUMORS

Current treatment modalities result in cure rates approaching 100% for patients with stage I malignant germ cell tumors and more than 75% for patients with advanced-stage disease (stages III and IV). Because most patients are young and most of these tumors are unilateral, fertility-sparing surgery consisting of unilateral salpingo-oophorectomy with preservation of the contralateral ovary and the uterus is appropriate. After unilateral adnexal excision, frozen-section examination should be performed to confirm the diagnosis preliminarily. Once a malignant ovarian germ cell tumor is documented, routine biopsy of a normal contralateral ovary should be avoided because such an intervention could lead to future infertility related to peritoneal adhesions or ovarian failure. If bilateral ovarian masses are encountered at surgery, a unilateral salpingo-oophorectomy of the more suspicious side is appropriate. If the opposite ovary contains tumor or is dysgenetic, bilateral salpingo-oophorectomy is generally indicated. In the case of bilateral ovarian dysgerminomas in nondysgenetic ovaries, although not proved to be entirely safe, unilateral salpingo-oophorectomy and contralateral ovarian cystectomy may be considered in an effort to preserve

Figure 33.20 A, Actuarial survival of 56 patients with malignant teratoma by neoplasm stage. B, By neoplasm grade. (From Norris HJ, Zirkin JH, Benson WL: Immature [malignant] teratoma of the ovary: a clinical and pathologic study of 58 cases. *Cancer*. 1976;37[5]:2359-2372.)

Figure 33.21 Dysgerminoma ($\times 300$). Dysgerminoma cells are demonstrated as well as infiltration of stroma by lymphocytes. (From Scully RE: Germ cell tumors of the ovary and fallopian tube. In Meigs JV, Sturgis SH, eds. *Progress in Gynecology*. Vol 4. New York: Grune & Stratton; 1963.)

fertility. Conversely, if a contralateral ovary contains a mature cystic teratoma, which is more likely because it is present in 10% to 15% of cases, ovarian cystectomy is indicated.

If the tumor appears to be grossly confined to the ovary, comprehensive surgical staging is recommended, with cytologic washings, omentectomy, peritoneal biopsies, and bilateral pelvic and para-aortic lymphadenectomy. If obvious extraovarian metastases are present, the guiding principle is maximum cytoreductive surgery. The philosophy regarding comprehensive surgical staging for patients with malignant ovarian germ cell tumors is based primarily on that for common epithelial ovarian cancers and may or may not apply. For example, a very different perspective prevails in the pediatric surgery community. Based on an intergroup study report in which deviations from standard surgical guidelines did not adversely influence survival, Billmire and colleagues proposed a different set of surgical guidelines: collection of ascites or cytologic washings, examination of peritoneal surfaces with biopsy or excision of any nodules, examination and palpation of retroperitoneal lymph nodes and sampling of any firm or enlarged nodes, inspection and palpation of omentum with removal of any adherent or abnormal areas, biopsy or excision of any other abnormal areas, and complete resection of the tumor-containing ovary with sparing of the fallopian tube if not involved.

Historically, for most patients with malignant ovarian germ cell tumors, postoperative chemotherapy has been recommended. Notable exceptions include patients with stage IA pure dysgerminoma and patients with stage IA, grade 1, immature teratoma; these patients have a high cure rate with surgery alone. In the 1970s, the VAC regimen (vincristine, 1.5 mg/m² IV weekly for 8 to 12 weeks, and actinomycin D, 300 mcg/m²/day for 5 days every 4 weeks, with cyclophosphamide [cytoxan] 150 mg/m²/day for 5 days every 4 weeks) was the first effective combination chemotherapy regimen for patients with malignant germ cell tumors. VAC was the most widely used regimen during the 1970s and early 1980s and produced a relatively high proportion of cures in stage I disease (82%), but in patients with metastatic disease, the cure rate was less than 50%. During the VAC era, conversion of an immature teratoma to a mature teratoma under the influence of chemotherapy, so-called retroconversion, was observed.

By the late 1970s, based on the experience in testicular cancer, the combination of vinblastine, bleomycin, and cisplatin (VBP) was beginning to be used for malignant ovarian germ cell tumors, with superior outcomes compared with those achieved with the VAC regimen, particularly for patients with advanced-stage disease. By the mid-1980s, the VBP regimen was replaced by the combination of bleomycin, etoposide, and cisplatin (BEP) because of the latter's superior toxicity profile. The BEP regimen remains the standard today. Generally, most patients require three to four cycles of therapy. In 1990, Gershenson and colleagues reported that 25 of 26 patients treated with BEP for malignant germ cell tumors were in sustained remission. Subsequently, Williams and associates, reporting the GOG experience, noted that 89 of 93 patients (96%) with completely resected stage I, II, or III disease remained continuously disease free.

Special note should be made regarding dysgerminoma. Historically, for patients with metastatic dysgerminoma, the traditional postoperative treatment was radiotherapy. Although dysgerminoma is exquisitely radiosensitive and survival rates with this treatment were excellent, most patients suffered loss of fertility. With the advent of successful combination chemotherapy,

such as BEP, chemotherapy has almost exclusively supplanted radiotherapy, with a high rate of fertility preservation. In a GOG report, adjuvant chemotherapy with etoposide and carboplatin for 39 patients with completely resected stage IC-III dysgerminoma resulted in no relapses.

Although second-look surgery was part of standard management for patients with malignant germ cell tumors until the mid-1980s, reports from the University of Texas M.D. Anderson Cancer Center and the GOG called into question the value of this procedure. Gershenson and coworkers reported their experience with second-look surgery, with negative findings in 52 of 53 patients; only 1 of the 52 negative patients relapsed and died of tumor. Subsequently, the GOG experience confirmed that the value of second-look surgery in patients with completely resected malignant germ cell tumors and incompletely resected malignant germ cell tumors not containing an immature teratoma element was negligible. For patients with incompletely resected malignant germ cell tumors with an immature teratoma element, however, second-look surgery appeared to have some impact. Advances in imaging technology may further minimize the need for second-look surgery, even in the latter group.

There has been a trend toward surveillance, with careful follow-up after surgery as an alternative to chemotherapy in select patients. Bonazzi and colleagues treated 32 patients with operation alone for stage I or II, grade 1 or 2, tumors. All patients with grade 3 or stage III tumors, or those with tumor recurrence, received cisplatin, etoposide, and bleomycin. Most patients underwent fertility-sparing surgery, and 10 received chemotherapy. All patients were free of disease with a median follow-up of 47 months, and 5 had delivered healthy infants. A Pediatric Oncology Group Study reported by Cushing and associates has indicated that patients younger than 15 years with a pure immature teratoma could be followed without chemotherapy; however, more than 90% of the tumors in their series were grade 1 or 2. Patterson and associates reported on surveillance in patients with stage IA malignant ovarian germ cell tumor. Relapses were reported in 8 of 22 (36%) patients with nondysgerminomatous tumors and 2 of 9 (22%) patients with dysgerminomas. All relapses occurred within 13 months of diagnosis, and one patient was not salvaged with chemotherapy. Mangili and colleagues reported 28 patients with stage I immature teratoma (9 grade 1, 12 grade 2, and 7 grade 3), 19 of whom were treated with surgery alone. Twenty-four of the patients underwent fertility-sparing surgery. Four patients treated with surgery alone relapsed—2 with mature teratoma and 2 with immature teratoma. All were salvaged with secondary surgery, with the 2 patients with immature teratoma receiving chemotherapy as well.

The Children's Oncology Group has conducted a clinical trial in the pediatric population. This trial included surveillance of a low-risk cohort, consisting of all patients with apparent stage I disease with close follow-up of serum markers and initiation of chemotherapy only if relapse occurred (Billmire, 2014). Twenty-five girls were enrolled in the trial. After a median follow-up of 42 months, 12 patients had persistent or recurrent disease. Eleven of the 12 patients were successfully salvaged with chemotherapy.

There is no standard surveillance for patients with malignant ovarian germ cell tumors after completion of primary therapy. For patients who have completed standard surgery plus chemotherapy, we generally recommend evaluation of serum tumor marker every 3 months for up to 2 years and then every 6 months

until 5 years from diagnosis. Patients treated with fertility-sparing surgery should be closely followed with periodic transvaginal ultrasound or CT evaluations. Office visits, with a physical examination, are generally recommended every 3 months for the first 2 years and less frequently thereafter.

With the success of cure in a high proportion of young patients with malignant ovarian germ cell tumors has come an increasing focus on the late effects of therapy, particularly fertility preservation. In a report of 40 patients, Gershenson and colleagues noted that 27 had normal menses after multiagent chemotherapy for germ cell tumors, and 11 of 16 patients who attempted pregnancy were successful in bearing 22 children. Most of these patients received nonplatinum-based chemotherapy. Peccatori and associates reported on 139 patients with malignant germ cell tumors, 108 of whom had fertility-sparing operations. Multiagent platinum-containing chemotherapy was used, with a 96% survival rate and a mean follow-up of 55 months. In a GOG study, Williams and associates reported on 93 patients treated adjuvantly with cisplatin, etoposide, and bleomycin for three cycles. Of 93 patients, 91 were free of disease 4 to 90 months after treatment, although leukemia developed in one patient and lymphoma in a second patient. Brewer and coworkers reported on 26 patients treated with BEP, with 25 alive and disease-free and a median follow-up of 89 months. They reported that 71% resumed normal menstrual function and 6 patients conceived. Three additional large studies from Australia, Italy, and the United States have provided further support for the concept of preservation of fertility in most treated with fertility-sparing surgery and chemotherapy. In a GOG matched control study of 132 survivors (all of whom were treated with surgery and platinum-based chemotherapy) and 137 controls, 71 (54%) survivors underwent fertility-sparing surgery. Of the fertile survivors, 87% reported having normal menstrual function and 24 survivors had 37 offspring after cancer therapy. However, compared with controls, cancer survivors had significantly greater reproductive concerns and less sexual pleasure.

Several nonrandomized studies have suggested that the gonadotropin-releasing hormone agonist prophylaxis may be worthwhile to preserve ovarian function in young patients receiving chemotherapy. Blumenfeld and coworkers administered gonadotropin-releasing hormone agonist during chemotherapy for nongynecologic tumors to women of reproductive age, and 15 of 16 surviving patients (93.7%) resumed menses and ovulation. However, randomized trials are needed to validate this approach. In a randomized trial for breast cancer patients, a GnRH analogue appeared to reduce the incidence of chemotherapy-induced premature menopause.

SPECIALIZED GERM CELL TUMORS: STRUMA OVARII AND CARCINOIDS

Specialized ovarian germ cell tumors are rare; two types are commonly recognized (see [Box 33.3](#)): the struma ovarii and carcinoids. Struma ovarii are dermoids with thyroid tissue exclusively or with thyroid tissue as a major component. The thyroid tissue can be functional, leading to clinical hyperthyroidism. Most of these tumors are benign, but malignant changes are possible. Metastatic disease, if present, has been reported to be effectively treated with ^{131}I , as for primary thyroid carcinoma.

Carcinoids are ovarian teratomas that histologically resemble similar tumors in the gastrointestinal tract. Carcinoids are rare

and are unilateral in the ovary. In approximately 30% of cases, a true carcinoid syndrome will develop, and 5-hydroxyindoleacetic acid can be detected and used to monitor the tumor postoperatively. These tumors occur primarily in older women and tend to grow slowly; the prognosis after hysterectomy and bilateral salpingo-oophorectomy is excellent. For a young woman desiring preservation of childbearing function, a stage IA carcinoid can be treated by unilateral salpingo-oophorectomy.

GONADOBLASTOMAS (GERM CELL SEX CORD-STROMAL TUMORS)

The term *gonadoblastoma* was introduced by Scully in 1953 to describe a tumor that consists of germ cell and sex cord-stromal elements. Approximately 100 cases have been reported. The germ cells usually resemble dysgerminoma, whereas the sex cord-stromal elements may consist of immature granulosa and Sertoli cells. Leydig cells and luteinized cells may be present. The tumor usually occurs in patients with abnormal (dysgenetic) gonads. Most patients have a female phenotype but may be virilized. These patients have a Y chromosome detected in their karyotype, and patients with gonadal dysgenesis and a Y chromosome are at risk for the development of gonadoblastoma or malignant germ cell tumors, predominantly dysgerminoma, which may occur in those as young as 6 months. Removal of these gonads is indicated when they are discovered. Both gonads should be removed; if the presence of pure gonadoblastoma is confirmed, the prognosis is excellent because these tumors have not been reported to metastasize.

SEX CORD-STROMAL TUMORS

Sex cord-stromal tumors are derived from the sex cords of the ovary and the specialized stroma of the developing gonad. The elements can have a male or female differentiation, and some of these tumors are hormonally active. This group accounts for approximately 6% of ovarian neoplasms and most hormonally

Figure 33.23 Granulosa cell tumor (×460). (From Scully RE, Morris J. Functioning ovarian tumors. In Meigs JV, Sturgis SH, eds. *Progress in Gynecology*. Vol 3. New York: Grune & Stratton; 1957.)

functioning ovarian tumors. For the female derivatives, the sex cord component is the granulosa cell and the stromal component is the theca cell or fibroblast. For the male counterpart, the similar components are the Sertoli cell and Leydig cell. Granulosa–theca cell tumors and Sertoli–Leydig cell tumors tend to behave as low-grade malignancies. Their clinical and morphologic aspects considered separately.

GRANULOSA-THECA CELL TUMORS

Granulosa cell tumors consist primarily of granulosa cells and a varying proportion of theca cells, fibroblasts, or both. One characteristic microscopic pattern is shown in [Figure 33.23](#), which demonstrates the so-called *Call-Exner bodies*, eosinophilic bodies surrounded by granulosa cells. Functional granulosa cell tumors are primarily estrogenic. Approximately 5% occur before puberty and they can be one cause of precocious puberty, but the tumors have been described in women of all ages. In postmenopausal women, these tumors can produce increased levels of blood estrogens, uterine bleeding, and occasionally endometrial carcinoma. It is estimated that approximately 5% of the granulosa cell tumors in adults are associated with endometrial carcinoma. In menstruating women, the functional granulosa cell tumor can produce abnormal menstrual patterns, menorrhagia, and even amenorrhea.

These tumors can become large and may present as a ruptured mass, leading to laparotomy for an acute abdomen with hemoperitoneum. Because of the low-grade malignant character of these tumors, recurrences are frequently more than 5 years after primary therapy. In general, prognosis does not correlate with the histologic pattern of the tumor. A total of 90% of granulosa cell tumors present as stage I. Advanced clinical stage, the presence of tumor rupture, a large primary tumor (>15 cm), and a high mitotic rate have been associated with a poorer prognosis. Overall 10-year survival rates of 90% have been reported. Studies by Klemi and colleagues and others have suggested that most granulosa cell tumors have a diploid pattern and a low (<60%) S-phase fraction when analyzed by flow cytometry. Those with an aneuploid pattern had a worse prognosis. A variant found predominantly in females younger than 20 years is known as *juvenile granulosa cell tumor*. It was described by Young and coworkers and has an excellent prognosis, particularly if the tumor is confined to one ovary.

Molecular profiling investigations have found that almost all granulosa cell tumors have a *FOXL2* mutation ([Shah, 2009](#)). *FOXL2* is a member of the forkhead-winged-helix family of transcription factors and one of the earliest markers of ovarian differentiation.

The primary therapeutic approach is surgery. Because these tumors are rarely bilateral (<5%), young patients with stage IA tumors can be treated by unilateral adnexectomy. Lack and colleagues reported on 10 cases of granulosa cell tumors in premenarchal female patients, all of whom were treated by unilateral salpingo-oophorectomy. Two tumors were ruptured. All 10 of the patients were alive with no evidence of disease 2 to 33 years after therapy. Evans and associates noted a higher recurrence rate in women who were treated by unilateral salpingo-oophorectomy for stage IA cases compared with those treated with bilateral salpingo-oophorectomy. This finding has led to the recommendation that women of reproductive age treated for

granulosa cell tumor by unilateral salpingo-oophorectomy have close follow-up. For women who have completed childbearing, abdominal hysterectomy and bilateral salpingo-oophorectomy are recommended. Regardless of the treatment of the pelvic organs, if a granulosa cell tumor is diagnosed on frozen-section examination, comprehensive surgical staging is recommended. Whether complete pelvic and para-aortic lymphadenectomy is indicated remains unresolved; there is some information that the incidence of lymph node metastases associated with this tumor type is low. Brown and coworkers evaluated the risk of lymph node metastasis in patients with sex cord–stromal tumors. A total of 262 patients were included in that study; of these, 178 patients were diagnosed with granulosa cell tumors. It was noted that none of the patients who underwent lymphadenectomy had evidence of lymph node metastasis.

Tumor markers may be helpful for monitoring the clinical course of granulosa cell tumors. Studies by Lappohn and colleagues have suggested that the peptide hormone inhibin is secreted by some granulosa cell tumors and serum measurements could serve as a tumor marker. In addition, serum CA-125, serum estradiol, or serum testosterone levels may occasionally serve as markers that should be followed serially.

Historically, radiotherapy, the VAC regimen (discussed earlier), or the combination of cisplatin, doxorubicin, and cyclophosphamide have been used for the treatment of metastatic granulosa cell tumors, but none of these options are currently recommended for general application. Many questions remain regarding recommendations for postoperative treatment. For patients with stage IA granulosa cell tumors, surgery alone is recommended. The recommendation for those with stage IC disease remains controversial, but consideration can be given to adjuvant therapy based on the probable increased risk of relapse. Postoperative therapy is recommended for all patients with stages II to IV disease, as well as for those patients with recurrent tumor.

Because of the rarity of granulosa cell tumors, no standard regimen exists. The GOG has reported the largest series of women treated with the BEP regimen. Homesley and associates reported on 57 eligible patients; 41 had recurrent disease and 16 had primary metastatic disease. Of these patients, 48 had granulosa cell tumors. Overall, 11 of 16 primary disease patients and 21 of 41 recurrent disease patients remained progression free at a median follow-up of 3 years. However, toxicity was fairly severe, with two bleomycin-related deaths reported.

Brown and coworkers reported the M.D. Anderson Cancer Center experience with taxane-based chemotherapy in a study of 44 patients with sex cord–stromal tumors of the ovary treated for primary metastatic or recurrent disease. The response rate for 30 patients treated with a taxane plus platinum for recurrent measurable disease was 42%. Thus the combination of paclitaxel and carboplatin is also an option for these patients. NRG Oncology (GOG) is conducting a randomized phase II study comparing BEP with the combination of paclitaxel and carboplatin for women with newly diagnosed or chemonaïve recurrent sex cord–stromal ovarian tumors. In general, however, the value of chemotherapy for ovarian sex cord-stromal tumors has been questioned ([Meisel, 2015](#); [van Meurs, 2014a](#)). The rarity of these tumors and the indolent nature of some subtypes are features that complicate the assessment of the efficacy of chemotherapy.

Figure 33.24 Sertoli-Leydig cell tumor. Tubules of Sertoli cells (right) and Leydig cells (left) are shown ($\times 250$). (Courtesy of Dr. R.E. Scully.)

Hormonal therapy may also be considered for patients with metastatic granulosa cell tumors. Responses of these tumors to medroxyprogesterone acetate and gonadotropin-releasing hormone antagonists have been reported. Fishman and colleagues treated six patients with recurrent or persistent granulosa cell tumors with leuprolide acetate; of five patients with assessable disease, two had partial responses and three had stable disease. More recently, van Meurs and associates reviewed the literature and made a case for hormonal therapy as a good treatment alternative for granulosa cell tumors (van Meurs, 2014b). In addition, a phase II trial of bevacizumab in patients with recurrent sex cord-stromal tumors showed an objective response rate of 16.7% (Brown, 2014).

THECOMAS AND FIBROMAS

A thecoma is a benign tumor that consists entirely of stroma (theca) cells. It predominantly occurs in women in their perimenopausal and menopausal years. These tumors can be associated with estrogen production but not as frequently as granulosa cell tumors. Removal of the tumor alone is adequate treatment for women in their reproductive years. For older women, total abdominal hysterectomy and bilateral salpingo-oophorectomy are performed. Rarely, thecomas have been reported to be malignant, and these are most likely fibrosarcomas. A closely related tumor is the fibroma, which is the most common benign solid ovarian tumor and accounts for 4% of all ovarian tumors. Like the thecoma, it can occur at any age but is more common in older women; it does not secrete hormones. These tumors contain spindle cells, and the tumors can grow to a large size. They are benign, and excision is adequate treatment. They are associated with ascites in approximately 40% of cases if the tumor is larger than 10 cm, according to Samanth and Black. They can also be responsible for hydrothorax with a benign ascites (Meigs syndrome), which regresses following tumor removal.

SERTOLI-LEYDIG CELL TUMORS (ANDROBLASTOMAS)

Sertoli-Leydig cell tumors are very rare. Sertoli (sex cord) and Leydig (stromal) cells are present in varying amounts, and the tumor may consist almost entirely of Sertoli or Leydig cells (Fig. 33.24). These tumors tend to occur in young women of reproductive age

and frequently are the cause of masculinization and hirsutism. The symptoms of virilization usually regress after tumor removal, but temporal hair recession and a deeper voice tend to remain. Rarely, they have also been reported to have estrogenic activity, leading to the same symptoms and signs as those of granulosa cell tumors. The tumors tend to behave as low-grade malignancies and the 5-year survival rate can vary from 70% to 90%. Poorly differentiated types tend to have a poor prognosis, as do higher-stage tumors. Young and Scully reviewed 207 cases; 75% were in those 30 years of age or younger and less than 10% were older than 50 years. One third of patients had evidence of androgen excess. Both ovaries were involved in only three cases. The well-differentiated tumors behaved clinically as benign tumors, whereas recurrence or extrauterine spread was noted occasionally in women with intermediate differentiation (11%) and frequently in those with poor differentiation (59%). Of 164 patients available for follow-up, 18% had metastasis or recurrence.

Studies have established that *DICER1* mutations are found in a relatively high percentage of patients with Sertoli-Leydig cell tumors (Heravi-Moussavi, 2012; Schultz, 2011). These mutations may be either germline or somatic and may be associated with familial pleuropulmonary blastoma.

Treatment of metastatic Sertoli-Leydig cell tumors is similar to that for granulosa cell tumors. In addition, because the prognosis for patients with stage I poorly differentiated Sertoli-Leydig cell tumors is so poor, consideration should be given to adjuvant treatment. However, it should be emphasized that there are no therapeutic data in this setting, and if treatment is recommended the optimal regimen remains unclear. The BEP regimen or the combination of paclitaxel and carboplatin may be considered for these patients.

OTHER SEX CORD-STROMAL TUMORS

Gynandroblastomas

Gynandroblastomas are rare sex cord-stromal tumors consisting of female (granulosa cells) and male (Sertoli cells) cell types. Theca or Leydig cells may also be present. Patients with this tumor typically present with androgenic manifestations, but stigmata associated with hyperestrogenism may also be observed. These tumors are usually unilateral and generally considered to be of low malignant potential.

Sex Cord Tumors with Annular Tubules

Sex cord tumors with annular tubules are unusual. As suggested by the name, there is a prominent tubular pattern. Features of both Sertoli and granulosa cell tumors are present. Young and colleagues reviewed 74 cases; 27 were associated with mucocutaneous pigmentation and gastrointestinal tract polyposis (Peutz-Jeghers syndrome). The tumors may have estrogenic manifestations. Those associated with Peutz-Jeghers syndrome are benign and those not associated with this syndrome can be malignant. It is of interest that 4 of these 74 cases were associated with a virulent form of cervical adenocarcinoma (adenoma malignum).

Leydig Cell and Hilus Cell Tumors

Leydig cell and hilus cell tumors are rare. They are composed of Leydig cells or cells of the ovarian hilus. Their cytoplasm contains hyaline bodies known as *crystalloids of Reinke*. They usually cause virilization and are benign. They tend to be small (< 6 cm) and develop primarily in perimenopausal women.

LIPID (LIPOID) TUMORS

Lipid tumors are infrequently occurring ovarian tumors composed of large cells that resemble Leydig cells, luteinized cells, or cells that arise in the adrenal cortex. Approximately 100 tumors have been reported. These tumors usually cause virilization but have also been associated with excess cortisol production. There is not enough experience with them to delineate an effective form of treatment. However, metastases of lipid cell tumors have been reported.

METASTATIC OVARIAN TUMORS

Tumors from distant primary sites can metastasize to the ovary. Frequently, metastases are from primary tumors that originate elsewhere in the female reproductive tract, particularly from the endometrium and fallopian tube. Distant sites of origin occur most frequently from the breast and gastrointestinal tract. Metastatic tumors from the gastrointestinal tract to the ovary can be associated with sex hormone production, which usually leads to estrogenic manifestations. One special type of metastatic ovarian tumor is known as a Krukenberg tumor, which histologically consists of nests of mucin-filled signet ring cells in a cellular stroma (Fig. 33.25). The most common gastrointestinal tract origin for these tumors is the stomach, and the next frequent is the large intestine. However, breast metastases to the ovary can on occasion reveal the same histologic picture. A few cases of Krukenberg tumors have been described, with no apparent distant primary malignancy, suggesting the rare possibility of a primary ovarian tumor with the histologic features of a Krukenberg tumor.

Figure 33.25 Krukenberg's tumor ($\times 256$). Mucin-filled signet-ring cells are present. (Courtesy of Dr. R.E. Scully.)

A primary gastrointestinal tract malignancy should be considered in older women with an adnexal mass, particularly if it is bilateral and solid. A pretherapy evaluation to rule out a gastrointestinal tract or breast primary tumor is indicated. The tumor should be removed when discovered, and the primary site should be treated. The prognosis is poor; it is rare for a woman to survive for 5 years or longer after treatment.

KEY POINTS

- Ovarian cancer is the leading cause of death from gynecologic cancer, but it occurs less frequently than endometrial cancers.
- Ovarian cancers in women older than 50 years are diagnosed at a more advanced stage, leading to a worse prognosis than for younger women.
- The risk of ovarian cancer is decreased by oral contraceptive use. Tubal ligation and hysterectomy also appear to decrease the risk.
- Most ovarian carcinomas are diagnosed in stage III or IV.
- Ovarian cancer risk rises from approximately 1.4% in general to 5% to 7% if the woman has one or two first- or second-degree relatives with ovarian cancer.
- Patients with ovarian cancer are at increased risk of developing breast cancer and endometrial cancer.
- It is important that the follow-up of ovarian cancer patients includes monitoring for breast cancer.
- Epithelial tumors are the most frequent ovarian neoplasm. They account for two thirds of all ovarian neoplasms and 85% of ovarian cancers.
- The major ovarian epithelial tumor cell types recapitulate müllerian-type epithelium (serous, endosalpinx; mucinous, endocervix; endometrioid, endometrium).
- Serous ovarian neoplasms are the most common type of epithelial tumors. Serous adenocarcinomas tend to be high grade, are the most virulent, and have the worst prognosis of epithelial adenocarcinomas. They are bilateral in 33% to 66% of cases.
- A cystic adnexal mass smaller than 8 cm in diameter in a menstruating female is most frequently functional.
- The normal postmenopausal ovary is approximately 1.5 to 2 cm in diameter.
- The risk of an ovarian tumor being malignant is approximately 33% in a woman older than 45, whereas it is less than 1 in 15 for those 20 to 45 years of age. More than 50% of ovarian cancers occur in women older than 50.
- There are three types of ovarian tumors with a serous histology: traditional serous adenocarcinomas, surface papillary tumors (ovary <4 cm), and primary peritoneal carcinomas (serous carcinomas metastatic to the ovary, with normal ovarian size).
- Most ovarian carcinomas start from small microscopic foci and spread throughout the peritoneum before becoming clinically evident (de novo origin), especially serous and poorly differentiated tumors.
- Ovarian carcinomas having a cystic origin are primary mucinous or endometrioid and are more likely to be discovered at a low stage.
- A vaginal ultrasound finding of a unilocular cyst of 5 cm or smaller in a perimenopausal woman can usually be followed without surgical intervention.

Continued

KEY POINTS—cont'd

- Vaginal ultrasonography may detect early ovarian carcinoma but has not been proved to be a cost-effective screening technique.
- The primary distribution spread of epithelial carcinoma is transcoelomic to the visceral and parietal peritoneum, diaphragm, and retroperitoneal nodes.
- The risk of retroperitoneal node spread of epithelial carcinoma in apparent stage I cases is greatest for poorly differentiated tumors, for which the risk can reach 10% to 20%. The risk of retroperitoneal node spread increases in higher-stage cases.
- The prognosis of a patient with ovarian epithelial carcinoma is related primarily to tumor stage and tumor grade, and to the amount of residual tumor remaining after primary resection.
- Laparoscopic or robotic staging of early ovarian cancers appears to be feasible and comprehensive, without compromising survival
- The 5-year survival rate for patients with borderline epithelial ovarian carcinoma (grade 0) is close to 100% for stage I cases and more than 90% for all stages.
- The overall 5-year survival rate for patients with stage I ovarian carcinoma is 65%. For stage I, grade 1, the survival rate is reported to be more than 80%.
- Optimal surgical debulking (R0-microscopic residual) appears to confer a survival advantage in cases of stages III and IV ovarian carcinoma.
- Interval cytoreduction has little additional effect on overall survival if a maximal attempt is made at primary surgery.
- Neoadjuvant chemotherapy can reduce surgical morbidity; a randomized trial has indicated that this strategy may be equivalent to standard treatment for advanced-stage patients with surgery followed by chemotherapy.
- IP chemotherapy appears to benefit patients with optimal cytoreduction more than conventional IV chemotherapy, but with greater toxicity.
- CT scanning for patients with ovarian cancer can be approximately 80% to 90% effective for detecting tumor in retroperitoneal nodes, but it is much less successful in detecting intra-abdominal disease.
- Assessing the ovarian CA-125 level is useful to help monitor patients with ovarian carcinoma. Reaction to the antigen is positive in approximately 80% of cases.
- A rapid decrease in CA-125 values after treatment indicates a more favorable prognosis.
- The initial response rate of ovarian epithelial carcinomas multiagent chemotherapy is more than 90%, but the proportion of patients who survive decreases to approximately 30% in 5 years. Initial treatment is usually with platinum and taxane agents.
- Recurrent ovarian cancer is difficult to cure.
- Factors determining response to recurrent chemotherapy regimens include time to treatment progression, distribution and volume of disease, and performance status.
- Combination chemotherapy for platinum-sensitive recurrent disease improves response rates, with a less clear effect on survival.
- Secondary cytoreduction appears to benefit patients with limited recurrent disease who undergo complete tumor removal. The benefit may be most evident before chemotherapy for recurrence.
- Germ cell tumors are the second most common type of ovarian neoplasms and account for approximately 20% to 25% of all ovarian tumors.
- In women younger than 30 years, the most frequent ovarian neoplasm is a germ cell tumor; approximately one third of these germ cell tumors are malignant in those younger than 21. For women younger than 30 years, the most common ovarian neoplasm is the dermoid.
- The most common germ cell tumor is the benign cystic teratoma (dermoid). It is bilateral in 10% to 15% of the cases. Approximately 30% are calcified.
- Malignant germ cell tumors are usually unilateral except dysgerminomas, which are bilateral in approximately 10% to 15% of patients.
- Dysgerminomas are the most common malignant germ cell tumors and account for 1% to 2% of ovarian cancers.
- The prognosis for a patient with an immature teratoma is related to tumor grade and tumor stage. These tumors are the second most common type of malignant germ cell tumor.
- The 5-year survival rate of stage IA pure dysgerminoma treated by unilateral salpingo-oophorectomy is more than 90%.
- Pure dysgerminomas are radiocurable. However, multiagent chemotherapy, particularly with etoposide and platinum, with or without bleomycin, will frequently result in complete remission. Approximately two thirds of cases present as stage IA.
- Most patients with malignant ovarian germ cell tumors can be treated successfully with fertility-sparing surgery followed by BEP chemotherapy. Patients who do not require postoperative chemotherapy include those with stage IA dysgerminoma and stage IA, grade 1, immature teratoma. However, there has been a trend toward surveillance rather than chemotherapy for patients with stage I tumors of any histologic subtype.
- Multiagent chemotherapy has improved survival in patients with malignant germ cell tumors, preserving childbearing function in most cases. Standard chemotherapy consists of the BEP regimen.
- Gonadoblastomas are sex cord–stromal germ cell tumors that usually arise in dysgenetic gonads in patients with a Y chromosome; these are cured by removal.
- Granulosa cell tumors and Sertoli-Leydig tumors usually behave as low-grade malignancies, but there may be late recurrences.
- For patients with primary metastatic or recurrent sex cord–stromal tumors of the ovary, platinum-based chemotherapy is the treatment of choice. Commonly used regimens include BEP and paclitaxel-carboplatin.
- Some metastatic granulosa cell tumors may respond to hormone therapy, such as leuprolide acetate, tamoxifen, or aromatase inhibitors.
- Fibroma is the most common benign solid ovarian tumor.
- The most frequent sites of origin of tumors metastatic to the ovary are the lower reproductive tract, gastrointestinal tract, and breast.

Fallopian Tube and Peritoneal Carcinoma

Kathleen M. Schmeler, David M. Gershenson

Fallopian tube and peritoneal cancers have similar clinical characteristics, patterns of spread, response to treatment, and survival rates when compared with ovarian cancer. In addition, the most common histologic type for all three malignancies is high-grade serous adenocarcinoma. However, fallopian tube and peritoneal cancers have several distinct clinical and pathologic findings. This chapter reviews current information on fallopian tube and peritoneal cancer, with particular emphasis on diagnosis, natural history, and clinical management.

CAUSES

FALLOPIAN TUBE CANCER

Fallopian tube carcinoma is rare, accounting for approximately 0.2% of cancers among women. The estimated incidence of fallopian tube cancer in the United States is 0.41 per 100,000 women (Stewart, 2007). However, it has been suggested that many cases of ovarian carcinoma may actually arise from the epithelial lining of the fallopian tube fimbria, thereby grossly underestimating the incidence of primary fallopian tube carcinoma (Kindelberger, 2007; Carlson, 2008a).

Similar to ovarian cancer, the primary risk factor for fallopian tube cancer is an inherited mutation in the *BRCA1* and *BRCA2* tumor suppressor genes associated with hereditary breast and ovarian cancer syndromes. Women with *BRCA1* and *BRCA2* mutations have a 40% to 60% and 20% to 30% lifetime risk, respectively, for developing ovarian, fallopian tube, or peritoneal cancer (Chen, 2007; Mavaddat, 2013). Furthermore, previous reports have shown that approximately 15% to 45% of women with fallopian tube cancers have a *BRCA* mutation (Levine, 2003; Cass, 2005). Risk-reducing bilateral salpingo-oophorectomy (rrBSO) is therefore recommended for women with a *BRCA* mutation once they have completed childbearing (Kauff, 2002; Rebbeck, 2002; Rebbeck, 2009; Domchek, 2010). However, in women without a *BRCA* mutation, the cause of fallopian tube carcinoma remains unclear. Similar to ovarian cancer, associated risk factors for fallopian tube and peritoneal cancer include infertility, low parity, early menarche, and late menopause (Gates, 2010). Protective factors include oral contraceptive use, multiparity, breastfeeding, and tubal ligation (Cibula, 2011; Tsilidis, 2011).

PERITONEAL CARCINOMA

Peritoneal carcinoma (previously known as *primary peritoneal carcinoma*) was first described in 1959 by Swerdlow (Swerdlow, 1959). It diffusely involves the peritoneal surfaces while sparing or minimally involving the ovaries and fallopian tubes. The incidence of peritoneal carcinoma in the United States has been estimated to be 0.46 per 100,000 women (Goodman, 2009); with a 1:10 ratio of peritoneal cancer to ovarian cancer cases. Peritoneal cancer is histologically indistinguishable from epithelial ovarian cancer and has similar clinical characteristics, patterns of spread, response to treatment, and survival rates (Fromm, 1990; Halperin, 2001). Risk factors for primary peritoneal carcinoma are similar to those for ovarian and fallopian tube cancer, including *BRCA* mutation and low parity. However, peritoneal cancer has also been associated with older age at diagnosis and increased rates of obesity when compared with ovarian cancer (Barda, 2004; Jordan, 2008).

The pathogenesis of peritoneal carcinoma is not well characterized. The germinal epithelium of the ovary and mesothelium of the peritoneum arise from the same embryonic origin, and it was previously suggested that primary peritoneal cancer may develop from a malignant transformation of these cells (Lauchlan, 1972). Another proposed theory was a field effect, with the coelomic epithelium lining the abdominal cavity (peritoneum) and ovaries (germinal epithelium) manifesting a common response to an oncogenic stimulus (Parmley, 1974; Truong, 1990). Molecular studies have been inconclusive in determining whether the tumor arises from the ovarian surface epithelium and spreads throughout the peritoneum or if a multifocal malignant transformation process occurs. Peritoneal carcinoma has therefore become a diagnosis of exclusion when a primary ovarian or fallopian tube carcinoma cannot be identified.

SEROUS TUBAL INTRAEPITHELIAL CARCINOMA

There is increasing evidence that many cases of ovarian and peritoneal carcinoma may actually arise from the fallopian tube (Kindelberger, 2007; Carlson, 2008a). This hypothesis is supported by studies of women with *BRCA* mutations who have undergone risk-reducing bilateral salpingo-oophorectomy (rrBSO). Between 5% and 15% of women undergoing rrBSO have been reported to have occult serous cancers (Lu, 2000; Leeper 2002; Finch, 2006; Callahan, 2007; Reitsma, 2013). A large number of these early cancers involve the fallopian tube as invasive fallopian tube

carcinoma or as a precursor lesion known as serous tubal intraepithelial carcinoma (STIC). In most cases, the tumor involves the fimbriated end of the fallopian tube. These studies have suggested that the fallopian tube may be the primary source of ovarian and peritoneal serous carcinomas in women with *BRCA* mutations. It is therefore recommended that the ovarian and fallopian tube specimens following rrBSO undergo careful examination for neoplasia. This consists of serial sectioning and extensively examining the fimbrial end of the fallopian tube using the sectioning and extensively examining the fimbriated end (SEE-FIM) protocol (Powell, 2005; Mehrad, 2010).

Studies of unselected women with ovarian and peritoneal cancer have also shown a significant number of cases to coexist with a STIC. Kindelberger and colleagues reported that a STIC was present in 47% of 43 tumors classified as primary ovarian cancers (Kindelberger, 2007). Similarly, Carlson and coworkers found a STIC present in the fallopian tube of 47% of 19 women with serous peritoneal cancers (Carlson, 2008a). In addition, *p53* mutational analyses have shown the same mutations in STIC and distant tumors, providing a genetic link between the two (Kuhn, 2012).

CLINICAL FINDINGS

FALLOPIAN TUBE CANCER

The mean age at diagnosis of fallopian tube carcinoma is 58 years, with a range of 26 to 85 years. However, in women with *BRCA*-associated fallopian tube carcinoma, the age at diagnosis is considerably younger. Cass and colleagues reported the median age at diagnosis to be 57 years in *BRCA* mutation carriers compared with 65 years in sporadic cases (Cass, 2005). Fallopian tube cancer is more common among white women (age-adjusted incidence rate, 0.41), compared with Black (0.27), Hispanic (0.27), and Asian and Pacific Islander women (0.25) (Stewart, 2007).

The presenting symptoms of fallopian tube carcinoma are largely related to the degree of obstruction of the distal tube. Many women are asymptomatic; however, the most commonly reported signs and symptoms include abnormal vaginal bleeding or serosanguineous vaginal discharge (35% to 60%), a palpable adnexal mass (10% to 60%), and crampy lower abdominal pain caused by tubal distention and forced peristalsis (20% to 50%). *Hydrops tubae profluens* is the term used to describe intermittent expulsion of clear or serosanguineous fluid from the vagina caused by contraction of a distended, distally occluded fallopian tube (Sinha, 1959). The discharge may be followed by shrinkage or resolution of the adnexal mass. The triad of intermittent serosanguineous discharge, colicky pain, and a mass (Latzko's triad) is considered to be pathognomonic of fallopian tube cancer but occurs in only approximately 15% of patients. In addition, approximately 10% to 40% of women with fallopian tube carcinoma have abnormal cervical cytology results, including adenocarcinoma or atypical glandular cells (AGUS). Evaluation with a cancer antigen 125 (CA-125) level and transvaginal ultrasound to rule out ovarian and fallopian tube cancer should be considered in women with these cytologic findings who have a negative workup for endocervical and endometrial carcinoma.

PERITONEAL CANCER

Patients with peritoneal cancer tend to be older than women with ovarian or fallopian tube cancer, with the median age at

diagnosis reported to range from 63 to 66 years. Similar to those with ovarian cancer, women with peritoneal cancer typically present with pain, abdominal distention, pressure, or gastrointestinal symptoms. A small proportion of patients are asymptomatic. Occasionally, primary peritoneal cancer is detected during exploratory surgery for other reasons.

DIAGNOSIS

Similar to ovarian cancer, the diagnosis of fallopian tube or peritoneal cancer may be suspected based on imaging studies, CA-125 level, or symptoms, as well as physical examination findings. However, a definitive diagnosis is usually made at the time of surgery.

ULTRASOUND

The classic ultrasound findings for fallopian tube cancer include a fluid-filled, tubular or ovoid mass—with internal papillary areas, mural nodules, or septations—that is separate from the uterus and ovaries. In peritoneal and fallopian tube cancers, ascites or peritoneal implants may be present. With both malignancies, the ovaries are often normal in appearance.

OTHER IMAGING MODALITIES

Computed tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography (PET) scans may provide additional information in women with suspected fallopian tube or peritoneal cancer. These studies can provide information regarding the extent of disease and sites of metastatic spread, allowing the physician to plan appropriate intervention and treatment.

CA-125 LEVEL

The CA-125 level is elevated in more than 80% of women with fallopian tube and peritoneal cancer. CA-125 value is useful for monitoring response to treatment or evaluating a woman in whom the disease is suspected.

STAGING

Both fallopian tube and peritoneal carcinomas are surgically staged. In 2014, the International Federation of Gynecology and Obstetrics (FIGO) revised and combined the staging for ovarian, fallopian tube and peritoneal cancer (Table 34.1) (Mutch, 2014). The updated system uses the same staging for all three entities due to the similar patterns of spread, surgical approach, treatment, and prognosis. However, the staging does require that the site of origin be noted if known (ovary, fallopian tube, peritoneum).

PATHOLOGIC FINDINGS

FALLOPIAN TUBE CARCINOMA

Fallopian tube carcinomas arise in either tube with similar frequency and are bilateral in 3% to 8% of cases. The fimbriated end of the fallopian tube is grossly occluded in approximately 50% of patients, resulting in a dilated lumen filled with tumor

Table 34.1 2014 FIGO Staging of Ovarian, Fallopian Tube, and Peritoneal Cancer

Stage	Features
I	Tumor confined to ovaries or fallopian tube(s)
IA	Tumor limited to one ovary (capsule intact) or fallopian tube; no tumor on ovarian or fallopian tube surface; no malignant cells in the ascites or peritoneal washings
IB	Tumor limited to both ovaries (capsules intact) or fallopian tubes; no tumor on ovarian or fallopian tube surface; no malignant cells in the ascites or peritoneal washings
IC	Tumor limited to one or both ovaries or fallopian tubes, with any of the following: IC1: surgical spill IC2: capsule ruptured before surgery or tumor on ovarian or fallopian tube surface IC3: malignant cells in the ascites or peritoneal washings
II	Tumor involves one or both ovaries or fallopian tubes with pelvic extension (below pelvic brim) or primary peritoneal cancer
IIA	Extension and/or implants on uterus and/or fallopian tubes and/or ovaries
IIB	Extension to other pelvic intraperitoneal tissues
III	Tumor involves one or both ovaries or fallopian tubes, or primary peritoneal cancer, with cytologically or histologically confirmed spread to the peritoneum outside the pelvis and/or metastasis to the retroperitoneal lymph nodes
IIIA1	Positive retroperitoneal lymph nodes only (cytologically or histologically proven): IIIA1(i): Metastasis up to 10 mm in greatest dimension IIIA1(ii): Metastasis more than 10 mm in greatest dimension
IIIA2	Microscopic extrapelvic (above the pelvic brim) peritoneal involvement with or without positive retroperitoneal lymph nodes
IIIB	Macroscopic peritoneal metastasis beyond the pelvis up to 2 cm in greatest dimension, with or without metastasis to the retroperitoneal lymph nodes
IIIC	Macroscopic peritoneal metastasis beyond the pelvis more than 2 cm in greatest dimension, with or without metastasis to the retroperitoneal lymph nodes (includes extension of tumor to capsule of liver and spleen without parenchymal involvement of either organ)
IV	Distant metastasis excluding peritoneal metastases
IVA	Pleural effusion with positive cytology
IVB	Parenchymal metastases and metastases to extra-abdominal organs (including inguinal lymph nodes and lymph nodes outside of the abdominal cavity)

From Mutch DG, Prat J. 2014 FIGO staging for ovarian, fallopian tube and peritoneal cancer. *Gynecol Oncol*. 2014;133(3):401-404.

or fluid (Figs. 34.1 and 34.2). Histologically, 80% to 90% of fallopian tube carcinomas are adenocarcinomas (Figs. 34.3 and 34.4). Most of these are serous carcinomas, followed by endometrioid and clear cell adenocarcinomas. Other rare histologic subtypes include sarcomas, carcinosarcomas, germ cell tumors, and gestational trophoblastic tumors.

Similar to ovarian cancer, most patients with fallopian tube cancer have grade 2 or 3 tumors, with less than 5% being grade 1

Figure 34.3 Microscopic appearance of an adenocarcinoma of fallopian tube confined to the endosalpinx, with minimal invasion into the muscular wall. (From Voet RL. *Color Atlas of Obstetric and Gynecologic Pathology*. St. Louis: Mosby-Wolfe; 1997.)

Figure 34.4 Poorly differentiated tubal carcinoma. (From Anderson MC, Robboy SJ, Russell P. The fallopian tube. In: Robboy SJ, Anderson MC, Russell P, eds. *Pathology of the Female Reproductive Tract*. Edinburgh: Churchill Livingstone; 2002.)

tumors. Previous reports have shown stage at diagnosis to be evenly distributed among localized disease, regional spread, and distant metastases. However, serous adenocarcinomas are more likely to be diagnosed at advanced stages and endometrioid adenocarcinomas at earlier stages (Stewart, 2007).

It can be challenging to distinguish primary fallopian tube carcinoma from ovarian or peritoneal carcinomas. Hu and colleagues (Hu, 1950) initially developed pathologic diagnostic criteria in 1950 for the diagnosis of primary fallopian tube carcinoma. These were subsequently modified by Sedlis and associates in 1978 (Sedlis, 1978), and included the following:

1. The main tumor lies in the tube and arises from the endosalpinx.
2. The histologic pattern reproduces the papillary epithelium of tubal mucosa.
3. A transition can be demonstrated between the malignant and nonmalignant tubal epithelium.
4. The ovaries and uterus are normal or contain less tumor than the fallopian tube.

Data also suggest that if a STIC is present and there is minimal involvement of the ovary, a primary fallopian tube origin should be assigned. In contrast, if the majority of the tumor is in the ovary and no STIC is present, then an ovarian origin is considered (Carlson, 2008b).

The patterns of spread of fallopian tube carcinoma are largely related to the degree of obstruction of the distal tube. If the fimbriated end of the tube is obstructed by tumor, previous injury, or infection, the by-products of tumor growth, such as blood and increased serous fluid, distend the tube and are discharged intermittently through the vagina. If the distal portion of the fallopian tube is patent, the malignancy spreads more easily out the distal end of the tube, resulting in tumor seeding of the peritoneal cavity, ascites, and omental caking. Intraperitoneal spread may also occur as the tumor grows through the muscular wall of the tube. The peritoneum is therefore the most frequent site of metastatic spread. However, lymphatic spread also occurs to the pelvic and paraaortic lymph nodes. Occult lymph node metastases may be present in patients with tumor that grossly appeared to be confined to the fallopian tube.

PERITONEAL CARCINOMA

Peritoneal carcinoma tends to involve the abdominal and pelvic surfaces diffusely. The most common histologic type is high-grade serous carcinoma, but cases of endometrioid, clear cell, mucinous, and carcinosarcoma have also been reported. Given the difficulty in distinguishing primary peritoneal carcinoma from ovarian carcinoma, the Gynecologic Oncology Group (GOG) previously developed the following pathologic criteria for the diagnosis of primary peritoneal carcinoma:

1. Both ovaries must be physiologically normal in size or enlarged by a benign process.
2. Involvement in the extraovarian sites must be greater than involvement on the surface of either ovary.
3. Microscopically, the ovarian component must be one of the following:
 - Nonexistent
 - Confined to the ovarian surface epithelium with no evidence of cortical invasion
 - Involving ovarian surface epithelium and underlying cortical stroma but with any given tumor size smaller than 5×5 mm
 - Tumor smaller than 5×5 mm within the ovarian substance, with or without surface disease
4. The histologic and cytologic characteristics of the tumor must be predominantly of the serous type that is similar or identical to ovarian serous papillary adenocarcinoma of any grade.

TREATMENT

The treatment of fallopian tube and peritoneal carcinoma is similar to that of ovarian carcinoma. In most cases, it includes a combination of surgery and chemotherapy.

SURGERY

Surgery for fallopian tube and primary peritoneal carcinoma generally includes collection of peritoneal washings or ascites, if present, followed by hysterectomy and bilateral salpingo-oophorectomy. A staging operation should be performed in patients with apparent early stage disease. This includes omentectomy, pelvic and paraaortic lymph node dissection, and peritoneal biopsies. In cases of advanced disease, cytoreductive surgery with removal of as much visible tumor as possible should be performed. Similar to ovarian cancer, improved survival rates are associated with optimal cytoreduction for fallopian tube and peritoneal cancers. Optimal cytoreduction may be more difficult to achieve in women with widespread peritoneal disease without a predominant pelvic or ovarian mass.

CHEMOTHERAPY

The chemotherapeutic regimens used for fallopian tube and peritoneal cancers are the same as those used for ovarian cancer. Patients with advanced-stage disease are typically treated with a combination of carboplatin and paclitaxel. Many clinical trials for ovarian cancer include fallopian tube and peritoneal cancers

because of their similar clinical and pathologic findings, as well as response to chemotherapeutic agents. Similar to ovarian cancer, neoadjuvant chemotherapy may be considered for patients with fallopian tube cancer and peritoneal cancer who have unresectable disease, a large tumor burden, or medical comorbidities precluding surgery. Given the limitations of existing imaging modalities to adequately assess the extent of disease, diagnostic laparoscopy is often used to determine resectability and decide whether primary surgery or neoadjuvant chemotherapy is more appropriate (Nick, 2015).

RADIATION THERAPY

Similar to ovarian cancer, radiation therapy is not routinely recommended for fallopian tube or peritoneal cancer. Because of the tendency of these cancers to spread throughout the abdominal cavity, external beam radiation therapy cannot be administered in therapeutic doses without causing excessive side effects, thereby minimizing its usefulness.

SURVEILLANCE

Surveillance following completion of treatment for fallopian tube and peritoneal cancer is identical to that for ovarian cancer. Follow-up visits are performed every 2 to 4 months for the first 2 years, every 3 to 6 months for the following 3 years, and then annually after 5 years. Visits include a physical examination with pelvic examination, as well as consideration of the measurement of the CA-125 level if initially elevated. Imaging studies are not

routinely performed unless clinically indicated because of the woman's symptoms, physical examination findings, or increasing CA-125 level. Pap tests are generally not indicated as part of the surveillance for ovarian, fallopian tube, or peritoneal cancer.

PROGNOSIS

As with ovarian cancer, the prognosis for patients with fallopian tube cancer is strongly related to the stage of disease. The 5-year survival rates are 81% for stage I disease, 67% for stage II disease, 41% for stage III disease, and 33% for stage IV disease (Heintz, 2006). Other prognostic factors for early stage disease include the degree of invasion of the fallopian tube wall, as well as the location of the tumor within the tube (fimbrial versus nonfimbrial). Similar to ovarian cancer, improved survival has been seen if the tumor can be completely removed at the time of surgery. In addition, patients with a *BRCA* mutation have been shown to have higher survival rates. Most studies have reported a better survival for patients with advanced-stage fallopian tube cancer compared with primary ovarian cancer. In contrast, retrospective case-control studies have shown no difference in survival rates between patients with peritoneal cancer and patients with ovarian cancer. This favorable prognosis for patients with fallopian tube cancer may be the result of a higher rate of *BRCA* mutation carriers among women with fallopian tube cancer compared with ovarian and peritoneal cancers. However, if a subset of ovarian and peritoneal carcinomas actually arises from the fallopian tube, the prognosis for women with fallopian tube, peritoneal, and ovarian cancer may actually be similar.

KEY POINTS

- There is increasing evidence that many cases of ovarian and peritoneal carcinoma may actually arise from the fallopian tube, thereby underestimating the incidence of fallopian tube carcinoma.
- Fallopian tube and peritoneal cancers are similar entities to epithelial ovarian cancer.
- Fallopian tube and peritoneal cancers have similar clinical characteristics, patterns of spread, and response to treatment compared with ovarian cancer.
- The primary risk factor for fallopian tube and peritoneal cancer is an inherited mutation in the *BRCA1* or *BRCA2* tumor suppressor gene.
- The most common histologic subtype of fallopian tube and peritoneal carcinoma is high-grade serous carcinoma.
- The treatment of fallopian tube and peritoneal cancer is identical to that for ovarian cancer and typically includes a combination of surgery and chemotherapy.
- Prognosis for ovarian and peritoneal cancer is most strongly related to the stage of disease and amount of residual tumor following the initial tumor reduction surgery.
- Fallopian tube cancer has been shown to have a better prognosis compared with ovarian and peritoneal cancer, but this may be because of a higher rate of *BRCA* mutation carriers in women with fallopian tube cancer.

Gestational Trophoblastic Disease Hydatidiform Mole, Nonmetastatic and Metastatic Gestational Trophoblastic Tumor: Diagnosis and Management

Geneviève Bouchard-Fortier, Allan Covens

The most curable of all gynecologic malignancies, gestational trophoblastic disease (GTD), represents an oncologic success story attributable primarily to early disease recognition, effective chemotherapy regimens, and accurate assessment of disease status with sensitive β -human chorionic gonadotropin (β -hCG) assays. Understanding the disease process cannot be overstated to the general gynecologist, who is usually responsible for the initial diagnosis and management of GTD, as well as the timely referral to gynecologic oncology for further management of gestational trophoblastic neoplasia (GTN). A structured approach to diagnosis and management will result in cure for most patients, even in the setting of advanced disease, without adversely affecting future fertility.

GTD describes a heterogeneous spectrum of diseases of abnormal trophoblastic proliferation ranging from benign to malignant, with varying predilections toward local invasion and distant metastasis. Historically, the various terminology and classification systems surrounding GTD have created confusion and complicated a thorough understanding of the disease. In 2000, the International Federation of Gynecology and Obstetrics (FIGO) released a new staging for GTD incorporating the modified World Health Organization (WHO) Prognostic Scoring System, which has standardized the method for reporting the disease (FIGO, 2009). GTD is classified according to histopathologic, cytogenetic, and clinical features, using the WHO classification of GTD. The various histologic categories of GTD include benign trophoblastic lesions (placental site nodule and exaggerated placental reaction), hydatidiform mole (HM), which includes complete hydatidiform mole (CHM) and partial hydatidiform mole (PHM), and gestational trophoblastic neoplasia encompassing persistent and invasive mole, gestational choriocarcinoma, placental site trophoblastic tumor (PSTT), and epithelioid trophoblastic tumor (ETT) (Box 35.1). GTN is diagnosed based on clinical, laboratory, and histologic criteria, and those tumors have a tendency to invade and metastasize.

HYDATIDIFORM MOLE

EPIDEMIOLOGY

Marked regional variations in the incidence of GTD are seen worldwide. The precise estimate of the incidence of GTD is difficult to establish due to a number of factors such as low prevalence of the disease, inconsistencies between hospital- and population-based data, and disparity in access to centralized pathology review (Lurain, 2010). Prior estimates based on hospital data overestimated the incidence as deliveries (as opposed to pregnancies) were used in the denominator. Nonetheless, with the introduction of census data, true denominators have added validity to reported incidence rates. Similarly, improvements in central reporting through tumor registries have increased the certainty of case ascertainment. Other factors leading to the improved accuracy of incidence estimations include standardized definitions of GTD variants, improvements in cytogenetics, and recognition of rare variants, such as PSTT and ETT.

Population-based studies suggest that the incidence of HM is higher in Asia than in North America or Europe. The incidence of PHM in the United Kingdom, where all GTD cases are registered in a national database, is 3/1000 pregnancies, and that of CHM ranges from 1 to 3/1000 pregnancies (Seckl, 2010). Ethnic groups such as Native American Indians, Inuits, Hispanics, and African American continue to have an increased incidence of GTD, and this has not been explained by looking at genetic traits, cultural factors, or difference in reporting. The geographic risk association reflects the distribution of different ethnic groups with a higher incidence of HM rather than environmental or climatic factors.

RISK FACTORS

Age

Pregnancy occurring at extremes of maternal age (<16 and >45 years) is a well-established risk factor for HM, with

Box 35.1 World Health Organization Classification of Gestational Trophoblastic Disease

Invasive mole
Choriocarcinoma
Placental site trophoblastic tumor
Epithelioid trophoblastic tumor

incidence rates following a J-shaped distribution curve (Sebire, 2002). Risk increases after age 35, and a five- to tenfold increase is seen in women conceiving after age 40, rising precipitously thereafter. This increase is accounted for by abnormal gametogenesis or abnormal fertilization with advanced maternal age. However, due to the decreased fecundity in this cohort, the overall effect on incidence rates is low. Teenagers have a 1.5- to twofold increased risk of GTD. The risk between maternal age and HM is best established for CHM, with studies showing no risk or only a small increase in PHM. Studies on the impact of advancing paternal age have been inconsistent.

Reproductive History

A reproductive history including HM is another risk factor, increasing the risk in future pregnancies by 5- to 40-fold that of the general population. Subsequent pregnancies have an approximate 1% risk, increasing to 25% when the number of previous HM is two or more (Seckl, 2013). The risk is not affected by changing partners. Bagshawe has shown that the risk following the first mole is 1 in 76 pregnancies, increasing to 1 in 6.5 pregnancies if more than one prior mole existed (Bagshawe, 1976). Patients with recurrent molar pregnancies are also at increased risk for the malignant sequelae of GTN. The impact of parity and prior abortion on HM risk is unclear, with studies showing conflicting results.

Diet

Dietary risk factor analyses have shown conflicting results. Several case control studies have shown an increased risk of CHM with decreasing consumption of animal fat and beta-carotene (precursor to vitamin A) (Berkowitz, 1985). Vitamin A deficiency is more prevalent in countries where the incidence of GTD is higher. Dietary factors may somewhat explain geographic variations in the incidence of CHM; however, other studies detailing food intake have failed to show a decreased incidence with increasing consumption of dietary protein or fat.

Genetics

A rare autosomal recessive disorder known as *familial recurrent HM* has been identified on chromosome 19q (Wang, 2009; Murdoch, 2006). Affected women have a mutation of *NLRP7* gene and, more rarely, *KHDC3L* gene, and they are predisposed to abnormal pregnancies characterized by CHM. CHM cases with familial recurrent HM are genetically normal with chromosome from each parent (diploid

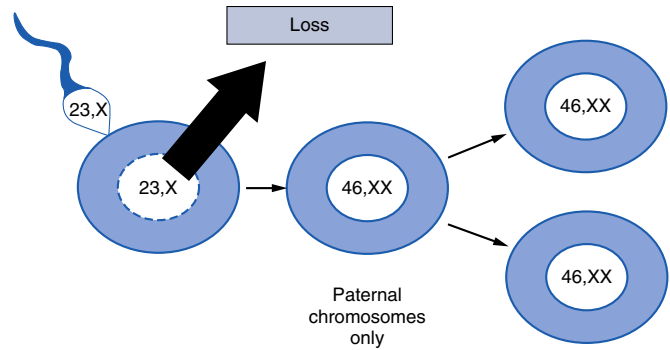

Figure 35.1 Paternal chromosomal origin of a complete classic mole (46,XX). *Left to right:* Entry of normal sperm with haploid set of 23,X into an egg whose 23,X haploid set is lost. The egg is taken over by paternal chromosomes, which duplicate (without cell division) to reach the requisite complement of 46. Observe that almost the same result can be obtained through fertilization by two sperm gaining entry into an empty egg (dispermy). (From Szulman AE, Surti UL. The syndromes of partial and complete molar gestation. *Clin Obstet Gynecol.* 1984;27:172-180.)

biparental CHM) as opposed to sporadic cases of CHM, which are androgenic in origin. Those women are unlikely going to achieve a normal pregnancy, and egg donation with in vitro fertilization is often necessary.

HISTOPATHOLOGY AND CYTOGENETIC FEATURES

During early embryonic differentiation, trophoblasts are derived from the outer blastocyst layer, with three distinct trophoblasts recognized: cytotrophoblasts, syncytiotrophoblasts, and intermediate trophoblasts. Cytotrophoblasts are the trophoblastic stem cells that differentiate along a villous and extravillous pathway. The villous trophoblast forms the interface between maternal and fetal tissues (chorionic villi) and is composed of cytotrophoblasts and syncytiotrophoblasts. This layer is responsible for molecular exchange across compartments and, in the case of syncytiotrophoblasts, production of the pregnancy-associated hormones β -hCG and human placental lactogen (HPL). Along the extravillous pathway, they differentiate into intermediate trophoblasts in the placental bed at the implantation site. This layer is responsible for establishing the maternal-fetal circulation and infiltrating the decidua, myometrium, and spiral arteries.

In HM, chromosomal abnormalities differentiate the disease, with complete and partial moles having distinct chromosomal profiles (Figs. 35.1 and 35.2). CHMs are completely derived from paternal origin, with greater than 90% having a 46,XX genotype, produced by fertilization of an empty (anuclear) ovum by a single haploid (23,X) sperm, which then duplicates in the ovum. A small percentage of CHMs have a 46,XY genotype, produced by dispermy, in which a 23,X sperm and a 23,Y sperm fertilize an empty ovum. Rarely, complete moles may be triploid or aneuploid. The mechanism for production of the empty ovum is unknown.

In contrast, PHMs are derived from paternal and maternal chromosomes, resulting in a triploid genotype. A haploid ovum is fertilized by two haploid spermatozoa, with 69,XXX or 69,XXY being the most common karyotypes. Although a triploid karyotype is usually seen in PHM, not all triploid

Figure 35.2 Triploid chromosomal origin of partial mole (69,XXY dispermy). Fertilization of an egg equipped with a normal 23,X complement by two independently produced sperm (dispermy) to give a total of 69 chromosomes. Observe that triploidy can also result through fertilization by sperm carrying father's total complement of 46,XY. (From Szulman AE, Surti UL: The syndromes of partial and complete molar gestation. *Clin Obstet Gynecol* 1984;27:172-180.)

pregnancies will show histologic changes consistent with a partial mole. In addition, PHM may present in conjunction with a viable fetus, showing signs of triploidy such as multiple congenital anomalies or severe growth retardation. Conditions that may be confused pathologically with PHM include Beckwith-Wiedemann syndrome, placental angiomatous malformation, twin gestation with complete mole and an existing fetus, early complete mole, and hydropic complete mole.

The histopathologic differences between CHM and PHM are well defined. The gross appearance of CHM may be impressive, with a large volume of grapelike vesicles made up of edematous enlarged villi (Fig. 35.3). Histopathologic characteristics include the following: (1) lack of fetal or embryonic tissues, (2) hydropic (edematous) villi, (3) diffuse trophoblastic hyperplasia, (4) marked atypia of trophoblasts at the implantation site, and (5) absence of trophoblastic stromal inclusions. In comparison, the gross appearance of PHM may only show subtle abnormalities, with generally a smaller volume of hydropic villi and the possible presence of a fetus or fetal tissue. The histopathologic features are the following: (1) presence of fetal or embryonic tissues; (2) less diffuse, focal hydropic swelling of villi; (3) focal trophoblastic hyperplasia; (4) less pronounced trophoblastic atypia at the molar implantation site; and (5) presence of trophoblastic scalloping and stromal inclusions.

Differentiation between CHM and PHM in early first-trimester abortions can be difficult due to less pronounced trophoblastic proliferation and only subtle hydropic swelling of the villi. Absence of the immunohistochemical nuclear stain p57 (a paternally imprinted, maternally expressed gene) suggests paternal origin and can be used to differentiate between CHM from PHM or nonmolar pregnancies. Further studies such as flow cytometry, ploidy analysis by in situ hybridization, or molecular genotyping have been described to differentiate PHM (triploid) from CHM and nonmolar hydropic abortions. A summary of the genetic and histopathologic differences between CHM and PHM is presented in Table 35.1.

Figure 35.3 **A**, Hydatidiform mole. A few vesicles approach 1 cm in diameter. The background is formed by smaller vesicles. **B**, Hydatidiform mole aborted by suction curettage. A large intact vesicle is near the center. Many vesicles, however, have been ruptured and have collapsed. (From Bigelow B. Gestational trophoblast disease. In: Blaustein A, ed. *Pathology of the Female Genital Tract*, 2nd ed. New York: Springer-Verlag; 1982.)

Table 35.1 Features of Complete and Partial Hydatidiform Moles

Feature	Complete Moles	Partial Moles
Fetal or embryonic tissue	Absent	Present
Hydatidiform swelling of chorionic villi	Diffuse	Focal
Trophoblastic hyperplasia	Diffuse	Focal
Trophoblastic stromal inclusions	Absent	Present
Genetic parentage	Paternal	Bipaternal
Karyotype	46,XX; 46,XY	69,XXY; 69,XYY
Persistent human chorionic gonadotropin	20% of cases	0.5% of cases

CLINICAL FEATURES

Dramatic presentations of advanced HMs have become less common in the developed world, largely due to the increased use of ultrasonography and improvements in the sensitivity of β -hCG assays, both leading to earlier detection. The average gestational age of diagnosis of CHM today is 9.6 weeks versus 17 weeks in the 1960s. Following a delayed menses, CHM typically presents in the first trimester as vaginal bleeding, with or without the passage of molar vesicles. Other classic signs of CHM include a large-for-date uterus, absence of fetal movement, anemia secondary to occult hemorrhage, gestational hypertension before 20 weeks' gestation, presence of theca lutein cysts, hyperemesis, hyperthyroidism, and respiratory distress from trophoblastic emboli to the lungs.

When uterine enlargement is more than 14 to 16 weeks, 25% of patients will have medical complications related to the high levels of β -hCG commonly seen in CHM and proportional to the volume of trophoblastic hyperplasia. β -hCG is homologous to thyrotropin-releasing hormone, and the β -hCG isoforms seen in CHM may have a greater affinity for the thyrotropin-stimulating hormone receptor than normal β -hCG, causing excessive thyroid stimulation in some patients. Similarly, β -hCG is homologous to luteinizing hormone (LH), the purported mechanism whereby ovarian stimulation leads to the formation of theca lutein cysts in some patients.

Despite the possible medical complications associated with the disease, data from the New England Trophoblastic Disease Center have revealed the changing clinical presentation over time of HM (Table 35.2). This change in clinical presentation of HM was also recently demonstrated in China and Thailand, suggesting a worldwide phenomenon. Presently, patients are more likely to present with minimal symptoms. Nonetheless, if medical complications are present, the woman should be stabilized, followed by evacuation of the HM as soon as possible.

PHM usually presents incidentally following histopathologic examination of the products of conception from uterine evacuation of a suspected missed or therapeutic abortion. Medical complications such as gestational hypertension, hyperthyroidism, theca lutein cysts, and respiratory distress are rare with PHM. With a low clinical suspicion for PHM, underdiagnosis is a risk, reflecting the importance of a thorough histopathologic examination of curettage specimens to ensure quality care.

Table 35.2 Changing Clinical Presentation of Complete Hydatidiform Mole at the New England Trophoblastic Disease Center (%)

Symptom or Sign	1988-1993 (N = 74)	1965-1975 (N = 306)
Vaginal bleeding	84	97
Size greater than dates	28	51
Anemia	5	54
Preeclampsia	1.3	27
Hyperemesis	8	26
Hyperthyroidism	0	7
Respiratory distress	0	2
Asymptomatic	9	0

Figure 35.4 Ultrasound scan of uterus demonstrating snowstorm appearance of hydatidiform mole.

DIAGNOSIS

The various symptoms associated with HM such as vaginal bleeding or a uterus large for dates often prompts an ultrasound (US) examination to determine if a pregnancy is viable. US is the standard imaging modality for the diagnosis of a mole. CHMs are easier to diagnose by US than PHM, which are difficult to differentiate from incomplete or missed abortion. A CHM has the appearance on US of an echogenic endometrial mass accompanying an enlarged uterus, the so-called “snowstorm appearance” (Fig. 35.4). As the molar pregnancy progresses into the second trimester, the anechoic spaces of the molar vesicles become more evident. A transvaginal US may show the interface between molar tissue, endometrium, and dilated vesicles in the first trimester better, but it can worsen vaginal bleeding in the setting of metastatic disease to the vagina. Features suggestive of CHM on US are (1) absence of fetal or embryonic tissue, (2) absence of amniotic fluid, (3) enlarged placenta with multiple cysts, and (4) ovarian theca lutein cysts. Features suggestive of PHM on US are (1) presence of fetal or embryonic tissue, (2) presence of amniotic fluid, (3) abnormal placenta with multiple cysts or increased echogenicity of chorionic villi, (4) increased transverse diameter of gestational sac, and (5) absence of theca lutein cysts (Benson, 2000).

Although US may be the imaging modality of choice, Fowler and associates reviewed 859 cases of histologically proven HM and have shown that only 44% of cases had a pre-evacuation US suggesting HM, reinforcing the importance of histology for diagnosis (Fowler, 2006). The accuracy was higher for CHM (79%) than for PHM (29%).

Human Chorionic Gonadotropin

The anterior pituitary produces a series of glycoproteins that differ only in their beta subunits, including hCG, follicle-stimulating hormone, LH, and thyroid-stimulating hormone. Outside of pregnancy, an elevated β -hCG level signifies the following: (1) GTN, (2) nongestational tumors secreting hCG, (3) false positives, and (4) menopause (secondary to LH elevation and cross reactivity of assays).

An unexpectedly elevated β -hCG level during pregnancy may suggest the diagnosis of CHM. β -hCG typically plateaus in pregnancy at approximately 10 weeks' gestation, with levels peaking at 100,000 IU/L and then falling thereafter. Genest and coworkers have shown that 46% of patients with CHM managed over a 10-year period had pretreatment β -hCG levels higher than 100,000 IU/L (Genest, 1991). Conversely, Berkowitz and colleagues have shown in one series that PHM presented with an elevated β -hCG above 100,000 IU/L in only 6% (2 of 30 cases) (Berkowitz, 1985).

TREATMENT

Pre-evacuation diagnosis of HM allows for optimal treatment planning, but the diagnosis of most patients will be made histologically after surgery. If HM is suspected preoperatively, a chest x-ray should be performed, as evacuation may transiently shower the lungs with trophoblastic emboli, complicating the interpretation of a post-evacuation chest x-ray. A complete blood count, blood type with antibody screen, β -hCG level, and liver function testing should also be performed. As the RhD factor is expressed on the trophoblasts, patients who are Rh negative with an Rh positive or Rh unknown partner should be treated with Rho(D) immune globulin post-evacuation.

Suction Dilation and Curettage

The preferred method of uterine evacuation of HM is suction dilation and curettage (D&C) under general anesthetic. The cervix is serially dilated and then a large suction curette is advanced just past the endocervix into the endometrial canal. After activating the suction device, a solution of crystalloid and oxytocin (20 U/L) is infused to increase uterine tone; this is continued post-operatively to reduce bleeding. A gentle sharp curettage may be performed to complete the procedure. Care must be taken during D&C to avoid perforation of the enlarged soft uterus in HM.

Hysterectomy

For patients diagnosed with HM preoperatively for whom continued fertility is not an issue, hysterectomy with preservation of the adnexa is a treatment option. This decreases local (myometrial) persistence, but it does not eliminate the risk of distant metastases. For women older than 40 years with HM, hysterectomy is reasonable as the risk of developing GTN is 53% in women older than 40 and 60% in women older than 50 (Elias, 2010; Elias, 2012).

Following hysterectomy, the risk of postmolar GTN is 3% to 5%, emphasizing the need for continued β -hCG monitoring.

Prophylactic Chemotherapy

Following surgical evacuation, postmolar GTN, usually in the form of a locally invasive mole, occurs in 15% to 20% of CHM cases (>50% when the woman is older than 50 years) and only rarely (<5%) following PHM (Curry, 1975). Figure 35.5 outlines a treatment algorithm for GTD. If post-evacuation follow-up is anticipated to be compromised, patients with high-risk CHM may be considered for treatment with prophylactic chemotherapy. In a nonrandomized clinical trial by Uberti and associates, prophylactic single-dose actinomycin D (ActD) at the time of surgical evacuation decreased the frequency of persistent HM in high-risk patients (determined at the time of evacuation) from 34.3% to 18.4% with, at worst, mild side effects reported in 21.5% of patients treated (Uberti, 2006). In the prophylactic ActD group, the relative risk for development of postmolar GTN was 0.54, and the number needed to treat (NNT) to prevent one case of GTN was 7. A 2012 Cochrane review evaluated the evidence for the effectiveness and safety of prophylactic chemotherapy to prevent GTN after molar pregnancy (Fu, 2012). Three randomized controlled trials including 613 women diagnosed with CHM showed that prophylactic chemotherapy (ActD or methotrexate) reduces the risk of GTN by 63% (relative risk [RR] 0.37, 95% confidence interval [CI] 0.24 to 0.57). Nonetheless, the authors are reluctant to support routine use of prophylactic chemotherapy given the poor methodologic quality and small size of studies available for analysis.

Therefore prophylactic chemotherapy is an option in high-risk patients who have limited access to follow-up; however, its routine use is not recommended due to the morbidity associated with even a single dose of chemotherapy, requirement for surveillance regardless, and ultimate high cure rates eventually achieved in GTN.

Surveillance Following Hydatidiform Mole Evacuation

Following evacuation of a HM, surveillance with serial β -hCG serum measurements are required to ensure a timely diagnosis of postmolar malignant GTN (discussed later in the section Gestational Trophoblastic Neoplasia, Clinical Features). Within 48 hours of evacuation, a baseline β -hCG level should be obtained and repeated weekly until the level returns to normal (<5 mIU/mL). Most cases of postmolar GTN will occur within 6 months of evacuation, so monthly β -hCG monitoring is recommended following normalization for an additional 6 to 12 months.

Although the minimum conventional period for observation is 6 months, such a long duration of follow-up has been questioned, particularly for women with a narrow window of fertility due to advanced age. Wolfberg and coworkers reviewed 1029 cases of CHM and found that when a β -hCG titer of less than 5 mIU/mL was used, no cases of invasive mole were encountered in patients who reached a negative titer (Wolfberg, 2004). Thus discontinuing surveillance after two negative β -hCG titers 1 week apart may spare patients unnecessary anxiety, limit resource expenditure, and obviate the problems of noncompliance inherent with prolonged follow-up. In a separate analysis, Wolfberg and associates found the risk of GTN to be 1.1% or less when the β -hCG dropped below 50 mIU/mL at any point during their follow-up (Wolfberg, 2005).

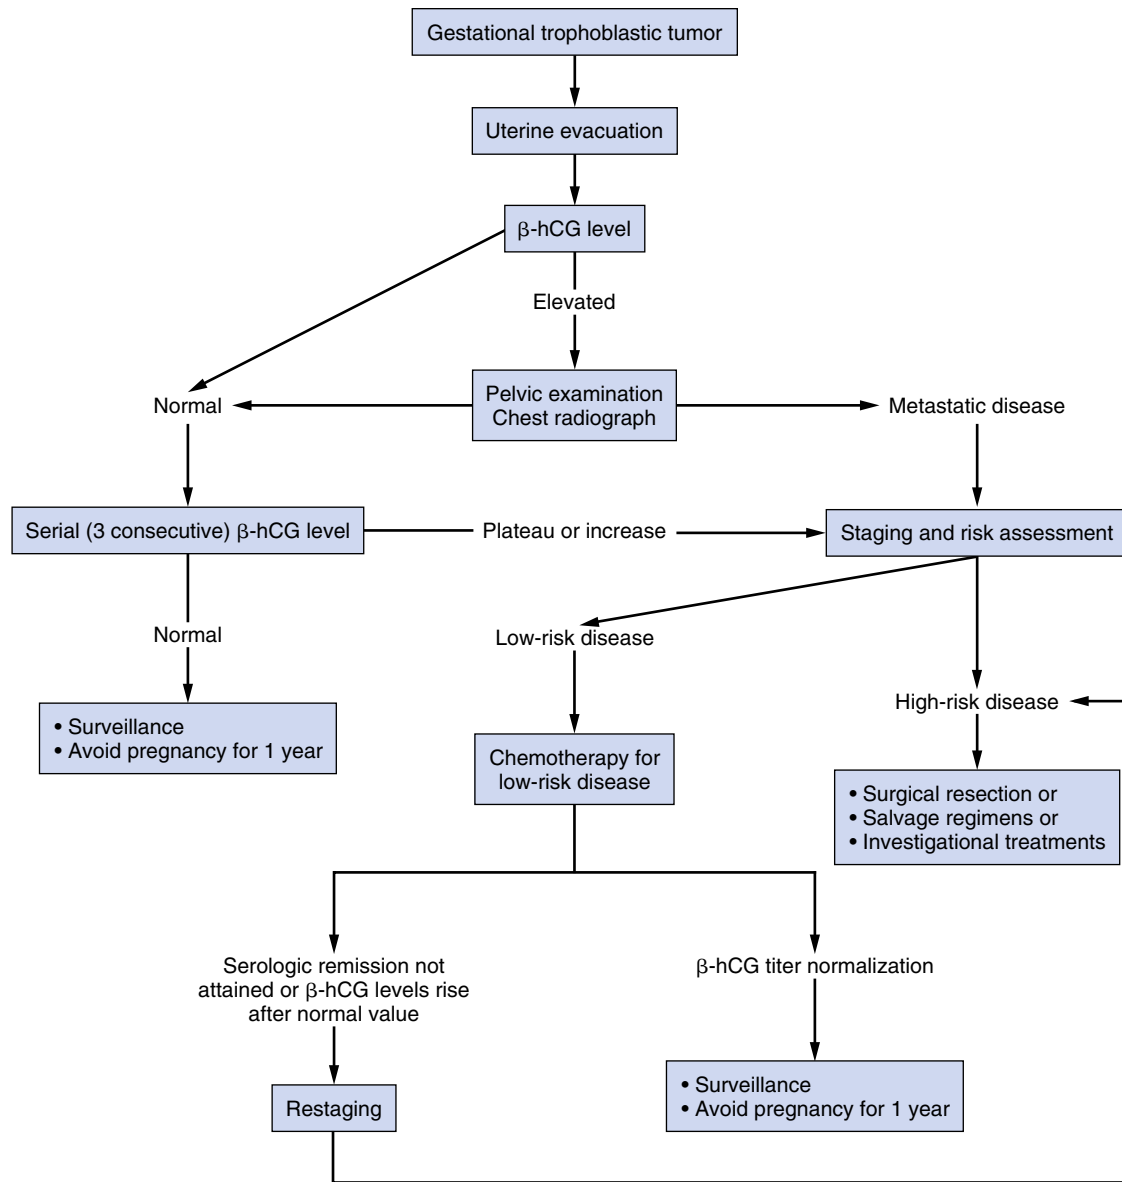

Figure 35.5 Treatment algorithm. This is a diagnostic and therapeutic approach to gestational trophoblastic disease as practiced at the University of Texas M.D. Anderson Cancer Center. *hCG*, Human chorionic gonadotropin. (Modified from Eifel PJ, Gershenson DM, Kavanagh JJ, Silva EG. *Gynecologic Cancer*. New York: Springer-Verlag; 2006:235.)

In another analysis of 320 patients who achieved one undetectable β -hCG titer, none developed relapse as GTN. In this cohort, the mean time to achieve nondetectable β -hCG levels was 5.8 weeks. Analysis of the Hydatidiform Mole Registry in Melbourne, Australia, has revealed no cases of persistent disease in the setting of CHM if the β -hCG level normalizes within 8 weeks, and no cases with PHM if the β -hCG level normalizes (Wielsma, 2006). Schmitt and coworkers published a large prospective cohort study of more than 2000 patients with a diagnosis of HM to evaluate the risk of GTN after the β -hCG level normalizes (Schmitt, 2013). They found that the risk of GTN was 0.36% (4 of 1122) following a CHM and 0 (0 of 593) following PHM. Therefore monitoring can be stopped after normalization of β -hCG level following PHM; however, after CHM they still recommend follow-up for 6 months after

normalization of β -hCG level. Despite these reports, most institutions still recommend a follow-up period of 6 months following normalization of β -hCG level.

During this period of surveillance, use of reliable contraception is strongly recommended to ensure that a rise in β -hCG level represents postmolar GTN and not a new pregnancy. One randomized controlled trial (RCT) has shown that use of the oral contraceptive pill (OCP) versus barrier methods of contraception results in 50% of the number of pregnancies during the surveillance period (Curry, 1989). In the past, there was concern that the OCP increased the risk of GTN, but two RCTs have shown no association between OCP use during postmolar surveillance and the incidence of GTN (Costa, 2006).

Prognostic factors associated with the development of GTN have been identified in various reports. The timing of molar evacuation was once felt to be a poor prognostic factor for the development of GTN; however, studies have demonstrated that advanced gestations do not contribute to an increased risk of invasive mole. As noted, advanced maternal age (>45 years) increases the risk of invasive mole, as does a history of HM. In addition, a β -hCG level higher than 100,000 IU/L on presentation may increase the risk of invasive mole. Other factors associated with persistent disease include uterine size large for date and bilateral ovarian enlargement (>8-cm theca lutein cysts) at the time of initial presentation. Ultrasound findings of uterine invasion may also be predictive of the development of GTN. In a retrospective analysis, Garavaglia and coworkers have shown that the presence of hyperechoic lesions (nodules) within the myometrium or increased signal intensity suggesting hypervascularization at baseline ultrasound was associated with an odds ratio (OR) of 17.57 for the development of GTN ($P < .001$) (Garavaglia, 2009).

Phantom β -Human Chorionic Gonadotropin

Persistent low levels of β -hCG must be evaluated to rule out false-positive assay results or phantom hCG, a rare finding that is secondary to heterophilic antibodies or proteolytic enzymes that mimic hCG. The diagnosis is made when a serum β -hCG is positive but a corresponding urine β -hCG samples taken at the same time tests negative. Alternatively, despite serial dilutions of serum, the test result will usually remain positive if heterophilic antibodies are the cause. Finally, physicians can test against multiple β -hCG assays, when available; heterophilic antibodies may cause a positive result in one test and a negative result in another. The reason for the negative urine β -hCG test is that heterophilic antibodies are large glycoproteins unable to cross the glomeruli and thus are not excreted in the urine. These antibodies—typically derived from exposure to mouse, rabbit, goat, or sheep antigens—are acquired through immunizations or time spent in agricultural settings, and they persist over time.

Quiescent Gestational Trophoblastic Disease

Following a hydatidiform mole, choriocarcinoma, or spontaneous abortion, the persistence of low levels (range, 1 to 212 IU/L) of β -hCG for 3 months or longer with no obvious increase or decrease in the β -hCG level trend along with the absence of clinical or radiologic evidence of GTN is termed *quiescent gestational trophoblastic disease*. This process is more common following a CHM but may occur after PHM, invasive mole, or choriocarcinoma and has been identified in patients treated with single-agent or multiagent chemotherapy. It is best described as a premalignant condition given that 25% of these cases progress to GTN-choriocarcinoma over a time frame ranging from 6 months to 10 years. Cole and colleagues have shown that the incorporation of hyperglycosylated hCG (hCG-H), a marker of invasive cytotrophoblasts, will detect 100% of quiescent GTD cases that require no further treatment, and 96% of self-resolving HM cases that require ongoing surveillance, differentiating these from GTN-choriocarcinoma cases that require further treatment (Cole, 2006; Cole, 2010). This methodology, however, requires validation in a prospective fashion.

GESTATIONAL TROPHOBLASTIC NEOPLASIA

This category includes invasive mole/postmolar GTN, choriocarcinoma, placental site trophoblastic tumor (PSTT), and epithelioid trophoblastic tumor (ETT).

CHARACTERISTICS

Histopathology and Cytogenetic Features

Invasive moles are HMs characterized by syncytiotrophoblast or cytotrophoblast hyperplasia, with the presence of villi. The presence of these villi extending into the myometrium constitutes invasion, and hence the name. Most of these tumors, as in HM, are diploid; anaplastic tumors are the exception.

The dominant histology in metastatic GTN is gestational choriocarcinoma following an HM or normal pregnancy and occurs in approximately 1 to 50 000 pregnancies (Smith, 2003). The characteristic appearance of choriocarcinoma is sheets of anaplastic trophoblastic tissue containing cytotrophoblast and syncytiotrophoblast cells without chorionic villi. These cells invade adjacent tissues with a propensity for vascular infiltration. Primary gonadal (nongestational) choriocarcinomas, a type of ovarian germ cell tumors, can develop without pregnancy and the estimated incidence is 1 in 369,000,000. They are highly aggressive, secrete β -hCG, and share the same histologic appearance as gestational choriocarcinoma. Nongestational choriocarcinomas are derived from differentiation of malignant germ cells into trophoblastic structures. The absence of paternal DNA within the tumor using DNA analysis differentiates nongestational choriocarcinomas from gestational choriocarcinomas. Furthermore, metastatic GTN must be distinguished from extragonadal germ cell tumors. Those rare tumors originating from midline locations such as anterior mediastinum and retroperitoneum have no primary tumor in the ovaries but do secrete β -hCG. The fluorescence in situ hybridization (FISH) method for identifying single-nucleotide variants in exons and introns on individual RNA transcripts is used to differentiate gestational choriocarcinoma from extragonadal germ cell tumors by quantifying allelic expression and differentiating maternal from paternal chromosomes.

PSTT is a rare tumor composed almost entirely of intermediate trophoblasts, lacking the syncytiotrophoblasts and cytotrophoblasts seen in other forms of GTD. PSTT has an infiltrative pattern, with nests or sheets of cells invading between myometrial cells and fibers. Compared with choriocarcinoma, PSTT is less prone to vascular invasion, necrosis, and hemorrhage. Immunohistochemical staining is positive in 50% to 100% for HPL and in less than 10% for β -hCG.

ETT was recognized by World Health Organization (WHO) tumor classification in 2003. It is considered a rare variant of PSTT and is also derived from intermediate trophoblasts. Similar to PSTT, these cells are arranged in sheets or nests and form tumor nodules in the myometrium. Immunohistochemical staining is positive for multiple markers such as cytokeratin and inhibin A.

Clinical Features

Symptoms associated with invasive mole include irregular vaginal bleeding, uterine subinvolution, and theca lutein cysts. Most GTN is identified in patients undergoing surveillance

following evacuation of HM on the basis of β -hCG criteria, as outlined by FIGO (Box 35.2). These include a plateau in β -hCG values (remain within $\pm 10\%$ of the previous results) over a 3-week period (four values day 1, 7, 14, and 21), a rising β -hCG value of 10% or more over a 2-week period (three values day 1, 7, 14), persistent β -hCG detectable for more than 6 months following evacuation for HM, a histologic diagnosis of choriocarcinoma or evidence of metastases (clinically or radiologically). Following surgical evacuation of HM, β -hCG values decrease exponentially, with an expected initial steep decline followed by a slower decrease in β -hCG levels. Observing low levels of β -hCG for longer than 2 to 3 weeks is permitted, as delay will not adversely affect the woman's survival. This is particularly helpful for physicians faced with a plateau or increase of a low β -hCG level, for which continued observation as opposed to initiation of chemotherapy may be warranted.

Locally Invasive Gestational Trophoblastic Neoplasia

With an invasive mole, myometrial invasion may involve local capillaries and veins, with persistent vaginal hemorrhage as the most commonly reported symptom. Uterine perforation with intraperitoneal hemorrhage, and infection secondary to tumor necrosis, may also occur. Although most of these tumors will regress spontaneously following evacuation, chemotherapy treatment may be initiated to prevent the serious morbidity and even mortality, which might ensue (see “Prophylactic Chemotherapy,” presented earlier).

Malignant Gestational Trophoblastic Neoplasia

Most metastatic GTN results from choriocarcinoma. Nonetheless, PSTTs are associated with metastases at the time of initial diagnosis in 40% of cases with lung metastasis being the most common site and 50% of ETT present with metastases at time of diagnosis. Both choriocarcinomas, PSTT and ETT, may follow after any pregnancy event. Metastases result from hematogenous dissemination, with almost any site possible. These tumors tend to be hemorrhagic and necrotic. Local metastases may include the vagina, with distant metastasis to the lung, brain, liver, gastrointestinal (GI) tract, and kidney having been seen. The lungs usually represent the first organ

involved, followed by dissemination via the systemic circulation. Metastatic lesions are highly vascularized with thin-walled fragile vessels. Symptoms of metastatic GTN, such as hemoptysis or headache, may be related to hemorrhage at involved sites. When metastases are suspected, image-guided biopsy is contraindicated due to the potential risk of uncontrollable hemorrhage.

CLASSIFICATION AND STAGING

In 2000, a revised FIGO-WHO Prognostic Scoring System was adopted to attain uniformity in reporting, while indicating the extent of disease spread and risk factors important for predicting persistent disease and therefore appropriate chemotherapy treatment (Table 35.3). The stage of the disease relates to tumor spread, with stage I disease confined to the uterus, stage II disease including spread to the adnexa, vagina, and broad ligament, stage III disease defined by lung metastases, and stage IV disease including all other sites of metastases. Prognostic factors included in the WHO Prognostic Scoring System are age, antecedent pregnancy, interval months from index pregnancy, pretreatment serum β -hCG levels, largest tumor size (cm), site of metastases, number of metastases, and previous failed chemotherapy. A WHO score of 6 or lower is considered low risk and 7 or greater is considered high risk. Generally, stage relates to risk scoring, with stage I patients usually low risk and stage IV patients high risk.

The WHO Prognostic Scoring System does not apply to patients with PSTT and ETT, but they are staged using FIGO stage I to stage IV. Therefore those tumors are not described as low or high risk.

Table 35.3 International Federation of Gynecology and Obstetrics (FIGO) 2000 Classification for Gestational Trophoblastic Neoplasia

Staging	Features			
Stage I	Disease confined to uterus			
Stage II	GTN extends outside uterus, but limited to genital structures (adnexa, vagina, broad ligament)			
Stage III	GTN extends to lungs, with or without known genital tract involvement			
Stage IV	All other metastatic sites			

Parameter	SCORING			
	0	1	2	4
Age (yr)	<40	≥40	—	—
Antecedent pregnancy	Mole	Abortion	Term	—
Interval from index pregnancy (mo)	<4	4 to <7	7 to <13	>13
Pretreatment β -hCG (IU/mL)	<10 ³	10 ³ to 10 ⁴	10 ⁴ to 10 ⁵	>10 ⁵
Largest tumor size (cm; including uterus)	—	3 to <5 cm	≥5 cm	—
No. of metastases	—	1 to 4	5 to 8	>8
Previous failed chemotherapy	—	—	Single drug	Two or more drugs

β -hCG, Beta-human chorionic gonadotropin; GTN, gestational trophoblastic neoplasia.

Box 35.2 International Federation of Gynecology and Obstetrics (FIGO) Criteria for Diagnosis of Gestational Trophoblastic Neoplasia

The International Federation of Gynecologists and Obstetricians (FIGO) standardized criterion for diagnosing gestational trophoblastic neoplasia GTN following a HM are the following:

1. Four β -hCG values plateauing ($\pm 10\%$) over a 3-week period (days 1, 7, 14, 21)
2. A rising β -hCG value of 10% or greater seen on three values measured over a 2-week period (days 1, 7, 14)
3. Persistence of detectable β -hCG for more than 6 months following evacuation of a HM
4. Histologic diagnosis of choriocarcinoma
5. Evidence of metastases (clinically or radiologically)

β -hCG, Beta-human chorionic gonadotropin; GTN, gestational trophoblastic neoplasia; HM, hydatidiform mole.

DIAGNOSIS

Diagnosis of persistent disease via β -hCG monitoring should prompt a complete history and physical examination accompanied by quantitative β -hCG, complete blood count (CBC), and renal, liver, and thyroid function testing. Invasive mole and choriocarcinoma typically have a high β -hCG level ranging from 100 to 100,000 mIU/mL, whereas PSTT and ETT produce low levels of β -hCG (usually <1000 mIU/mL). As a diagnostic imaging test, US will rule out concurrent intrauterine pregnancy and provides superior visualization to computed tomography (CT) for discerning the interface between normal myometrium and trophoblastic tissue. Examination via Doppler US may show hypervascularity and areas of tumor necrosis. In addition, US will identify patients whose large-volume uterine disease is best treated surgically. Following US of the pelvis, FIGO recommends a chest x-ray as the test of choice to rule out lung metastases. If the chest x-ray is negative, CT of the thorax may demonstrate small-volume metastases, but the importance of these findings is unclear (Ngan, 1998). In high-risk cases, up to 41% of patients will have findings identified on CT but not chest x-ray. Identification of lung metastases necessitates further imaging with CT or US of the abdomen, which includes assessment of the spleen, kidneys, GI tract, and liver. Use of intravenous (IV) contrast will identify metastases as round enhanced masses, which are usually multiple, heterogenous, and hypoechoic in appearance. An assessment of central nervous system (CNS) involvement, typically found at the gray-white matter junction, is best done with magnetic resonance imaging (MRI). MRI is also preferred for assessment of vaginal or parametrial lesions. Extrauterine diseases are more common in patients with a diagnosis of choriocarcinoma, PSTT, or ETT; therefore those patients should be screened with pelvic ultrasound, CT of the abdomen, and brain MRI. The role of ^{18}F -fluorodeoxyglucose positron emission tomography (FDG-PET) in GTN is undefined, but its high sensitivity and specificity in other disease sites may make it a useful test when other modalities are equivocal; studies to date are limited to small case series. For asymptomatic patients with a negative chest x-ray and CT scan of thorax, further investigation is not required to assign a risk score, as high-risk sites of metastasis are rarely seen without evidence of pulmonary metastases.

TREATMENT

Low-Risk Gestational Trophoblastic Neoplasia

Low-risk GTN includes localized and metastatic disease and is defined by a WHO prognostic score of 6 or lower. The management of malignant GTN is based more on clinical presentation than histologic diagnosis. For these patients, clinicians can expect an excellent outcome with single-agent chemotherapy consisting of either methotrexate (MTX) or actinomycin D (ActD). While on chemotherapy, patients require monitoring of β -hCG level as well as hematologic and metabolic studies to gauge treatment toxicity. In addition, patients require reliable contraception, preferably with OCP, to prevent intercurrent pregnancies that would be adversely affected by the teratogenic chemotherapy and confuse the evaluation of β -hCG follow-up.

For patients with localized disease for whom fertility preservation is not an issue, hysterectomy may be undertaken to decrease the total number of chemotherapy cycles. Even with surgery,

chemotherapy may still be required to treat occult disease. There have been no RCTs of combined hysterectomy and chemotherapy but, if chemotherapy has been given preoperatively, it should be continued postoperatively until β -hCG levels are normal.

Some authors advocate for a second D&C in the setting of localized GTN. The purpose of this debulking is to decrease the percentage of patients requiring chemotherapy and limit the treatment volume of chemotherapy in patients for whom a second curettage is not curative. Many believe that it is more than a debulking effect and may involve an inflammatory or immune response that contributes to the clinical response. There have been patients in whom no tumor was found on a second D&C, and the woman's β -hCG level has decreased. The cohort analysis by von Trommel and associates compared 85 patients who underwent a second D&C for persistent low-risk GTN with 209 patients who proceeded directly to chemotherapy (van Trommel, 2005). Of those treated surgically, 9.4% required no further treatment. The therapeutic effect of a second curettage was also seen, with a median of six cycles of chemotherapy in the control group versus five cycles in the D&C cohort ($P = .036$). Major complications were seen in 4.8% of patients in the D&C group, with two uterine perforations seen and patients experiencing blood loss of more than 1000 mL. Schlaerth and coworkers demonstrated a similar magnitude of benefit with a second D&C, with cure achieved in 16% of patients and an 8% uterine perforation rate (Schlaerth, 1990). Preliminary results from a prospective multicenter Gynecologic Oncology Group (GOG) cohort study exploring the response of a second D&C in patients with persistent low-risk nonmetastatic GTN found that second curettage resulted in β -hCG normalization for 6 months in 38% of patients. Interestingly, four patients (6.3%) had PSTT in the second curettage pathology suggesting that some low-risk, non-metastatic GTN may undergo malignant de-differentiation later. Second curettage may allow earlier diagnosis of those patients. An analysis of predictor of surgical failure is under way. Nonetheless, the value of repeated D&C remains controversial given chemotherapy achieves exceptional cure rate (nearly 100%) without the additional surgical risks.

A review of first-line therapies in low-risk GTN cases has identified 14 different treatment regimens. The most commonly used first-line treatments are MTX and ActD, with various dosing schedules used. MTX can be given on a 5-day schedule, once weekly, or every 2 weeks on an 8-day schedule, with or without folinic acid rescue; ActD can be given on a 5-day schedule or every 2 weeks (pulsed ActD). There is no consensus on the optimal regimen given the lack of RCTs.

Worldwide, the most common first-line agent (regimen) for low-risk disease is 8-day MTX alternating with folinic acid rescue due to factors such as established activity, low toxicity, and low cost. MTX use requires normal liver and renal function due to altered hepatic metabolism followed by renal excretion of the drug. Depending on the regimen used, patients may experience cutaneous side effects, mucositis, serositis, GI toxicities, alopecia, or hematologic suppression. ActD side effects increase with more dose-intensive regimens. The 5-day regimen side effects include alopecia, nausea, and myelotoxicity. It is a vesicant, causing tissue necrosis if IV extravasation occurs. The effectiveness of pulse ActD versus the 5-day regimen appears to be equivalent, with decreased toxicity, cost, and fewer patient visits with the pulsed regimen.

The use of MTX with folinic acid rescue has been reported by McNeish and associates in a series of 485 low-risk patients (McNeish, 2002). Administration of methotrexate, 50 mg IM on days 1, 3, 5, and 7 with folinic acid, 7.5 mg PO on days 2, 4, 6, and 8 achieved a primary remission in 67% of women. The same regimen was used by Chalouhi and coworkers on 142 low-risk patients, with 78% primary remission achieved and a mean time to β -hCG level normalization of 21 weeks (Chalouhi, 2009). A 2012 Cochrane review of 5 RCTs (517 women) compared the efficacy and safety of MTX and ActD. ActD was associated with improved primary cure rate (RR 0.64, 95% CI 0.54 to 0.76), whereas MTX had more treatment failure (RR 3.81, 95% CI 1.64 to 8.86) (Alazzam, 2012). No difference in toxicity was identified; however, the results are inconclusive given the heterogeneity and the limited number of complications. This meta-analysis was criticized, as the studies included in the analysis were underpowered and compared various chemotherapy regimens that are not commonly used presently. A phase III trial (GOG-174) comparing weekly MTX to pulsed ActD in 216 patients with low-risk GTN demonstrated that biweekly ActD is superior to MTX (Osborne, 2011). Complete response was achieved in 70% of patients treated with pulsed ActD compared with 53% of those treated with weekly MTX ($P = .01$). One criticism is that the GOG-174 used a dose of weekly MTX (30 mg/m²) that is lower than what is often used in clinical practice (MTX 50 mg/m²), and this may explain the difference observed. The results of a large phase III GOG RCT of pulse ActD versus multiday MTX for the treatment of low-risk GTN should help standardize the treatment of low-risk GTN worldwide.

Traditionally, chemotherapy treatment of low-risk disease has been given on a fixed time interval. The New England Trophoblastic Disease Center treats low-risk GTN on the basis of the β -hCG regression curve (Berkowitz, 1986). Following administration of single-agent MTX, further doses are withheld provided that the β -hCG level falls progressively. Their indications for further chemotherapy include the following: (1) a β -hCG plateau for 3 or more consecutive weeks and (2) failure of the β -hCG level to be 10 times smaller within 18 days of the previous chemotherapy. Chan and colleagues used a similar treatment strategy, with 45% of patients in their low-risk cohort achieving complete remission following a single dose of methotrexate (Chan, 2006).

Although most women with low-risk GTN will be cured with a first-line chemotherapy regimen, tumor resistance and relapse do occur. Resistance is defined as a 20% rise of β -hCG level over two consecutive measurements or a β -hCG level plateauing or decreasing by less than 90% over a 3-week period. In patients treated with single-agent MTX, resistance requiring a change to alternative first-line treatment can be expected in 10% to 31% of patients. The experience from the Charing Cross Hospital GTD database reveals that relapse after attaining a normal β -hCG level occurs in 3% of cases.

Box 35.3 provides an overview of management for low-risk GTN. Following normalization of the β -hCG level, chemotherapy is usually continued to reduce the risk of recurrence. The number of recommended consolidation cycles varies between one and three cycles and depends largely on the slope of the serum β -hCG regression curve. A steadily falling β -hCG level in a patient treated with single-agent chemotherapy for low-risk GTN might require only one or two consolidation cycles, whereas three cycles are likely necessary if the shape of the β -hCG regression

Box 35.3 Management of Low-Risk Gestational Trophoblastic Neoplasia

Following metastatic evaluation and determination of low-risk disease:

1. Initiate single-agent methotrexate or actinomycin D; consider hysterectomy, if fertility is not desired.
 - Monitor hematologic, renal, and hepatic indices before each cycle of chemotherapy.
 - Monitor β -hCG levels while on treatment.
 - If severe toxicity or resistance develops, consider switching to the alternative single agent.
- If resistance to the alternative agent develops:
2. Repeat the metastatic evaluation.
3. Consider hysterectomy if disease confined to uterus.
4. Multiagent therapy with EMA/CO (see treatment of high-risk GTN).

Modified from Soper JT, Spillman M, Sampson JH, et al. High-risk gestational trophoblastic neoplasia with brain metastases: individualized multidisciplinary therapy in the management of four patients. *Gynecol Oncol*. 2007;104(3):691-694. Remission is defined as three consecutive weekly β -hCG values in the normal range. Following the first normal β -hCG, continue with one or two cycles of maintenance or consolidation chemotherapy. Monitor β -hCG levels for 12 months, with reliable contraception used in this time period. β -hCG, Beta-human chorionic gonadotropin; EMA/CO, etoposide, methotrexate, actinomycin D, cyclophosphamide, vincristine; GTN, gestational trophoblastic neoplasia.

curve is flatter with a longer time to reach β -hCG normalization. The conventional period of observation with monthly β -hCG measurements before attempting pregnancy is 12 months, as most relapses will occur during this period. Irrespective of which first-line agent is used, cure rates approaching 100% can be achieved with diligent follow-up and salvage therapy for failures. Salvage therapy with pulsed ActD after failed MTX treatment in low-risk GTN achieved complete response in 74% with a median of four cycles in a phase III trial (GOG-176) (Covens, 2006).

High-Risk Gestational Trophoblastic Neoplasia

In the developed world, high-risk GTN cases are uncommon. The timely involvement of specialist teams with experience in treating high-risk disease is key to achieving optimal outcomes. Patients with high-risk GTN, defined as a WHO prognostic score of 7 or higher, are at increased risk of treatment failure with single-agent therapy, hence the use of combination chemotherapy for this group (Lurain, 1995). As for low-risk disease, multiple treatment regimens exist, but no quality RCTs have been conducted comparing regimens. A 2012 Cochrane review design to determine the efficacy and safety of combination chemotherapy in treating high-risk GTN found only one RCT (42 women) comparing MAC (MTX, ActD, and chlorambucil) or the modified CHAMOCA (cyclophosphamide, hydroxyurea, ActD, MTX, doxorubicin, melphalan, and vincristine) (Deng, 2013). Direct comparison is further complicated by the various scoring systems used to classify the disease over time.

The greatest experience with combination treatment for high-risk GTN is with EMA/CO (etoposide, methotrexate, actinomycin D, cyclophosphamide, vincristine); however, no RCTs have been done (Table 35.4) (Lurain, 2006). This intensive regimen consists of etoposide, MTX, and ActD alternating with cyclophosphamide and vincristine. A number of case series, the largest from the Charing Cross group, have reported complete response rates of

Table 35.4 Chemotherapy Regimens for Intermediate- and High-Risk Gestational Trophoblastic Disease

Drug Regimen	Administration
EMA/CO (Preferred Regimen)—Course I (EMA)*	
Day 1	
Etoposide	100 mg/m ² IV over 30 min
Methotrexate	100 mg/m ² IV bolus
Methotrexate	200 mg/m ² IV as 12-hr continuous infusion
Actinomycin D	0.5 mg IV bolus
Day 2	
Etoposide	100 mg/m ² IV over 320 min
Folinic acid	15 mg IV/IM/PO every 6 hr for four doses
Actinomycin D	0.5 mg IV bolus
Course II (CO)	
Day 8	
Cyclophosphamide	600 mg/m ² IV over 30 min
Vincristine	1 mg/m ² IV bolus (up to 2 mg)

Modified from Kantarjian HM, Wolf RA, Koller CA: *M.D. Anderson Manual of Medical Oncology*. New York: McGraw-Hill; 2006.

*Cytokine support may be used.

EMA/CO, Etoposide, methotrexate, actinomycin D, cyclophosphamide, vincristine.

78% to 80% using primary treatment with EMA/CO (Newlands, 1991). In the Charing Cross cohort, 17% developed resistance to EMA/CO, but 70% of these were salvaged with the addition of platinum-based chemotherapy. Deaths from GTN occurred in 4% of patients, and two women developed acute myeloid leukemia following treatment with EMA/CO. Side effects include universal alopecia, stomatitis, and hematologic and gastrointestinal toxicities. Patients may require granulocyte colony-stimulating factor to prevent dose delays in the setting of neutropenia. The risk of secondary malignancies (e.g., acute myeloid leukemia, colon cancer, breast cancer), mainly related to cumulative etoposide dosing, is 50% greater than expected in a standardized nontreated cohort.

Although less than 5% of patients with low-risk disease will relapse following apparent remission, this increases to 25% in patients with high-risk disease. Consolidation therapy with at least three additional course of chemotherapy after normalization of β -hCG level is warranted to reduce risk of relapse. The approach to these patients is multimodality treatment, including surgical resection of chemotherapy resistance sites and salvage second-line (or third-line) chemotherapy. EMA/EP (substituting etoposide and cisplatin for cyclophosphamide and vincristine in EMA/CO) achieves complete response in 90% of recurrent patients, but alternative regimens, including TE-TP (taxol, etoposide, *cis*-platinum), BEP (bleomycin, etoposide, cisplatin), VIP (vinblastine, ifosfamide, cisplatin), and ICE (ifosfamide, carboplatin, etoposide), have also been used, with success.

HIGH-RISK SITES OF METASTASES

Central Nervous System Metastases

Brain metastases portend a poor prognosis. Favorable outcomes have been achieved using a combination chemotherapy, with select craniotomy in some cases, with 30 of 39 patients in one series in remission (Newlands, 2002). Whole-brain radiotherapy to achieve hemostasis and tumor shrinkage has been used in conjunction with chemotherapy for patients with brain metastasis, but given the high success with chemotherapy and the deleterious

long-term effects on overall function in survivors, including global intellectual impairment, chemotherapy is the preferred option. Many authors initiate steroid treatment and use one dose of single-agent MTX as a first regimen prior to EMA/CO to limit massive tumor necrosis, which may precipitate an intracranial bleed. Anti-epileptic drugs are not routinely given. Others have used a modified EMA/CO regimen, including intrathecal MTX in the CO portion of scheduling. However, given the vascular nature of these tumors and the fact that they are not protected by the blood-brain barrier, intrathecal chemotherapy is probably unnecessary. Nonetheless, a study of 27 GTN patients with brain metastases used EMA/CO or EMA-EP with an enhanced CNS MTX dose combined with intrathecal MTX (Savage, 2015). Eighty-five percent (23 of 27) were long-term survivors with only 4 deaths. All the patients who died had chemotherapy refractive disease.

Pulmonary Metastases

Respiratory failure secondary to pulmonary metastases is a concern in patients with chest pain, cyanosis, anemia, and more than 50% lung field opacification. Cao and associates reported on 62 patients who underwent lobectomy for pulmonary metastasis, with complete response (CR) seen in 89% of recurrent cases, 79% of drug-resistant cases, and 100% of cases in whom a satisfactory response to chemotherapy was seen in the setting of residual pulmonary lesion (Cao, 2009). They recommended operative treatment of pulmonary metastases for recurrent drug-resistant cases in patients with adequate performance status to tolerate surgery, no evidence of active tumor elsewhere, and pulmonary metastases limited to one lung.

Liver Metastases

Patients with liver metastases are at increased risk of hemorrhage with chemotherapy initiation. In addition to high-risk chemotherapy regimens, other treatment modalities described include radiation therapy, embolization, and surgical resection.

Vaginal Metastases

Patients with vaginal metastases are at high risk for hemorrhage. Embolization or surgery may be used to control acute bleeding.

TREATMENT OF PLACENTAL SITE TROPHOBLASTIC TUMOR AND EPITHELIOID TROPHOBLASTIC TUMOR

PSTTs and ETTs are rare trophoblastic tumors occurring with a frequency of less than 1%, with clinical behavior ranging from relatively benign to highly malignant. Metastases are seen in 40% to 50% of patients at the time of diagnosis and develop in a further 10% during posttreatment follow-up. Those types of GTN are relatively chemoresistant compared with invasive mole and choriocarcinoma. In a descriptive study of patients with PSTT, 61% of patients initially treated with chemotherapy had no or only incomplete response. Therefore surgery is the cornerstone for the treatment of nonmetastatic PSTT and ETT, with hysterectomy being sufficient provided that the ovaries are normal. Patients with metastatic PSTT and ETT have a poor prognosis. A retrospective study found that 83% (5/6) stage IV PSTT died despite multiagent chemotherapy (Hyman, 2013). Despite the lack of strong evidence, surgery, followed by combination chemotherapy with

EMA/EP or TP-TE (alternating weekly paclitaxel-cisplatin and paclitaxel-etoposide), has been recommended in advanced disease. The International Society for the Study of Trophoblastic Diseases (ISSTD) is currently collecting all the cases of PSTT and ETT to establish the largest international database in order to further inform on management of those rare tumors.

SURVEILLANCE FOLLOWING GESTATIONAL TROPHOBLASTIC NEOPLASIA

After β -hCG remission is achieved for three weekly cycles, patients with high-risk GTN require repeat testing every 2 weeks for 3 weeks and then monthly for 1 year. Stage IV patients are encouraged to maintain monthly testing for 24 months. The risk of relapse beyond the first year is less than 1%. In patients who relapse, sustained remissions are achieved in more than 50%, suggesting value to prolonged β -hCG monitoring every 6 months, extending as long as 5 years.

The heterogeneity of β -hCG molecules in GTN is increased compared with that in normal gestation, with higher proportions of nicked β -hCG, β core fragment, and free β -hCG, stressing the requirement of an assay that detects both β -hCG as well as its fragments and metabolites. An assay with poor sensitivity may fail to detect low levels of β -hCG, leading to incorrect clinical decisions regarding treatment effect and disease persistence.

Reliable contraception in the post-GTN period is required, and the OCP is the method of choice. Cross-reactivity of LH, and therefore false positives, may occur with some assays. Furthermore, patients treated with multiagent chemotherapy may develop ovarian dysfunction, either transient or eventually premature ovarian failure, particularly those in their 30s or 40s. OCP has been recommended for those patients with the thought that it may suppress the production of LH from the pituitary glands and therefore protect the ovaries, although it remains controversial due to lack of high-quality studies.

RECURRENCE

Recurrences following remission relate to the initial stage of disease. Goldstein and coworkers reported recurrences in 3% for stage I disease, 8% for stage II, 4% for stage III, and 9% for stage

IV (Goldstein, 2012). The mean time from the last detectable β -hCG to recurrence was 6 months. For all stages I, II, and III patients, remissions were achieved with additional chemotherapy, whereas all stage IV patients with recurrences died of their disease. Ngan and colleagues found no relationship between time to relapse and mortality, with an overall survival of 78% in relapsed patients (Ngan, 2007). In contrast, the reported recurrence rate of PSTT and ETT are ranging from 20% to 30%, and despite salvage treatment (chemotherapy or surgery), only 30% will achieve long-term remission.

PREGNANCY FOLLOWING GESTATIONAL TROPHOBLASTIC NEOPLASIA

Following molar pregnancy or GTN, patients can expect normal reproductive outcomes. Garner and associates summarized pregnancy outcomes following GTD from multiple centers (Garner, 2002). In a total of 2657 pregnancies following treatment for persistent GTN, 77% had live births, with 72% term deliveries, 5% preterm births, 1% stillbirths, 14% spontaneous abortions, and 2% of children born with congenital anomalies—pregnancy outcomes similar to those of the general population.

Following a molar pregnancy, however, there is an increased risk of subsequent molar pregnancy, increasing from roughly 1 to 3/1000 pregnancies to 1 to 2/100. Following two molar pregnancies, the risk in a subsequent pregnancy may be as high as 20%. Changing partners has not been proved to decrease this risk.

PSYCHOSOCIAL CONSIDERATIONS

Diagnosis and treatment for GTN may have long-lasting psychosocial sequelae for patients, including sadness with a sense of loss following pregnancy, low self-esteem, sexual dysfunction, and anxiety about future pregnancies. Petersen and coworkers used validated questionnaires to assess quality of life in patients following treatment for molar pregnancy and found that more than 50% showed psychological symptomatology suggestive of an underlying psychiatric disorder (Petersen, 2005). They recommended a multidisciplinary approach to care to address the emotional and social aspects of a woman's well-being following treatment for GTN.

KEY POINTS

- Persistent abnormal bleeding following normal pregnancy, abortion, or ectopic pregnancy should lead to a consideration of the diagnosis of GTD. Pulmonary nodules present on chest x-ray after a normal pregnancy suggest GTD. β -hCG levels will be elevated in these situations.
- Investigation of a young woman with metastatic disease of unknown primary should include a β -hCG level measurement.
- The risk of GTN after CHM is 15% to 20%, and it is only 1% to 5% after PHM.
- Approximately 50% of cases of GTN follow molar pregnancy, 25% follow normal pregnancy, and 25% follow abortion or ectopic pregnancy.
- The major risk factors for molar pregnancy include maternal age (>45 and <16 years) and a history of prior HM.
- The risk of HM is approximately 0.75 to 1/1000 pregnancies in North America.
- The risk of a subsequent HM after a primary mole increases 5- to 40-fold.
- Complete moles are of paternal origin, are diploid, and carry a 20% risk of GTD sequelae.
- Partial moles are of maternal and paternal origin, are triploid, and are rarely (2% to 4%) followed by GTD. They nonetheless require follow-up for potential malignant sequelae, as done for a complete mole.
- The monitoring of trophoblastic disease and its follow-up is accomplished by measurement of the β -hCG level.

KEY POINTS—cont'd

- The diagnosis of a molar pregnancy can be established with ultrasonography and may coexist with a normal pregnancy.
- Hydatidiform moles are effectively and safely evacuated from the uterus using suction D&C.
- Medical complications of HM are rare but may include anemia, gestational hypertension before 20 weeks, hyperthyroidism, hyperemesis gravidarum, cardiac failure, and, rarely, pulmonary insufficiency.
- Patients are classified into low- or high-risk categories. Low-risk patients are treated with single-agent methotrexate or actinomycin D; high-risk patients receive combination chemotherapy, usually with EMA/CO.
- The cure rate for low-risk patients approaches 100%.
- Patients with high-risk metastatic GTN are successfully treated with chemotherapy in more than 70% of cases.
- Surgery plays an important role in the treatment of PSTT and ETT. They are both relatively chemoresistant.
- Patients treated for GTD should not become pregnant for approximately 6 months after treatment to allow accurate follow-up of β -hCG levels.
- Fertility rates and pregnancy outcomes are similar in patients treated for GTD compared with those in the general population.
- Patients treated with the EMA/CO regimen have an increased rate of secondary malignancies, particularly hematologic malignancies.

Molecular Oncology in Gynecologic Cancer Immunologic Response, Cytokines, Oncogenes, and Tumor Suppressor Genes

Premal H. Thaker, Anil K. Sood

Cancer develops because of the accumulation of successive and multiple molecular lesions that result in an altered cellular phenotype that is self-sufficient in growth signaling, is insensitive to antigrowth signals and capable of tissue invasion and metastasis, and has limitless replicative potential, sustained angiogenesis, and evading apoptosis (Hanahan, 2000). These molecular changes can include overexpression, amplification, or mutation of oncogenes; the failure of tumor suppressor gene function because of a mutation, deletion, or viral infection; and the inappropriate expression of cytokines, growth factors, or cellular receptors. Also, natural or induced immune responses may play a role in the modulation of cancer growth because immune cells such as tumor-associated macrophages may actually cause tumors to grow. Based on a growing understanding of the immune response, biologic pathways, and cancer development, new immunotherapy and targeted therapies to gynecologic malignancies are being developed and are reviewed and summarized in this chapter.

IMMUNOLOGIC RESPONSE

The immune system has adapted to fight off bacterial or viral infections, but it also plays a role in the surveillance and control of cancer cell growth. The immune system has two types of responses, innate and adaptive. Innate responses are non-antigen-specific and rapid and do not increase with repetitive exposure to a given antigen. Components of the innate immune system include physical barriers such as epithelial surfaces, macrophages, natural killer (NK) cells, neutrophils, dendritic cells, and components of the complement system. Dendritic cells and macrophages are phagocytic cells that act as antigen-presenting cells (APCs). Macrophages also play an important role in the production of cytokines. Innate immune responses form the initial immune response to invading pathogens and contribute to adaptive immunity, which is composed of T lymphocytes (T cells) and B lymphocytes (B cells) that are involved in cell-mediated immunity and humoral immunity, respectively (Berek, 2005).

INNATE IMMUNITY

In contrast to the adaptive immune system, which can recognize a variety of foreign substances, including tumor antigens, the innate immune system can only recognize microbial substances. For the most part, neutrophils, macrophages, NK cells, and dendritic cells are involved in the innate immune response and depend on the recognition of pattern recognition receptors (PRRs), which are encoded in the germline and identically expressed by effector cells. These receptors recognize pathogen-associated molecular patterns (PAMPs), which are expressed by microbes and trigger intracellular signaling cascades that result in inflammation and microbial death. PRRs are expressed constitutively in the host and are not dependent on immunologic memory (Fig. 36.1). Toll-like receptors (TLRs) are PRRs that stimulate type 1 interferon (IFN) production, which has antimicrobial, antiviral, and anticancer activity (Akira, 2006). TLR agonists are being evaluated in a phase II study of VTX-2337 and pegylated liposomal doxorubicin in platinum-resistant ovarian cancer patients based on promising phase I data of 13% partial response and 63% stable disease (Monk, 2013). NK cells are a subset of the lymphocyte population, can directly kill infected cells, and recognize cells that lack major histocompatibility complex (MHC) class I molecules, such as bacteria. Moretta and colleagues reported that NK cells are cytotoxic to tumor cells, probably because of a similar lack of MHC class I molecules.

The complement system plays an important role in the innate immune system and is a complex system, consisting of a large group of interacting plasma proteins. Activation by binding to antigen-complexed antibody molecules activates what is termed the *classical pathway*. In contrast, the alternative pathway is activated by recognition of microbial surface structures in the absence of antibody. Activation of these pathways leads to cleavage of C3 protein into a larger C3b fragment that is deposited on the microbial surface, leading to complement activation of C3a, which serves as a chemoattractant for neutrophils. Complexing of downstream complement proteins C6, C7, C8, and C9 produces a membrane pore in tagged cells that ultimately results in cell lysis. Unfortunately, tumor cells are often resistant

Figure 36.1 Toll-like receptors (TLRs). TLRs are pattern recognition receptors that recognize microbes, viruses, and cancer cells. TLRs recruit MyD88, which is an adaptor protein that ultimately activates interferon and proinflammatory cytokines. *IKKα*, Inhibitor of nuclear factor-κB (IκB) kinase; IRAK1, interleukin-1R-associated kinase-1; IRAK4, interleukin-1R-associated kinase-4; IRF7, interferon regulatory factor-3; TRAF6, TNF receptor-associated factor 6. (From Takeuchi O, Akira S. Recognition of viruses by innate immunity. *Immunol Rev.* 2007;220:214-224.)

to complement-dependent cytotoxicity. The innate immune system is intricately linked to the adaptive immune system by activated macrophages that enhance T-cell activation and complement fragments that can activate B cells and antibody production.

ADAPTIVE IMMUNITY

Humoral Immunity: B Cells and Immunoglobulins

In humans, B cells are derived from hematopoietic stem cells and aggregate in the lymph nodes, gastrointestinal tract, or spleen. B lymphocytes synthesize antibodies in response to an activated CD8⁺ cell or helper T cell (Th2). Then, the B lymphocytes differentiate into plasma cells that secrete large quantities of antibody (immunoglobulin) in response to an antigen. Unlike T cells, B cells recognize antigens in an unprocessed state. Each B cell is programmed to secrete a specific type of antibody, and it is estimated that more than 10⁷ different antibodies are capable of being produced in response to the presence of foreign antigens (Fig. 36.2).

Overall, antibodies have the same basic structure, except for extensive variability in the portion of the structure binding to the

specific antigen. Two identical heavy and light chains constitute the basic immunoglobulin (Ig) structure. Each pair is connected by a disulfide bond. Both the heavy and light chains have a variable (V) region at the amino terminus and a constant region (C) at the carboxy terminus. The V region participates in antigen recognition and confers specificity, and the C region enables the antibody to bind to the phagocyte. Five immunoglobulin molecules (IgG, IgM, IgA, IgD, and IgE) exist and serve different effector functions. Early in the antibody response, IgM and IgD production occurs and the membrane-bound form of IgM and IgD binds antigen and activates naive B cells, leading to B-cell proliferation and clonal selection. Also, IgM is involved in the activation of the classical pathway of the complement system. Later in the antibody response the IgG response develops, which has a higher specificity for particular antigens. IgG is also responsible for neonatal immunity in the transfer of maternal antibodies across the placenta and gut. Also, IgG causes opsonization of the antigen for phagocytosis by macrophages and neutrophils, as well as activation of the classical pathway of the complement system. NK cells and other leukocytes can bind to IgG- and IgE-coated cells to facilitate antibody-dependent cytotoxicity. IgE mediates hypersensitivity reactions, and IgA is responsible for mucosal immunity.

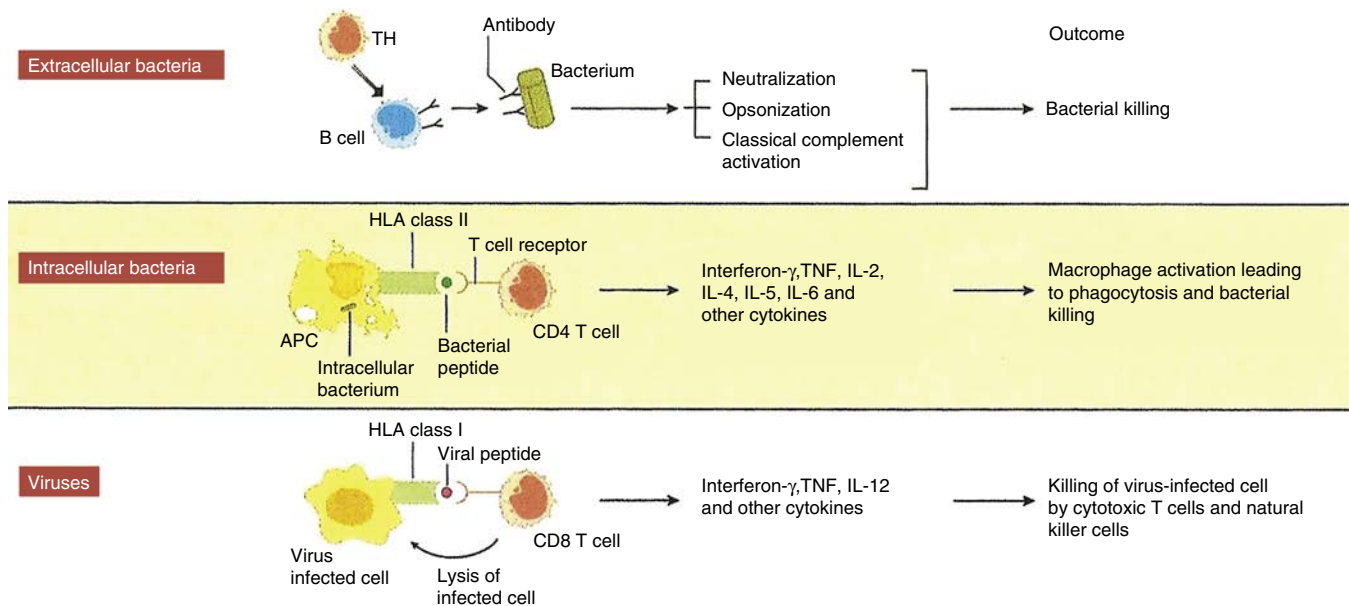

Figure 36.2 Overview of specific immune responses. *Top row*, Humoral immunity. B lymphocytes eliminate microbes by secreting antibodies. *Middle and lower rows*, Cell-mediated immunity. Helper T lymphocytes activate macrophages or dendritic cells that kill phagocytosed molecules or cytotoxic T lymphocytes that eliminate infected cells. (From Chapel H, Haeney M, Misbah S, Snowden N. *Essentials of Clinical Immunology*. 5th ed. Malden, MA: Blackwell; 2006:35.)

Cellular Immunity: T Cells

T cells originate in the bone marrow, differentiate in the thymus, and then circulate in the blood or are harbored in the lymph nodes, spleen, or Peyer patches of the intestine. In contrast to the humoral response, the cellular immune response (cellular immunity) depends on direct cell-cell contact. Although antibodies and B-cell receptors may recognize multiple types of antigens, T cells are restricted to peptide antigens and only recognize peptide sequences in the context of membrane-bound host proteins called *MHC molecules* (Fig. 36.3). There are two classes of MHC molecules. Each class presents antigens to different populations of T cells and is responsible for various functions in the cellular immune response. Th cells (which are CD4⁺) respond to antigens bound to class II MHC molecules to secrete cytokines that stimulate the proliferation and differentiation of T cells as well as other B cells and macrophages. Class II MHC molecules are expressed primarily by professional APCs, which present phagocytosed and processed extracellular peptides to Th cells. There are two subsets of Th cells, which differ in their cytokine profiles and elicit different responses. Th1 cells secrete interleukin (IL)-2 and interferon-gamma (IFN-γ) to elicit a cell-mediated inflammatory response. Th2 cells secrete IL-4, IL-5, IL-6, and IL-10 to promote antibody secretion and the humoral response. Although both types are involved in most immune responses, they regulate the magnitude of each through mutual inhibition of cytokine production such that Th2 cell cytokines suppress production of Th1 cell cytokines and vice versa.

Unlike class II MHC molecules, class I MHC molecules are expressed by all nucleated cells in the body and are used to present intracellular peptides for surveillance to circulating cytotoxic T lymphocytes (CTLs). CTLs are also known

as CD8⁺ T cells and directly destroy cells that express foreign antigens that arise after a viral infection or are expressed as a result of tumorigenesis. Therefore CTLs are considered to be primarily responsible for the antitumor immune response. Zhang and colleagues reported that the presence of intratumoral T cells improves progression-free and overall survival in ovarian cancer patients. This effect was confirmed by Sato and colleagues, who documented a survival advantage in patients with a higher CD8⁺/CD4⁺ ratio of intratumoral cells in ovarian cancer patients compared with the lowest tertile of this cohort. Han and associates found that antigen-processing machinery component down-regulation and the subsequent lack of intratumoral T cells are independent prognostic factors for decreased survival of ovarian cancer patients.

A third class of T cells, regulatory T cells (Tregs), consists of CD4⁺ T cells that are present in the peripheral circulation, inhibit immune responses, and prevent autoimmunity. Because most tumor-associated antigens are self-antigens, recognition by immune effector cells is regulated by Tregs through peripheral tolerance. High numbers of Tregs have been found in the peripheral blood of patients with epithelial ovarian cancer and Tregs preferentially accumulate in the tumor environment, such as ascites and ovarian tumor islets. Curiel and associates have shown that high levels of Tregs were found to predict poor overall survival in a cohort of 70 patients with ovarian cancer. Based on these data, a goal of immunotherapy is to eliminate Tregs in the hope of enhancing innate antitumor immunity. Denileukin diftitox (an engineered protein combining IL-2 with diphtheria toxin causing apoptosis of CD25⁺ cells) selectively eliminates Tregs and has been investigated in ovarian cancer patients in a small phase I study. Results indicate that it induces tumor regression or stabilization, with low toxicity in about 50% of patients (Barnett, 2005).

Figure 36.3 Different routes of antigen presentation. After the antigen is processed into smaller fragments, the major histocompatibility complex class (I or II) and these fragments interact with the receptor on the surface of the T cell to activate cytotoxic or helper T cells. (From Chapel H, Haeney M, Misbah S, Snowden N. *Essentials of Clinical Immunology*. 5th ed. Malden, MA: Blackwell; 2006:7.)

CYTOKINES

Cytokines are proteins secreted by immune cells that are produced in different phases of the immune response to control its duration and extent. During the activation phase of the immune response system, cytokines stimulate growth and differentiation of lymphocytes, whereas in the effector phase of the immune response, they activate other effector cells to help eliminate antigens and microbes. The major classes of cytokines include those that regulate innate immunity, regulate adaptive immunity, and stimulate hematopoiesis.

Cytokines That Mediate Innate Immunity

Interleukins

Interleukins are potent cytokines produced by some leukocytes to affect other leukocytes. IL-1 is released in response to cell damage by macrophages, endothelial cells, and some epithelial cells. Although IL-1 has actions similar to those of tumor necrosis factor (TNF), it lacks the ability to cause septic shock

symptoms. Macrophages can secrete a variety of ILs. M1 macrophages secrete IL-12, IL-18, IL-23, IFN- γ , and TNF- α and promote immune responses against tumors and intracellular microbes. IL-12 plays an important role in the transition between cell-mediated immunity and adaptive immunity. IL-12 stimulates NK cells and T cells to produce IFN- γ , which activates macrophages to kill phagocytosed foreign substances. Also, IL-12 increases cytolytic activity by stimulating CD8⁺ cells. M2 macrophages produce vascular endothelial growth factor (VEGF), IL-6, IL-10, and prostaglandin E₂, all of which have immunosuppressive functions and are found selectively in established tumors. The other ILs stimulate NK and T-cell activation and proliferation, as well as IFN- γ synthesis.

Chemokines

Chemokines are small secreted proteins that are part of the largest known cytokine family. The chemokines are subdivided based on the number and positioning of highly conserved cysteines. Functionally, chemokines released in response to inflammatory stimuli that cause leukocyte recruitment are considered to be inflammatory, whereas chemokines that cause migration of leukocytes to lymphoid organs are considered to be homeostatic. Chemokines affect tumor establishment in the following ways: determining the extent and type of leukocyte infiltration, promoting angiogenesis, controlling site-specific metastasis, and affecting tumor cell proliferation. The CXC chemokines (CXCL9, CXCL10, and CXCL11) are induced by IFN- γ and are typical chemoattractants of NK cells.⁶ In ovarian cancer patients, the expression of CXCR4/CXCL12 correlates with decreased progression-free and overall survival. Because of the importance of chemokines in gynecologic and other malignancies, CXCR4 inhibitors such as peptide antagonists and neutralizing antibodies have been developed and are in clinical trial (Muralidhar, 2014).

Interferons

Type 1 IFN, IFN- α and IFN- β , are stimulated by intracellular TLRs and mediate the early innate immune response to viral infections. These cytokines inhibit viral replication, increase expression of class I MHC molecules, and promote a Th1 cell-mediated immune response by promoting T-cell proliferation and NK cell cytolytic activity. IFN- γ , a type II IFN, is principally responsible for macrophage activation and the effector functions of innate and adaptive immune responses.

Cytokines That Mediate Adaptive Immunity

In addition to IFN- γ and transforming growth factor beta (TGF- β), IL-2, IL-4, IL-5, and IL-13 are all involved in the regulation of adaptive immunity. After T cells recognize the antigen, the T cells produce IL-2, which causes clonal expansion of activated T cells and additional production of cytokines such as IFN- γ and IL-4. IL-2 stimulates antibody synthesis and B cells by acting as a growth factor. IL-4 not only promotes IgE production from B cells but also stimulates the development of Th2 cells from naive T cells. IFN- γ is produced by T cells in response to antigen recognition or by NK cells in response to microbes or IL-12. IFN- γ activates the microbicidal function of macrophages, stimulates the expression of class I and II MHC and costimulatory molecules by antigen-presenting cells (APC), promotes the maturation of cells expressing CD4 into Th1 cells, and inhibits the Th2 cell pathway, thereby effectively promoting a cellular immune

response. TGF- β inhibits the proliferation and differentiation of T cells and contributes to immune evasion of tumor cells by inhibiting antitumor host immune responses.

Cytokines That Mediate Hematopoiesis

Colony-Stimulating Factors

IL-3 is a multilineage colony-stimulating factor that allows for the differentiation of cells into myeloid progenitor cells, granulocytes, monocytes, and dendritic cells. Granulocyte colony-stimulating factor (G-CSF) is a cytokine produced by macrophages, fibroblasts, and endothelial cells and promotes the mobilization of neutrophils from the bone marrow. Granulocyte-macrophage colony-stimulating factor (GM-CSF) is produced by T cells, macrophages, endothelial cells, and fibroblasts. GM-CSF stimulates the maturation of bone marrow cells into dendritic cells and monocytes. G-CSF and GM-CSF are available pharmacologically and are used in patients undergoing chemotherapy and bone marrow transplantation.

TUMOR CELL KILLING AND IMMUNOTHERAPY

Immunotherapy has been developed to recognize and destroy tumor cells. Immune modulation, passive therapy, and active therapy are the three major classes of immunotherapy. Immune modulation relies on nonspecific means such as the administration of IL-2, IFNs, or bacille Calmette-Guérin to elicit an immune response. Passive therapy transfers components of the acquired immune system to the cancer patient (passive immunity). An example of passive therapy is the use of monoclonal antibodies directed toward tumor-specific antigens. Active therapy uses the woman's immune system to elicit a response; an example would be vaccines composed of peptides, proteins, DNA, or RNA.

Immune modulation has been used in ovarian cancer in the form of adjuvant IFN treatment after surgery and as consolidation therapy after surgery and standard chemotherapy. A phase III trial randomized patients with advanced ovarian cancer to IV cisplatin and cyclophosphamide chemotherapy versus the same regimen with intraperitoneal IFN- γ . Windbichler and colleagues have shown an improvement in progression-free but not overall survival in the IFN arm, with acceptable toxicity. Possible explanations for the improvement in the chemotherapy plus IFN include induction of cytotoxic T lymphocytes, stimulation of NK cells and macrophages, an antiangiogenic effect on tumor vasculature, and the direct inhibition of oncogene expression by high IFN- γ levels in the tumor microenvironment. This study was redone with the standard chemotherapy of carboplatin and paclitaxel with IFN- γ versus chemotherapy alone and showed a survival disadvantage in patients receiving IFN- γ , but no difference in progression-free survival (Alberts, 2008). Because of the mixed results, further trials investigating the potential synergistic effect of IFN administration and cytotoxic chemotherapy are needed to rigorously evaluate this approach for treatment.

Tumor cells have specific tumor-associated antigens or receptors on their surface that may distinguish them from normal cells. The antigen most often targeted in ovarian cancer is cancer antigen 125 (CA-125), a glycoprotein present at elevated levels in the serum of more than 80% of patients with epithelial ovarian cancer. A murine monoclonal antibody (MAb) to CA-125 (oregovomab) was investigated for its therapeutic usefulness as a consolidation treatment in

ovarian cancer patients but did not demonstrate an overall survival advantage over controls. However, a subset of patients who had evidence of a robust antiantibody immune response in the form of antimurine antibodies had evidence of tumor protection after treatment (Berek, 2008). Trials of oregovomab, with or without chemotherapy, have also been conducted in patients with recurrent disease, and induction of anti-CA-125 T-cell responses may correlate with improved survival times in a minority of patients. Abagovomab (an anti-idiotypic MAb) stimulated human antimouse antibodies and an anti-anti-idiotypic as well as a CA125-specific cellular immune response in most patients, but it did not correspond into a prolonged progression-free or overall survival (Sabbatini, 2013). Bevacizumab (Avastin) is a monoclonal antibody directed against VEGF. In a phase II study of persistent or recurrent ovarian cancer patients, it showed an unprecedented 21% response rate, and 40% of patients did not have progression at 6 months. Two double-blind placebo-controlled phase III trials (GOG 218 and ICON7) enrolled over 3400 women to evaluate the benefit of bevacizumab to first-line intravenous chemotherapy of carboplatin and paclitaxel every 3 weeks and found an approximately 4-month improvement in progression-free survival in patients who received bevacizumab (Burger, 2011; Perren, 2011). Additionally, in the AURELIA open-label randomized phase III trial, 361 patients with platinum-resistant recurrent ovarian cancer received either weekly paclitaxel, weekly and/or five day topotecan, or pegylated doxorubicin per physician preference and were randomized to either chemotherapy alone and/or bevacizumab. The median progression-free survival in patients with chemotherapy alone was 3.4 months versus 6.7 months with a bevacizumab-containing therapy ($P < .001$) (Pujade-Lauraine, 2014). This trial did not show an overall survival benefit, as that was not the primary objective of the trial and crossover to the use of bevacizumab was allowed. The AURELIA trial led to U.S. Food and Drug Administration (FDA) approval of bevacizumab for ovarian cancer patients.

Adoptive T-cell immunotherapy uses the transfer of T cells expanded ex vivo in large numbers because of their ability to kill tumor cells specifically and to proliferate and persist for long periods after transfer. A strong rationale exists for the development of adoptive T-cell therapies in the treatment of ovarian cancer. First, tumor-specific T cells can be found in the peripheral circulation or in tumors in up to 50% of ovarian cancer patients. Second, the presence of intratumoral T cells being associated with improved survival suggests that administering adoptive immunotherapy could produce clinical results. Unfortunately, the advancement of adoptive T-cell therapies suffers from their complexity and labor-intensive manufacture, as well as toxicity from cross-reactivity and antigenic mimicry. Therefore trials in ovarian cancer are somewhat limited but ongoing using dendritic cells or naturally or genetically modified T-cell therapies (Kandalaft, 2011).

Targeting immune checkpoints, such as programmed cell death protein 1 (PD1), programmed cell death 1 ligand (PDL1), and cytotoxic T-lymphocyte antigen 4 (CTLA4), have shown clinical benefit in melanoma and lung cancer by blocking immunoinhibitory signals and enabling patients to mount an effective antitumor response. Varga and colleagues presented preliminary phase IB data in a heavily pretreated PDL1 positive ovarian cancer population and found that one patient had a complete response, two patients had a partial response, and six patients had stable disease by taking pembrolizumab. Clinical trials in all gynecologic malignancies are ongoing with these novel agents.

Another promising immunotherapy in gynecology has been the human papillomavirus vaccine (HPV) for the prevention of vulvar, vaginal, or cervical dysplasia and the corresponding cancers. A study conducted by Joura and workers has shown that the nine-valent vaccine against HPV 6, 11, 16, 18, 31, 33, 45, 52, and 58 decreases the incidence of dysplasia or cancer significantly; the vaccine was 96.7% effective (Joura, 2015). Currently, *Listeria monocytogenes*, which secretes the antigen HPV-16 E7 and is fused to a nonhemolytic listeriolysin O protein, has been used as a therapeutic vaccine for patients with advanced cervical cancer (Basu, 2014). The use of HPV vaccine therapy is efficacious and has tremendous implications for the treatment of gynecologic HPV-related dysplasias and cancers.

MOLECULAR ONCOLOGY

Cancer development can be sporadic if it is caused by acquired mutations or can be hereditary if caused by inheritance of a mutated gene followed by acquisition of an acquired mutation in the other allele or loss of the other allele, also known as *loss of heterozygosity*. Genetic alterations occur in three major categories of genes—oncogenes, tumor suppressor genes, and DNA mismatch repair genes (MMRs). Knowledge of how these genes function is a rapidly expanding field and well beyond the scope of this chapter, but a general overview is provided here.

ONCOGENES

An oncogene refers to a set of genes that when altered are associated with the development of a malignant cell. Functionally, oncogenes are involved in cell proliferation, signal transduction, and transcriptional alteration. Mechanisms of alteration in oncogene function include gene amplification (increase in the number of copies of the genes in the cell), translocation, or overexpression, which refers to excessive and abnormal protein production. Several classes of oncogenes such as peptide growth factors, cytoplasmic factors, and nuclear factors exist. Examples are described in the following section (Table 36.1).

Peptide Growth Factors

Epidermal Growth Factor Receptor Family
There are four types of *ErbB* receptors: *ErbB1* (commonly known as *epidermal growth factor receptor [EGFR]*), human epidermal growth factor receptor [HER]1), *ErbB2* (also known as *HER2/neu*), *ErbB3* (also known as *HER3*), and *ErbB4* (also known as *HER4*). All *ErbB* receptors share an extracellular domain that binds ligand, a transmembrane domain, and an intracellular tyrosine kinase domain. In the *ErbB* pathway, homodimers and heterodimers are formed from the various classes of receptors, resulting in activation of the Ras-Raf–mitogen-activated protein kinase (MAPK) pathway and the phosphoinositide 3-kinase (PI3K)–activated AKT pathway. Although *ErbB3* lacks intrinsic kinase activity and *ErbB2* has no specific ligand, the formation of heterodimers leads to activation of these classes of receptors.
The Ras-Raf-MAPK pathway is a major downstream target of the *ErbB* family of receptors and leads to the activation of Ras, causing the activation of MAPKs to regulate transcription of molecules linked to cell proliferation, survival, and transformation. Also, the PI3K-activated AKT pathway serves as another

Table 36.1 Classes of Genes Involved in Growth Stimulatory Pathways

Peptide Growth Factors	Corresponding Receptors
Epidermal growth factor (EGF) and transforming growth factor- α (TGF- α)	EGF receptor (<i>erb-B1</i>), <i>erb-B2</i> (Her-2/Neu), <i>erb-B3</i> , <i>erb-B4</i>
Heregulin	
Vascular endothelial growth factor (VEGF) A, VEGF-B, VEGF-C, VEGF-D, VEGF-E, placental growth factor (PIGF) 1, PIGF2	VEGFR-1, VEGFR-2, VEGFR-3, neuropilins
Insulin-like growth factors (IGF-I, IGF-II)	IGF-I and IGF-II receptors
Platelet-derived growth factor (PDGF)	PDGF receptor
Fibroblast growth factor (FGF)	FGF receptors
Macrophage colony-stimulating factor (M-CSF)	M-CSF receptor (FMS)
Cytoplasmic Factors	Examples
Tyrosine kinases	Eph family
G proteins	K-Ras, H-Ras, N-Ras
Serine-threonine kinases	AKT
Non receptor tyrosine kinases	Focal adhesion kinase (FAK), Src
Nuclear Factors	Examples
Transcription factors	C-myc, C-jun, C-fos
Cell cycle progression factors	Cyclins, E2F

Modified from Boyd J, Berchuck A. Oncogenes and tumor suppressor genes. In: Hoskins WJ, Young RC, Markman M, et al, eds. *Principles and Practice of Gynecologic Oncology*. Philadelphia: Lippincott Williams & Wilkins; 2005:93-122.

downstream target of the *ErbB* pathway; it drives tumor progression *via* cell growth, proliferation, survival, and motility. A number of mechanisms such as receptor gene amplification and overexpression, receptor mutations, and autocrine ligand production cause *ErbB* pathway disruption, leading to tumor formation. EGFR gene mutations have been found in glioblastomas, nonsmall cell lung cancer, and ovarian cancer. Slamon and colleagues reported that Her2/neu amplification is found in 20% to 30% of breast cancers and 10% of ovarian cancers. Because of the multitude of cancers with genetic alterations or changes in the *ErbB* family, several potential strategies exist for targeting EGFR, including monoclonal antibodies, low-molecular-weight tyrosine kinase inhibitors (TKIs), antisense oligonucleotides, and intracellular single-chain Fv fragments of antibodies, and many are used in clinical practice. Trastuzumab, a MAb that binds to HER2/neu, is currently used in the treatment of breast cancers that overexpress this receptor. Currently, monoclonal antibodies to the extracellular domain of EGFR such as cetuximab have been approved by the FDA for the treatment of metastatic colorectal cancer along with chemotherapy, as well as for the treatment of locally or regionally advanced head and neck cancer with radiation therapy.

Angiogenesis and Vascular Endothelial Growth Factor

Cancer growth requires a sufficient blood supply to extend beyond 1 mm³ in size (Carmeliet, 2000). Angiogenesis occurs by sprouting (branching of new blood vessels from preexisting blood vessels) or by nonsprouting (requires the enlargement and splitting of preexisting blood vessels). The tumor

vascular environment is characterized by vessels that are irregular in shape, dilated, tortuous, and disorganized. Angiogenesis is dependent on the relative increase of proangiogenic factors such as VEGF, platelet derived-growth factor (PDGF), and ephrins and their receptors. Also, endothelial cells are genetically stable, unlike tumor cells, thereby increasing the therapeutic value of targeting angiogenesis for cancer therapy.

VEGF is critical to endothelial cell survival, vascular permeability, cell fenestration, and vasodilation. There are seven proteins in this family: VEGF-A, VEGF-B, VEGF-C, VEGF-D, VEGF-E, placental growth factor (PlGF) 1, and PlGF2. Most human tumors, including those of the lung, thyroid, breast, gastrointestinal tract, female reproductive tract, and urinary tract, have marked expression of VEGF. There are three vascular endothelial growth factor receptors: VEGFR-1, VEGFR-2, and VEGFR-3. VEGFR-3 is expressed on the vascular and lymphatic endothelium, unlike the other two receptors, which are expressed only on the vascular endothelium. Also, there is a second class of VEGFRs known as the *neuropilins* (NRP), which potentiate VEGF-A- and VEGFR-2-mediated actions. Similar to the EGFR family, there are many ligands to receptors in the VEGF family (Dvorak, 2002). Ultimately, activation of the VEGF receptors can lead to downstream effects on the mitogen-activated protein kinase (MAPK) pathway, v-src sarcoma viral oncogene homologue (SRC), PI3K-AKT, focal adhesion kinase (FAK), and Ras-Raf-MAPK (Ras-Raf-MAPK) superfamily. Because of the clinical significance of the VEGF pathway in many cancers, anti-VEGF antibodies such as bevacizumab, VEGFR tyrosine kinase inhibitors, and vascular targeting agents have been developed to target this critical pathway. In ovarian cancer, bevacizumab has been evaluated in conjunction with standard carboplatin and paclitaxel for first-line treatment, consolidation therapy, and in both platinum-sensitive and -resistant recurrent settings. A phase I/II study of docetaxel and aflibercept in 46 recurrent ovarian cancer patients with up to two previous chemotherapy regimens had an overall response rate of 54% without any gastrointestinal perforations or reversible posterior leukoencephalopathy, which can be serious side effects of bevacizumab (Coleman, 2011). The authors concluded that further evaluation is warranted. Another interesting phase II study evaluated the use of a polyadenosine diphosphate [ADP]-ribose polymerase (PARP) inhibitor olaparib with and without an anti-angiogenic agent cediranib, which has activity against VEGFR1, VEGFR2, and VEGFR3 in recurrent platinum-sensitive ovarian cancer patients. The median progression-free survival was 17.7 months for the oral combination versus 9 months in the olaparib-only group ($P = .005$) (Liu, 2014a). Additional clinical testing with this combination is underway.

Ephrin Family of Ligands and Receptors

Tyrosine kinases provide a transfer of a phosphate from adenosine triphosphate (ATP) to tyrosine residues on specific cellular proteins; however, they can also play a role in the development of cancer and tumor progression. Attention has been given to elucidating the role of the ephrin receptor A2 (EphA2) in tumorigenesis and therapeutic targeting. EphA2 belongs to the largest known family of protein tyrosine kinase receptors, the Eph family, and there are two Eph receptors, A and B, that have corresponding ligands. The normal cellular function of EphA2 in epithelial tissue is not completely understood, but in cancer, EphA2 modulates cell growth, survival, migration, and

angiogenesis (Pasquale, 2008). EphA2 overexpression has been correlated with disease severity and is predictive of a poor outcome in ovarian cancer patients (Thaker, 2004). There are several therapeutic approaches for targeting EphA2, including agonist monoclonal antibody, immunotherapy, soluble EphA receptors, and neutral liposomal small interfering RNA (siRNA), some of which are already in clinical trials (Ozcan, 2015).

Phosphoinositide 3-Kinase Pathway

The PI3K family is composed of lipid and serine-threonine kinases that control second messengers through phosphorylation. AKT is the predominant downstream target of PI3K and has many targets, including mammalian target of rapamycin (mTOR), signal transducer and activation of transcription (STAT), MAPK, nuclear factor- κ B, and protein kinase C. The activation of the PI3K-AKT pathway controls cell survival with inhibition of apoptosis, cell growth, cell metabolism, RNA translation, and cell proliferation. Also, this pathway has been implicated in chemotherapy resistance (Hennessy, 2005).

RAS is another cytoplasmic factor. It is a G protein involved in the transmission of growth stimulatory signals from the cell membrane to the nucleus. The RAS family of G proteins is positioned downstream of cell surface receptor tyrosine kinases and upstream of the cytoplasmic cascade of kinases, such as mitogen-activated protein (MAP) kinases. MAP kinases in turn activate nuclear transcription factors such as c-myc, c-jun, and c-fos. Currently, it is estimated that about one third of cancers have point mutations in RAS genes, such as *KRAS*, *HRAS*, and *NRAS*. Because RAS requires the posttranslational modification of the addition of a farnesyl group to the C terminus to move from the cytoplasm to the inner plasma membrane, inhibitors to farnesylation have been developed and clinical trials have been completed but results are still pending.

The RAF family of genes encodes serine-threonine kinases that interact with RAS proteins and continue signaling by activating MAP kinases, which translocate to the nucleus. Many cancers that lack a RAS mutation will have a *BRAF* mutation.

Tumor Suppressor Genes

Tumor suppressor genes control cell growth and cellular proliferation and aberrations in tumor suppressor genes can cause malignancy. The retinoblastoma (*Rb*) gene was the first tumor suppressor gene to be identified and encodes a nuclear protein that regulates G1 phase cell cycle arrest. Knudson and colleagues have proposed the “two-hit” theory to explain the action of tumor suppressor genes. The first hit is the inheritance of the *Rb* mutated gene, and the second hit is the somatic mutation or loss that occurs later and leads to cancer (Amin, 2015).

In gynecologic malignancies, the most common tumor suppressor gene is *p53*, which is located on the short arm of chromosome 17. *p53* has key roles as a transcription factor and regulator of the cell cycle and apoptosis. Normal *p53* binds to transcriptional regulatory elements in the DNA and acts as a gatekeeper of the genome by responding to DNA damage with the activation of apoptotic effectors such as BAX, FAS, and bcl-2. Missense mutations that change a single amino acid in the encoded protein in exons 5 to 8 are the most common mutations of *p53*. The resultant mutant proteins can no longer bind to DNA but can bind to and inactivate any normal *p53* in a cell. Cells with mutant *p53* do not experience cell cycle

arrest at the G₁-S checkpoint before DNA replication and at the G₂-M checkpoint prior to mitosis, nor do they undergo apoptosis.

Inactivation of the tumor suppressor gene TP53 is among the most frequent genetic events in endometrial cancers, and *p53* mutations are found in approximately 10% to 20% of endometrioid cancers, predominantly grade 3, and in 96% of late and sporadic ovarian cancers per the Cancer Genome Atlas Research Network (TCGA) (Cancer Genome Atlas Research Network, 2011; 2013). In cervical carcinogenesis, the E6 oncoprotein of HPV types 16 and 18 associates with *p53* and targets it for degradation, and the E7 oncoprotein of HPV type 16 binds to *Rb* in infected cells to up-regulate proliferation (Asiaf, 2014). Although the *p53* mutation is one of the most common mutations in cancer, therapeutic targeting of *p53* has met with less than optimal results in several disease sites.

Phosphatase and tensin homologue (PTEN) is the regulatory counterpart of PI3K, and it does so by dephosphorylating proteins phosphorylated by PI3K. *PTEN* is a tumor suppressor gene and is found in approximately 20% of endometrial hyperplasia and 77.7% of endometrioid cancers per TCGA data (Cancer Genome Atlas Research Network, 2013). Mutations of *PTEN* occur in exons 3, 4, 5, 7, and 8 targeting the phosphatase domain and regions that control protein stability and localization. Decreased or absent expression of *PTEN* results in many of the mutations found in endometrioid cancers. Also, epigenetic mechanisms such as promoter hypermethylation and subcellular localization can affect *PTEN* function in the absence of intragenic mutations.

BRCA1* and *BRCA2

Approximately 5% to 10% of breast and ovarian cancers arise in the setting of a genetic predisposition. The majority of these cases are associated with germline mutations in the *BRCA1* gene located on chromosome 17q21 and the *BRCA2* gene located on chromosome 13q12.3. The pattern of inheritance is autosomal dominant, and the prevalence of the mutated gene occurs more frequently in Ashkenazi Jewish and certain French Canadian women. The following women with no personal history of cancer but with a family history as listed here should be tested for a *BRCA* mutation (NCCN Guidelines, 2015).

- A known mutation in a cancer susceptibility gene within the family
- A woman with a family history of two or more women with breast cancer on the same side of the family
- A woman with greater than two breast cancer primaries in the same individual
- A first- or second-degree relative with breast cancer ≤ 45 years of age
- A woman with at least one family member with invasive ovarian, fallopian tube, or primary peritoneal cancers
- Male breast cancer
- Personal or family history of three or more of the following cancers: pancreatic cancer, prostate cancer, gastric cancer, melanoma, brain tumors

The cumulative risk of developing ovarian cancer by the age of 70 years is 40% to 50% for *BRCA1* mutation and 20% to 25% for *BRCA2* mutation carriers, but there is equal breast cancer penetrance in *BRCA1* or *BRCA2* mutation carriers. The *BRCA2* mutation is also associated with male breast cancer and pancreatic, urinary tract, and biliary tract cancers. Unfortunately, a

woman with this mutation develops breast or ovarian cancer at a younger age than sporadic cancers.

BRCA1 and *BRCA2* are tumor suppressor genes that encode for large proteins. Similar to other hereditary cancer syndromes, inheritance of a *BRCA* mutation confers an increased susceptibility to cancer, but not an absolute guarantee of developing cancer unless a second inactivation of the allele occurs. Both *BRCA1* and *BRCA2* encode proteins that are involved in the repair of DNA strand breaks. Most detected mutations are nonsense or frameshift alterations that lead to truncated proteins. *BRCA1* and *BRCA2* proteins are involved in the pathway mediated by RAD51, which is a protein important in repairing double DNA strand breaks. *BRCA1* is also involved in tumor suppression by transcriptional regulation of gene expression, such as being a *p53* independent transactivator of cyclin kinase inhibitor p-21. *BRCA2* has been identified as an FANCD1 gene, a member of the Fanconi anemia complex. Cells with deficient *BRCA1* or *BRCA2* are incapable of repairing DNA strand breaks, which leads to genetic instability and tumorigenesis. In *BRCA*-deficient cells, the defective maintenance of genomic integrity may not only accelerate cancer initiation and progression but may also render the cancer more susceptible to therapeutic agents whose cytotoxic potential is mediated through the induction of a specific type of DNA damage that *BRCA* normally functions to repair. For example, cisplatin and radiation cause DNA interstrand cross-links (Burgess, 2014). In a phase II study, PARP inhibitors such as olaparib have been used in the treatment of high-grade serous ovarian cancer patients with or without *BRCA1* and *BRCA2* mutations and were found to have an objective response rates of 41% for patients with *BRCA1/2* mutations and 24% for those without such mutations. The PARP inhibitors have an acceptable toxicity profile (Gelmon, 2011). The study that led to FDA approval for olaparib in the treatment of ovarian cancer evaluated olaparib as maintenance therapy in platinum-sensitive patients with unknown *BRCA* status who had received two or more platinum-based regimens and demonstrated a highly significant progression-free survival of 8.4 months versus 4.8 months upon completion of chemotherapy (Ledermann, 2012). PARPs are a family of multifunctional enzymes that repair DNA single-strand breaks through the repair of base excisions. The inhibition of PARPs leads to the accumulation of DNA double-strand breaks, which are normally repaired by *BRCA* proteins and thereby provide selectivity of treatment in this *BRCA* mutation population. Currently, clinical trials combining various PARP inhibitors and chemotherapy are ongoing in a *BRCA* mutation positive cancer population (Liu, 2014b), but the use of PARP inhibitors for therapy is a good example of how molecular oncology can be exploited for therapeutic value. Bolton and colleagues, as well as others, have demonstrated that women with *BRCA* mutations, especially *BRCA2* mutations, survive longer than their sporadic cancer counterparts (Bolton, 2012).

DNA Mismatch Repair Genes

Hereditary nonpolyposis colorectal cancer (HNPCC), also known as *Lynch syndrome*, is an autosomal dominant cancer syndrome that predisposes an individual to colorectal, endometrial, gastric, biliary tract, urinary tract, or ovarian cancer. This syndrome is thought to account for all cases of hereditary endometrial cancer and up to 5% of hereditary ovarian cancers. The estimated lifetime risk for endometrial cancer in HNPCC gene carriers is 40% to 60%, corresponding to a relative risk of 13 to

20, whereas that of ovarian cancer is 6% to 20%, corresponding to a relative risk of 4 to 8. Linkage analysis of high-risk families led to the discovery of Lynch syndrome. It was found to be caused by germline mutations in genes responsible for recognizing and fixing errors in the DNA helix, resulting from incorrect pairings of nucleotides during replication or the formation of abnormal loops of DNA. *MSH2* (MutS homologue 2) and *MLH1* (Mut L homologue 1) are the most commonly mutated mismatch repair genes and are located on chromosomes 2p16 and 3p21, respectively. Other mismatch repair genes are *MSH6*, *MSH3*, *PMS1*, and *PMS2*, but these occur at a lower frequency. Cells with a defective mismatch repair system exhibit microsatellite instability (MSI). MSI occurs as DNA mismatches cause a shortening or lengthening of repetitive DNA sequences and these mismatches go unchecked. This results in the cancer containing a greater or lesser number of repeats than are present in the normal cells of the individual. There is a consensus panel of five microsatellite markers (D2S123, D5S346, D17S250, Bat 25, and Bat 26) that can be used to identify HNPCC-related cancers compared with sporadic ones. In endometrial cancer, MSI can occur from promoter methylation and must be distinguished from MSI caused by an inherited mismatch repair defect.

Taking a family history is the first step in identifying patients with HNPCC. The Bethesda criteria (Box 36.1) seem to be the most sensitive for predicting mismatch repair mutations, but the Amsterdam II criteria are more specific. Amsterdam II criteria include the following: colorectal carcinoma and/or endometrial cancer or transitional cell of the ureter or renal pelvis or

carcinoma of the small bowel in at least three individuals, one of the patients is a first-degree relative of two other patients, disease occurs in at least two other family members, one of the diagnoses should be made before the age of 50 years, histologic confirmation of the diagnosis; and familial adenomatous polyposis has been excluded (NCCN Guidelines, 2014). However, many academic centers have gone to a universal screening protocol with immunohistochemistry in all endometrial cancer patients, which leads to a higher acceptance of genetic testing compared with referral based on risk factors alone (Frolova, 2015).

FUTURE DIRECTIONS

With the continued improved understanding of molecular oncogenesis and tumor progression, promising biologically targeted therapies will emerge. One such therapy is siRNA, which can be designed to target and silence oncogenes involved in all steps of cancer initiation, proliferation, and metastasis. Unlike small molecule inhibitors or fully humanized antibodies, siRNAs can aim at multiple downstream pathways or targets specifically and effectively based on direct, homology dependent, post-transcriptional gene silencing. The major challenges to the development of siRNA as a therapeutic tool have been its degradation by serum nucleases, poor cellular uptake, and rapid renal clearance following administration. However, the development of nuclease-resistant chemically modified siRNAs and neutral nanoliposomes such as 1,2-dioleoyl-*sn*-glycero-3-phosphatidylcholine (DOPC) for improved delivery should overcome these obstacles (Ozcan, 2015). Preclinically, neutral nanoliposomal EphA2 siRNA injection every 4 days decreased tumor growth in two ovarian cancer cell lines compared with control siRNA, and when EphA2-targeted siRNA was combined with paclitaxel there was a statistically significant decrease in tumor growth in both cell lines. Since the completion of safety studies, early stage clinical testing is under way.

Another potential therapeutic target is noncoding RNA (ncRNA). This includes a broad range of regulatory RNA molecules, such as ribozymes, antisense, siRNA, microRNA (miRNA), and aptamers. MiRNA negatively regulates protein expression in either cancer or normal cells. Changes in miRNA expression can occur by direct interaction between the stromal cells and cancer cells, by paracrine factors, or by direct communication between cells and secreted miRNAs. Once the miRNA communication pathways between the tumor microenvironment and the cancer cells can be decoded, miRNAs could be used for early detection, monitoring therapeutic responses, or targeted therapy with miRNA replacement (Kohlhapp, 2015). Small ncRNAs elicit at least four types of responses that trigger specific gene inactivation, which are important in a variety of cancers: destruction of homologous messenger RNA, inhibition of translation, de novo methylation of genomic regions that block transcription of target genes, and chromosomal rearrangement. These flexible molecules have proved to have enormous potential as diagnostic and therapeutic tools in cancer medicine.

Box 36-1 Bethesda and Amsterdam II Criteria for Hereditary Nonpolyposis Colorectal Cancer

Any one of the following meet the Bethesda Criteria:

1. Colorectal cancer less than 50 years.
2. Presence of synchronous or metachronous HNPCC-related carcinomas regardless of age (colorectal, endometrial, stomach, ovarian, pancreas, ureter, renal pelvis, biliary tract, sebaceous gland, and small bowel).
3. Colorectal cancer with microsatellite instability high histology in individuals less than 60 years of age.
4. Colorectal cancer diagnosed in one or more first-colorectal-degree relatives with colorectal cancer or other HNPCC-related tumors. One of the cancers must have been diagnosed before the age of 50 years (this includes adenomas, which must have been diagnosed before the age of 40 years).
5. Colorectal cancer in two or more first- or second-degree relatives with a HNPCC-related tumor, regardless of age.

Or

All of the following meet the Amsterdam II Criteria:

1. Colorectal and/or endometrial cancer or transitional cancer of the ureter or renal pelvis or cancer of the small bowel in at least three individuals in the same family.
2. One of the patients is a first-degree relative of the other patients.
3. Disease occurs in at least two other family members in successive generations.
4. At least one of the diagnoses was made before the age of 50.
5. The diagnoses must be histologically confirmed.
6. Familial adenomatous polyposis is excluded in cases of colorectal cancer.

Data from National Comprehensive Cancer Network Guidelines, Version 2, 2015, Lynch Syndrome. Available at www.nccn.org.

GYNECOLOGIC MALIGNANCIES

Cancer is a complex multistep process that requires self-sufficient growth signals, insensitivity to anti-growth signals, tissue invasion

and metastasis, limitless replicative potential, sustained angiogenesis, and evasion of apoptosis. The clinical diversity of gynecologic cancers such as histologic type, stage, and outcome is probably attributable to molecular differences among cancers. The roles of oncogenes and tumor suppressor genes vary not only among cancers but also within a given type of cancer. With the data from TCGA, there is a better understanding of the molecular characterization of gynecologic cancers. This project sponsored by the National Institutes of Health carried out multiple “omics” studies including RNA, DNA, epigenetic, and protein analyses. With this improved characterization, TCGA identified four gene expression subtypes of high-grade ovarian cancer: mesenchymal, immunoreactive, differentiated, and proliferative. However, it is unclear whether these groupings will be clinically useful ([Cancer Genome Atlas Research Network, 2011](#)). Nevertheless, there are a number of findings that have increased our knowledge of the underpinnings of the cancers studied in TCGA. The following sections describe the roles of oncogenes and tumor suppressor genes that lead to the development of gynecologic cancers.

ENDOMETRIAL CANCER

Endometrial Cancer and Tumor Suppressor Genes

Endometrial cancer is divided into two types: type I, which is thought to be due to unopposed estrogen and develops in a background of endometrial hyperplasia, and type II, which comprises nonendometrioid and more aggressive cancers. Inactivation of tumor suppressor gene *p53* is among the most frequent genetic events in endometrial cancer occurring in about 20% to 30% of cases. Also, overexpression of *p53* occurs more frequently in advanced stage endometrial cancer and has been associated with worse survival after controlling for stage, suggesting that loss of *p53* tumor suppressor function leads to a more aggressive phenotype. There is a disproportionate frequency of *p53* mutations in 90% of serous and 33% of high-grade endometrioid cancers. In uterine sarcomas, overexpression of mutant *p53* occurs in the majority of malignant mixed mesodermal tumors (MMMTs) and in some leiomyosarcomas.

The *PTEN* gene is on chromosome 10q and encodes a phosphatase that functions by opposing the activity of PI3K. *PTEN* is the most commonly mutated gene in endometrial carcinoma. Mutations in this gene are usually deletions, insertions, or nonsense mutations that lead to truncated protein products and are associated with endometrioid histology, early stage, and favorable clinical behavior. Deltas and workers found that loss of *PTEN* and p27 protein expression in obese endometrial cancer patients is associated with a significantly better prognosis. Loss of *PTEN* in these cancers leads to increased activity of PI3K/AKT signaling cascade. Sometimes, *PTEN* mutation status can be used to differentiate an ovarian metastasis from an endometrial cancer *versus* synchronous primary cancers.

TCGA found other significantly mutated genes such as FBXW7, ARID1A, and PPP2R1A ([Cancer Genome Atlas Research Network, 2013](#)). FBXW7 regulates mTOR signaling and is mutated in about 30% of serous carcinomas. ARID1A, a large protein involved in chromatin remodeling, was initially reported to be mutated in ovarian endometrioid and clear cell tumors but now has been found to be mutated in 40% of endometrioid endometrial cancers. PPP2R1A is a regulatory subunit of the protein phosphatase 2A and controls cell growth and

division. Interestingly, it is mutated in uterine serous carcinomas but not ovarian carcinomas.

Germline mutations in DNA mismatch repair genes are essential to HNPCC. Endometrial cancer is the second most common malignancy observed in women with HNPCC after colon cancer. Unlike in colon cancer, loss of mismatch repair function in endometrial cancer has not been consistently associated with improved survival (see DNA Mismatch Repair Genes, presented earlier, for further details).

Endometrial Cancer and Oncogenes

Unlike inactivation of tumor suppressor genes, fewer alterations in oncogenes have been found in endometrial cancer. *Her2/neu* has been found to be expressed in approximately 3% of endometrioid and 25% of serous carcinomas and was associated with aggressive phenotype and poor survival in a population-based series. Racial differences in the expression of *Her2/neu* have been found as well. Regardless, the levels of *Her2/neu* overexpression are much lower than in breast cancer ([Engelsen, 2008](#)). There have been clinical trials using trastuzumab (anti-*Her2/neu* antibody) for treatment of endometrial cancer, but without significant responses ([Fleming, 2010](#)).

KRAS mutations occur most often in type I endometrial cancers as well as in hyperplasias, suggesting that *KRAS* mutation is an early event in the development of type I endometrial cancers. The *BRAF* mutations were found in endometrial cancers with mismatch repair deficiency and have different frequencies in various populations ([Feng, 2005](#)).

The beta-catenin (β -catenin) gene maps to chromosome 3p21 and is important for cell differentiation, maintenance of normal tissue architecture, and signal transduction. Mutations in exon 3 of β -catenin result in stabilization of the protein, cytoplasmic and nuclear accumulation, and participation in signal transduction and transcriptional activation through the formation of complexes with DNA binding proteins. These mutations occur in approximately 15% to 50% of endometrial cancers and are independent of the presence of microsatellite instability and the mutational status of *PTEN* and *KRAS*. β -catenin exon 3 mutations were found to be a driver that characterizes an aggressive subset of low-grade and low-stage endometrioid adenocarcinomas in younger women, and this subset of patients may warrant more aggressive therapeutic management ([Liu, 2014c](#)).

The fibroblast growth factor receptor 2 (*FGFR2*) gene encodes one of a family of tyrosine kinase growth factor receptors that receive signals from a large family of ligands. Pollock and colleagues evaluated the *FGFR2* gene for activating mutations in a series of endometrial cancers and found them in approximately 10% of endometrioid cancers. The Gynecologic Oncology Group has completed a phase II trial evaluating an anti-*FGFR2* tyrosine kinase inhibitor brivanib in recurrent endometrial cancer; due to its tolerability and median PFS of 3.3 months, it warrants further development ([Powell, 2014](#)).

Immunotherapy and Endometrial Cancer

Although endometrial cancer is the most frequent gynecologic cancer and the fourth most common cancer in women, immunotherapy is just emerging as a viable option for the treatment of endometrial cancer. Investigations have revealed that endometrial cancer is immunogenic and could be a reasonable target for immunotherapy. Santin and coworkers found that a strong *in vitro* tumor-specific response could be generated by tumor

lysate-pulsed autologous dendritic cells in uterine papillary serous carcinoma. Although limited by few patients, a strong cytotoxic T-cell and Th1 response was characterized by enhanced IFN- γ and low IL-4 expression (Santin, 2002). In Belgium, a phase I/II clinical trial of six patients with recurrent uterine cancer who received autologous dendritic cell electroporated with Wilms tumor gene 1 showed feasibility of this approach, but the transient oncological responses were in human leukocyte antigen (HLA)-A2-positive patients (Coosemans, 2013). Immunotherapy for endometrial cancer is still in its infancy.

OVARIAN CANCER

Ovarian Cancer and Tumor Suppressor Genes

To date, alteration of the *p53* tumor suppressor gene is the most frequent genetic event in ovarian cancers. Advanced stage and serous cancers have a higher frequency of *p53* mutations than do early stage and nonserous cancers. Overall, 70% of advanced stage ovarian cancers have missense or truncation mutations in *p53*. Evidence suggests that inactivation of *Rb* greatly enhances tumor formation in ovarian cells with *p53* mutations.

Cyclin-dependent kinase inhibitors (CDKIs) also act as tumor suppressors because they inhibit cell cycle progression from the G1 to S phase. The *p16* gene (CDKN2A) undergoes homozygous deletion in approximately 15% of ovarian cancers. *BRCA1* and *p16* may be inactivated by transcriptional silencing because of promoter methylation rather than mutation or deletion. TCGA analysis found that only a small number of high-grade serous ovarian cases had deletions in PTEN and *Rb*, but endometrioid and clear cell ovarian cancers had higher mutation rates in ARID1A, PI3K, PTEN, and β -catenin (Cancer Genome Atlas Research Network, 2011).

Oncogenes and Ovarian Cancer

Unlike in breast cancer, in which 30% express increased levels of *Her2/neu*, a minority of ovarian cancers have increased *Her2/neu* expression. The Gynecologic Oncology Group has conducted a trial to evaluate the response rate of ovarian cancer patients to single-agent anti-*Her2/neu* antibody therapy and found the rate of response to be approximately 7%. *KRAS* mutations are commonly found in borderline tumors of the ovary and mucinous ovarian cancers, but not in serous ovarian tumors. Additionally, in low-grade ovarian cancers, *BRAF* and *KRAS* mutations are found, and inhibitors of the *MEK 1/2* have been found to be active therapeutic agents with a 63% disease control in patients with recurrent low-grade serous carcinoma (Farley, 2013). PI3K and β -catenin are rarer mutations, but they are more likely to be found in endometrioid and clear cell tumors of the ovary.

Immunotherapy and Ovarian Cancer

Because the clinical history of ovarian cancer entails periods of remission and relapse of sequentially shortened duration as chemotherapy resistance develops, immune-based strategies should be contemplated in women with minimal disease burden. The immune system protects the host against the development of cancer, but it also creates tumor immunogenicity. Immunotherapy trials generally focus on the effector phase of the immune response to elicit primarily an antibody response, produce humoral and cellular responses, or cause the activation or generation of

antigen-specific CTLs and Th cells. The cancer-testis antigen NY-ESO-1 vaccines have been developed and used in a clinical trial of high-risk ovarian cancer patients in first clinical remission. Overall, these vaccines were found to have a low side effect profile and induced specific T-cell immunity, but they did not delay progression-free survival (Diefenbach, 2008). Also, anti-idiotypic vaccines, which try to increase the immunogenicity of tumor-associated antigens by presenting the desired epitope to the host in a different molecular environment, have been used to increase antibody production. A phase I/II randomized trial of dendritic cell vaccination loaded with *Her2/neu*, human telomerase reverse transcriptase, and pan-DR epitope peptides with or without cyclophosphamide for consolidation therapy for advanced ovarian cancer patients in first or second remission demonstrated modest immunologic responses but was associated with a delayed progression-free survival and 3-year overall survival of 90% (Chu, 2012). In a phase I study utilizing intraperitoneal IL-12 plasmid formulated with the lipopolymer polyethyleneglycol-polyethyleneimine-cholesterol in combination with pegylated liposomal doxorubicin in patients with recurrent or persistent ovarian cancer, Thaker and colleagues found a clinical benefit of 57.1% and are developing additional clinical trials (Thaker, 2015). Check-point family members are involved in the Wnt, hedgehog, and Hippo pathway and modulate key regulatory proteins involved in tumorigenesis such as *p53*, β -catenin, and mouse double minute 2 homologue (MDM2). Clinical trials for check point inhibitors are in their infancy (Knippschild, 2014). Radionuclides conjugated with antibodies such as yttrium conjugated to the *MUC1* gene have been shown to have no difference in overall survival in ovarian cancer patients (Verheijen, 2006). Although, to date, numerous nonrandomized phase II immune targeted trials have shown benefit in terms of survival and presence of respective effectors, these have not been confirmed in phase III trials, but further investigation is warranted in ovarian cancer.

CERVICAL CANCER: ONCOGENES, TUMOR SUPPRESSOR GENES, AND IMMUNOTHERAPY

Because only a small proportion of women with HPV develop cervical cancer, the inactivation of the TP53 tumor suppressor gene leads to genomic instability that results in secondary genetic alterations that lead to the development of cervical cancer. However, compared with other gynecologic cancers, the roles of oncogenes and tumor suppressor genes are not as well elucidated. The allelic loss of possible tumor suppressor genes at loci on chromosomes 3p, 11p, and others has been noted, but specific tumor suppressor genes remain unidentified. The RAS and MYC genes are key oncogenes in cervical carcinomas. Also, Mamas and colleagues found that the oncogenes *Hi* and *NRAS* are up-regulated in cervical cancer independently of HPV infection. Similar to endometrial and ovarian cancers, gene silencing caused by promoter hypermethylation may also be involved in cervical cancer development. The methylation status of the oncogene human telomerase reverse transcriptase and the tumor suppressor genes death-associated protein kinase and O6-methylguanine DNA methyltransferase could be used to distinguish the progression from normal to cervical dysplasia to invasive cancer. In terms of immunotherapy for the treatment of cervical cancer, ADXS11-001 is a live attenuated *Listeria monocytogenes* bioengineered to secrete an HPV-16 E7 fusion protein targeting HPV transformed

cells. A prospective phase II study conducted in India with 110 recurrent cervical cancer patients receiving either three or four doses of the ADXS11-001 with cisplatin chemotherapy had a 12-month survival of 36% and 18-month survival of 28%. The total disease control rate was 43% in the patient population with very few options (Basu, 2014). This trial is also being conducted in the United States. Another approach is to use peptide-based vaccines, which have the advantages of relative tolerability, stability, and ease of production. However, they tend to have poor immunogenicity and require adjuvants to enhance vaccine potency. An ongoing clinical trial is utilizing ISA101, a HPV-16 E6/E7 long peptide vaccine, at varying doses with or without interferon alfa in combination with carboplatin and paclitaxel in women with HPV-16 positive advanced stage, metastatic or recurrent cervical cancer. Another exciting trial is the use of adoptive T-cell therapy in the treatment of nine patients with metastatic cervical cancer.

All patients underwent isolation and ex vivo expansion of tumor-specific infiltrating T cells and three of six patients with HPV reactivity had objective tumor responses. This trial is being expanded for the recruitment of 35 patients. There are many other immunotherapy options in cervical cancer such as checkpoint inhibitors and using chimeric T-cell receptor antigens; the hope is that these trials will lead to durable cures (Eskander, 2015).

CONCLUSION

Cancer pathogenesis is a complex process, but with the advent of high-throughput molecular technologies, a new understanding is rapidly advancing. This understanding of the biology and immunology of the disease offers hope for better means for prevention, early detection, and treatment.

KEY POINTS

- The immune system consists of the innate and adaptive immune systems. The innate system is present at birth and consists of natural barriers, NK cells, macrophages, and the complement system. The adaptive immune system adapts to infection and consists of T and B cells.
- The cellular immune response occurs as a result of T lymphocytes reacting via a surface TCR that processes antigens presented to it by an APC in conjunction with MHC molecules.
- T-cell activation can result in activation of helper or inducer (Th) cells, cytotoxic or suppressor T cells, or cytokine production.
- Th cells recruit macrophages and cytotoxic or suppressor cells.
- Cytotoxic T cells have the ability to lyse infected cells or signal B cells to produce antibody.
- Humoral immunity results from antigenic stimulation of a B lymphocyte, which differentiates into a plasma cell and secretes antibody (immunoglobulin).
- The complement cascade provides a basis for the inflammatory response and can also mediate cytotoxicity.
- Cytokines (lymphokines) are regulatory substances of the immune system produced as a result of T-cell activation, cell damage by a virus, or other cells, such as macrophages and monocytes, involved in the immune response.
- Passive therapy transfers components of the acquired immune system to the recipient with cancer (e.g., monoclonal antibodies directed toward tumor-specific antigens).
- Active immunotherapy uses a patient's own immune system for protection against infection (e.g., vaccines).
- There are three types of genes associated with malignant development: oncogenes, tumor suppressor genes, and DNA mismatch repair genes.
- Malignant change is seen with point mutations, chromosomal aberration, gene amplification (increase in number of copies), or chromosomal translocation.
- *Ras* oncogenes are part of a group of signal transducer oncogenes that relay messages from the membrane to the cell nucleus. They are activated generally by point mutations.
- Growth factor genes include *C-erb-B2 (Her-2/neu)*, which can be overexpressed and act as a tumor-specific target for monoclonal antibody therapy; these are especially useful in breast cancer therapy.
- Nuclear oncogenes include *myc* and *fos* and can activate other genes as well as stimulate DNA replication.
- Angiogenesis is the formation of new blood vessels in order for tumors to grow.
- Tumor suppressor genes such as *Rb* and *p53* restrain cell growth. They have two copies and, in general, alteration of both copies leads to a mutant expression, which allows tumorigenesis to occur.
- *BRCA1* and *BRCA2* mutations confer a high lifetime risk of breast or ovarian cancer. Mutation screening may be appropriate for women with family histories, suggesting a hereditary predisposition to breast or ovarian cancer.
- DNA mismatch repair genes act by recognizing and fixing errors in the DNA helix resulting from incorrect pairings of nucleotides. They prevent the accumulation of genetically damaged material in the cell.

Primary and Secondary Dysmenorrhea, Premenstrual Syndrome, and Premenstrual Dysphoric Disorder Etiology, Diagnosis, Management

Vicki Mendiratta

Dysmenorrhea, premenstrual syndrome, and premenstrual dysphoric disorder afflict a large percentage of women in their reproductive years. These conditions have a negative effect on the quality of these women's lives and the lives of their families, and they are also responsible for a huge economic loss as a result of the cost of medications, medical care, and decreased productivity. This chapter discusses current thinking with respect to the causes, pathophysiology, and management of these three conditions.

DYSMENORRHEA

Dysmenorrhea is defined as a cyclic, painful cramping sensation in the lower abdomen often accompanied by other biologic symptoms, including sweating, tachycardia, headaches, nausea, vomiting, diarrhea, and tremulousness, all occurring just before or during the menses. The term *primary dysmenorrhea* refers to pain with no obvious pathologic pelvic disease. It is currently recognized that these patients are suffering from the effects of endogenous prostaglandins. The term *secondary dysmenorrhea*, on the other hand, is associated with pelvic conditions or pathology that causes pelvic pain in conjunction with the menses (Smith, 2016). Primary dysmenorrhea almost always first occurs in women younger than 20. Indeed, the woman will report pain as soon as she establishes ovulatory cycles. Secondary dysmenorrhea may, of course, occur in women younger than 20, but it is most often seen in women older than 20.

INCIDENCE AND EPIDEMIOLOGY

A number of studies have attempted to determine the prevalence of dysmenorrhea; a wide range (16% to 90%) have been reported. These studies have been performed on students, teenagers and their mothers, and individuals from various specific populations, such as industrial workers or college students. The best estimate of the prevalence of primary dysmenorrhea is approximately 75%. Andersch and Milsom, 1982, surveyed all the 19-year-old women in the city of Gothenburg, Sweden. A total of 90.9% of these women

responded to a randomly distributed questionnaire, and 72.4% of these stated that they suffered from dysmenorrhea. In addition, 34.3% of the total population reported mild menstrual symptoms, 22.7% cited moderate symptoms that required analgesia, and 15.4% stated that they had severe dysmenorrhea that clearly inhibited their working ability and that could not be adequately assuaged by general analgesia (Andersch, 1983) (Table 37.1). A 2005 Canadian study of 1546 menstruating women reported that 60% had primary dysmenorrhea and 60% reported their pain as moderate or severe (Burnett, 2005). Similarly, 17% missed school or work. Factors that may reduce the risk of developing dysmenorrhea include younger age at first childbirth, higher parity, and physical exercise. Women who have vaginally delivered a child are less likely to have dysmenorrhea. Pregnancy itself without actual birth does not seem to alleviate dysmenorrhea, because women who have had ectopic pregnancies or spontaneous or voluntary terminations of pregnancy are not relieved of their symptoms. Risk factors that have been reported to increase the risk of dysmenorrhea include age less than 30, body mass index (BMI) less than 20, premenstrual syndrome, pelvic inflammatory disease, sterilization, history of sexual assault, and heavy smoking (Lathe, 2006).

RELATIONSHIP TO MENSTRUATION AND THE MENSTRUAL CYCLE

Andersch and Milsom, 1982 have demonstrated a significant positive correlation between the severity of dysmenorrhea and duration of menstrual flow, amount of menstrual flow, and early menarche. They showed no relationship with the actual duration of the menstrual cycle. In their series, 38.3% of patients reported that they had experienced dysmenorrhea for the first time during the first year after menarche, and only 20.8% reported that dysmenorrhea had not occurred until 4 years after menarche.

FAMILY HISTORY

Dysmenorrhea has been reported to be increased significantly in mothers and sisters of women with dysmenorrhea.

Table 37.1 Severity of Primary Dysmenorrhea*

Severity	Number of Women	Percentage of Total
None	162	27.6
Mild†	201	34.3
Moderate‡	133	22.7
Severe§	90	15.4

Data from Andersch B, Milsom I: An epidemiologic study of young women with dysmenorrhea. *Am J Obstet Gynecol* 144:655, 1982.

*In a population of 586 19-year-old Swedish women.

†No systemic symptoms, medication rarely required, work rarely affected.

‡Few systemic symptoms, medication required, work moderately affected.

§Multiple symptoms, poor medication response, work inhibited.

PRIMARY DYSMENORRHEA

PATHOGENESIS

The pathogenesis of dysmenorrhea shows there is a close association between elevated prostaglandin F_{2α} (PGF_{2α}) levels in the secretory endometrium and the symptoms of dysmenorrhea, including uterine hypercontractility, complaints of severe cramping, and other prostaglandin-induced symptoms. Arachidonic acid, the precursor to prostaglandin production, has been found in increased amounts in the endometrium during ovulatory cycles. Arachidonic acid is converted to PGF_{2α}, PGE₂, and leukotrienes, which are involved in increasing myometrial contractions. During menses, these contractions decrease uterine blood flow and cause ischemia and sensitization of pain fibers (Fig. 37.1). Endometrial concentrations of PGF_{2α} and PGE₂ correlate with the severity of dysmenorrhea; cyclooxygenase inhibitors decrease menstrual fluid prostaglandin levels and decrease pain. In small studies, ultrasound and magnetic resonance imaging (MRI) have correlated dysmenorrhea with myometrial changes and decreased blood flow. PGF_{2α} and PGE₂ affect other organs such as the bowel and result in nausea, vomiting, and diarrhea.

DIAGNOSIS

The diagnosis of primary dysmenorrhea is made largely by the history and physical exam. Patients typically complain of midline, crampy, lower abdominal pain, which begins with the onset of menstruation. The pain can be severe and can also involve the low back and thighs. The pain gradually resolves over 12 to 72 hours. Pain does not occur at times other than menses and only occurs in ovulatory cycles. Diarrhea, headache, fatigue, and malaise may be reported. Women with primary dysmenorrhea have a normal pelvic examination. There are no laboratory or imaging abnormalities associated with primary dysmenorrhea. In adolescents experiencing dysmenorrhea in the first 6 months from menarche, an obstructing malformation of the genital tract in the differential diagnosis should be considered.

TREATMENT

Treatment for primary dysmenorrhea begins with providing patient education and reassurance. Individualized, supportive therapy can then be tailored to the patient's specific symptoms, degree of disability from those symptoms, and other health care considerations, such as need for contraception (Smith, 2016).

Figure 37.1 Mechanisms contributing to generation of pain in primary dysmenorrhea. (From Dawood MY. Nonsteroidal anti-inflammatory drugs and reproduction. *Am J Obstet Gynecol*. 1993;169:5.)

NONPHARMACOLOGIC INTERVENTIONS

Exercise

Cochrane conducted a systematic review of the literature in 2010. Only one randomized controlled trial (RCT) was included that demonstrated efficacy of aerobic exercise in reducing dysmenorrhea. The many other benefits from exercise, however, warrant its recommendation as first-line therapy for women suffering from significant dysmenorrhea (Brown, 2010).

Heat

Two RCTs have shown that heat applied to the low abdomen, in the form of a patch or wrap, was effective in reducing dysmenorrhea. Unlike medications, this intervention has no side effects.

BEHAVIORAL INTERVENTIONS

In 2007, a Cochrane review revealed some evidence from five RCTs that a variety of behavioral interventions may help to reduce cyclic menstrual pain. However, the authors cautioned that the data were of limited quality with a small sample size and suffered from some methodologic limitations. Interventions that have been utilized and studied include relaxation training, biofeedback, Lamaze exercises, hypnotherapy, imagery, coping strategies, and desensitization procedures (Proctor, 2007).

VITAMINS AND DIET

Dietary and vitamin therapies may be beneficial but, to date, have not been studied in a rigorous fashion. A low-fat vegetarian

diet decreased menstrual pain in one study, and vitamin E was more effective than placebo in reducing dysmenorrhea in adolescents. Vitamins B₁ and B₆, fish oil supplements, and a Japanese herbal combination have been helpful in reducing pain compared with placebo in small trials.

MEDICATIONS

Nonsteroidal anti-inflammatory drugs (NSAIDs) are first-line therapies for primary dysmenorrhea. NSAIDs are prostaglandin synthetase inhibitors (PGSIs) that have been demonstrated to alleviate symptoms of dysmenorrhea. These substances are non-steroidal and anti-inflammatory. They are generally divided into two chemical groups: the arylcarboxylic acids, which include acetylsalicylic acid (aspirin) and fenamates (mefenamic acid), and the arylalkanoic acids, including the arylpropionic acids (ibuprofen, naproxen, and ketoprofen) and the indoleacetic acids (indomethacin). The more specific cyclooxygenase (COX-2) inhibitors such as celecoxib have similarly been shown to alleviate the primary dysmenorrheal symptoms. COX-2 expression in the uterine glandular epithelium was maximal during menstruation in one trial of ovulatory women, suggesting a possible association with the cause. The increased expression of COX-2 was eliminated with continuous use of oral contraceptives (OCs), which also offer an effective treatment (discussed later). The specific effect of these agents on the uterine musculature is reduction of contractility, as measured by reduction of intrauterine pressure. COX-2 inhibitors may be considered for women with gastrointestinal toxicity due to NSAIDs; however, these agents carry a risk of serious adverse events and now contain a black box warning. These medications therefore should only be used with caution and full disclosure.

In 2010, Marjoribanks provided a review to the Cochrane Database of RCTs of NSAIDs in the treatment of dysmenorrhea. Seventy-three RCTs were included. NSAIDs were substantially more effective than placebo in pain reduction (odds ratio [OR] 4.50, 95% confidence interval [CI]: 3.85–5.27) (Marjoribanks, 2010).

Previously, in 1984, Owen reviewed the effectiveness of NSAIDs for the treatment of primary dysmenorrhea in 51 trials carried out in 1649 women. More than 72% of the women suffering from dysmenorrhea reported significant pain relief with NSAIDs, 18% reported minimal or no pain relief, and 15% showed a placebo response. Owen concluded that PGSI compounds were effective and safe for most women with primary dysmenorrhea (Owen, 1984). The fenamates seemed to be more effective in relieving pain than ibuprofen, indomethacin, or naproxen. All the compounds demonstrated minimal NSAID-associated side effects, with the exception of indomethacin. In trials with indomethacin, the dropout rate was higher, primarily because of symptoms involving the central nervous system (CNS) and gastrointestinal (GI) tract. Efficacy with the COX-2 inhibitors is similar, although several drugs in this class have been removed from the market because of serious adverse cardiovascular events.

Smith has demonstrated that the effectiveness of NSAIDs is related to tissue concentration. Using meclofenamate in 18 subjects who participated in a double-blind, placebo-controlled, crossover study, a parallel in time response curves was seen between the plasma levels of the drug and decrease in uterine contractility. Figure 37.2 demonstrates the average intrauterine pressure relationships between placebo-treated

Figure 37.2 Average pressure, meclofenamate versus placebo. (Modified from Smith RP. The dynamics of nonsteroidal anti-inflammatory therapy for primary dysmenorrhea. *Obstet Gynecol.* 1987;70:785.)

and drug-treated patients over time. Intrauterine pressure declined 20% to 56% in these patients during meclofenamate therapy (Smith, 1987).

NSAIDs should be given the day prior to the expected menses or at the onset of menses. If one NSAID is ineffective, switching to a different class of NSAIDs may be helpful. NSAIDs should not be given to patients who have shown previous hypersensitivity to such drugs. They are also contraindicated for women who have had nasal polyps, angioedema, and bronchospasm related to aspirin or NSAIDs. In addition, these agents are contraindicated for individuals with a history of chronic ulceration or inflammatory reaction of the upper or lower GI tract and for those with preexisting chronic renal disease. During the use of these agents, autoimmune hemolytic anemia, rash, edema and fluid retention, and CNS symptoms, such as dizziness, headache, nervousness, and blurred vision, can occur. In up to 15% of users, a slight elevation of hepatic enzyme levels may also be found. Table 37.2 lists some NSAIDs commonly used for the treatment of dysmenorrhea.

Combined contraceptives (CCs) containing estrogen and progesterone will relieve the symptoms of primary dysmenorrhea in approximately 90% of patients. This may be because CCs suppress ovulation and endometrial proliferation and the progestin component also blocks the production of the precursor to prostaglandin formation. The thinned endometrium from CCs then contains less arachidonic acid, which is the precursor to prostaglandins. If the woman also requires contraception, CC therapy may prove to be the treatment of choice.

In 2009, Wong and colleagues provided a review to the Cochrane Database of RCTs comparing combined oral contraceptives (COCs) with other COCs, placebo, and NSAIDs. Six studies revealed that COCs were significantly more effective than placebo for the treatment of dysmenorrhea (OR of 2.99, 95% CI: 1.76, 5.07) (Wong, 2009).

In small RCTs, low-dose OCs (with 20 µg ethinyl estradiol) were effective in reducing dysmenorrhea in adolescents and adult women. Continuous OC administration compared with traditional monthly cyclic dosing has been shown to reduce the menstrual pain symptoms. Breakthrough bleeding can be an undesirable side effect, although a review of RCTs reported bleeding and discontinuation rates to be similar. The extended-cycle

Table 37.2 Commonly Used Nonsteroidal Anti-inflammatory Drugs*

Class	Brand Name	Generic Name	Usual Regimen (mg)*	Initial Dose	Subsequent Dose
Propionic acid	Motrin	Ibuprofen	400 (qid)-800 (tid)	500	250 tid-qid
	Naprosyn	Naproxen	250 (qid)-500 (bid)		
	Anaprox	Naproxen sodium	275 (qid)-550 (bid)		
	N/A	Ketoprofen	25-75 (tid)

	Voltaren	Diclofenac	75 (bid)		
	N/A	Tolmetin	400 (tid)		
	N/A	Diflunisal	500 (bid)		
	N/A	Etodolac	400 (tid-qid)		
	Toradol	Ketoralac	10 (qid)		
Oxicams	Feldene	Piroxicam	20 (qd)	500	250 qid

*Maximum doses.

OCs available are also associated with less dysmenorrhea than are monthly cyclic OCs.

The vaginal ring CC has also been shown to reduce dysmenorrhea in a similar fashion as COCs. Dysmenorrhea was not, however, as well controlled in women using the transdermal CC patch as compared with COCs (Smith, 2016).

Progestin-Only Formulations

Depot medroxyprogesterone, a long-acting injectable contraceptive, has not been studied specifically for primary dysmenorrhea. Trials in contraceptive studies report a reduction in dysmenorrhea in adolescents. Because this often causes a thinned endometrium and light menses or amenorrhea, it theoretically should be effective.

The 20 µg levonorgestrel-releasing intrauterine system (LNG-IUS) has been shown in randomized controlled trials to reduce menstrual pain. Levonorgestrel is a 19-nortestosterone derivative affecting endometrial progesterone receptors, leading to an atrophic endometrial lining. In 2013, a smaller LNG-IUS containing only 14 µg of levonorgestrel was approved by the U.S. Food and Drug Administration (FDA) and may represent another option for the management of dysmenorrhea (Smith, 2016). Of note, by comparison, the copper T380A intrauterine device (IUD) often increases dysmenorrhea.

The single-rod etonogestrel-releasing contraceptive (Implanon) has also been shown in clinical trials to reduce dysmenorrhea. This and the newer version, Nexplanon, represent additional progestin-only options.

Tocolytics

Because of its ability to block uterine contractility, tocolytics may be beneficial in the treatment of dysmenorrhea. Studies using nifedipine at a dose of 20 to 40 mg orally have demonstrated pain relief. Moderate pain relief was noted in 36 of 40 women, but side effects of facial flushing, tachycardia, and headache can occur. Glyceryl trinitrate and magnesium have also been studied in limited fashion and have demonstrated effectiveness in reducing cyclic menstrual pain. Ongoing large-scale research is needed to assess safety and efficacy; therefore these medications are not often utilized for contemporary management of dysmenorrhea.

OTHER TREATMENTS

Narcotic analgesics are often utilized in treating patients with chronic pain. Caution should be used, however, due to the very real potential for dependency or abuse. Short-term use may be considered as a bridge to other nonopioid options.

A meta-analysis of three trials has reported that transcutaneous electrical nerve stimulation (TENS) is more effective than placebo in relieving dysmenorrhea, although it is not as effective as analgesics. Milsom and colleagues, in Sweden, and Smith and Heltzel, in the United States, have noted that TENS relieves menstrual pain without reducing intrauterine pressure, suggesting that its mode of action may be in the CNS. High-frequency TENS provides more dysmenorrheal pain relief compared with placebo or low-frequency TENS. (Milsom, 1994; Smith, 1991).

Acupuncture and acupressure have been used for the management of dysmenorrhea. Several studies have evaluated the effectiveness of these complementary alternatives; however, they were of low quality. There is limited evidence that acupuncture may be of benefit.

A 2005 meta-analysis of eight RCTs of surgical interruption of nerve pathways concluded that there was insufficient evidence to advise laparoscopic uterine nerve ablation (LUNA) or laparoscopic presacral neurectomy (LPSN) for primary dysmenorrhea (Proctor, 2005).

SECONDARY DYSMENORRHEA: CAUSES AND MANAGEMENT

Many other conditions cause or are associated with dysmenorrhea. Pelvic disease should be considered in patients who do not respond to NSAIDs or CCs or a combination of these agents for presumed primary dysmenorrhea. The diagnosis should also be considered when symptoms appear after many years of painless menses. Pelvic pathology may occur at any age and, in most cases, the pain experienced is secondary to the pathologic process of the condition or a specific result of it. These constitute the secondary dysmenorrhea group of problems and include cervical stenosis, endometriosis, adenomyosis, fibroids, pelvic inflammation, pelvic congestion, congenital obstructive müllerian

Box 37.1 Causes of Secondary Dysmenorrhea**Gynecologic Pathology**

Cervical stenosis
 Endometriosis and adenomyosis
 Pelvic infection and adhesions
 Uterine polyps or fibroids
 Ovarian cyst or mass
 Pelvic congestion

 Urinary tract disease
 Ureteral obstruction
 Interstitial cystitis
 Nephrolithiasis

malformations, diseases of the gastrointestinal tract, and mental health conditions (Box 37.1)(Howard, 2013).

CERVICAL STENOSIS

Severe narrowing of the cervical canal, particularly at the level of the internal os, may impede menstrual flow, causing an increase in intrauterine pressure at the time of menses. In addition, retrograde menstrual flow through the fallopian tubes into the peritoneal cavity may take place. Thus severe cervical stenosis may eventually be associated with pelvic endometriosis as well. The origin of cervical stenosis may be congenital or secondary to cervical injury, such as with electrocautery, cryocautery, or operative trauma (e.g., conization). The condition may also result from an inflammatory process caused by infection, the application of caustic substances, or hypoenestrogenism. After any of these conditions, the cervical canal may narrow because of the contraction of scar tissue.

The possibility of cervical stenosis should be considered if there is a history of scant menstrual flow and if severe cramping continues throughout the menstrual period. Hematometra or pyometra may occur.

The diagnosis is suspected when the external os appears scarred or when it is impossible to pass a cervical Pap smear brush or uterine sound through the internal os during the proliferative stage of the menstrual cycle. Diagnosis is generally documented by the inability to pass a thin probe of a few millimeters' diameter through the internal os or by a hysterosalpingogram, which demonstrates a thin, stringy-appearing canal. If hysteroscopy and dilation and curettage (D&C) are performed, finding the passage through the internal os with a thin probe is often difficult but can frequently be accomplished with patience. Ultrasound guidance can be of great benefit to reduce the risk of making a false passage. Having the woman self-administer buccal or intravaginal misoprostol before the procedure may aid in the ease with which cervical dilation can be accomplished.

Figure 37.3 Hysteroscopy. Anteroposterior (A) view and lateral (B) views of an 18-year-old patient with severe disabling dysmenorrhea. At hysteroscopy, she was found to have a tissue band across the internal os and an endocervical polyp at this site. Removal of the polyp and transection of the band completely relieved the dysmenorrhea.

Misoprostol is not FDA approved for this particular indication, but many studies have evaluated its effectiveness for procedures such as IUD insertion and hysteroscopy.

Treatment consists of dilating the cervix, which may be accomplished by D&C with progressive dilators or by the use of progressive *Laminaria* tents. Unfortunately, cervical stenosis often recurs after therapy, necessitating repeat procedures. Pregnancy and vaginal delivery often afford a more lasting cure.

Often other problems obstructing the cervix can have a similar presentation. Figure 37.3 shows anteroposterior and lateral views of a hysteroscopy in an 18-year-old nulliparous woman who had a 2-year history of severe disabling dysmenorrhea that usually required morphine therapy with each menstrual period. At hysteroscopy, she was found to have a tissue band across her internal os, at which site a large endocervical polyp had formed. Transecting the band and removing the polyp completely relieved the dysmenorrhea, and she had no further symptoms after 3 years.

ECTOPIC ENDOMETRIAL TISSUE

Endometriosis

The presence of endometrial glands and stroma outside of the uterus defines endometriosis. Endometriosis is a chronic condition that may manifest in generalized pelvic pain, cyclic pain, dysmenorrhea, dyspareunia, infertility, and bowel or bladder dysfunction. This condition affects 6% to 10% of reproductive age women and is found in approximately 70% to 80% with chronic pelvic pain (ACOG, *Practice Bulletin #114*). Approximately one third of women undergoing diagnostic laparoscopy due to chronic pelvic pain (CPP) will have endometriosis confirmed visually or by biopsy. Endometriosis should be considered when there is a history of pain becoming more severe during menses. Pertinent physical findings may include uterosacral ligament nodules, evidence for endometriosis in the vagina or cervix, and lateral displacement of the cervix. Treatment options for endometriosis are discussed in [Chapter 19](#).

Adenomyosis

The presence of endometrial glands and stroma in the myometrium defines adenomyosis. This ectopic endometrial tissue may induce hypertrophy and hyperplasia of the adjacent myometrium. It typically manifests in heavy, painful menses that tends to be progressive. Women may appreciate bulk symptoms as the uterus enlarges.

Koike and colleagues, in an in vitro experiment using tissue slices, found that the prostaglandin level in endometriosis implants is significantly higher than in normal endometrium, myometrium, leiomyomata, and normal ovarian tissue, and that adenomyosis implants produce larger amounts of 6-keto-PGF₁ when the dysmenorrhea has been severe. They believe that prostaglandins in these conditions increase painful menstruation (Koike, 1994). Treatment options for adenomyosis are discussed in [Chapter 18](#).

PELVIC INFLAMMATION

Pelvic infections secondary to gonorrhea, chlamydia, or other microbes may cause pelvic inflammation or pelvic abscess and, with healing, may be associated with pelvic adhesions and tubal damage that may cause pelvic pain. Pelvic inflammatory disease (PID) can lead to chronic pelvic pain in up to 30% of women. This may often be aggravated during menses, causing dysmenorrhea. Infections secondary to other conditions, such as appendicitis or IUD use, may create a similar response. The pain may be secondary to the congestion and edema that occur normally at menses, which may subsequently be aggravated by the healed inflammatory areas and adhesions. Pelvic infections are further discussed in [Chapter 23](#).

PELVIC CONGESTION SYNDROME AND PELVIC VENOUS SYNDROMES

Pelvic congestion syndrome (PCS), which was first described by Taylor in 1949, results from the engorgement of pelvic vasculature. Controversy exists regarding whether this is an actual disorder because it has been difficult to prove. It is a poorly understood disorder of the pelvic venous circulation. PCS is defined by chronic pelvic discomfort (often burning or throbbing in nature) worsened by prolonged standing and intercourse in women who have periovarian varicosities on imaging studies. The etiology of

PCS is unclear and the optimum treatment is uncertain. Development of an evidence-based approach to managing these patients has been limited by the absence of definitive diagnostic criteria.

Physical examination of the vagina and cervix may reveal vasocongestion, uterine enlargement and global tenderness of the cervix, uterus, and adnexa on palpation. Diagnosis is made by history and physical imaging, such as pelvic ultrasound, venography, computed tomography (CT), or magnetic resonance imaging (MRI), and by laparoscopy, which not only rules out other causes of pelvic pain but also demonstrates congestion of the uterus and engorgement or varicosities of the broad ligament and pelvic sidewall veins. If laparoscopy is used for diagnosis, it is important to observe the broad ligament vasculature as the pressure of the carbon dioxide or nitrous oxide is released. At full pressure during the procedure, these vessels may collapse as the pneumoperitoneal pressure exceeds venous pressure, but the dilated veins will reappear as pressure is released.

Other pelvic venous syndromes have been described that can cause pelvic pain and probably include what Taylor first described (Taylor, 1949). Vulvar varices, hypogastric vein insufficiency, and gonadal venous insufficiency have been described in a review of 57 female patients ages 24 to 48 years. Symptoms included pelvic pain, dysuria, dysmenorrhea, and dyspareunia. These disorders are poorly understood and poorly studied, so they often go undiagnosed. Diagnosis in this study was made by physical examination and a variety of radiologic investigations, including Doppler scans, duplex ultrasound scans, CT, MRI, and angiography. No standard therapeutic approach is available, so therapies range from ovarian hormone suppression, local sclerotherapy (for vulvar varices), and embolization of the hypogastric vein to resection of the gonadal vein to hysterectomy. A 2010 systematic review by Tu and coworkers has found 6 diagnostic and 22 treatment studies, but no consensus on diagnostic studies or treatment, although progestins and gonadotropin-releasing hormone (GnRH) agonists were effective in decreasing pain symptoms (Tu, 2010).

MENTAL HEALTH CONDITIONS

In individuals with strong family histories of dysmenorrhea, or when a careful history demonstrates a possibility for societal reward or control because of the symptoms of pain, a conditioned behavior should be considered. It is important to obtain a careful medical and social history and to rule out all other causes of acquired dysmenorrhea. Conditions that may manifest in chronic pelvic pain including dysmenorrhea include somatization, opiate dependency, history of physical or sexual abuse, and depression. Women with chronic pelvic pain often have psychological issues, so careful evaluation of the patient's past and present social situation, administering a depression screen, and performing a mental status exam may be revealing. Referral to a mental health provider may be beneficial for further diagnostic testing, counseling, or medical therapy.

RELATION TO FUNCTIONAL BOWEL DISEASE

Crowell and coworkers studied 383 women ages 20 to 40 using a Neuroticism-Extraversion-Openness (NEO) Personality Inventory on entry into the program, a Moos' Menstrual Distress Questionnaire, and a bowel symptom inventory every 3 months for 12

Figure 37.4 Submucous myoma blocking the internal os causing secondary dysmenorrhea.

months. Dysmenorrhea was diagnosed in 19.8% of these women. Functional bowel disorder, defined as abdominal pain with altered bowel function, occurred in 61% of the women with dysmenorrhea but in only 20% of the others ($P < .05$) (Crowell, 1994). Bowel symptoms were significantly correlated with dysmenorrhea, even after controlling for the effects of neuroticism. Prostaglandin levels in vaginal fluid were elevated in patients with dysmenorrhea but did not consistently differentiate the diagnostic groups. It was concluded that there was a strong covariance of menstrual and bowel symptoms, along with an overlap in their diagnosis, suggesting a common physiologic basis.

In a study of women with irritable bowel syndrome (IBS) and menstrual cycle symptoms, dysmenorrhea was twice as prevalent among women with IBS than controls (21% versus 10%; $P = .09$), although this was not statistically significant. Women with IBS on OCs had significantly less dysmenorrhea than women in the control group who were not on OCs (11% versus 28%, $P = .02$). One case report found an association of celiac sprue and dysmenorrhea, but little is known about this finding.

OTHER CAUSES

At times, dysmenorrhea may be related to unusual pathologic findings. These include small leiomyomas or polyps at the junction of the internal os and lower uterine segment (Fig. 37.4). Such a condition may produce a valvelike effect at the os at the time of menses. Frequently, myomas or polyps become engorged or edematous at the time of menses, accentuating the problem. Diagnosis is generally made by history and by saline infusion sonohysterography, hysterosalpingography, or hysteroscopy. Therapy consists of excising the pathologic tissue. In the case of a myoma, a myomectomy or hysterectomy may be necessary.

There are nongynecologic causes for pain during menses that should be considered in the differential diagnosis. These include appendicitis, lactose intolerance, celiac sprue, abdominal mass, and a number of urinary tract conditions (e.g., urinary tract infection, interstitial cystitis, nephrolithiasis, ureteral obstruction).

PREMENSTRUAL SYNDROME AND PREMENSTRUAL DYSPHORIC DISORDER

Premenstrual syndrome (PMS) is defined as a group of mild to moderate symptoms, physical and behavioral, that occur in the second half of the menstrual cycle and that may interfere with work and personal relationships. Common physical complaints include breast tenderness, bloating, and headache. Common behavioral symptoms may include irritability, anxiety, and depression. These are followed by a period entirely free of symptoms. Frank first described the condition in 1931 and attempted to relate symptoms of then so-called *premenstrual tension* with hormonal changes of the menstrual cycle (Frank, 1931). The term *premenstrual syndrome* was first used by Dalton in 1953. The symptoms vary from woman to woman, and more than 150 symptoms have been linked with the disorder.

Premenstrual dysphoric disorder (PMDD) represents a more severe disorder, with marked behavioral and emotional symptoms. This condition is included in the American Psychiatric Association *Diagnostic and Statistical Manual*, fifth edition (DSM-V) (APA, 2014). PMDD differs from PMS in the severity of symptoms and the fact that women with PMDD must have one severe affective symptom. These include markedly depressed mood or hopelessness, anxiety or tension, affective lability, or persistent anger, which occur regularly during the last week of the luteal phase in most menstrual cycles. A number of physical symptoms may also be present. PMDD also differs from PMS because there is substantial impairment in personal functioning (Box 37.2). PMS and PMDD are similar in that the symptoms manifest in the luteal phase of the menstrual cycle and resolve during menses.

INCIDENCE AND EPIDEMIOLOGY

Premenstrual symptoms occur in 75% of women at some point in their reproductive lives. The incidence of clinically relevant PMS occurs in 3% to 8% of women. Using DSM-V diagnostic criteria, 2% of reproductive-age women will suffer from PMDD (Yonkers, 2016). The average age of onset is 26 years. Likely risk factors for PMS include family history of PMS in the mother, personal past or current psychiatric illness involving mood or anxiety disorders, history of alcohol abuse, and history of postpartum depression. Some studies have found that nulliparity, earlier menarche, higher alcohol and caffeine intake, more stress, and higher body mass index are risk factors for certain PMS symptoms. Studies have supported earlier reports that familial and stress factors play a role in the syndrome. Younger women may experience more severe symptoms of PMDD. Some racial and ethnic differences have been reported, but PMS appears consistently in all cultures studied. Data from a California HMO PMS severity study of 1194 women found that Hispanics reported greater severity of symptoms than whites and blacks, and Asian women reported less (Sternfeld, 2002). Similar to PMS, PMDD prevalence is noted in many countries studied, including Croatia, Italy, Iceland, and Japan. A Japanese study found a 1.2% prevalence of PMDD, suggesting a cultural difference in prevalence or reporting (Gehlert, 2009).

In the Harvard Study of Moods and Cycles by Cohen and colleagues, a population-based, cross-sectional sample of 4164

Box 37.2 Premenstrual Dysphoric Disorder, DSM-V**Diagnostic Criteria****625.4 (N94.3)**

- A. In the majority of menstrual cycles, at least five symptoms must be present in the final week before the onset of menses, start to *improve* within a few days after the onset of menses, and become *minimal* or absent in the week postmenses.
- B. One (or more) of the following symptoms must be present:
 - Marked affective lability (e.g., mood swings; feeling suddenly sad or tearful, or increased sensitivity to rejection).
 - Marked irritability or anger or increased interpersonal conflicts.
 - Marked depressed mood, feelings of hopelessness, or self-deprecating thoughts.
 - Marked anxiety, tension, and/or feelings of being keyed up or on edge.
- C. One (or more) of the following symptoms must additionally be present, to reach a total of *five* symptoms when combined with symptoms from Criterion B above.
 - Decreased interest in usual activities (e.g., work, school, friends, hobbies).
 - Subjective difficulty in concentration.
 - Lethargy, easy fatigability, or marked lack of energy.
 - Marked change in appetite; overeating; or specific food cravings.
 - Hypersomnia or insomnia.
 - A sense of being overwhelmed or out of control.
 - Physical symptoms such as breast tenderness or swelling, joint or muscle pain, a sensation of “bloating,” or weight gain.
- Note:* The symptoms in Criteria A–C must have been met for most menstrual cycles that occurred in the preceding year.
- D. The symptoms are associated with clinically significant distress or interference with work, school, usual social activities, or relationships with others (e.g., avoidance of social activities; decreased productivity and efficiency at work, school, or home).
- E. The disturbance is not merely an exacerbation of the symptoms of another disorder, such as major depressive disorder, panic disorder, persistent depressive disorder (dysthymia), or a personality disorder (although it may co-occur with any of these disorders).
- F. Criterion A should be confirmed by prospective daily ratings during at least two symptomatic cycles. (**Note:** The diagnosis may be made provisionally prior to this confirmation.)
- G. The symptoms are not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication, other treatment) or another medical condition (e.g., hyperthyroidism).

From American Psychiatric Association (APA). Premenstrual dysphoric disorder. In: *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed (DSM-V). American Psychiatric Association: Arlington, VA; 2014.

premenopausal women was studied retrospectively regarding PMDD prevalence. A PMDD diagnosis was made in 6.4% of the women, and PMDD was associated with lower education, a history of major depression, and current smoking (Cohen, 2002). This confirms the results of earlier studies reporting a significant lifetime comorbidity of PMDD and affective disorders. Past sexual abuse has been reported more frequently in women attending PMS clinics compared with women in the general population.

SYMPTOMS

In a review by O'Brien, a number of common somatic and affective symptoms were enumerated (see Box 37.2). The most

common somatic symptoms relate to abdominal bloating, breast tenderness, and various pain constellations, such as headache. Psychological symptoms vary from fatigue, irritability, and tension to anxiety, labile mood, and depression (O'Brien, 1982). In Sternfeld and associates' severity of PMS symptoms study in a health maintenance organization (HMO) population of 1194 women, consistency of symptoms was found over two consecutive cycles, especially for emotional symptoms (Sternfeld, 2002).

Depression is a common complaint in the population in general and also in PMS-PMDD sufferers during the luteal phase. Mortola and coworkers have shown that 16 PMS patients had marked worsening of scores on the Profile of Mood States and Beck Depression Inventory during the luteal phase compared with 16 controls. However, six patients suffering from endogenous depression had scores threefold higher on both indices than PMS patients who were in the luteal phase. Also, the amplitude of cortisol secretion pulses was higher in the depressed patients than in the PMS patients or control patients (Mortola, 1989). The data demonstrate that PMS patients have more episodes of depression during the luteal phase compared with controls, but these episodes are distinctly different from those suffered by patients with endogenous depression. The National Institute of Mental Health's Sequenced Treatment Alternatives to Relieve Depression (STAR-D) trial of clinically depressed women found that 64% of 433 subjects not on OCs reported worsening of their depressive symptoms before menses (Kornstein, 2005). Therefore it can be challenging to differentiate women with PMS from women with depression and premenstrual exacerbations of depressive symptoms.

In addition, Rapkin and colleagues have demonstrated that PMS patients show no deficit in cognitive processing and performance, as well as no loss in ability to concentrate and sustain attention and motivation. No such alterations were seen in 10 PMS patients during the luteal phase. Their performance was similar to nine controls when tested in these areas (Rapkin, 1989). In a later study, this group studied 30 patients with PMS and 31 controls during the follicular and luteal phases. Despite feelings of inadequacy, patients showed no statistically significant differences from controls in tests for attention, memory, cognitive flexibility, and overall mental agility.

A PMS diagnosis not only affects quality of life but also economic issues. Slight increases in direct costs (medical expenses) have been noted. Indirect costs to the employer in work absence and lost productivity amount to \$4333/patient annually.

CAUSES

When Frank first described the syndrome, it was attributed to estrogen excess. Others have offered theories that the disorder is related to an imbalance of estrogen and progesterone, endogenous hormone allergy, hypoglycemia, vitamin B₆ deficiency, prolactin excess, fluid retention, inappropriate prostaglandin activity, elevated monoamine oxidase (MAO) levels, endorphin malfunction, and a number of psychological disturbances. In 1981, Reid and Yen reviewed the subject and concluded that PMS was a multifactorial psychoendocrine disorder (Reid, 1981). Figure 37.5 shows a schematic of the proposed causes. Studies indicate that cyclic gonadal hormonal alterations and serotonergic neuronal mechanisms in the CNS may interact and be major causative factors for PMS in susceptible women. Evidence for this conclusion is indirect but includes successful clinical trials with selective serotonin

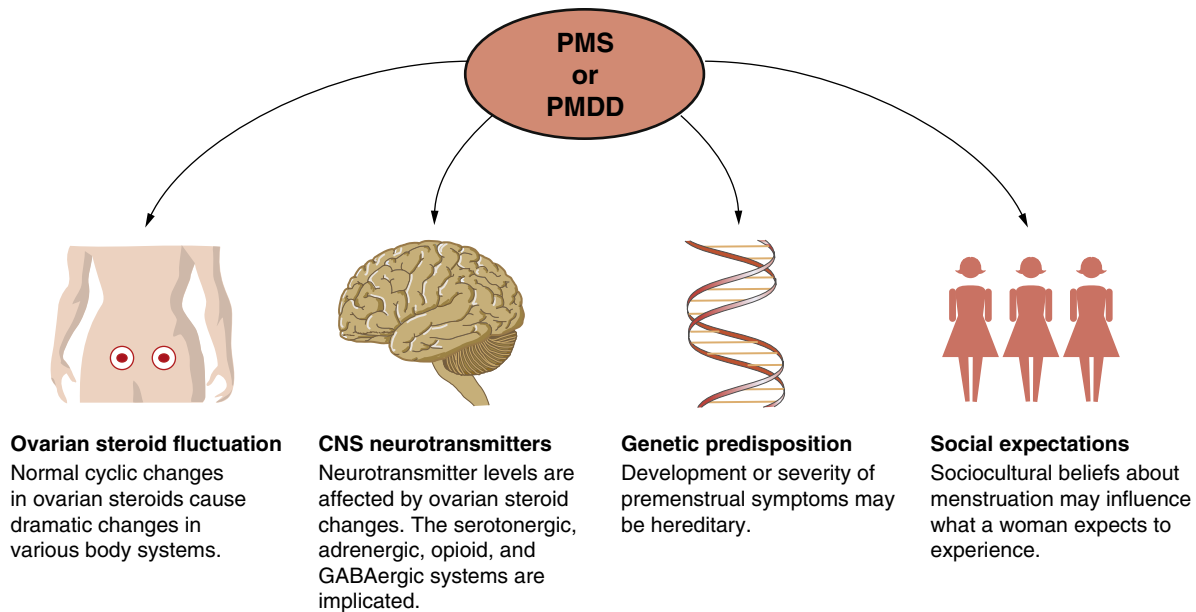

Figure 37.5 Proposed causes of premenstrual syndrome and premenstrual dysphoric disorder. GABA, γ -Aminobutyric acid. (From Ling F, Mortola J, Pariser S, et al. *Premenstrual Syndrome and Premenstrual Dysphoric Disorder: Scope, Diagnosis, and Treatment*. Crofton, MD: Association of Professors of Gynecology and Obstetrics; 1998.)

reuptake inhibitors (SSRIs) and other neurotropic agents thought to affect the serotonin pump mechanism between CNS neurons. Other indirect evidence includes the fact that platelet tritium-labeled, imipramine-binding sites are thought to be reduced in patients suffering from depression and are believed to represent receptor sites that label for a presynaptic serotonin transporter on the presynaptic nerve terminal. In some studies, binding sites returned to normal several months after clinical remission of depression or during the response to psychotropic medications or electroconvulsive therapy. These platelet-binding sites have therefore been used as an indirect measure of the neuron receptor site. Steege and coworkers have demonstrated lower platelet tritium-labeled imipramine binding in women with late luteal phase dysphoric disorder (now called *PMDD*); they believe that this result supported the hypothesis that such patients suffer from alterations of the central serotonergic systems (Steege, 1992). More recently, beta-endorphin and gamma-aminobutyric acid (GABA) neurotransmitters have been implicated. Estrogen has been found to modulate neurotransmitters such as GABA and dopamine, which may serve as inhibitory or excitatory agents in the brain.

That ovarian steroids and, in particular, ovulation and therefore progesterone production are important in this syndrome has been known for some time. Studies related to the relationship of estrogen and progesterone in the circulation and the severity of the symptoms have not been fruitful. There are no consistent differences between estrogen and progesterone levels in PMS sufferers and those in controls. These women may have an abnormal response to normal cyclic ovarian steroid changes. Although symptom relief has been noted in several studies using GnRH agonists to block ovulation completely, no relief was found in a study by Chan and colleagues, who blocked progesterone receptors with the progesterone antagonist RU-486 (Chan, 1994). Rapkin and colleagues have evaluated the anxiolytic 3α , 5α reduced progesterone metabolite allopregnanediol during the luteal phase of 35 women with PMS and 36

controls (Rapkin, 1997). Serum progesterone and allopregnanediol levels were measured on days 19 and 26 of the cycles as determined by luteinizing hormone (LH) kits. Allopregnanediol levels were significantly lower in the PMS patients than controls on day 26, but there were no significant differences with respect to progesterone itself. They concluded that because PMS patients had lower levels of this anxiolytic metabolite during the luteal phase, they could be at greater susceptibility for various mood symptoms such as anxiety, tension, and depression. Allopregnanediol enhances GABA-A receptor function. Chuong and associates have demonstrated that beta-endorphin levels throughout the periovulatory phase are lower in PMS patients than in controls, especially in postovulatory days 0 to 4 (Chuong, 1994). Similarly, Halbreich and coworkers have demonstrated that PMS patients treated with 200 mg/day of danazol for 90 days have complete relief of symptoms in 23 anovulatory cycles, but relief of symptoms occurred in only 6 of 32 ovulatory cycles. They concluded that the beneficial effect of danazol in the treatment of PMS was achieved only when the anovulatory state eliminated the hormonal cyclicality of the normal cycle and not because of action of the drug per se (Halbreich, 1991). O'Brien and Abukhalil have advanced further evidence for this conclusion. They studied 100 women with PMS and premenstrual breast pain using a randomized, double-blind, placebo-controlled study of three menstrual cycles, using danazol, 200 mg/day, as the active drug. Treatment was given only during the luteal phase. Danazol did not effectively reduce the general symptoms of PMS, but it did relieve mastalgia (O'Brien, 1999). Severe PMS has been shown to be relieved by total abdominal hysterectomy and bilateral salpingo-oophorectomy, even with hormone replacement therapy using an estrogen, but some women on cyclic estrogen and progesterone therapy postmenopausally continue to complain of PMS symptoms. A 2003 study by Roca and colleagues has suggested that women with PMS may have an abnormal response to progesterone. Women with PMS failed to show a normal increased luteal phase hypothalamic-pituitary-adrenal axis response to exercise stress testing compared with controls

(Roca, 2003). This response is distinctly different in PMS patients compared with women with major depression.

Another potential causative factor is a genetic contribution. Twin studies have demonstrated a high heritability of PMS symptoms; the concordance rate is twice as high in monozygotic twins than in dizygotic twins.

Concerning other possible causes, most dietary and vitamin deficiency theories have been difficult to prove and have not been found to be a major cause of this syndrome. However, data from Bertone-Johnson and associates' case-control study involving the Nurses' Health Study II cohort (2005) have suggested that a high intake of calcium and vitamin D may reduce the risk of PMS, so further research is needed. Several studies have looked for prolactin excess because some of the women complain of breast tenderness, but no positive findings have been found. Although some of the symptomatology seems to relate to prostaglandin activity, and these symptoms are often reduced with treatment with NSAIDs, a direct cause and effect has not been established.

In summary, the cause of PMS and PMDD is associated with ovarian steroids and ovulation, which seem to produce alterations in neurohormones and neurotransmitters that lead to a reduction of serotonergic function during the luteal phase. The most effective evidence-based treatment for moderate to severe PMS and PMDD symptoms are SSRIs and agents that block ovulation. The temporal relationship between menstrual phase PMS and PMDD symptoms suggests a role of the reproductive hormones—not a direct linear role, but a more complex vulnerability to these cyclic hormonal shifts. Only 60% of women with PMDD respond to SSRI treatment, so serotonergic dysfunction may not be the only pathway involved. Beta-endorphin, GABA, the autonomic nervous system, and social expectations may all play a role in these complex disorders.

DIAGNOSIS

The diagnosis of PMS and PMDD is made by the history of two consecutive menstrual cycles demonstrating luteal phase symptoms of PMS and PMDD. The facts given by the woman may allow the physician to construct a specific, individualized treatment regimen. It is important that the physician have a clear understanding of the woman's symptoms before undertaking therapy. After a complete history and physical examination, the physician should rule out any medical problems that could be influencing the symptomatology. There is limited utility in blood tests; however, it is reasonable to screen for thyroid disease with a serum thyroid-stimulating hormone (TSH). The physician should then ask the woman to keep a diary of her symptoms throughout two menstrual cycles. Although she and her physician may focus on the second half of the menstrual cycle, the woman should be encouraged to keep track of all symptoms, regardless of the stage of the menstrual cycle. A number of validated tools with diary sheets and symptom checklists are available. The Daily Record of Severity of Problems (DRSP) is most commonly utilized. It can be useful to have the woman write the symptoms that she perceives in her own words using validated visual analog scales rather than give her clues to specific response patterns. It is necessary to track symptoms for a full 2 months in order to compare follicular phase symptoms to luteal and menstrual phase data. At the end of two cycles, the physician should review the symptom diary with the woman and carefully

discuss those symptoms that seem to be causing her the most difficulty. A change in the symptom severity score between 30% and 50% between the follicular and luteal phases suggests PMS and PMDD. It can be challenging for women to complete a diary with 2 months of symptoms.

The American College of Obstetricians and Gynecologists (ACOG) defines PMS as the presence of at least one symptom during the luteal phase of the cycle leading to significant impairment in functioning. It is important to differentiate PMS from other illnesses with similar symptomatology. Women with depression and anxiety disorders may present believing that they have PMS. A differentiating aspect is that PMS patients suffer their symptoms only during the luteal phase. Diagnosis can be difficult because women with depression and anxiety disorders can have premenstrual exacerbation of their symptoms, and PMS and PMDD can coexist with psychiatric disorders.

Many women who do not actually have PMS may be self-referred to a facility that treats this condition. In one study, Plouffe and coworkers carefully analyzed 100 consecutive women prospectively entering the uniform diagnostic and treatment protocol for PMS and found that 38 women had PMS, 24 had premenstrual magnification syndrome (i.e., other conditions that were magnified during the luteal phase), and 13 had affective or other psychiatric disorders. Only 44% of the women previously given a diagnosis of PMS were found to have this syndrome. Overall, in this study, 84% of the women with PMS and premenstrual magnification syndrome responded to treatment (Plouffe, 1993). A variety of currently accepted therapies were used.

Other conditions to consider based on patient symptoms include anemia, diabetes, endometriosis, autoimmune disorders, chronic fatigue syndrome, collagen vascular disorders, and many psychiatric disorders (e.g., depression, anxiety, dysthymia, bipolar disorder).

The diagnosis of PMS is therefore made by symptom diary and by the elimination of other diagnoses.

The diagnosis of PMDD is made following the DSM-V criteria, which require 5 of 11 symptoms of PMS, including one affective symptom (APA, 2014). These symptoms should be occurring for most of the preceding year. Affective symptoms include feeling sad or hopeless or having self-deprecating thoughts, anxiety or tension, mood lability and crying, and persistent irritability, anger, and increased interpersonal conflicts. Prospective menstrual cycle charting is required for the diagnosis. Box 37.3 lists physical and psychiatric disorders that should be considered in the differential diagnosis of PMDD.

Box 37.3 Considerations in the Differential Diagnosis of Premenstrual Dysphoric Disorder

- Premenstrual syndrome
- Endometriosis
- Dysmenorrhea
- Physical disorders with premenstrual exacerbations
- Autoimmune disorders
- Diabetes mellitus
- Anemia
- Hypothyroidism
- Psychiatric disorders with luteal phase exacerbation
- Depression
- Anxiety
- Dysthymic disorder
- Bipolar disorder

TREATMENT

Diet, Supplements, Exercise, and Lifestyle Changes

Reassuring women with mild PMS without serious coexisting gynecologic disorders that this is a common problem should be part of the counseling. Thus the selection of medications and lifestyle changes should be tailored to the symptomatic needs of the patient. Lifestyle modifications can be recommended for 2 months while the woman completes the prospective diary for diagnosis.

Several dietary studies have been performed, but most were not rigorously controlled. Two trials have studied increasing complex carbohydrate intake, which reduced the severity of PMS mood symptoms. Complex carbohydrates may increase tryptophan availability and thereby increase serotonin. Because food cravings or increased appetite, mood changes, sleep disturbances and irritability, and fluid retention are listed among the key 17 symptoms, symptom severity may be affected by reducing or eliminating sugar, alcohol, caffeine, salty foods, and red meat.

A multicenter RCT of 466 women has shown that 1200 mg of calcium/day for three cycles reduces PMS symptoms significantly compared with placebo (48% versus 30%; $P < .001$) (Thys-Jacobs, 1998). This is a treatment to cautiously consider, as some amount of calcium supplementation is helpful for bone health. Caution must be taken, however, as higher supplementation may be linked to heart disease.

Vitamin B₆ (pyridoxine) deficiency in PMS patients has been suggested because vitamin B₆ is a coenzyme in the biosynthesis of dopamine and serotonin, and neurotransmitters have been implicated in the cause of PMS. A review of nine RCTs of vitamin B₆ for the treatment PMS found no high-quality trials, although several suggested relief of PMS symptoms over placebo (Wyatt, 1999). A double-blind placebo-controlled trial of 94 women with PMDD found a greater decrease in psychiatric symptoms with 80 mg of vitamin B₆ (Kashanian, 2007). Vitamin B₆ supplement at the rate of 50 mg/day can be tried for mild PMS symptoms. Higher doses of pyridoxine should be administered with caution because neuropathy can occur in patients treated with as little as 200 mg/day. Other side effects, such as sensory deficit, paresthesia, numbness, ataxia, and muscle weakness, may occur.

There is inconclusive evidence from four RCTs that magnesium (200 to 400 mg/day) reduces PMS symptoms (Canning, 2006).

Patients should be encouraged to regularly exercise for general health reasons. A general recommendation is exercise for at least 30 minutes, on most days of the week, including during the luteal phase when symptoms are present. Small trials have suggested aerobic exercise to be beneficial for PMS sufferers, and one trial found high-intensity aerobic exercise to be superior to low-intensity aerobic exercise for PMS treatment.

Many other adjunct treatments as well as complementary and alternative medicines (CAMs) have been studied. These therapies include massage, biofeedback, yoga, acupuncture, chiropractic manipulation, evening primrose oil, and Chinese herbal medicines. A 2009 Cochrane review concluded that there is insufficient evidence to recommend the use of Chinese herbal therapies for this condition (Jing, 2009). A systematic review of several trials has suggested that of all the alternative therapies, bright light therapy, which may increase serotonin, may be a reasonable option for PMDD. Avoiding stressful activities in the luteal phase and having enough sleep may also alleviate PMS and PMDD symptoms.

Cognitive Behavioral Therapy

Studies in the 1950s showed that 50% of patients improved with psychotherapy alone. More recently, Lustyk and coworkers reviewed seven studies, three of which were RCTs, and reported efficacy of cognitive behavioral therapy for the management of PMS and PMDD (Lustyk, 2009). If patients have obvious psychiatric problems, as detected by history, psychotherapy should be added, but it is less effective as a primary therapy. Group psychoeducation in managing symptoms of PMS has been efficacious. Relaxation therapy may benefit patients with significant stress and anxiety components.

Pharmacologic Agents

Psychoactive Drugs

SSRIs have been shown to be extremely effective for treating PMS and have become first-line treatment for PMDD. In 2013, a Cochrane review included 31 RCTs studying 4372 women affected with PMS. Included studies compared paroxetine, sertraline, escitalopram, fluoxetine, or citalopram versus placebo. The authors concluded that both continuous and luteal phase SSRIs were effective for PMS (Marjoribanks, 2013). Medication dosages are generally lower than those used for depression. The onset of action can be rapid, within 1 to 2 days, unlike when SSRIs are used for depression (for dosing, see Table 37.3). Some patients may prefer a luteal phase regimen as it is less expensive and has fewer side effects. This is started on cycle day 14 and continues until the onset of menses or for a few more days thereafter. Even for PMDD, using the psychoactive drugs in only the luteal phase of the menstrual cycle can be effective. However, Shah and colleagues' 2008 meta-analysis of 20 RCTs and 2964 women found that SSRIs are effective for treating PMS and PMDD (OR 0.40; 95% confidence interval [CI]: 0.31-0.51), but intermittent dosing was less effective (OR 0.55) than continuous dosing (OR 0.28) (Shah, 2008). If luteal phase treatment is not effective after 3 months, a trial of continuous SSRIs is warranted. No SSRI was demonstrably better than another. If one SSRI is ineffective, other agents may still be effective. SSRIs are effective in approximately 60% of PMS sufferers. Venlafaxine, a serotonin and norepinephrine reuptake inhibitor, has also been found in RCTs to be more effective than placebo (Freeman, 2001). This medication may be helpful for patients who have side effects or no benefit on other SSRIs. After three cycles of SSRI treatment for PMDD, symptoms recurred with the first cycle after drug discontinuation, suggesting that prolonged therapy may be necessary. Serious adverse effects can occur and must be weighed against the severity of the woman's symptoms.

Approximately 15% of women on SSRIs have significant side effects, including sexual dysfunction (anorgasmia), sleep alterations, GI distress (including nausea), and CNS complaints such

Table 37.3 SSRIs for Premenstrual Dysphoric Disorder

SSRI	Effective Doses
Fluoxetine hydrochloride	20 mg/day
Sertraline hydrochloride	50-150 mg/day
Paroxetine hydrochloride	20-30 mg/day
Paroxetine controlled release (CR)	25 mg/day
Citalopram	20-30 mg/day
Escitalopram	10-20 mg/day

as headache and jitteriness. Some SSRIs can precipitate anxiety reactions, so caution should be used if anxiety symptoms predominate. Increased suicide rates have been observed with some SSRIs, so caution is needed if significant depressive symptoms are noted. This should be a low risk, given the low dose and intermittent luteal phase dosing.

In a carefully performed double-blind, placebo-controlled, crossover study of 19 patients suffering from PMS using alprazolam (Xanax), Smith and coworkers noted that the drug significantly relieved the severity of premenstrual nervous tension, mood swings, irritability, anxiety, depression, fatigue, forgetfulness, crying, cravings for sweets, abdominal bloating, cramps, and headaches compared with the placebo. They prescribed alprazolam, 0.25 mg three times/day, on days 20 to 28 of each cycle and then tapering to 0.25 mg twice daily on day 1 and 0.25 mg on day 2 (Smith 1987). Several RCTs have shown that doses higher than 0.75 mg/day are necessary to reduce PMS symptoms significantly. Alprazolam may be more effective for depressive and anxiety symptoms than for other PMS complaints. However, approximately 50% of women complain of drowsiness and sedation on these doses. Patients with a strong tendency to habituation should not be treated with this regimen. Therefore alprazolam is considered second-line treatment. Buspirone has less addictive potential than alprazolam and has been found in two RCTs to reduce symptoms. Continuous use of psychoactive drugs, such as tricyclics and lithium, has not yielded good PMS symptom relief.

Before using psychoactive drugs, it is extremely important to be sure of the diagnosis, because these drugs may not be effective and may actually be contraindicated in other psychiatric conditions that mimic PMS.

Hormonal Suppression

Progesterone

Although a common treatment previously, many studies to date have shown progestogens to have mixed results in the treatment of PMS and PMDD. In 2012, a Cochrane review concluded that progestin therapy did not show a significant improvement for patients with PMS (Ford, 2009).

Oral Contraceptives

Early RCTs and descriptive studies using cyclic OCs have shown mixed results for the treatment of PMS, but OCs are likely beneficial because they inhibit ovulation. OCs mainly help physical symptoms such as breast pain, bloating, acne, and appetite. If used, monophasic OCs appear to be better. In Sulak and associates' retrospective review of 220 patients using an extended OC regimen and shortened hormone-free interval (3 to 4 days), 45% of patients chose this regimen for control of PMS symptoms and 40% for dysmenorrhea and pelvic pain symptoms (Sulak, 2004). Continuous combined OCs should suppress ovulation and provide symptom relief. A 2005 review found that few studies have reported on premenstrual symptoms on continuous- or extended-use OCs, but relief was noted in headaches, tiredness, bloating, and menstrual pain (Edelman, 2005). Finally, a prospective 2006 study by Coffee and colleagues has shown that an extended regimen of 30 µg of ethinyl estradiol with 3 mg of drospirenone for 168 days significantly reduces PMS symptoms compared with typical 21-day cyclic OCs. The FDA has approved a 20-µg ethinyl estradiol and 3-mg drospirenone combination OC for the treatment of PMDD, although limiting use to women with PMDD who also need contraception

was mentioned. Because of drospirenone's antimineral corticoid and antiandrogenic properties, it has been hypothesized to be more effective (Coffee, 2006). A 2012 Cochrane systematic review supported its efficacy (Lopez, 2012). For women with PMS/PMDD who also desire contraception, this OC is a reasonable first therapy.

Nonsteroidal Anti-inflammatory Drugs

For patients who complain of cramping or other systemic symptoms—such as aches, diarrhea, or heat intolerance—a trial with an NSAID may be useful. RCTs with mefenamic acid and naproxen have shown improvement in pain, mood, and somatic symptoms. It should be noted, however, that a toxic complication of NSAID use is nonoliguric renal failure. Because it is more likely to occur with NSAID use associated with severe dehydration, the agent should be discontinued if severe diarrhea is present and should not be used with diuretics.

Diuretics

Historically, potassium-sparing diuretics were included in treatment consideration if the woman's complaints involve bloating, fluid retention, and a perceived change in body habitus during the luteal phase of the cycle. Study results on efficacy of this treatment, however, have been mixed. Spironolactone (100 mg/day) has been studied in four RCTs; three trials demonstrated moderate efficacy for breast tenderness and fluid retention, and two found reduced irritability symptoms. Diuretics should be avoided in patients with chronic renal disease or in those who are suffering from diarrhea or other fluid loss.

Bromocriptine

Bromocriptine may be used for patients with cyclic mastalgia and may be helpful for some other symptoms of PMS, although its use in any individual case will need to be evaluated. A dose of 5 mg/day during the luteal phase is appropriate.

Gonadotropin-Releasing Hormone Agonists

At least 10 RCTs have shown GnRH agonists (leuprolide, 3.75 mg IM monthly) to be effective for ovulation suppression and treatment of PMS and the physical symptoms of PMDD. GnRH agonists are less effective in treating the psychiatric symptoms of PMDD. However, they are expensive, can have marked side effects, and are limited in duration of use because of hypoestrogenism and osteoporosis. Using add-back estrogen and progesterone has been studied to offset the hypoestrogenic side effects without aggravating PMS and PMDD symptoms. The optimal add-back regimen is unclear from existing studies if GnRH agonists are to be used long term. Minimizing hormonal fluctuations with continuous estrogen and progesterone or minimizing the periods of exposure to progesterone seems prudent.

Surgical Treatment: Bilateral Oophorectomy with or without Hysterectomy

For women with severe, disabling symptoms who have been refractory to other medical therapies, surgical management may be considered. Three observational studies found bilateral oophorectomy, typically with hysterectomy, to be effective in this group of rare patients. Although this approach is not offered as standard therapy for severe PMS, it may be a reasonable alternative for select patients for whom all other treatment regimens have failed. The use of a GnRH analogue for 3 to 6 months, with or without

estrogen add-back, demonstrating efficacy is important prior to determining if the patient may benefit from surgical treatment.

The physician should be cautious when determining a treatment regimen for any individual patient and should attempt to verify the patient's symptoms and add medications

only when relief has not been achieved. Because of the myriad of PMS symptoms, it is not surprising that individualization of treatment is essential. Many of the therapies mentioned, however, offer relief of most symptoms and hope for many sufferers.

KEY POINTS

- Primary dysmenorrhea almost always occurs before the age of 20 years. Secondary dysmenorrhea may occur at any time during the menstrual years.
- Approximately 75% of all women complain of primary dysmenorrhea. Approximately 15% have severe symptoms.
- Education, supportive therapy, and NSAIDs are the treatments of choice for primary dysmenorrhea. Seventy-two percent of women suffering from dysmenorrhea report significant pain relief with this treatment strategy.
- COCs reduce the prevalence and severity of dysmenorrhea. They can be used in extended cycles for better relief. This is also a reasonable first-line treatment, especially if contraception is desired.
- If dysmenorrhea symptoms are not relieved with NSAIDs, OCS, or their combination, additional evaluation for pelvic pathology should be considered.
- Approximately 3% to 8% of all women suffer from clinically relevant PMS, with 2% demonstrating PMDD.
- PMS patients often suffer depression during the luteal phase, but it is not as severe as the depression noted by patients with endogenous depression when measured by standard depression scales. It can be difficult to distinguish PMS from depression with luteal phase exacerbation.
- The most useful diagnostic tool in caring for PMS and PMDD patients is a prospective symptom diary.
- Educating patients about the diagnosis of PMS or PMDD is critical. Exercise along with consideration for judicious calcium or vitamin B₆ supplementation may relieve PMS symptoms.
- Therapy with psychoactive drugs, particularly the SSRIs, has been demonstrated in RCTs to relieve PMS and PMDD symptoms. These medications should be considered first-line therapy. Specific cautions for the use of these agents must be followed. For women who also desire contraception, COCs are a valid option with demonstrated improvement in PMS/PMDD symptoms.

Primary and Secondary Amenorrhea and Precocious Puberty Etiology, Diagnostic Evaluation, Management

Roger A. Lobo

Amenorrhea is defined as the absence of menstrual bleeding and may be primary (never occurring) or secondary (cessation sometime after initiation). **Cryptomenorrhea** is another condition caused by anatomic disorders interfering with the outflow of menses, such as an imperforate hymen or transverse vaginal septum, although these women are actually menstruating. These disorders are discussed in [Chapter 11](#), so they will not be discussed here.

Primary amenorrhea is defined as the absence of menses in a woman who has never menstruated by the age of 15 years ([Practice Committee, American Society for Reproductive Medicine, 2008](#).) Another definition includes girls who have not menstruated within 5 years of breast development, if occurring by age 10. Breast development (thelarche) should occur by age 13 or otherwise requires evaluation as well. The incidence of primary amenorrhea is less than 0.1%. **Secondary amenorrhea** is defined as the absence of menses for an arbitrary period, usually longer than 6 to 12 months. The incidence of secondary amenorrhea of more than 6 months' duration in a survey of a general population of Swedish women of reproductive age was found to be 0.7% but has been cited to be as high as 3%. ([Practice Committee, American Society for Reproductive Medicine, 2008](#).) The incidence is significantly higher in women younger than 25 years and those with a prior history of menstrual irregularity.

Outside the United States, it is common to see women who have been categorized according to the World Health Organization (WHO) classification. WHO type I usually refers to women with low estrogen levels and low follicle-stimulating hormone (FSH) and prolactin (PRL) levels without central nervous system (CNS) lesions; type II refers to a normal estrogen status with normal FSH and PRL levels; WHO type III refers to low estrogen levels and a high FSH level, denoting ovarian failure.

DELAYED MENARCHE

Before the onset of menses, the normal female goes through a progressive series of morphologic changes produced by the pubertal increase in estrogen and androgen production. In 1969, Marshall and Tanner defined five stages of breast development

and pubic hair development ([Marshall, 1969](#); [Carel, 2008](#)) ([Fig. 38.1](#), [Table 38.1](#)). These changes sometimes are combined and called *Tanner*, or *pubertal*, stages 1 through 5. The first sign of puberty is usually the appearance of breast budding followed within a few months by the appearance of pubic hair.

Thereafter, the breasts enlarge, the external pelvic contour becomes rounder, and the most rapid rate of growth occurs (peak height velocity). These changes precede menarche. Thus breast budding is the earliest sign of puberty and menarche the latest. The mean ages of occurrence of these events in American women are shown in [Table 38.2](#) and the mean intervals (with standard deviation [SD]) between the initiation of breast budding and other pubertal events are shown in [Table 38.3](#) ([Frisch, 1971](#)). The mean interval between breast budding and menarche is 2.3 years, with an SD of approximately 1 year. Some individuals can progress from breast budding to menarche in 18 months, and others may take 5 years. As stated previously, if thelarche has not occurred by age 13, a diagnostic evaluation should be performed.

The mean time of onset of menarche was previously thought to occur when a critical body weight of approximately 48 kg (106 lb) was reached. However, it is now believed that body composition is more important than total body weight in determining the time of onset of puberty and menstruation. Thus the ratio of fat to both total body weight and lean body weight is probably the most relevant factor that determines the time of onset of puberty and menstruation. Individuals who are moderately obese, between 20% and 30% above the ideal body weight, have an earlier onset of menarche than nonobese women. Malnutrition, such as occurs with [anorexia nervosa](#) or starvation, is known to delay the onset of puberty.

One of the major links between body composition and the hypothalamic-pituitary-ovarian axis, and thus menstrual cyclicity, is the adipocyte hormone [leptin](#). Leptin is produced by adipocytes and correlates well with body weight. Leptin is also important for feedback involving gonadotropin-releasing hormone (GnRH) and luteinizing hormone (LH) pulsatility and also binds to specific receptor sites on the ovary and endometrium. Leptin administration has been shown to affect LH pulsatile activity ([Laughlin, 1997](#)), and to restore cyclicity in women

Figure 38.1 Pubertal rating according to Tanner stage. **Top row**, Breast development in girls is rated from 1 (prepubertal) to 5 (adult). Stage 2 breast development (appearance of the breast bud) marks the onset of gonadarche. **Bottom row**, For girls, pubic hair stages are rated from 1 (prepubertal) to 5 (adult). Stage 2 marks the onset of adrenarche. (From Herring JA. *Tachdjian's Pediatric Orthopedics: From the Texas Scottish Rite Hospital for Children*. 5th ed. Philadelphia: Elsevier; 2014.)

Table 38.1 Classification of Breast Growth and Pubic Hair Growth

Classification	Description
Breast Growth	
B1	Prepubertal: elevation of papilla only
B2	Breast budding
B3	Enlargement of breasts with glandular tissue, without separation of breast contours
B4	Secondary mound formed by areola
B5	Single contour of breast and areola
Pubic Hair Growth	
PH1	Prepubertal—no pubic hair
PH2	Labial hair present
PH3	Labial hair spreads over mons pubis
PH4	Slight lateral spread
PH5	Further lateral spread to form inverse triangle and reach medial thighs

Table 38.2 Mean Ages of Girls at the Onset of Pubertal Events (United States)

Event	Mean Age \pm SD (yr)
Initiation of breast development	10.8 \pm 1.10
Appearance of pubic hair	11.0 \pm 1.21
Menarche	12.9 \pm 1.20

Modified from Frisch RE, Revelle R. Height and weight in menarche and a hypothesis of menarche. *Arch Dis Child*. 1971;46:695. SD, Standard deviation.

with amenorrhea (Welt, 2004). Another hormone, a gastric peptide, ghrelin, interacts with leptin in this regard particularly when menstrual function is perturbed (Schneider, 2006).

Body weight and body fat content have been shown to be important for menstruation; a fatness nomogram is depicted in Figure 38.2 (Frisch, 1971). Well-nourished individuals

Table 38.3 Pubertal Intervals

Interval	Mean Age \pm SD (Years)
B2—peak height velocity	1.0 \pm 0.77
B2—menarche	2.3 \pm 1.03
B2-PH2	3.1 \pm 1.04
B2-B5 (average duration of puberty)	4.5 \pm 2.04

Modified from Frisch RE, Revelle R. Height and weight in menarche and a hypothesis of menarche. *Arch Dis Child*. 1971;46:695. B2, Initiation of breast development; PH2, appearance of pubic hair; SD, standard deviation.

with prepubertal strenuous exercise programs resulting in less total body fat have also been shown to have a delayed onset of puberty. Warren and colleagues have reported that ballet dancers, swimmers, and runners have menarche delayed to approximately age 15 if they began exercising strenuously before menarche (Warren, 1980) (Fig. 38.3). It is greater in those athletic activities requiring lower body weight, and where success is more subjective (ballet, gymnastics) as compared with swimming. It was also determined that stress per se is not the cause of the **delayed menarche** in these exercising girls, because girls of the same age with stressful musical careers did not have a delayed onset of menarche (Warren, 1980). Young women with strenuous exercise programs have sufficient estrogen to produce some breast development and thus do not need extensive endocrinologic evaluation if concern arises about the lack of onset of menses. Frisch and coworkers have reported that for girls engaged in premenarchal athletic training, menarche is delayed 0.4 year for each year of training. Individuals who exercise strenuously should be counseled that they will usually have a delayed onset of menses, but it is not a health problem. They should be told that they will most likely have regular ovulatory cycles when they stop exercising or become older.

Figure 38.2 Fatness index nomogram. (Modified from Frisch RE, Revelle R. Height and weight in menarche and a hypothesis of menarche. *Arch Dis Child*. 1971;46:695.)

Figure 38.3 Ages of menarche in ballet dancers compared with those of three other groups. (From Warren MP. The effects of exercise on pubertal progression and reproductive function in girls. *J Clin Endocrinol Metab*. 1980;51:1150.)

The metabolic features of amenorrheic athletes, who are considered to be in a state of negative energy balance, are fairly characteristic. These include elevated serum FSH, insulin-like growth factor-binding protein 1 (IGFBP-1), and lowered insulin-like growth factor (IGF) levels.

Emotional stress can lead to inhibition of the GnRH axis. The mechanism involves an increased secretion of corticotropin-releasing hormone (CRH), releasing adrenocorticotrophic hormone (ACTH), opioid peptides such as β -endorphin, and cortisol. CRH itself is known to inhibit GnRH.

Before puberty, circulating levels of LH and FSH are low with an FSH/LH ratio >1 . The CNS–hypothalamic axis is extremely sensitive to the negative feedback effects of low levels of circulating estrogen. As the critical weight or body composition is approached, the CNS–hypothalamic axis becomes less sensitive to the negative effect of estrogen and GnRH is secreted in greater amounts, causing an increase in LH and, to a lesser extent, FSH levels. This release from the prepubertal “brake” on GnRH secretion is depicted in [Figure 38.4](#), which also illustrates the integral role of neuropeptides such as kisspeptin ([Terasawa, 2013](#)). The initial endocrinologic change associated with the onset of puberty is the occurrence of episodic pulses of LH occurring during sleep ([Boyar, 1974](#)) ([Fig. 38.5](#)). These pulses are absent before the onset of puberty. After menarche, the episodic secretions of LH occur during sleep and while awake. The last endocrinologic event of puberty is activation of the positive gonadotropin response to increasing levels of E_2 , which results in the midcycle gonadotropic surge and ovulation.

PRIMARY AMENORRHEA

It is important that the clinician understand the sequential endocrinologic and morphologic chronologic changes taking place during normal puberty so as to make the differential diagnosis between delayed menarche and primary amenorrhea. Although the former condition requires only reassurance, the latter requires an endocrinologic evaluation.

CAUSES OF PRIMARY AMENORRHEA

Although numerous classifications have been used for the various causes of primary amenorrhea, it has been found useful to group causes on the basis of whether secondary sexual characteristics (breasts) and female internal genitalia (uterus) are present or absent ([Box 38.1](#)). Thus the findings on a physical examination can alert the clinician to possible causes and indicate which laboratory tests should be performed. In a series of 62 individuals reported by Mashchak, the largest subgroup with primary amenorrhea (29) were those in whom breasts were absent but where a uterus was present; the second largest subgroup (22) had both breasts and a uterus; lack of a uterus together with breast development accounted for the third largest category (9); and those without breasts or a uterus were the least common (2) ([Mashchak, 1981](#)). This breakdown of the various accompanying conditions of primary amenorrhea reflects the referral pattern to the center and not necessarily the true incidence of each category. Other figures for the prevalence of various types of amenorrhea have been reported.

Breasts Absent and Uterus Present

It would seem logical, as breast development is a biomarker of ovarian estrogen production, that individuals with no breast development and a uterus present have no estrogen production. This is either the result of a primary ovarian disorder or a CNS hypothalamic-pituitary abnormality, which provides the normal signal to the ovary. The phenotype of individuals with either of these causes of low estrogen status is similar.

Figure 38.4 A model for the control of the timing of puberty. The figure depicts the key role of kisspeptin (KP) signaling in generating GnRH release. In the juvenile state (*left panel*) a physiologic “brake” is operational, and in the pubertal state (*right panel*) the “brake” is off, allowing for kisspeptin and GnRH release and a fully integrated negative feedback system for testosterone (blue) in the male or estradiol (gold) in the female. (Modified from Terasawa E, Guerrier KA, Plant TM. Kisspeptin and puberty in mammals. In: Kauffman AS, Smith JT, eds. *Kisspeptin Signaling in Reproductive Biology*. New York: Springer; 2013:253.)

However, because the cause of the disorder and the prognosis for fertility differ, it is important to establish the specific diagnosis.

Gonadal Failure (Hypergonadotropic Hypogonadism)

Failure of gonadal development is the most common cause of primary amenorrhea, occurring in almost 50% of those with this symptom. **Gonadal failure** is most frequently caused by a chromosomal disorder or deletion of all or part of an X chromosome, but it is sometimes caused by another genetic defect and, rarely, 17 α -hydroxylase deficiency. The chromosomal disorders are usually caused by a random meiotic or mitotic abnormality (e.g., nondisjunction, anaphase lag) and thus are not inherited. However, if gonadal development is absent in the presence of a 46,XX (called **pure gonadal dysgenesis**), a gene disorder may be present, because it has been reported to occur in siblings. Rein-dollar reported that all individuals with gonadal failure and an X chromosome abnormality were shorter than 63 inches in height (Reindollar, 1981). Approximately one third also had major cardiovascular or renal anomalies.

Deletion of the entire X chromosome (as occurs in Turner syndrome) or of the short arm (p) of the X chromosome results in short stature. Deletions of only the long arm (q) usually do not affect height. In place of the ovary a band of fibrous tissue called a **gonadal streak** is present (Federman, 1967) (Fig. 38.6). When ovarian follicles are absent, synthesis of ovarian steroids and inhibin does not occur. Breast development does not occur because of the low circulating E₂ levels. Because the negative hypothalamic-pituitary action of estrogen and inhibin is not present, gonadotropin levels are markedly elevated, with FSH levels being higher

than LH. Estrogen is not necessary for müllerian duct development or wolffian duct regression, so the internal and external genitalia are phenotypically female.

An occasional individual with mosaicism, an abnormal X chromosome, pure gonadal dysgenesis (46,XX), or even Turner syndrome (45,X) may have a few follicles that develop under endogenous gonadotropin stimulation early in puberty and may synthesize enough estrogen to induce breast development and a few episodes of uterine bleeding, resulting early in **premature ovarian failure**, usually before age 25. Rarely, ovulation and pregnancy can occur.

Goldenberg reported that all individuals with primary amenorrhea and plasma FSH levels higher than 40 mIU/mL have no functioning ovarian follicles in the gonadal tissue. Thus in women with primary amenorrhea, the diagnosis of gonadal failure can be established if the FSH levels are consistently elevated, without requiring ovarian tissue evaluation.

45,X Anomalies

Turner syndrome occurs in approximately 1 per 2000 to 3000 live births but is much more frequent in abortions. In addition to primary amenorrhea and absent breast development, these individuals have other somatic abnormalities, the most prevalent being short stature (<60 inches in height), webbing of the neck, a short fourth metacarpal, and cubitus valgus. Cardiac abnormality, renal abnormalities, and hypothyroidism are also more prevalent. The diagnosis is usually made before puberty (see Chapter 2).

A wide variety of chromosomal mosaics are associated with primary amenorrhea and normal female external genitalia, the most common being X/XX. In addition, individuals with

Figure 38.5 Plasma luteinizing hormone (LH) concentration measured every 20 minutes for 24 hours in normal prepubertal girl (*upper panel*), early pubertal girl (*center panel*), and normal late pubertal girl (*lower panel*). In top and center panels, sleep histogram is shown above period of nocturnal sleep. Sleep stages are awake, rapid eye movement (REM), and stages I to IV by depth of line graph. Plasma LH concentrations are expressed as mIU/mL. (Modified from Boyar RM, Katz J, Finkelstein JW, et al. Anorexia nervosa: immaturity of the 24-hour luteinizing hormone secretory pattern. *N Engl J Med*. 1974;291:861.)

X/XXX and X/XX/XXX mosaicism have primary amenorrhea. These individuals are generally taller and have fewer anatomic abnormalities than individuals with a 45,X karyotype. In addition, some of them may have a few gonadal follicles and approximately 20% have sufficient estrogen production to menstruate. Occasionally, ovulation may occur, as stated earlier. Isolated phenotypic features of Turner syndrome (without gonadal failure) may also occur in males and is known as *Noonan syndrome*.

Structurally Abnormal X Chromosome

Although individuals with this disorder have a 46,XX karyotype, part of one X chromosome is structurally abnormal. If there is deletion of the long arm of the X chromosome (Xq), normal height has been reported to occur but, in Reindollar's series, these

Box 38.1 Classification of Disorders with Primary Amenorrhea and Normal Female Genitalia

I. Absent breast development; uterus present

A. Gonadal failure

1. 45,X (Turner syndrome)
2. 46,X, abnormal X (e.g., short- or long-arm deletion)
3. Mosaicism (e.g., X/XX, X/XX,XXX)
4. 46,XX or 46,XY pure gonadal dysgenesis
5. 17 α -hydroxylase deficiency with 46,XX

B. Hypothalamic failure secondary to inadequate GnRH release

1. Insufficient GnRH secretion because of neurotransmitter defect
2. Inadequate GnRH synthesis (Kallmann syndrome)
3. Congenital anatomic defect in central nervous system
4. CNS neoplasm (craniopharyngioma)

C. Pituitary failure

1. Isolated gonadotrophin insufficiency (thalassemia major, retinitis pigmentosa)
2. Pituitary neoplasia (chromophobe adenoma)
3. Mumps, encephalitis
4. Newborn kernicterus
5. Prepubertal hypothyroidism

II. Breast development; uterus absent

- A. Androgen resistance (testicular feminization)
- B. Congenital absence of uterus (uterovaginal agenesis)

III. Absent breast development; uterus absent

- A. 17,20-desmolase deficiency
- B. Agonadism
- C. 17 α -hydroxylase deficiency with 46,XY karyotype

IV. Breast development; uterus present

- A. Hypothalamic cause
- B. Pituitary cause
- C. Ovarian cause
- D. Uterine cause

CNS, Central nervous system; GnRH, gonadotropin-releasing hormone.

Figure 38.6 Internal genitalia of patient with gonadal dysgenesis (Turner syndrome), featuring normal but infantile uterus, normal fallopian tubes, and pale, glistening streak gonads in both broad ligaments. (From Federman DD. Disorders of gonadal development: gonadal dysgenesis [Turner syndrome]. In: Federman DD, ed. *Abnormal Sexual Development: A Genetic and Endocrine Approach to Differential Diagnosis*. Philadelphia: WB Saunders; 1967.)

individuals were all relatively short (Reindollar, 1981). They have no somatic abnormalities. However, if there is deletion of the short arm of the X chromosome (Xp), the individual will be short. A similar phenotype occurs in those with isochromosome of the long arm of the X chromosome. Other X chromosome

abnormalities include a ring X and minute fragmentation of the X chromosome.

Pure Gonadal Dysgenesis (46,XX and 46,XY with Gonadal Streaks)

As noted, this abnormality may have a familial/genetic association and has been reported in siblings. Abnormalities in genes involved in gonadal development are expected to be involved. These individuals have normal stature and phenotype, absence of secondary sexual characteristics, and primary amenorrhea. Some of these women have a few ovarian follicles, develop breasts, and may even menstruate spontaneously for a few years.

46,XY gonadal dysgenesis is the result of an abnormal testis in utero. There can be incomplete forms with some degree of testicular tissue, but in this context the “pure” form as a dysgenetic streak as in other forms of ovarian dysgenesis and previously has been referred to as **Swyer syndrome**.

If a Y chromosome is present (as in 46,XY gonadal dysgenesis) or is found as part of a mosaic karyotype, with or without any clinical signs of androgenization, gonadectomy should be performed.

17 α -Hydroxylase Deficiency with 46,XX Karyotype

A rare gonadal cause of primary amenorrhea without breast development and normal female internal genitalia is deficiency of the enzyme 17 α -hydroxylase (P450 C17) in an individual with a 46,XX karyotype (it can also occur in genetic males 46,XY) who may present in a similar fashion. Only a few such individuals have been described in the literature, but it is important for the clinician to be aware of this entity because, in contrast to those described earlier, these individuals have hypernatremia and hypokalemia. Because of decreased cortisol, ACTH levels are elevated. The mineralocorticoid levels are also elevated, because 17 α -hydroxylase is not necessary for the conversion of progesterone to deoxycortisol or corticosterone. Thus there is excessive sodium retention and potassium excretion, leading to hypertension and hypokalemia. Serum progesterone levels are also elevated because progesterone is not converted to cortisol. In addition to sex steroid replacement, these individuals need cortisol administration. They usually have cystic ovaries and viable oocytes. Pregnancies have been documented following in vitro fertilization–embryo transfer (IVF-ET), despite low levels of endogenous sex steroids.

Genetic Disorders with Hyperandrogenism

Hyperandrogenism occurs in approximately 10% of women with gonadal dysgenesis. Most have a Y chromosome or fragment of a Y chromosome, but some may only have a DNA fragment that contains the testes-determining gene (probably *SRY*) without a full Y chromosome. Those with hypergonadotropic hypogonadism and a female phenotype who have any clinical manifestation of hyperandrogenism, such as hirsutism, should have a gonadectomy, even if a Y chromosome is not present, because gonadal neoplasms are frequent.

Central Nervous System–Hypothalamic–Pituitary Disorders
With CNS–hypothalamic–pituitary disorders, the low estrogen levels are caused by an abnormal or absent signal to the ovary, resulting in very low circulating gonadotropin levels. The cause of low gonadotropin production may be morphologic or endocrinologic.

Central Nervous System Lesions

Any anatomic lesion of the hypothalamus or pituitary can cause low gonadotropin production. These lesions can be congenital (e.g., stenosis of aqueduct, absence of sellar floor) or acquired (tumors). Many of these lesions, particularly pituitary adenomas, result in elevated prolactin levels (see [Chapter 39](#)).

However, non–prolactin-secreting pituitary tumors (**chromophobe adenomas**), as well as craniopharyngiomas, may not be associated with hyperprolactinemia and can rarely be the cause of primary amenorrhea with low gonadotropin levels. Thus all individuals with primary amenorrhea and low gonadotropin levels, with or without an elevated prolactin level, should have computed tomography (CT) scanning or magnetic resonance imaging (MRI) of the hypothalamic–pituitary region to rule out the presence of a lesion.

Inadequate Gonadotropin-Releasing Hormone Release (Hypogonadotropic Hypogonadism)

Those without a demonstrable lesion and a low gonadotropin level were previously thought to have primary pituitary failure (**hypogonadotropic hypogonadism**). However, when they are stimulated with GnRH, there is an increase in FSH and LH levels, indicating that the basic defect is either hypothalamic with insufficient GnRH synthesis or a CNS neurotransmitter defect, resulting in inadequate GnRH synthesis, release, or both. Although a single bolus of GnRH may not initially cause a rise in gonadotropin level in these individuals, after 4 days of GnRH administration (priming), the women will have a rise in gonadotropin levels after a single GnRH bolus. Because GnRH secretion occurs after migration of these specific cells from the olfactory lobe to the hypothalamus during embryogenesis, anosmia may also occur in some patients with gonadotropin deficiency. This is caused by a specific defect of the *KAL* gene (Xp 22-3), which is responsible for neuronal migration. Other genetic defects resulting in gonadotropic deficiency may occur on the X chromosome or autosomes and include *FGFR1*, *PROKR2*, and *GNRHR* ([Caronia, 2011](#)) as well as loss of function mutations in the kisspeptin-1 receptor ([Seminara, 2003](#)).

Females with Kallmann syndrome and related forms of gonadotropic deficiency have normal height and an increase in growth of long bones, resulting in a greater wingspan-to-height ratio. Men affected by gonadotropic deficiency have hypogonadism, an increased wingspan-to-height ratio, and altered spatial orientation abilities. Anosmia in Kallmann syndrome must be tested for by blinded testing of certain characteristic smells, such as coffee, cocoa, or orange. Not all women in this category of GnRH deficiency states will have anosmia, which is specific for some patients with Kallmann syndrome.

There is a tendency for GnRH deficiency to be familial/inherited through a variety of mechanisms, although the majority of cases, over two thirds, are sporadic.

Isolated Gonadotropin Deficiency (Pituitary Disease)

Rarely, individuals with primary amenorrhea and low gonadotropin levels do not respond to GnRH, even after 4 days of administration. This is known as **isolated gonadotropin deficiency**. They almost always have an associated disorder such as thalassemia major (with iron deposits in the pituitary) or retinitis pigmentosa. Occasionally, this pituitary abnormality has

been associated with prepubertal hypothyroidism, kernicterus, or mumps encephalitis.

Estrogen Resistance

This rare condition was first described in men and now has been described in a woman (breast absent, uterus present.) A mutation in ER α does not allow estrogen signaling and a biologic response to estrogen action. Endogenous estrogen levels are high, gonadotropins are higher than the normal range (to try to provoke an estrogen response), and the ovaries are cystic. Exogenous estrogen does not normally induce changes except minimal changes with very high pharmacologic doses (Quaynor, 2013).

Breast Development Present and Uterus Absent

Two disorders present with primary amenorrhea are associated with normal breast development and an absence of a uterus: androgen resistance and congenital absence of the uterus. The former is a genetically inherited disorder, whereas the latter is an accident of development and does not have an established pattern of inheritance.

Androgen Resistance

Androgen resistance syndrome, originally termed **testicular feminization**, is a genetically transmitted disorder in which androgen receptor synthesis or action does not occur. It is rare, with an incidence of 1/60,000. The syndrome is caused by the absence of an X-chromosome gene responsible for cytoplasmic or nuclear testosterone receptor function. It is an X-linked recessive or sex-linked autosomal dominant disorder, with transmission through the mother. These individuals have an XY karyotype and normally functioning male gonads that produce normal male levels of testosterone and dihydrotestosterone. However, because of a lack of receptors in target organs, there is lack of male differentiation of the external and internal genitalia (Gustafson, 1994). The external genitalia remain feminine, as occurs in the absence of sex steroids. Wolffian duct development, which normally occurs as a result of testosterone stimulation, fails to take place. Because müllerian duct regression is induced by anti-müllerian hormone (AMH), also called *müllerian-inhibiting substance* (MIS, a glycoprotein synthesized by the Sertoli cells of the fetal testes), this process occurs normally in these individuals because steroid receptors are unnecessary for the action of glycoproteins. Thus women with this disorder have no female or male internal genitalia, normal female external genitalia, and a short or absent vagina. Pubic hair and axillary hair are absent or scanty as a result of a lack of androgenic receptors, but breast development is normal or enhanced. It is known that testosterone is responsible for inhibiting breast proliferation. Thus in androgen resistance, the absence of androgen action allows even low levels of estrogen to cause unabated breast stimulation. Estrogen levels here are in the normal male range, and LH is slightly elevated.

Testes that are intraabdominal or that occur in the inguinal canal have an increased risk of developing a malignancy (gonadoblastoma or dysgerminoma), with an incidence reported to be approximately 20%. However, these malignancies rarely occur before age 20. Therefore it is usually recommended that the gonads be left in place until after puberty is completed to allow full breast development and epiphyseal closure to occur. After these events occur, which is typically around age 18, the gonads should be removed. It is recommended that those with androgen

resistance be informed that they have an abnormal sex chromosome, without specifically mentioning a Y chromosome, because it is widely known that an XY karyotype indicates maleness. Currently, however, some families choose to have full disclosure and a complete understanding of the abnormality. In addition, because psychologically and phenotypically these individuals are female and have been raised as such, the term *gonads* should be used instead of *testes*. These individuals should also be informed that they can never become pregnant because they do not have a uterus and that their gonads must be removed after age 18 because of their high potential for malignancy.

Congenital Absence of the Uterus (Uterine Agenesis, Uterovaginal Agenesis, Mayer-Rokitansky-Küster-Hauser Syndrome)

The *Hox* genes are important for uterine development, and mutations (e.g., in *Hox-A13*) have been found in genetic syndromes with uterine abnormalities (e.g., hand-foot-genital and Guttacher syndromes) and also in cases of bicornuate uterus. To date, however, no abnormalities have been found in cases of congenital absence of the uterus.

This disorder is the second most frequent cause of primary amenorrhea. It occurs in 1 in 4000 to 5000 female births and accounts for approximately 15% of individuals with primary amenorrhea. Individuals with complete uterine agenesis have normal ovaries, with regular cyclic ovulation and normal endocrine function. Women with this disorder have normal breast and pubic and axillary hair development but have a shortened or absent vagina, in addition to absence of the uterus (Jones, 1971) (Fig. 38.7). Although often there are no bulbous structures, but merely streak-line tissue, in 7% to 10% of cases there are two nonfused rudimentary horns as in the figure. On occasion one or both horns may have some functioning endometrium. In this

Figure 38.7 Congenital absence of vagina. Laparotomy revealed rudimentary uterus that showed evidence of failure of fusion of Müllerian ducts. This is a common finding in this condition and indicates that the disorder is more extensive than simple anomaly of the vagina. (Modified from Jones HW Jr, Scott WW, eds. *Hermaphroditism, Genital Anomalies and Related Endocrine Disorders*. 2nd ed. Baltimore: Williams & Wilkins; 1971.)

setting of obstructed outflow, cyclic pelvic pain, which may be severe at times, may be encountered. Congenital renal abnormalities occur in approximately one third of these individuals and skeletal abnormalities in approximately 12%. Cardiac and other congenital abnormalities also occur with increased frequency. Occasional defects in the bones of the middle ear can also occur, resulting in some degree of deafness. The overwhelming majority of these disorders are caused by an isolated developmental defect, but on occasion the condition is genetically inherited. It is usually easy to differentiate these individuals from those with androgen resistance by the presence of normal pubic hair, but some with incomplete androgen resistance have some pubic hair. Because women with congenital absence of the uterus are endocrinologically normal females, and those with androgen resistance are endocrinologically male, with male testosterone levels and an XY karyotype, the differential diagnosis is easily made.

Women in this category are normal endocrinologically and have been able to have children using a surrogate or gestational carrier. Most recently a woman underwent a uterine transplantation from a donated postmenopausal uterus and was able to have a live birth (Brännström, 2015).

Absent Breast and Uterine Development

Individuals with no breast or uterine development are rare. They usually have a male karyotype, elevated gonadotropin levels, and testosterone levels in the normal or below-normal female range. The differential diagnosis for this phenotype includes 17 α -hydroxylase deficiency, 17,20-desmolase deficiency, and agonadism (Mashchak, 1981). Individuals with the first disorder have testes present but lack the enzyme necessary to synthesize sex steroids, and thus have female external genitalia. Because they have testes, AMH-MIS is produced and the female internal genitalia regress; with low testosterone levels, the male internal genitalia do not develop. Insufficient estrogen is synthesized to develop breasts. A similar lack of sex steroid synthesis occurs in males with a 17,20-desmolase deficiency. Individuals with agonadism, sometimes called the *vanishing testes syndrome*, have no gonads present, but because the female internal genitalia are also absent, it has been postulated that testicular AMH-MIS production occurred during fetal life but the gonadal tissue subsequently regressed.

Secondary Sex Characteristics (Breast) Present and Female Internal Genitalia (Uterus) Present

This is the second largest category of individuals with primary amenorrhea, accounting for approximately one third of them. In the series reported by Mashchak, approximately 25% of these individuals had hyperprolactinemia and prolactinomas (Mashchak, 1981). The remaining women had profiles similar to those with secondary amenorrhea and thus should be subcategorized and treated similarly as women with secondary amenorrhea, which will be discussed in a separate section.

Primary Amenorrhea with Absent Endometrium

This is a rare condition in this category of primary amenorrhea with uterus and breast present. Endocrine function is completely normal, as are the uterus, ovaries, and fallopian tubes. However, in two reported cases the endometrium was found to be absent, with repeated biopsies (Berker, 2008; Nigam, 2014). It is likely that some genetic defect is responsible for this rare finding, but

the reported association of a translocation between chromosomes 4 and 20 (Nigam, 2014) is unlikely to be the cause.

DIFFERENTIAL DIAGNOSIS AND MANAGEMENT

After a history is obtained and a physical examination performed, including measurement of height, span, and weight, those with primary amenorrhea can be grouped into one of the four general categories listed in Box 38.1, depending on the presence or absence of breasts and a uterus. If breasts are absent but a uterus is present, the diagnostic evaluation should differentiate between CNS-hypothalamic-pituitary disorders and failure of normal gonadal development. Although individuals with both of these disorders have similar phenotypes because of low E₂ levels, a single serum FSH assay can differentiate between these two major diagnostic categories (Mashchak, 1981) (Fig. 38.8). Women with hypergonadotropic hypogonadism (FSH >30 mIU/mL), not those with hypogonadotropic hypogonadism, should have a peripheral white blood cell karyotype obtained to determine whether a Y chromosome is present. If a Y chromosome is present, the streak gonads should be excised, because the incidence of subsequent malignancy, mainly gonadoblastomas, is relatively high. If a Y chromosome is absent, it is unnecessary to remove the gonads unless there are signs of hyperandrogenism. It is also unnecessary to perform a karyotype on the gonadal tissue to detect possible mosaicism with a Y chromosome in the gonad unless there is some evidence of hyperandrogenism.

All women with an elevated FSH level and an XX karyotype should have electrolyte and serum progesterone levels measured to rule out 17 α -hydroxylase deficiency; a clue is if the patient is hypertensive. In addition to hyponatremia and hypokalemia, individuals with 17 α -hydroxylase deficiency have an elevated serum progesterone level (>3 ng/mL), a low 17 α -hydroxyprogesterone level (<0.2 ng/mL), and an elevated serum deoxycorticosterone level (>17 ng/100 mL) and usually have hypertension. Doses of conjugated equine estrogen (CEE) in the range of 0.625 mg or its equivalent are usually sufficient to cause breast proliferation. These rare individuals with 17 α -hydroxylase deficiency need to have adequate cortisol replacement in addition to sex steroid treatment.

Women with ovarian failure or hypergonadotropic hypogonadism who wish to become pregnant may undergo egg donation. As long as the uterus is normal, which is usually the case, high pregnancy rates in the range of 60% to 70% per cycle may be expected.

If the FSH level is low, the underlying disorder is in the CNS-hypothalamic-pituitary region, and the serum PRL level should be determined. Even if the PRL level is not elevated, all women with hypogonadotropic hypogonadism should have a head CT scan or MRI to rule out a lesion. It is unnecessary to perform a karyotype, because all those with hypogonadotropic hypogonadism are expected to be 46,XX. The use of GnRH testing is optional but is usually clinically unnecessary unless GnRH is going to be used for ovulation induction. Ovulation can be induced in women with this disorder because their ovaries are normal. Initially, they should receive estrogen-progestogen treatment to induce breast development and cause epiphyseal closure. When fertility is desired, human menopausal gonadotropins or pulsatile GnRH should be administered. Clomiphene citrate will be ineffective because of low endogenous E₂ levels.

Figure 38.8 Levels of serum FSH, LH, and estradiol in patients with primary amenorrhea who have an intact uterus and no breast development. *FSH*, Follicle-stimulating hormone; *LH*, luteinizing hormone. (From Mashchak CA, Kletzky OA, Davajan V, et al. Clinical and laboratory evaluation of patients with primary amenorrhea. *Obstet Gynecol.* 1981;57:715.)

The differential diagnosis of androgen resistance from uterine agenesis can easily be made by the presence in the latter condition of normal body hair, ovulatory and premenstrual-type symptoms, biphasic basal temperature, and a normal female testosterone level. Because women with uterine agenesis have normal female endocrine function, they do not require hormone therapy. A renal scan should be performed because of the high incidence of renal abnormalities. They may need surgical reconstruction of an absent vagina (McIndoe procedure), but progressive mechanical dilation with plastic dilators, as described by Frank, should be tried first and is usually successful in motivated individuals, particularly when using pressure from body weight, as with a bicycle seat. These women can now have their own genetic children. After ovarian stimulation and follicle aspiration, fertilized oocytes can be placed in the uterus of a surrogate recipient (gestational carrier). As noted earlier, a case report of a woman having a live birth after uterus transplantation has been reported (Brännström, 2015).

Individuals with androgen resistance have an XY karyotype and male levels of testosterone. After full breast development is attained and epiphyseal closure occurs, the gonads should be removed because of their malignant potential. Thereafter, estrogen therapy should be administered. They do not need progestogen therapy in the absence of a uterus, and lower doses of estrogen are sufficient (see Chapter 14).

The rare individuals without breast development and no internal genitalia should be referred to an endocrine center for the extensive evaluation necessary to establish the diagnosis. If gonads are present, they should be removed, because a Y chromosome is present. Hormone therapy should be administered to these individuals.

SECONDARY AMENORRHEA

CAUSES

The symptom of amenorrhea associated with hyperprolactinemia or excessive androgen or cortisol production will not be considered in this chapter because these disorders are discussed in Chapter 39 and Chapter 40. If amenorrhea is present without galactorrhea, hyperprolactinemia, or hirsutism, the symptom can result from disorders in the CNS-hypothalamic-pituitary axis, ovary, or uterus. In a review of 262 patients presenting with secondary amenorrhea during a 20-year period at a tertiary medical center, Reindollar reported that 12% of cases resulted from a primary ovarian problem, 62% from a hypothalamic disorder, 16% from a pituitary problem (including prolactinomas), and 7% from a uterine disorder. The uterine cause of secondary amenorrhea is the only one in which normal endocrine function is present and will be discussed first.

Uterine Factor

Intrauterine adhesions (IUA) or **synechiae** (Asherman syndrome) can obliterate the endometrial cavity and produce secondary amenorrhea. Rarely, a missed abortion or endometrial tuberculosis can also cause endometrial destruction. The most frequent antecedent factor of IUAs is endometrial curettage associated with pregnancy—either evacuation of a live or dead fetus by mechanical means or postpartum or postabortal curettage. Curettage for a missed abortion results in a high incidence of IUA formation (30%). IUAs may also occur after diagnostic dilation and curettage (D&C) in a nonpregnant woman, so this procedure should be performed only when indicated and not

routinely at the time of other surgical procedures (e.g., diagnostic laparoscopy). A less common cause of IUA is severe endometritis or fibrosis following a myomectomy, metroplasty, or cesarean delivery. This cause of amenorrhea should be considered most likely if a temporal relationship exists between the onset of symptoms and uterine curettage.

Confirmation of the diagnosis is usually made by a hysterosalpingogram (Fig. 38.9) or another form of imaging including hysteroscopy. Although it has been suggested that sequential administration of estrogen-progestogen be used as the initial diagnostic procedure when IUA is suspected, withdrawal bleeding occurs following administration of the estrogen/progestogen in many women with IUA and should not be relied upon.

Central Nervous System and Hypothalamic Causes

Central Nervous System Structural Abnormalities

The same anatomic lesions in the brain stem or hypothalamus, which have been discussed as causing primary amenorrhea (by interfering with GnRH release), can also cause secondary amenorrhea. Hypothalamic lesions include craniopharyngiomas, granulomatous disease (e.g., tuberculosis, sarcoidosis), and sequelae of encephalitis. When such uncommon lesions are present, circulating gonadotropins and E_2 levels are low, and withdrawal uterine bleeding will not occur after progestogen administration.

Drugs

Phenothiazine derivatives, certain antihypertensive agents, and other drugs listed in Chapter 39 can also produce amenorrhea without hyperprolactinemia, although usually the PRL level is elevated. Therefore every individual with secondary amenorrhea

Figure 38.9 Hysterosalpingogram from an infertile woman who had previously undergone a dilation and curettage procedure. Filling defects are noted throughout the cavity. (Courtesy of Dr. MGK Murthy, Dr. Sumer Sethi, Dr. Srujana, and Mr. Verkat. From Sethi S. Asherman syndrome-HSG. In: Sumer's Radiology Blog, 2013. www.sumerdoc.blogspot.com.)

should have a detailed medication history obtained, even if galactorrhea is not present. Oral contraceptive steroids inhibit ovulation by acting on the hypothalamus to suppress GnRH and directly on the pituitary to suppress FSH and LH. Occasionally, this hypothalamic-pituitary suppression persists for several months after oral contraceptives are discontinued, producing the syndrome termed *postpill amenorrhea*. This oral contraception-induced suppression should not last longer than 6 months. It has been reported that the incidence of amenorrhea persisting more than 6 months after discontinuation of oral contraceptives (0.8%) is approximately the same as the incidence of secondary amenorrhea in the general population (0.7%). Thus the reason for amenorrhea persisting more than 6 months after discontinuation of oral contraceptives is probably unrelated to their use, except that the regular withdrawal bleeding produced by oral contraceptives masks the development of this symptom.

Stress and Exercise

Stressful situations, including a sudden change in environment (e.g., going away to school), death in the family, or divorce, can produce amenorrhea. A high percentage of women who had been placed in concentration camps or those sentenced for execution also became amenorrheic as a result of stress.

Feicht and colleagues reported that the incidence of secondary amenorrhea in runners has a positive correlation with the number of miles run per week (Feicht, 1978) (Fig. 38.10). In a comparison of amenorrheic and eumenorrheic athletes, they reported that physical parameters such as age, weight, lean body mass, and body fat were similar. The only significant difference between the two groups was the fact that the amenorrheic athletes ran more miles weekly. McArthur and associates have also reported there is no significant difference in the percentage of body fat in amenorrheic runners compared with runners who were menstruating. Both stress and exercise can increase brain-derived factors that can inhibit GnRH release (CRH, opioid peptides etc.) In a longitudinal study of competitive swimmers, it has been suggested that inhibition of the GnRH axis is characterized by higher levels of catechol estrogens and opioid peptides (particularly β -endorphin [β -EP]). Adashi showed that catechol estrogen infusion can suppress the release of GnRH and LH; and Reid demonstrated the inhibition of LH by β -EP. It is probable that emotionally stressful situations such as divorce or a sudden change

Figure 38.10 Correlation between training mileage and amenorrhea. Each point represents an average of 21 respondents. Statistical significance of relationship was obtained from point-biserial correlation (1 mile [1.6 km]). (From Feicht CB, Johnson TS, Martin BJ. Secondary amenorrhoea in athletes. *Lancet*. 1978;2:1145.)

in environment can also alter brain chemistry. When the stressful situation abates, whether emotional in origin or related to strenuous exercise, normal cyclic ovarian function and regular menses usually resume in a few months.

Weight Loss

Both male and female animals that are malnourished have decreased reproductive capacity. Weight loss is also associated with amenorrhea in women and has been classified into two groups: the moderately underweight group, which includes individuals whose weight is 15% to 25% below ideal body weight, and severely underweight women, whose weight loss is more than 25% of ideal body weight. Weight loss can occur from excessive dietary restrictions as well as malnutrition. Vigersky demonstrated that women with amenorrhea associated with simple weight loss have direct and indirect evidence of **hypothalamic dysfunction**, but pituitary and end organ function is normal. Mason showed that in contrast to women with normal cycles, a group of women with weight loss amenorrhea had similar mean levels of LH as well as LH pulse amplitude, but they had a decreased frequency of LH pulses. Thus the amenorrhea associated with weight loss appears to be caused mainly by failure of normal GnRH release, with the lack of a pituitary response under extreme conditions. Hypoleptinemia, alterations in ghrelin, as well as GH and thyroid dysfunction contribute to these findings.

A severe psychiatric disorder called anorexia nervosa is also associated with severe weight loss and amenorrhea. This condition is covered in [Chapter 9](#).

Polycystic Ovary Syndrome

Polycystic ovary syndrome (PCOS) is a heterogeneous disorder that may present with prolonged periods of amenorrhea, although the more typical menstrual pattern is one of irregularity or oligomenorrhea. Women need not be overweight or obese, or have symptoms and signs of hyperandrogenism, which typically occurs. Although most women will have an elevated serum LH level, this level may be normal, and measurement of LH is not required as a diagnostic criterion. Nevertheless, the diagnosis of PCOS may be confirmed by visualizing polycystic ovaries on ultrasound, particularly in the absence of classic findings such as hyperandrogenism. According to the European Society of Human Reproduction and Embryology–American Society for Reproductive Medicine (ESHRE-ASRM) criteria for the diagnosis of PCOS, women may be diagnosed as having PCOS with only the menstrual disturbance (in this case amenorrhea) and polycystic ovaries seen with ultrasound. This subject is discussed in detail in [Chapter 41](#).

Functional Hypothalamic Amenorrhea

Women with secondary amenorrhea who do not ingest drugs, do not engage in strenuous exercise, are not undergoing environmental stress, have not lost weight, and who have no pituitary, ovarian, or uterine abnormalities have an entity called **functional hypothalamic amenorrhea** (FHA). During normal ovulatory cycles, LH is secreted in a pulsatile manner that varies in frequency and amplitude at different times of the cycle, being more rapid in the follicular phase than in the luteal phase ([Reame, 1984](#)) ([Fig. 38.11](#)). Women with amenorrhea caused

Figure 38.11 Serial measurements of plasma LH and FSH in two subjects sampled every 10 minutes at weekly intervals during cycles in which LH surge was observed on one of the sampling days. E_2 , Estradiol; FSH, follicle-stimulating hormone; LH, luteinizing hormone; P, pregnadiol. (From Reame NE, Sauder SE, Kelch RP, et al. Pulsatile gonadotropin secretion during the human menstrual cycle: evidence for altered frequency of gonadotropin-releasing hormone secretion. *J Clin Endocrinol Metab.* 1984;59:328.)

Figure 38.12 Pulsatile pattern of LH secretion in women with hypogonadotropic hypogonadism and hypothalamic amenorrhea. E_2 , Estradiol; LH, luteinizing hormone; M.F., S.R., and N.D. are the three patients' initials. (From Crowley WF Jr, Filicori M, Spratt DL, et al. The physiology of gonadotropin-releasing hormone [GnRH] secretion in men and women. *Rec Prog Hormone Res.* 1985;41:473.)

by hypothalamic dysfunction do not exhibit these characteristic cyclic alterations in LH pulsatility. They either have no pulses (Crowley, 1985) (Fig. 38.12) or have a persistent pattern of pulsatility that is normally found in only one portion of the ovulatory cycle, usually the slow frequency normally found in the luteal phase, despite having a steroid milieu similar to that in the follicular phase (see Fig. 38.12). Because each LH pulse represents a response to a pulse of GnRH, it appears that those with FHA have an abnormality in the normal cyclic variations of GnRH pulsatility, probably because of an abnormality in the CNS neurotransmitters and possibly produced by increased opioid activity. As reported by Ferin and colleagues, administration of the opioid antagonists naloxone and naltrexone to women with FHA is followed by an increase in frequency of LH pulses, as well as by induction of ovulation (Ferin, 1984).

Berga and associates measured several pituitary hormones at frequent intervals in a 24-hour period in 10 women with FHA and 10 women with normal cycles (Berga, 1989). As also reported by others, they found a 53% reduction in LH pulse frequency among the women with FHA; however, the LH pulse amplitude was similar in the two groups. In addition to reduced secretion of LH, there was reduced secretion of FSH, PRL, and thyroid-stimulating hormone (TSH), as well as altered rhythms of growth hormone (GH) and cortisol with elevated cortisol levels. However, the pituitary response to releasing hormones was unchanged. Thus a number of hormonal alterations occur in FHA as an adaptive central neuroendocrine event. Some data from Tschugguel and Berga have suggested that in stress-induced hypothalamic amenorrhea, hypnotherapy and cognitive behavior therapy may be able to restore ovarian activity (Tschugguel, 2003). Although this is a difficult approach that is not easy to duplicate, it is a logical approach from a physiologic perspective. Also, this method may be beneficial in that chronic stress reduction is generally beneficial for general health and can prevent cardiovascular problems and immune compromise. In a controlled study over 20 weeks, normal ovarian activity was restored in approximately 80% of women (Berga, 2003) (Fig. 38.13).

When sufficient GnRH is produced to facilitate gonadotropin stimulation of the ovaries producing E_2 levels sufficient to proliferate the endometrium (usually about 30 pg/mL), the term *hypothalamic-pituitary "dysfunction"* is used to characterize this

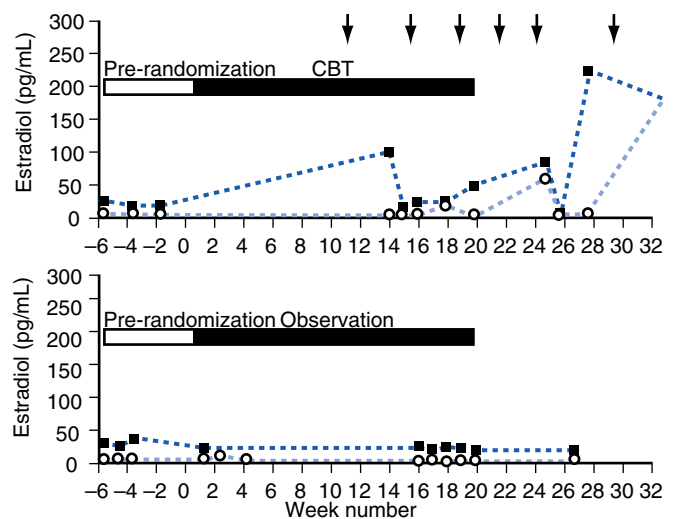

Figure 38.13 Estradiol (dot) and progesterone levels (square) in a woman with functional hypothalamic amenorrhea (FHA) who had a return of ovulatory menstrual cycles while undergoing cognitive behavioral therapy (CBT) (top panel), and estradiol and progesterone levels in a woman with FHA who remained anovulatory and amenorrheic during observation for 20 weeks (bottom panel). (From Berga, SL, Marcus MD, Loucks, et al. Recovery of ovarian activity in women with functional hypothalamic amenorrhea who were treated with cognitive behavior therapy. *Fertil Steril.* 2003;80:976.)

disorder. However, when the E_2 levels fall below 40 pg/mL, the term *hypothalamic-pituitary "failure"* has been used, although these terms are arbitrary. There is not a marked distinction between women with dysfunction and failure, and this designation is merely a matter of severity of the hypothalamic suppression. Also, E_2 levels may fluctuate in this narrow range, and many clinical laboratories are not often able to measure these lower levels accurately. Accordingly, the functional or biologic estrogen status of these patients can be suggested by administering a progestogen. If endogenous E_2 has been sufficient to allow the endometrium to proliferate, then progestogen administration will result in withdrawal bleeding. This can also be determined by visualizing the endometrial stripe by ultrasound scan.

If the thickness is less than 4 mm, hypoestrogenism is clearly present. The importance of knowing the estrogen status of these patients is that with the severe hypoestrogenism of hypothalamic “failure,” bone loss occurs in these young women at a critical time, when attainment of peak bone mass should be occurring (up to age 30).

Pituitary Causes (Hypoestrogenic Amenorrhea)

Neoplasms

Although most pituitary tumors secrete prolactin, some do not and may be associated with the onset of secondary amenorrhea without hyperprolactinemia. Chromophobe adenomas are the most common non-prolactin-secreting pituitary tumors; however, basophilic (ACTH-secreting) and acidophilic (GH-secreting) adenomas may not secrete prolactin. Individuals with the latter types of tumor, although having secondary amenorrhea, frequently have other symptoms produced by these lesions and present to the clinician with symptoms of acromegaly or Cushing disease.

Nonneoplastic Lesions

Pituitary cells can also become damaged or necrotic as a result of anoxia, thrombosis, or hemorrhage. When pituitary cell destruction occurs as a result of a hypotensive episode during pregnancy, the disorder is called *Sheehan syndrome*. When the disorder is unrelated to pregnancy, it is called *Simmonds disease*. It is important to diagnose this cause of secondary amenorrhea because, in contrast to the hypothalamic disorders, pituitary damage can be associated with decreased secretion of other pituitary hormones, particularly ACTH and TSH, in addition to LH and FSH. Specific stimulation studies are needed to characterize the different possible deficiencies. Thus these women may have secondary hypothyroidism or adrenal insufficiency that may seriously impair their health, in addition to their decreased estrogen levels.

Ovarian Causes (Hypergonadotropic Hypogonadism)

The ovaries may fail to secrete sufficient estrogen to produce endometrial growth if the follicles are damaged as a result of infection, interference with blood supply, or depletion of follicles caused by bilateral cystectomies. These women may become amenorrheic after a variable period of time has elapsed following medical treatment of a bilateral tubo-ovarian abscess, after bilateral cystectomy for benign ovarian neoplasms, or sometimes after a hysterectomy during which the vascular supply to the ovaries is compromised (also called *cystic degeneration of the ovaries*).

Occasionally, the ovaries cease to produce sufficient estrogen to stimulate endometrial growth several years before the age of physiologic menopause. When this condition occurs before the age of 40, the term *premature ovarian failure (POF)* or *premature ovarian insufficiency (POI)* (Cooper, 2011) is used instead of premature menopause to best describe the clinical entity. A more in-depth discussion of POI may also be found in Chapter 14.

Coulam estimated that as many as 1% of women younger than 40 years have hypergonadotropic amenorrhea, with the incidence steadily increasing from ages 15 to 39. Frequently, the condition of POI is transient before permanent ovarian failure occurs; occasionally, women with a diagnosis of POI may ovulate and conceive during this transition period. POI frequently occurs after gonadal irradiation or systemic chemotherapy and has also been reported in women with steroid hormonal enzyme deficiencies who menstruate temporarily and then

Figure 38.14 Histology of an ovarian section from a woman with premature ovarian insufficiency, devoid of follicles. (From Ramnani D. Ovarian failure. WebPathology.com, 2015.)

Figure 38.15 Histologic section of an ovary showing follicles up to the preantral stage, which is typical of a woman presenting with insensitive or “resistant” ovary syndrome. (From Shaco-Levy R, Robboy SJ. Normal ovaries, inflammatory and non-neoplastic conditions. In: Mutter GL, Prat J. *Pathology of the Female Reproductive Tract*. 3rd ed. Philadelphia: Elsevier; 2014.)

have secondary amenorrhea. Approximately 16% of women who carry the premutation for Fragile X may experience POI (Allingham-Hawkins, 1999). Other genetic susceptibilities are also known to exist and are discussed in Chapter 14.

Histologically, women with POI have two types of ovarian pathologic findings. In most of them, there is generalized sclerosis similar to the findings of a normal postmenopausal ovary (Fig. 38.14), whereas in up to 30%, numerous primordial follicles with no progression past the early antrum stage are seen, which looks identical to a normal ovary (Fig. 38.15). The latter condition is due either to an **autoimmune state**, which is more common (discussed later), or to a gonadotropin receptor defect and is called **gonadotropin-resistant ovary syndrome**. Women with ovarian resistance syndrome often have primary amenorrhea, but usually sufficient estrogen is produced so that they menstruate for several months or

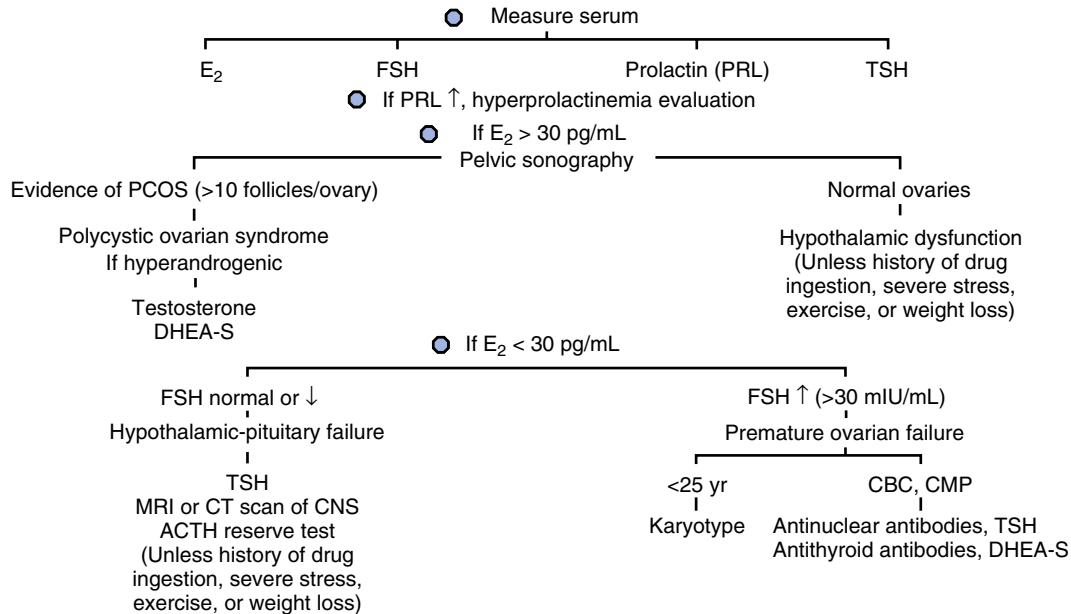

even years. More common are those individuals who have an autoimmune process with autoimmune diseases such as hypoparathyroidism, Hashimoto thyroiditis, or Addison disease. Many women with POI who do not have clinical evidence of an autoimmune disease have antibodies to gonadotropins as well as to several other endocrine organs, such as the thyroid and adrenal glands, suggesting an autoimmune origin. Although it is not recommended to do ovarian biopsies (which requires a full-thickness section) to make this diagnosis, the histologic findings often show lymphocytic infiltration along with the normal histology as shown in [Figure 38.15](#).

Alper estimated that approximately 30% to 50% of women with chromosomally normal POI without a history of irradiation or chemotherapy have an associated autoimmune disease, most commonly thyroid disease, which was present in 85% of the group with an autoimmune disorder ([Alper, 1985](#)). Using sophisticated immunofluorescence techniques, Mignot demonstrated that 92% of women with POI have laboratory evidence of autosensitization ([Mignot, 1989](#)). Approximately two thirds of these were positive for non-organ-specific antibodies, mainly antinuclear antibodies and rheumatoid factors, and 50% had organ-specific antibodies. Although most of these women had no evidence of autoimmune disease, it is recommended that immunologic screening be performed in young women with POI. In the absence of symptoms, such as weakness, lethargy, or pain, which may suggest systemic disease, it is probably sufficient to obtain a complete blood count (CBC) and comprehensive metabolic panel, as well as TSH and antithyroid antibody levels. If adrenal failure (e.g., weakness) is suspected, adrenal antibodies (against 21-hydroxylase) and cortisol may be obtained; rarely, an ACTH stimulation test is warranted. It may be sufficient to obtain

a general screen for adrenal function by obtaining levels of dehydroepiandrosterone sulfate (DHEA-S). Nevertheless some data point to slightly lower (age-specific) levels of DHEA-S in women with POI. Although available clinically, measurements of antiovarian antibodies have not been properly validated.

DIAGNOSTIC EVALUATION AND MANAGEMENT

All women who consult a clinician for the symptom of **secondary amenorrhea** should have a diagnostic evaluation. The clinician should first take a detailed history and perform a physical examination to rule out pregnancy as a cause of the amenorrhea. The possibility of IUAs should be entertained initially. Any instrumentation of the endometrial cavity, particularly temporally related to pregnancy, should alert the clinician to the possibility of IUAs. If IUAs are ruled out, the history should disclose whether medications are currently being used or if oral contraceptives have been recently discontinued. In addition, questions regarding diet, weight loss, stress, and strenuous exercise are pertinent. A history of hot flashes, decreasing breast size, or vaginal dryness and physical examination are helpful in estimating the degree of estrogen deficiency. If the history and physical examination fail to reveal the cause of the amenorrhea, a CBC, urinalysis, and serum chemistries should be carried out to rule out systemic disease. A sensitive thyroid-stimulating hormone (TSH) assay should also be performed to rule out the uncommon asymptomatic thyroid disorders that produce secondary amenorrhea, and serum E_2 , FSH, and prolactin levels should be measured ([Fig. 38.16](#)). If prolactin levels are elevated, a diagnostic

*The threshold level for E_2 is dependent on the normal follicular phase range of the laboratory but is typically around 30 pg/mL.

Figure 38.16 Diagnostic evaluation of secondary amenorrhea. ACTH, Adrenocorticotrophic hormone; CBC, complete blood count; CMP, comprehensive metabolic panel; CNS, central nervous system; CT, computed tomography; DHEA-S, dehydroepiandrosterone sulfate; E_2 , estradiol; FSH, follicle-stimulating hormone; MRI, magnetic resonance imaging; PCOS, polycystic ovary syndrome; TSH, thyroid-stimulating hormone.

evaluation for the cause of this problem should be undertaken (see [Chapter 39](#)). Administration of injectable progesterone or oral progestogen is an indirect means of determining whether sufficient estrogen is present to produce endometrial growth that will slough after the progesterone levels fall (progesterone challenge test). However, it is preferable to order a sensitive E_2 assay, with organic solvent extraction, to determine the true estrogen status. As noted, the thickness of the endometrial stripe on ultrasound is also beneficial.

Women who exercise or who have PCOS, moderate stress, weight loss, or hypothalamic-pituitary dysfunction will usually have E_2 levels of at least 30 pg/mL and withdrawal bleeding after progestogens usually occur. Those with pituitary tumors, ovarian failure, severe dietary weight loss or anorexia nervosa, severe stress, or the rare hypothalamic lesion will usually have very low E_2 levels, typically in the postmenopausal range.

If a sensitive serum E_2 value is above 30 pg/mL, and ultrasound confirms the presence of polycystic ovaries, the diagnosis of PCOS may be considered (see [Chapter 41](#)). If there is no sonographic evidence of polycystic ovaries and the woman has a history of drug ingestion, stress, weight loss, or strenuous exercise, she should be told that hypothalamic-pituitary dysfunction is present and the exact cause cannot be determined with current technology because frequent LH sampling is costly and impractical. She should also be informed that hypothalamic-pituitary dysfunction is usually a self-limiting disorder and not a serious threat to health or a cause of untreatable infertility.

Women with low E_2 and low FSH levels have a CNS lesion or hypothalamic-pituitary failure. Women with low E_2 and elevated FSH levels (>30 mIU/mL) have POI. If severe weight loss, strenuous exercise, or severe stress is not present, and FSH and E_2 levels are low, CT or MRI of the hypothalamic-pituitary region should be performed to rule out a lesion, even if the prolactin level is normal. If a lesion is seen or if there is a history compatible with possible **pituitary destruction** (hypotension during pregnancy), a test of ACTH reserve should be performed. An **insulin tolerance test** in which hypoglycemia is induced should normally cause a cortisol increase of 7 μ g/100 mL within 120 minutes and is a satisfactory test of ACTH function. An alternative test is administration of CRH. If no lesion is identified, the term *hypothalamic-pituitary failure* may be used as a nonspecific diagnosis. Frequently, individuals with this diagnosis resume normal ovarian function without treatment.

If POI is diagnosed because of an elevated FSH level and no cause of ovarian destruction is elicited, the possibility of autoimmune disease should be considered, particularly in younger women. Therefore antithyroid and antinuclear antibody levels should be measured and other screening tests should be performed, as noted previously. Although commercially available tests for antiovarian and antiadrenal antibodies are available, they are not measured routinely.

To rule out mosaicism or a dysgenetic gonad, including the possibility of a Y cell line, a karyotype should be obtained in women with POF who are 25 years of age or younger. Biopsy of the gonads by laparoscopy or laparotomy is not indicated. Suppression of gonadotropin levels with estrogen, oral contraceptives, and GnRH analogues has been advocated to induce rebound ovulation following their withdrawal. Although these agents suppress gonadotropins, these techniques are usually

ineffective for inducing ovulation. If ovulation occurs following such treatment, it is a sporadic event and not a result of the therapy. Most cases of spontaneous pregnancy have occurred during estrogen replacement.

The appropriate treatment depends on the diagnosis and on whether conception is desired. Non-prolactin-secreting pituitary tumors should be surgically excised, if possible. Those who have lost weight should be advised to gain weight. If strenuous exercise results in low estrogen levels (<30 pg/mL), the amount of exercise should be reduced or estrogen supplementation administered to prevent possible development of osteoporosis. Several investigators have shown that amenorrheic and oligomenorrheic athletes with decreased E_2 levels have decreased density of trabecular bone in the lumbar spine ([Lloyd, 1988](#)) ([Fig. 38.17](#)).

Klibanski showed that women with low E_2 levels caused by hypothalamic amenorrhea who have normal nutrition and activity levels have a profound reduction in spinal bone mineral density. The reduction in bone loss is independent of whether the PRL level is elevated or not. Bone loss has been found to be similar in hyperprolactinemic amenorrheic women with low estrogen levels and women with normal prolactin and low estrogen levels ([Fig. 38.18](#)). A group of women with hyperprolactinemia and regular menses did not have bone loss.

If women with PCOS or hypothalamic-pituitary dysfunction desire conception, clomiphene citrate or letrozole administration is successful in inducing ovulation. If pregnancy is not desired, periodic progestogen administration (medroxyprogesterone acetate, 10 mg/day, for 10 to 12 days) should be given to reduce the increased risk of endometrial cancer associated with unopposed estrogen. It may be sufficient to administer the progestogen every 3 months. If a woman with hypothalamic-pituitary "failure" (low estrogen levels) desires fertility, ovulation can be induced with exogenous gonadotropins or pulsatile GnRH. Clomiphene is not successful if the estrogen

Figure 38.17 Relationship between bone density and number of missed menses in collegiate women athletes. For each subject, number of missed menses was determined from her menarche to age 19. Asterisk indicates a significant difference from the control group. (From Lloyd T, Myers C, Buchanan JR, et al. Collegiate women athletes with irregular menses during adolescence have decreased bone density. *Obstet Gynecol.* 1988;72:639.)

Figure 38.18 Spinal bone density in 13 women with hyperprolactinemic amenorrhea (top panel), 12 eumenorrheic hyperprolactinemic women (middle panel), and 11 women with hypothalamic amenorrhea (bottom panel). Mean (solid lines) and standard deviation (\pm SD, dashed lines) for 19 normal women are shown. (From Klibanski A, Biller BM, Rosenthal DI, et al. Effects of prolactin and estrogen deficiency in amenorrheic bone loss. *J Clin Endocrinol Metab.* 1988;67:124.)

levels are low. If pregnancy is not desired, estrogen-progestogen treatment is indicated for all amenorrheic women with low E_2 levels, including those with POI, to reduce the risk of osteoporosis. Young women with POI and chronic hypothalamic hypogonadotropic status are also vulnerable to accelerated atherosclerosis. There is no increased cardiovascular risk in prescribing estrogen to these women. Women with POI may become pregnant with the use of donor oocytes and the priming of their endometrium with estrogen and progesterone for embryo transfer.

PRECOCIOUS PUBERTY

Puberty in the female is the process of biologic changes and physical development, after which sexual reproduction becomes possible. This is a time of accelerated linear skeletal growth and development of secondary sexual characteristics, such as breast development and the appearance of axillary and pubic hair. The usual sequence of the physiologic events of puberty begins with breast development and the subsequent appearance of pubic and axillary hair, followed by the period of maximal growth velocity and, finally, menarche. Menarche may occur before the appearance of axillary or pubic hair in 10% of normal females. Normal puberty occurs over a wide range of ages. Figure 38.19 gives the mean and ranges for pubertal onset and types of development in girls (Lee, 2003). The rate of growth is also of interest. Prior to breast development the growth velocity is close to 6 cm/year. At peak height velocity, around age 12, the velocity is around 8 cm/year; and by the completion of puberty, around age 14, the velocity is down to 1 cm/year, explained by closure of the epiphyses (Biro, 2006).

Precocious puberty is arbitrarily defined as the appearance of any signs of secondary sexual maturation at an early age. Puberty in girls is now recognized to be occurring earlier than in previous studies (Table 38.4). In an article by Kaplowitz and associates, it was suggested that girls with breast development or pubic hair should be evaluated when these signs occur before age 7 in whites and age 6 in black girls (Kaplowitz, 1999). This has been somewhat controversial, and others have suggested that an evaluation is not warranted until age 8 in girls, because suggesting a diagnosis earlier may mask the ability to identify other diseases (Midyett, 2003). Accordingly, we favor carrying out a complete evaluation of precocious puberty at 8 years of age.

Precocious puberty is associated with a wide range of disorders. It should be emphasized that regardless of the cause, precocious puberty is a rare disorder. The incidence of this condition in the United States is estimated to be approximately 1 in 10,000 young girls. When it is diagnosed, the physician should undertake a detailed investigation of the cause of the condition so as not to overlook a potentially correctable pathologic lesion. The two primary concerns of parents of children with precocious puberty are the social stigma associated with the child being physically different from her peers and the diminished ultimate height caused by the premature closure of epiphyseal growth centers.

Puberty is a time of accelerated growth, skeletal maturation, and resulting epiphyseal closure. Although precocious puberty may occur early in a child's life, it usually develops in the normal sequence. Early in the course of the disease the girls are taller and heavier than their chronologic peers who have not experienced the growth spurt (Fig. 38.20). However, although the patient is tall as a child, her eventual adult height will be shorter than normal because of premature closure of the epiphyses. Without therapy, approximately 50% of girls with precocious puberty will not reach the height of 5 feet.

TYPES OF DISORDERS

Precocious puberty is subdivided into GnRH dependent (complete, true) and GnRH independent (incomplete, pseudo), and these causes have been subcategorized as feminizing (previously termed isosexual) or virilizing (previously termed heterosexual) disorders. These categories are of clinical value only after the eventual diagnosis has been established. The pathophysiology

Puberty and its disorders. In: Lifshitz F, ed. *Pediatric Endocrinology*. 4th ed. New York: Marcel Dekker; 2003:212.)

Table 38.4 Prevalence of Breast and Pubic Hair Development in White and Black Girls*

Parameter	AGE RANGE (YR)				
	5.00-5.99	6.00-6.99	7.00-7.99	8.00-8.99	9.00-9.99
Prevalence of breast development at Tanner stage 2 or higher (%)					
White girl	1.6	2.9	5.0	10.5	32.1
Black girl	2.4	6.4	15.4	37.8	62.6
Prevalence of pubic hair development at Tanner stage 2 or higher (%)					
White	0.4	1.4	2.8	7.7	20.0
African American	3.4	9.5	17.7	34.3	62.6

From Kaplowitz PB, Oberfield SE. Reexamination of the age limit for determining when puberty is precocious in girls in the United States: Implications for evaluation and treatment. Drug and Therapeutics and Executive Committees of the Lawson Wilkins Pediatric Endocrine Society. *Pediatrics*. 1999;104:937.

*Between 5 and 10 years of age.

and corresponding categories of precocious puberty may change during the course of the disease; for example, congenital adrenal hyperplasia initially is GnRH independent but subsequently, over many months, eventually becomes a GnRH dependent form of precocious puberty.

The pathophysiology of precocious puberty is divided into two distinct categories: a normal physiologic process involving GnRH secretion with an integrated hypothalamic-pituitary axis, which occurs at an abnormal time, or an abnormal physiologic process independent of an integrated hypothalamic-pituitary-ovarian axis.

GnRH dependent precocious puberty involves premature maturation of the hypothalamic-pituitary-ovarian axis and includes normal menses, ovulation, and the possibility of pregnancy. GnRH independent precocious puberty involves premature female sexual maturation, which may lead to estrogen-induced uterine stimulation and bleeding without any normal ovarian follicular activity. Both categories have increased circulating levels of estrogen. In the latter syndrome, however, secretion of estrogens is independent of hypothalamic-pituitary

control. Depending on when the patient is first seen in relationship to the natural history of her disease, it may be necessary to observe her at regular intervals (for 2 to 3 years) to distinguish one syndrome from another (Table 38.5). Prolonged follow-up is sometimes necessary to rule out subtle, slow-growing lesions of the brain, ovary, or adrenal gland.

The majority of girls with precocious puberty (70%) develop a GnRH-dependent process. Figure 38.4 depicts the normal maturation of the HPO axis, with the integral role of kisspeptin facilitating GnRH release with puberty occurring when the physiologic “brake” is off. The exact cause of most cases of GnRH dependent precocious puberty is unknown (constitutional); however, approximately 30% are secondary to CNS disease. Kisspeptin, a hypothalamic peptide that stimulates the release of GnRH, is involved in the initiation of puberty. Two activating mutations of the kisspeptin receptor have been described in girls with central precocious puberty (Teles, 2008; Silveira, 2010). Another genetic mutation (MKRN3) has been found in a number of affected families (Abreu, 2013).

Figure 38.20 Child age 7 years with constitutional precocious puberty. Note increased height for age. (From Dewhurst CJ. *Practical Pediatric and Adolescent Gynecology*. New York: Marcel Dekker; 1980.)

A definitive diagnosis is established more often for pseudoprecocious puberty, which is usually related to an ovarian or adrenal disorder. If the secondary sex characteristics are discordant with the genetic and phenotypic gender, the condition is termed *heterosexual* or *virilizing precocious puberty*. This is premature virilization in a female child and includes development of masculine secondary sexual characteristics. The androgens that cause heterosexual precocious puberty usually come from the adrenal gland.

Premature Thelarche

Premature thelarche is defined as isolated unilateral or bilateral breast development as the only sign of secondary sexual maturation. It is not accompanied by other associated evidence of pubertal development, such as axillary or pubic hair or changes in vaginal epithelium. Estrogen levels are normal (prepubertal) as shown in the [Figure 38.21](#) together with estrogen levels in pubertal girls, those with precocious puberty and adults ([Escobar, 1976](#)). Breast hyperplasia is a normal physiologic phenomenon in the neonatal period and may persist until the child is up to 6 months of age. Premature thelarche usually occurs in 2 waves: within the first 2 years, and between ages 6 and 8. The breast buds enlarge to 2 to 4 cm, and sometimes this process is asymmetric. Nipple development is absent. This is a benign self-limiting condition that does not require treatment. Often, the breast enlargement spontaneously regresses. It is important to observe these children closely for other signs of precocious puberty. It is associated with normal linear growth and a normal bone age. The cause of premature thelarche is not understood. It has been postulated to be related to a slight increase in estrogen-like activity, either due to transient low circulating estrogen levels (from transient ovarian follicular activity) or from exogenous sources including the possibility of exposure to environmental or dietary estrogen mimics. This disorder may be associated with female infants who had extremely low birth weights.

Table 38.5 Physical Findings among Patients with Various Precocious Puberty Syndromes

Findings	Premature Thelarche	Premature Adrenarche	GnRH-DEPENDENT AND GnRH-INDEPENDENT SYNDROMES			
			Idiopathic	McCune-Albright Syndrome	Central Nervous System Tumor	Hypothyroid
Breast enlargement	Yes	No	Yes	Yes	Yes	Yes
Pubic hair	No	Yes	Yes	Yes	Yes	Unusual

Gonadotropin-Releasing Hormone-Independent Precocious Puberty

The most common cause of pseudo or feminizing precocious puberty is an estrogen-secreting ovarian cyst or large functioning follicle. Granulosa cell tumors are the most common type of solid ovarian tumor resulting in precocious puberty. These tumors are usually larger than 8 cm in diameter when associated with precocious puberty; 80% can be palpated abdominally. Other ovarian tumors that may be associated with precocious puberty include thecomas, luteomas, teratomas, Sertoli-Leydig tumors, choriocarcinomas, and benign follicular cysts. Usually, thecomas and luteomas are much smaller than granulosa cell tumors and cannot be palpated. Overall, these tumors are rare during childhood, with only 5% of granulosa cell tumors and 1% of thecomas occurring before puberty. The ability of many tumors, including teratomas, choriocarcinomas, and dysgerminomas, to secrete estrogen, human chorionic gonadotropin (hCG), α -fetoprotein, and other markers has been established.

Adrenocortical neoplasms may produce isosexual (feminizing) or heterosexual (virilizing) precocious puberty. The relationship between congenital adrenal hyperplasia and puberty depends on the time of initial diagnosis and therapy. If the disease is diagnosed in the neonatal period and treated, normal puberty ensues. If the disease is untreated, the girl usually develops heterosexual precocious puberty (signs of androgen excess) from the adrenal androgens over time. However, if congenital adrenal hyperplasia is diagnosed late in childhood, isosexual precocious puberty may follow initial treatment of the adrenal disease. In this category, apart from adrenal imaging, measurements of steroids to rule out the various forms of adrenal hyperplasia due to enzymatic deficiencies (e.g., 21- or 11 β -hydroxylase or 3 β -ol dehydrogenase) have to be carried out.

McCune-Albright syndrome (MAS) is a rare condition caused by a mutation in the G3 protein leading to activation of adenylate cyclase (Shenker, 1993). This leads to a constant stimulation of pituitary hormones, including FSH, LH, TSH, and GH. It presents as precocious puberty with the first sign usually being vaginal bleeding. Clinically there is a triad of café-au-lait spots, polyostotic fibrous dysplasia, and cysts of the skull and long bones (Fig. 38.22). These patients also have facial asymmetry. Apart from vaginal bleeding due to high levels of estrogen from ovarian cysts that develop from constant stimulation, there are bony defects and a lifetime increased risk of malignancy.

Iatrogenic or factitious precocious puberty results when a young female has used hormone cream or ingested adult medications such as oral estrogen or birth control pills. The secondary sexual characteristics regress after discontinuation of the medication.

DIAGNOSIS

The diagnostic workup of a young child with precocious puberty begins with a meticulous history and physical examination. The primary emphasis should be to rule out life-threatening neoplasms of the ovary, adrenal gland, or CNS. The secondary emphasis is to delineate the speed of the maturation process, because this is crucial in making decisions concerning therapy. The height of the girl and exact stage of pubertal development, including Tanner stage, should be recorded. Similar to other syndromes with a long list of causes, a number of tests, including imaging studies of the brain, serum estradiol level, FSH level, and thyroid function tests, may have to be carried out to establish the diagnosis. With the acceleration of development, the sex steroid and adrenal androgen (DHEA-S) levels are elevated, regardless of the cause. Acceleration of growth is one of the

Figure 38.22 A 5-year-old girl with precocious puberty and McCune-Albright syndrome. Note the breast development and the typical café-au-lait spots, the pattern of which is referred to as “the coast of Maine.” (From Dumitrescu CE, Collins MT. McCune-Albright syndrome. *Orphanet J Rare Dis*. 2008;3:12.)

earliest clinical features of precocious puberty. Thus bone age should be determined by hand-wrist films and compared with standards for a patient's age (Fig. 38.23). Usually, these films are repeated at 6-month intervals to evaluate the rate of skeletal maturation and the corresponding need for active treatment of the disease. Advancement of bone age more than 95% of the norm for the child's chronologic age indicates an estrogen effect.

Diseases of the CNS are suggested by symptoms such as headaches, seizures, trauma to the head, and encephalitis. These conditions are confirmed or excluded by a series of tests, including neurologic and ophthalmologic examinations, EEGs, and brain imaging.

Hypothalamic hamartomas can be categorized based on the tumor topology on MRI. This classification has been shown to

correlate with the clinical manifestations of precocious puberty. Ultrasound, CT, or MRI of the abdomen and pelvis should be performed to evaluate enlargement of the ovaries (ovarian volume), uterus, or adrenal glands.

Serum levels of FSH, LH, prolactin, TSH, E_2 , testosterone, DHEA-S, hCG, androstenedione, 17-hydroxyprogesterone, triiodothyronine (T_3), and thyroxine (T_4) may be of value in establishing the differential diagnosis.

A GnRH agonist stimulation test is diagnostic in differentiating incomplete from true precocious puberty as described previously, but it does not specifically identify children with CNS lesions. See Table 38.6 for summary.

TREATMENT

The treatment of precocious puberty depends on the cause, extent, and progression of precocious signs and whether the cause may be removed operatively. For example, removal of a granulosa cell tumor and subtotal removal of a hypothalamic hamartoma are successful treatments because they remove the hormonal force. Because most cases involve premature maturation of the hypothalamic-pituitary-ovarian axis without a lesion, this discussion will focus on the medical management of this condition. Girls with menarche before age 8 years, progressive thelarche and pubarche, and bone age 2 years more than their chronologic age definitely should be treated. The goals of therapy are to reduce gonadotropin secretions and reduce or counteract the peripheral actions of the sex steroids, decrease the growth rate to normal, and slow skeletal maturation to allow development of maximal adult height.

The present drug of choice for GnRH dependent precocious puberty is one of the potent GnRH agonists, which have been studied extensively (Tanaka, 2005; Badaru, 2006). These drugs are typically given by monthly or trimonthly injections or, rarely, intranasally. GnRH agonists are safe and effective treatments for children with the disease secondary to disturbances in the hypothalamic-pituitary-ovarian axis. Therapy should be initiated as soon as possible after the diagnosis is established so that the child can achieve maximal adult height. The effect on adult height depends on the chronologic age at which therapy is initiated. Therapy is most effective in 4- to 6-year-olds. Continuous chronic administration of the drug is maintained until the median age of puberty. The optimal dosage of medication may be confirmed by determining that peripheral E_2 levels are in a normal prepubertal range. Medical treatment produces involution of secondary sexual characteristics, with amenorrhea and regression of breast development and amount of pubic hair. LH and FSH pulsations are abolished. Most important, the drug

Figure 38.23 Hand and wrist X-rays used for the assessment of skeletal age taken from an assessment atlas. **A**, The standard for boys 48 months old and girls 37 months old; the standard for boys 156 months old and girls 128 months old. **B**, Note that greater ossification has occurred in the small wrist bones and the larger ossified area at the epiphyseal plates of the hand bones and the forearm bones. (From Pyle SI. *A radiographic standard of reference for the growing hand and wrist*. Chicago: Year Book Medical; 1971:53:73.)

Table 38.6 Laboratory Findings in Disorders Producing Precocious Puberty

Disorder	Gonadal Size	Basal FSH, LH	FINDINGS		
			Estradiol or Testosterone	DHAS	GnRH Response
Idiopathic	Increased	Increased	Increased	Increased	Pubertal
Cerebral	Increased	Increased	Increased	Increased	Pubertal
Gonadal	Unilaterally increased	Decreased	Increased	Increased	Flat
Albright	Increased	Decreased	Increased	Increased	Flat
Adrenal	Small	Decreased	Increased	Increased	Flat

Modified from Speroff L, Glass RH, Kase NG. *Clinical Gynecology Endocrinology and Infertility*. 6th ed. Baltimore: Lippincott Williams & Wilkins; 1999:396. DHAS, Dehydroepiandrosterone sulfate; GnRH, gonadotropin-releasing hormone; FSH, follicle-stimulating hormone; LH, luteinizing hormone.

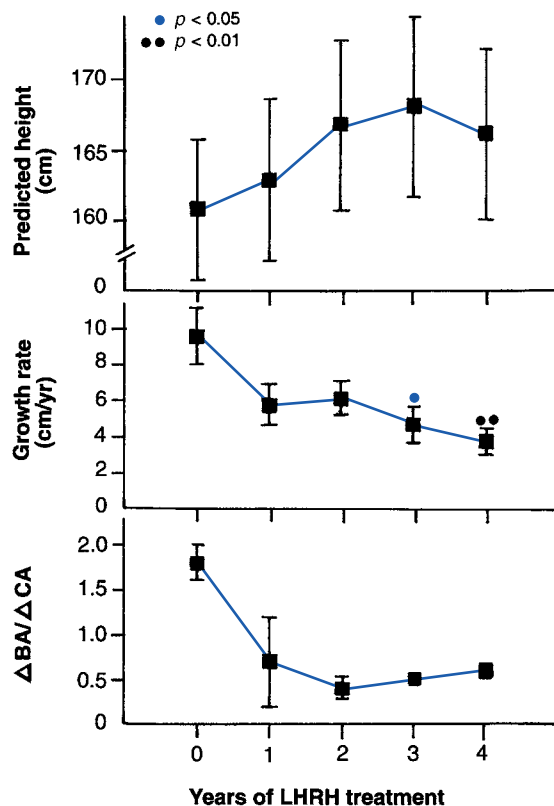

Figure 38.24 Predicted height, growth rate, and rate of bone age advancement in six children with central precocious puberty who received 4 years of therapy with the long-acting analogue of luteinizing hormone-releasing hormone (LHRH). Asterisks indicate significant differences compared with pretreatment value. $\Delta BA / \Delta CA$, Change in bone age/change in chronologic age. (Modified from Comite F, Cassorla F, Barnes KM, et al. Luteinizing hormone-releasing hormone analogue therapy for central precocious puberty: long-term effect on somatic growth, bone maturation, and predicted height. *JAMA*. 1986;255:2615.)

not only reverses the ovarian cycle but definitely changes the growth pattern. Growth velocity is usually decreased by approximately 50% (Fig. 38.24). In one series, the predicted adult height increased a mean of 6.5 cm in girls who were 6 years of age or younger when therapy was initiated.

A number of studies have documented that agonist therapy decreases gonadotropin levels within 1 week and decreases sex

steroid levels to the prepubertal range within the first 2 weeks of therapy. Serial ultrasound examinations have documented that the size of the ovaries and uterus regresses to a normal prepubertal shape and size. The most commonly observed side effect to agonists was a cutaneous reaction at the site of injection. However, approximately one in four girls experienced recurrent and sometimes prolonged vaginal bleeding while receiving GnRH agonists. The effects of these drugs are reversible when the agonists are discontinued after normal height has been achieved.

Although 3-month regimens are available, therapy usually begins with a once-per-month preparation at a dose of 0.3 mg/kg of leuprolide or its equivalent. Leuprolide acetate can be administered at doses of 7.5 mg, 11.25 mg, and 15 mg; the larger dose can be used if there is evidence for pubertal progression despite treatment. Treatment usually continues until around age 11.

It has been suggested that rare forms of GnRH-independent precocious puberty that do not respond to agonist therapy may be successfully treated using a GnRH antagonist. Here, there may be a direct antagonist effect on the ovary mediated through gonadotropin receptors. Small studies have suggested a minimal benefit from adding growth hormone to GnRH agonist therapy in girls with suboptimal growth (Walvoord, 1999). The initial observations of combination therapy have been encouraging, but the clinical data were from small series and of a preliminary nature.

McCune-Albright syndrome is caused by an activating mutation of a G protein that is coupled with gonadotropin receptors, resulting in the ovaries being stimulated autonomously. Girls may be treated with aromatase inhibitors (anastrozole, letrozole), which prevent the conversion to biologically active estrogens. Unfortunately this treatment has had limited success, as has the use of tamoxifen (Shulman, 2008). The most promising treatment appears to be the use of the “pure” estrogen receptor antagonist, fulvestrant. In early studies, monthly injections of fulvestrant have shown benefit (Sims, 2012).

The child with precocious puberty and her family need intensive counseling. The child will have the psychosocial and behavioral maturation of children of her chronologic age, not the age reflected by her physical appearance. She may be exposed to ridicule by her peers and to sexual exploitation. Thus the child needs extensive sex education and help in anticipating and confronting various social experiences. Often, it is possible to dress the child in clothes that diminish the recognition of her advanced sexual maturation until the effects of her disease have been inhibited by drug therapy.

KEY POINTS

- Primary amenorrhea is diagnosed if no menstrual function has occurred by age 15, or 5 years after initial breast development.
- The incidence of secondary amenorrhea of more than 6 months' duration in the general population is approximately 0.7%.
- The incidence of amenorrhea lasting more than 6 months after discontinuation of oral contraceptives is 0.8%.
- The most important and probably most common cause of amenorrhea in adolescent girls is anorexia nervosa.
- An adolescent 13 years of age or older without any breast development has estrogen deficiency caused by an abnormality, which needs diagnostic evaluation.
- Menarche is delayed approximately 0.4 year for each year of premenarchal athletic training.
- Gonadal failure is the most common cause of primary amenorrhea, accounting for almost 50% of patients with this disorder.
- Individuals with gonadal failure and an X chromosome abnormality are shorter than 63 inches in height.

KEY POINTS—cont'd

- The testes of individuals with androgen resistance have approximately a 20% chance of becoming malignant after the age of 20 years.
- Uterovaginal agenesis is the second most common cause of primary amenorrhea, with an incidence of approximately 15% of individuals with this symptom.
- Approximately one third of individuals with gonadal failure have major cardiovascular or renal abnormalities.
- Congenital renal abnormalities occur in approximately one third of women with congenital absence of the uterus.
- The differential diagnosis between estrogen deficiency caused by gonadal failure and hypogonadotropic hypogonadism is best established with measurement of serum FSH.
- The diagnosis of gonadal failure, or hypergonadotropic hypogonadism, can be established if the FSH level exceeds 30 mIU/mL.
- Individuals with gonadal failure should have a peripheral karyotype obtained to determine whether a Y chromosome is present. If it is present, or if there are signs of hyperandrogenism, the gonads should be excised to prevent the development of malignancy, mainly a gonadoblastoma.
- Individuals with primary amenorrhea and hypogonadotropic hypogonadism do not need karyotyping but need a cranial CT scan to rule out a CNS tumor.
- The most frequent cause of IUAs is curettage performed during pregnancy or shortly thereafter.
- When women experience weight loss to 15% or more below ideal body weight, amenorrhea can occur because of CNS-hypothalamic dysfunction. The normal cyclic pattern of LH pulsatility is not present in individuals with functional hypothalamic amenorrhea. Either there is no LH pulse activity or there are pulses of slow frequency, similar to those in the normal luteal phase.
- The GnRH alterations, as reflected in LH pulsatility, in persons with severe weight loss and anorexia nervosa are similar to those seen in normal prepubertal girls. When they regain weight, GnRH changes similar to those occurring during puberty take place.
- When uterine bleeding fails to occur after progestin is administered, E₂ levels are usually lower than 30 pg/mL.
- In contrast to hypothalamic disorders, pituitary causes of amenorrhea can be associated with ACTH and TSH deficiency.
- Individuals with premature ovarian failure or insufficiency have two different histologic findings: generalized sclerosis or primordial follicles scattered through the stroma.
- Women with premature ovarian failure or insufficiency may have antibodies to gonadotropins and other endocrine organs, indicating an autoimmune origin.
- A karyotype should be obtained in women with premature ovarian failure or insufficiency who are younger than 25 years but is not necessary in those who are older.
- Amenorrhea with low estrogen levels is associated with decreased bone density.
- The most frequent cause of secondary amenorrhea is hypothalamic dysfunction.
- Physiologic development in females with precocious puberty usually follows the normal sequence of changes of secondary sexual characteristics.
- If signs of pubertal progression (precocious puberty) are present in a girl, a workup is warranted by the age of 8 years.
- The two primary concerns of parents of children with precocious puberty are the social stigma associated with the child being physically different from her peers and the diminished ultimate height caused by the premature closure of epiphyseal growth centers.
- The exact cause of the majority of cases of GnRH-dependent (true or complete) precocious puberty is unknown; however, approximately 30% of cases are secondary to CNS disease.
- A definitive diagnosis is established more often for GnRH-independent (pseudoprecocious or incomplete) puberty and is usually related to an ovarian or adrenal disorder.
- Breast hyperplasia is a normal phenomenon in neonates and may persist until up to 6 months of age.
- The most common cause of GnRH independent precocious puberty is a functioning ovarian tumor. Granulosa cell tumors are the most common type, accounting for approximately 60% of neoplasms.
- The primary emphasis of the diagnostic workup of a child with precocious puberty should be to rule out life-threatening neoplasms of the ovary, adrenal glands, or CNS. The secondary emphasis is to delineate the speed of the maturation process, because this is critical when making a decision about therapy.
- The goals of therapy for precocious puberty are to reduce gonadotropin secretion, reduce or counteract the peripheral actions of sex steroids, and decrease the growth rate to normal and thus slow skeletal maturation. This is best accomplished with the use of GnRH agonists.
- The effect on adult height depends on the chronologic age at which GnRH therapy is initiated, with greater success if initiated at a younger age. The child with precocious puberty and her family need intensive counseling.

Hyperprolactinemia, Galactorrhea, and Pituitary Adenomas Etiology, Differential Diagnosis, Natural History, Management

Roger A. Lobo

Prolactin (PRL) is a polypeptide hormone containing 198 amino acids and with a molecular weight (MW) of 22 kDa. It circulates in different molecular sizes: a monomeric (small) form (MW = 22 kDa), a polymeric (big) form (MW = 50 kDa), and an even larger polymeric (big-big) form (MW >100 kDa). Big PRL is presumed to be a dimer, and big-big PRL may represent an aggregation of monomeric molecules. The larger forms also contain added sugar moieties (glycosylation), which decreases biologic activity. The small form is biologically active and approximately 80% of the hormone is secreted in this form. Most immunoassays measure the small and large forms of PRL. The polymeric forms have reduced biologic activity and reduced binding to mammary tissue membranes. Women have been identified with high levels of PRL on routine immunoassay and who are completely normal clinically. This is because of “clumping” of abnormal forms of PRL, and if this unusual situation arises, where there is no reason to suspect a PRL elevation, the assay should be repeated, as will be described later.

PRL is synthesized and stored in the pituitary gland in chromophobe cells called *lactotrophs*, which are located mainly in the lateral areas of the gland. PRL is encoded by its gene (10 kb) on chromosome 6. At the molecular level, it is stimulated and suppressed by a number of factors. The principal stimulating factor is thyroid-releasing hormone (TRH), and the major inhibiting factor is dopamine, which has been suggested to be the prolactin-inhibiting factor (PIF). Estrogen also improves PRL secretion by enhancing the effects of TRH and inhibiting the effects of dopamine. A potential direct effect may also be mediated via galanin. The principal receptor with which dopamine interacts is D2, which is the target for various dopamine agonists used in the treatment of **hyperprolactinemia**.

In addition, PRL is synthesized in decidualized stroma of endometrial tissue. From these tissues, PRL is secreted into the circulation and, in the event of pregnancy, into the amniotic fluid. The control of decidual PRL is different from that of the pituitary and does not respond to dopamine. PRL is normally present in measurable amounts in serum, with mean levels of approximately 8 ng/mL in adult women. It circulates in an unbound form, has a 20-minute half-life, and is cleared by the

liver and kidney. The main function of PRL is to stimulate the growth of mammary tissue as well as to produce and secrete milk into the alveoli; thus it has mammogenic and lactogenic functions. Specific receptors for PRL are present in the plasma membrane of mammary cells, as well as in many other tissues.

PHYSIOLOGY

PRL synthesis and release from the lactotrophs are controlled by central nervous system neurotransmitters, which act on the pituitary via the hypothalamus. The major control mechanism is inhibition, because pituitary stalk section results in increased PRL secretion. It appears that the major physiologic inhibitor of PRL release is the neurotransmitter dopamine (PIF), which acts directly on the pituitary gland. There are specific dopamine receptors on the lactotrophs, and dopamine inhibits PRL synthesis and release in pituitary cell cultures. Although a hypothalamic prolactin-releasing factor (PRF) has not been isolated, it is known that the neurotransmitter serotonin and thyrotropin-releasing factor stimulate PRL release. Because the latter stimulates PRL release only minimally unless infused, it appears that serotonin is a PRF or is responsible for its secretion. The rise in PRL levels during sleep appears to be controlled by serotonin.

PRL is secreted episodically and serum levels fluctuate throughout the day and throughout the menstrual cycle, with peak levels occurring at midcycle. Although changes in PRL levels are not as marked as the pulsatile episodes of luteinizing hormone (LH), estrogen stimulates PRL production and release. Under the influence of estrogen, PRL levels increase in females at the time of puberty; there is a slight decline in levels after menopause.

During pregnancy, as estrogen levels increase, there is a concomitant hypertrophy and hyperplasia of the lactotrophs. The maternal increase in PRL levels occurs soon after implantation, concomitant with the increase in circulating estrogen. Circulating levels of PRL steadily increase throughout pregnancy, reaching approximately 200 ng/mL in the third trimester; the rise is directly related to the increase in circulating levels of estrogen.

However, there is a wide range of values of PRL in pregnancy, and values as high as 400 ng/mL can be found in normal pregnancy. Despite the elevated PRL levels during pregnancy, lactation does not occur because estrogen inhibits the action of PRL on the breast, most likely blocking PRL's interaction with its receptor. A day or two following delivery of the placenta, estrogen and PRL levels decline rapidly and lactation is initiated. PRL levels reach basal levels in nonnursing women in 2 to 3 weeks. Although basal levels of circulating PRL decline to the nonpregnant range approximately 6 months after parturition in nursing women, following each act of suckling, PRL levels increase markedly and stimulate milk production for the next feeding.

Nipple and breast stimulation also increase PRL levels in the nonpregnant female, as does trauma to the chest wall. Other physiologic stimuli that increase PRL release are exercise, sleep, and stress. In addition, PRL levels normally rise following ingestion of the midday meal. Thus PRL levels normally fluctuate throughout the day, with maximal levels observed during the night while asleep and a smaller increase occurring in the early afternoon. When the amount measured in the circulation in the nonpregnant woman exceeds a certain level, usually 20 to 25 ng/mL, the condition is called *hyperprolactinemia*. The optimal time to obtain a blood sample for assay to diagnose hyperprolactinemia is in the fasting state and, ideally, during the mid-morning hours. Increases in PRL levels above the normal range can occur without a pathologic condition if the serum sample is drawn from a woman who has recently awakened, has exercised, or has had recent breast stimulation (such as breast palpation) during a physical examination.

The most frequent cause of slightly elevated PRL levels is stress, particularly the stress caused by visiting the physician's office. All women with initial PRL levels lower than 50 ng/mL should have subsequent samples drawn 60 minutes after resting in a quiet room to determine whether true pathologic hyperprolactinemia is present. Figure 39.1 depicts normalization of PRL only in those with stress-related elevations, which occurred during a 60-minute rest period (referred to in the study as a "test").

Hyperprolactinemia can produce disorders of gonadotropin sex steroid function, resulting in menstrual cycle derangement (oligomenorrhea and amenorrhea) and anovulation, as well as inappropriate lactation, or **galactorrhea**. The mechanism whereby elevated PRL levels interfere with gonadotropin release appears to be related to abnormal gonadotropin-releasing hormone (GnRH) release. Women with hyperprolactinemia have abnormalities in the frequency and amplitude of LH pulsations, with a normal or increased gonadotropin response following GnRH infusion.

This abnormality of GnRH cyclicity thus inhibits gonadotropin release but not its synthesis. The reason for this abnormal secretion of GnRH is an inhibitory effect of dopamine and opioid peptides at the level of the hypothalamus. In addition, elevated PRL levels have been shown to interfere with the positive estrogen effect on midcycle LH release. It has also been shown that elevated levels of PRL directly inhibit basal and gonadotropin-stimulated ovarian secretion of estradiol and progesterone. However, this mechanism is probably not the primary cause of anovulation, because women with hyperprolactinemia can have ovulation induced with various agents, including pulsatile GnRH. Some women with moderate hyperprolactinemia, as determined by radioimmunoassay, have a greater than normal

Figure 39.1 Serum prolactin levels (mean plus or minus standard error [\pm SE]) in women with prolactinoma ($N = 20$) and idiopathic ($N = 30$) and stress-related ($N = 20$) hyperprolactinemia before (pretest I and II) and during hyperprolactinemia test. Differences ($*P < .01$) are in relation to time zero values. (Mean prolactin values among groups were also significantly different [$P < .01$] at all times.) (From Muneyyirci-Delale O, Goldstein D, Reyes FI, et al. Diagnosis of stress-related hyperprolactinemia: evaluation of the hyperprolactinemia rest test. *NY State J Med*. 1989;89[4]:205-208.)

proportion of the big-big forms. Because of the reduced bioactivity of this form of PRL, they can have normal pituitary and ovarian function.

The clinician should measure serum PRL levels in all women with galactorrhea, as well as those with oligomenorrhea and amenorrhea not explained by another reason such as ovarian failure (elevated level of follicle-stimulating hormone [FSH]). Hyperprolactinemia has been reported to be present in 15% to 20% of women who present with menstrual disturbances.

SPECIAL CASES IN THE MEASUREMENT OF PROLACTIN

Because of possible aggregation of molecular forms of PRL when levels are high, if a tumor (adenoma) is suspected and values of PRL are only mildly elevated, the test should be repeated in a diluted sample. This has been called the "hook" effect and is explained by high endogenous levels of PRL binding up all the assay antibody, leaving an inadequate quantity for the assay (St-Jean, 1996).

The opposite occurrence was mentioned earlier, when PRL is found to be elevated in a woman who is normal clinically. This is due to "clumping" of glycosylated PRL with immunoglobulin and can be corrected by gel electrophoresis or merely by adding polyethylene glycol to the serum, which precipitates the abnormal forms (Leslie, 2001).

GALACTORRHEA

Galactorrhea is defined as the nonpuerperal secretion of watery or milky fluid from the breast that contains neither pus nor blood. The fluid may appear spontaneously or after palpation.

Figure 39.2 Fat droplets seen under microscope from a patient with galactorrhea. (From Kletzky OA, Davajan V. Hyperprolactinemia: diagnosis and treatment. In: Mishell DR, Davajan V, Lobo RA, eds. *Infertility, Contraception and Reproductive Endocrinology*. 3rd ed. Cambridge, MA: Blackwell Scientific; 1991.)

To determine whether galactorrhea is present, the clinician should palpate the breast, moving from the periphery toward the nipple in an attempt to express any secretion. The diagnosis of galactorrhea can be confirmed by observing multiple fat droplets in the fluid when examined under low-power magnification (Fig. 39.2). The incidence of galactorrhea in women with hyperprolactinemia has been reported to range from 30% to 80%, and these differences probably reflect variations in the techniques used to detect mammary excretion. Unless there has been continued breast stimulation after a pregnancy, the presence of galactorrhea serves as a biologic indicator that the PRL level is abnormally elevated.

CAUSES OF HYPERPROLACTINEMIA

Pathologic causes of hyperprolactinemia, in addition to a PRL-secreting pituitary adenoma (**prolactinoma**) and other pituitary tumors that produce acromegaly and Cushing disease, include hypothalamic disease, various pharmacologic agents, hypothyroidism, chronic renal disease, or any chronic type of breast nerve stimulation, such as may occur with thoracic operation, herpes zoster, or chest trauma. Box 39.1 lists the causes of hyperprolactinemia.

One of the most frequent causes of galactorrhea and hyperprolactinemia is the ingestion of pharmacologic agents, particularly tranquilizers, narcotics, and antihypertensive agents (Box 39.2). Of the tranquilizers, the phenothiazines and diazepam can produce hyperprolactinemia by depleting the hypothalamic circulation of dopamine or by blocking its binding sites and thus decreasing dopamine action.

The tricyclic antidepressants block dopamine uptake and propranolol, haloperidol, phentolamine, and cyproheptadine block hypothalamic dopamine receptors. The antihypertensive agent reserpine depletes catecholamines, and methyldopa blocks the conversion of tyrosine to dihydroxyphenylalanine (dopa). Ingestion of oral contraceptive steroids can also mildly increase PRL levels, with a greater incidence of hyperprolactinemia occurring with older higher estrogen formulations. Nevertheless, galactorrhea does not usually occur during oral contraceptive ingestion because the exogenous estrogen blocks the binding of PRL to its receptors.

Women who develop galactorrhea while ingesting oral contraceptives or any of the other drugs listed in Box 39.2 should ideally discontinue the medication, and the PRL level should be measured 1 month thereafter to determine if the level has returned to normal. If the medication cannot be discontinued, the PRL level should be measured and, if elevated above 100 ng/mL, imaging of the sella turcica should be performed to determine whether a **macroadenoma** is present.

Primary hypothyroidism can also produce hyperprolactinemia and galactorrhea because of decreased negative feedback of thyroxine (T_4) on the hypothalamic-pituitary axis. The resulting increase in TRH stimulates PRL secretion and

SSRIs, Selective serotonin reuptake inhibitors.

thyroid-stimulating hormone (TSH) secretion from the pituitary. Approximately 3% to 5% of individuals with hyperprolactinemia have hypothyroidism. Therefore TSH, the most sensitive indicator of hypothyroidism, should be measured in all individuals with hyperprolactinemia. If the TSH level is elevated, triiodothyronine (T_3) and T_4 should be measured to confirm the diagnosis of primary hypothyroidism, because a TSH-secreting pituitary adenoma will occasionally be present. Treatment with appropriate thyroid replacement usually returns the TSH and PRL levels to normal within a short time.

Hyperprolactinemia can occur in those with abnormal renal disease resulting from decreased metabolic clearance and increased production rate. The cause of the latter is unknown.

Mild hyperprolactinemia (30 to 50 ng/mL) may occur in women with polycystic ovary syndrome (PCOS). This occurs in up to 30% of women and may be related to the chronic state of unopposed estrogen stimulation.

CENTRAL NERVOUS SYSTEM DISORDERS

Hypothalamic Causes

Diseases of the hypothalamus that produce alterations in the normal portal circulation of dopamine can result in hyperprolactinemia. These include **craniopharyngioma** and infiltration of the hypothalamus by sarcoidosis, histiocytosis, leukemia, or carcinoma. All these conditions are rare, with craniopharyngioma being the most common. These tumors arise from remnants of Rathke's pouch along the pituitary stalk. Grossly, they can be cystic, solid, or mixed, and calcification is usually visible on a radiograph. They are most frequently diagnosed during the second and third decades of life and usually result in impairment of secretion of several pituitary hormones.

Pituitary Causes

Various types of pituitary tumors, lactotroph hyperplasia, and the **empty sella syndrome** can be associated with hyperprolactinemia. It has been estimated that as many as 80% of all pituitary adenomas secrete PRL. The most common pituitary tumor associated with hyperprolactinemia is the prolactinoma, arbitrarily defined as a **microadenoma** if its diameter is less than 1 cm and as a **macroadenoma** if it is larger (Fig. 39.3). Hyperprolactinemia has been reported to occur in approximately 25% of those with acromegaly and 10% of those with Cushing disease, indicating that these pituitary adenomas, which mainly secrete growth hormone (GH) and adrenocorticotrophic hormone (ACTH), frequently also secrete PRL. Hyperplasia of lactotrophs has been reported to occur in approximately 8% of pituitary glands examined at autopsy. Individuals with hyperplasia of the lactotrophs cannot be distinguished from those having a microadenoma by any clinical, laboratory, or radiologic method. The diagnosis can be made only at the time of surgical exploration of the pituitary gland. Pituitary enlargement with suprasellar extension caused by lactotroph hyperplasia has been reported. *Functional hyperprolactinemia* is the term used for the clinical diagnosis of cases of elevated PRL levels without imaging evidence of an adenoma.

Another cause of hyperprolactinemia is the primary empty sella syndrome. The term *primary empty sella syndrome* describes a clinical situation in which an intrasellar extension of the subarachnoid space results in compression of the pituitary gland and an enlarged sella turcica. The cause is believed to result from a congenital or acquired (by radiation or surgery) defect in the sella diaphragm that allows the subarachnoid membrane to herniate into the sella turcica (Fig. 39.4). The syndrome is usually associated with normal pituitary function, except for hyperprolactinemia. Although some with primary empty sella syndrome have a coexistent prolactinoma, Gharib and colleagues have reported a series of 11 patients with an empty sella and hyperprolactinemia who had no histologic evidence of a prolactinoma or hyperplasia of the lactotrophs (Gharib, 1983). They stated that approximately 5% of those with the empty sella have hyperprolactinemia, amenorrhea-galactorrhea, or both. It is theorized that with this syndrome, distortion of the infundibular stalk results in decreased levels of dopamine reaching the pituitary to inhibit

Figure 39.3 **A**, Magnetic resonance imaging scan of the side view of the head (midway through the brain) showing a prolactinoma. **B**, Same image, colorized, showing that the top part of the tumor (shown in red) elevates the optic nerve (actually, the optic chiasm). In: Mishell DR, Davajan V, Lobo RA, eds. *Infertility, Contraception and Reproductive Endocrinology*. 3rd ed. Cambridge, MA: Blackwell Scientific; 1991.)

PRL. Serum PRL levels are usually less than 100 ng/mL with the empty sella syndrome, and some women with this syndrome have normal PRL levels, with or without galactorrhea. Kleinberg and coworkers have reported that approximately 10% of all individuals with an enlarged sella turcica have the empty sella syndrome (Kleinberg, 1977). The best modality for diagnosing this condition is magnetic resonance imaging (MRI). It is important to establish the diagnosis because the syndrome has a benign course.

PROLACTINOMAS

In an unselected series of 120 autopsies of individuals with no clinical evidence of pituitary disease, Burrow and associates found pituitary microadenomas to be present in 32 (27%) (Burrow, 1981). Molitch has noted that PRL incidentalomas occur in 11% of subjects at autopsy (Molitch, 1997). It has also been reported that adenomas were found in 78 of 486 (16%) of pituitary glands examined after unselected autopsies. In all series, PRL was found in approximately 50% of the glands, indicating that more than 10% of those in the general population have an undiagnosed prolactinoma.

Overall, approximately 50% of women with hyperprolactinemia have a prolactinoma. The incidence is higher when the PRL levels exceed 100 ng/mL, and almost all individuals with PRL levels greater than 200 ng/mL have a prolactinoma. There is an approximate positive correlation between the size of the adenoma and the PRL level. The majority of prolactinomas in women are microadenomas (<1 cm). Kleinberg and coworkers have reported that 20% of those with galactorrhea and 35% of women with amenorrhea-galactorrhea have radiologic evidence of pituitary tumors (Kleinberg, 1977).

Galactorrhea need not be present in all cases of adenoma. In approximately 20% of women with hyperprolactinemia and menstrual irregularities without galactorrhea, an adenoma may be found. Approximately 70% of women with hyperprolactinemia and galactorrhea, and secondary amenorrhea with low estrogen levels, have radiologic evidence of a pituitary adenoma. There is a correlation between the degree of suppression of the hypothalamic-pituitary-ovarian axis (resulting in hypoestrogenism) and the presence of an adenoma. However, an adenoma may be present in 20% to 30% of women with hyperprolactinemia and normal menses, oligomenorrhea, or secondary amenorrhea with normal estrogen status. No adenoma is found characteristically in individuals with normal menses, galactorrhea, and normal PRL levels.

Figure 39.5 depicts various possible causes of prolactinoma formation. In the past, it was firmly believed that adenomas or hyperplasia resulted from hypothalamic dopamine dysregulation, which was a functional defect or the result of altered blood supply. It is now believed that adenomas arise from single cell mutations, with clonal proliferation occurring subsequently. However, a search for mutations in oncogenes, the dopamine D2 or TRH receptor, signal transduction mechanisms, or transcription factors has not been rewarding to date. Prolactinomas that occur in 20% of patients with multiple endocrine neoplasia type 1 (MEN-1) may be caused by an inactivating mutation of the *MENIN* gene (Burgess, 1996), although this special case is clearly different from the usual type of prolactinomas.

It is also important to note that prolactinomas may also secrete other hormones with GH being the most common

PATHOGENESIS OF PITUITARY TUMORS

Figure 39.5 Possible mechanisms leading to the formation of a prolactinoma. *Top*, Normal regulation. *Middle*, Tumors could arise because of an increase in prolactin-releasing factor (PRF) or a decrease in PRL-inhibiting factor (dopamine). *Bottom*, Tumors could arise de novo without hypothalamic influence. (From Molitch ME. Clinical features and epidemiology of prolactinomas in women. In: Olefsky JM, Robbins RJ, eds. *Prolactinomas: Practical Diagnosis and Management*. New York: Churchill Livingstone; 1986:67-95.)

companion. Also, up to 40% of primarily GH-secreting adenomas also secrete PRL. Combinations of PRL and ACTH, PRL and TSH, and PRL and FSH have been described. Indeed even “nonfunctioning” adenomas have been found to secrete isolated α and β subunits of gonadotropins.

Long-term studies of individuals with microadenomas have demonstrated that enlargement is uncommon and that many of these tumors regress spontaneously. The natural progression from micro- to macroadenoma has been estimated to be less than 7%. In a longitudinal retrospective study of women with hyperprolactinemia and a radiologic diagnosis of microadenoma, March and colleagues found that only 2 of 43 women had evidence of enlargement of the adenoma, with a

mean duration of follow-up of 5 years (March, 1981). Of these 43 women, three had spontaneous regression of their hyperprolactinemia and resumption of normal menses. Koppelman and associates have reported similar results. Of 25 women with prolactinomas (18 with microadenomas and 7 with minimally enlarged sella) followed up for a mean duration of 11 years without treatment, only 1 woman had slight progression of a sella abnormality. None had visual field or other pituitary function changes, seven resumed normal menses spontaneously, and galactorrhea spontaneously resolved in six (Koppelman, 1984).

The results of these retrospective studies have been confirmed by two prospective studies of untreated microprolactinomas. In a 3- to 7-year prospective longitudinal study of 30 hyperprolactinemic women, Schlechte and coworkers found that of 13 women with initially abnormal radiographic findings, 4 became normal, 7 did not change, and 2 had evidence of progressive growth. Of 17 women with initially normal radiographic findings, the radiographic findings of 4 became minimally abnormal. None of the 30 developed a macroadenoma or pituitary hypofunction (Schlechter, 1989). In this study, as in the two retrospective studies reported earlier, more sensitive radiographic techniques (e.g., tomography, followed by computed tomography [CT]) were used as the study progressed and could account for the minimal evidence of tumor growth. Martin and coworkers followed the natural history of 41 women with idiopathic hyperprolactinemia and amenorrhea-galactorrhea for up to 11 years. During this time, 9 women conceived spontaneously and 16 resumed spontaneous menses with cessation of galactorrhea. Only one woman developed a microadenoma (Martin, 1985). Thus hyperprolactinemia with or without a microadenoma follows a benign clinical course in most women, and therapy is unnecessary unless pregnancy is desired or estrogen levels are low.

Several studies have reported that pregnancy is beneficial for women with functional hyperprolactinemia or PRL-secreting microadenomas. Following pregnancy, PRL levels decrease in approximately 50% of women. Crosignani and associates have reported that PRL levels normalized in approximately 30% of 176 hyperprolactinemic women after pregnancy. PRL levels decreased to normal in 36% of women with functional hyperprolactinemia and 17% of those with adenomas (Crosignani, 1992). Therefore if women with hyperprolactinemia desire to become pregnant, they should be encouraged to do so, because pregnancy is likely to result in normal or lowered PRL levels.

DIAGNOSTIC TECHNIQUES

IMAGING STUDIES

Current recommended techniques are to obtain a CT scan with intravenous contrast or an MRI with gadolinium enhancement. The latter provides better soft tissue definition, without radiation (23 rad; 0.03 Gy), and the CT scan is principally beneficial for bony structural abnormalities. The MRI provides 1-mm resolution and thus should be able to detect all microadenomas; it is currently the recommended imaging study to obtain.

RECOMMENDED DIAGNOSTIC EVALUATION

It is recommended that PRL levels be measured in all women with galactorrhea, oligomenorrhea, or amenorrhea who do not

have an elevated FSH level. PRL is also frequently measured in the workup of infertility. If the PRL level is elevated, a TSH assay should be performed to rule out the presence of primary hypothyroidism. If the TSH level is elevated, T_3 and T_4 should be measured to rule out the rare possibility of a TSH-secreting pituitary adenoma. If the TSH level is elevated and hypothyroidism is present, appropriate thyroid replacement should begin and the PRL level will usually return to normal. If the TSH level is normal and the woman has a normal PRL level with galactorrhea, no further tests are necessary if she has regular menses.

If PRL levels are elevated and the TSH level is normal, an MRI (preferably) or CT scan should be obtained to detect a microadenoma or macroadenoma. Macroadenomas are uncommon and rarely present with a PRL level less than 100 ng/mL. If the PRL level is more than 100 ng/mL or the woman complains of headaches or visual changes, the likelihood of a tumor extending beyond the sella turcica is increased. Microadenomas are a common cause of hyperprolactinemia and remain stable in most cases. Neither pregnancy, oral contraceptives, nor hormone therapy stimulates the growth of these small tumors; therapy is unnecessary unless ovulation induction is desired or hypogonadism is present.

Routine visual field testing and measurements of ACTH, GH, and thyroid function are not necessary unless warranted clinically. However, these evaluations, particularly visual field testing, should be performed in women with macroadenomas because suprasellar extension of the tumor may exert pressure on the optic chiasm, resulting in bitemporal visual field defects and interference with vision. The size of these tumors may also affect other aspects of pituitary function. With a macroadenoma, dynamic tests of pituitary function should be performed.

TREATMENT

EXPECTANT TREATMENT

Women with radiologic evidence of a microadenoma or functional hyperprolactinemia who do not wish to conceive may be followed without treatment by measuring PRL levels once annually. However, if estrogen is deficient, low estrogen levels in combination with hyperprolactinemia has been shown to be associated with the early onset of osteoporosis; thus exogenous estrogen should be administered. Hormonal therapy, as is used for postmenopausal women, or oral contraceptives may be used. Corenblum and Donovan have reported that a group of women with functional hyperprolactinemia and PRL-secreting pituitary microadenomas who were treated with cyclic estrogen and progestogen or oral contraceptives for several years did not have an increase in the size of the adenomas or increased PRL levels. Mean PRL levels actually declined with both treatment regimens (Corenblum, 1983). Testa also reported that 2 years of oral contraception use in a group of women with hyperprolactinemia with microadenoma did not alter the size of the adenoma (Testa, 1998). Because side effects and cost are less and compliance is better with exogenous estrogen than with dopamine agonist therapy, it is not necessary to use the latter unless ovulation and pregnancy are desired. Those with hyperprolactinemia, with or without microadenomas, who have adequate estrogen levels and

who do not wish to conceive should be treated with periodic progestogen withdrawal (e.g., medroxyprogesterone acetate, 5 to 10 mg/day for 10 days each month) or with combination oral contraceptives to prevent endometrial hyperplasia.

MEDICAL TREATMENT OF PROLACTINOMAS

The initial treatment for women with macroadenomas, as well as for those women with hyperprolactinemia who are anovulatory and wish to conceive, should be the administration of a dopamine receptor agonist. Cabergoline, bromocriptine, and pergolide have been used successfully; pergolide is currently not available.

Bromocriptine

The greatest amount of clinical experience has been with the use of bromocriptine. This semisynthetic ergot alkaloid was developed in 1967 to inhibit PRL secretion. It directly stimulates dopamine 2 receptors and, as a dopamine receptor agonist, it inhibits PRL secretion in vitro and in vivo. After ingestion, bromocriptine is rapidly absorbed, with blood levels reaching a peak 1 to 3 hours later. Serum PRL levels remain depressed for approximately 14 hours after ingestion of a single dose, after which time the drug is not detectable in the circulation. Therefore the drug is usually given at least twice daily, with initial therapy being started at half of the 2.5-mg tablet to minimize side effects. The most frequent side effects are orthostatic hypotension, with an incidence of 15%, which can produce fainting and dizziness as well as nausea and vomiting. To minimize these symptoms, the initial dose should be taken in bed and with food at night. Less frequent adverse symptoms include headache, nasal congestion, fatigue, constipation, and diarrhea. Most of these reactions are mild, occur early in the course of treatment, and are transient. To reduce the adverse symptoms, the dose should be gradually increased every 1 to 2 weeks until PRL levels fall to normal. The greatest decrease in PRL occurs in the first 2 to 4 weeks. The therapeutic dose is usually titrated to normalize PRL. Figure 39.6 shows the rapid decline in PRL with

bromocriptine as well as cabergoline in this randomized comparison study (Webster, 1994). Adverse effects of bromocriptine such as nausea, vomiting, and nasal congestion occur in approximately 50% of women and may cause them to discontinue treatment. Vermesh and colleagues have reported that the drug is well absorbed vaginally, without side effects. Furthermore, when a single tablet is placed deep into the posterior vaginal fornix, therapeutic blood levels persist for more than 24 hours, during which time PRL levels remain suppressed (Vermesh, 1988). Ginsburg and coworkers subsequently reported that this method of bromocriptine administration is well accepted and effective. The tablet was digitally placed deep into the vagina nightly at bedtime. A single 2.5-mg dose reduced PRL concentrations in 90% of patients treated and brought the levels to normal in one third of the women. Higher doses did not appear to be more effective (Ginsburg, 1992). In women wishing to conceive, sperm function is not adversely affected (Chenette, 1991).

Cabergoline

Cabergoline is a long-acting dopamine receptor agonist and is currently preferred over bromocriptine for primary therapy, because of greater efficacy and fewer side effects (Ferrari, 1992; Wang, 2012). This agent directly inhibits pituitary lactotrophs, thereby decreasing PRL secretion. It is given orally in doses of 0.25 to 1 mg twice weekly. The initial dose is half a 0.5-mg tablet twice a week. Peak plasma levels occur in 2 to 3 hours, and the drug has a half-life of 65 hours. Its slow elimination and long half-life produce a prolonged PRL-lowering effect. The initial dose is 0.25 mg twice weekly, and the dosage may be increased at intervals of 4 weeks to achieve a satisfactory response (see Fig. 39.6). In a randomized trial with bromocriptine, cabergoline lowered PRL levels to normal in 83% of women, and only in 59% with bromocriptine. Cabergoline induced ovulation in 72% and eliminated galactorrhea in 90%. The effectiveness of cabergoline was greater than that of bromocriptine (Webster, 1994). Adverse effects, particularly nausea, headaches, and dizziness, occurred with both agents but were less frequent, less severe, and of shorter duration with cabergoline. In patients with pituitary adenoma who had been unsuccessfully treated previously with bromocriptine, cabergoline has been found to be effective (Table 39.1).

In Table 39.1, cabergoline has been compared with other agents in regard to effectiveness for reducing tumor size. It may be concluded that in women who have never been treated,

Figure 39.6 Serum prolactin in women with hyperprolactinemic amenorrhea randomized to treatment with cabergoline or bromocriptine and followed for 24 weeks. (Data from Webster J Piscitelli MD, Polli A, et al. A comparison of cabergoline and bromocriptine in the treatment of hyperprolactinemic amenorrhea. Cabergoline Study Group. *N Engl J Med.* 1994;331[14]:904-909.)

Table 39.1 Comparison of Efficacy of Dopamine Agonists in Affecting Tumor Size Reduction*

Dopamine Agonist	No. of Cases	TUMOR SIZE REDUCTION (%)			
		>50	25-50	<25	No Change

Pergolide*	61	75.4	9.8	8.2	6.5
Quinagolide*	105	48.1	20.2	17.3	14.4
Cabergoline*	130	25.4	46.9	6.9	21.5

Modified from Molitch ME. Prolactin in human reproduction. In: Strauss JF III, Barbieri R, eds. *Yen and Jaffe's Reproductive Endocrinology*. Philadelphia: Elsevier; 2004:109.

*It should be noted that in many of the studies of pergolide, quinagolide, and cabergoline, many patients had previously been found to be resistant to or intolerant of bromocriptine.

cabergoline is the agent of choice for reducing PRL levels and effecting tumor shrinkage (Wang, 2012). It is recommended that after serum PRL levels have remained normal for 6 months, cabergoline be discontinued to determine whether the PRL levels will stay low without therapy. A potential concern with cabergoline and pergolide (now not available) is the development of cardiac valvular lesions. However, this has only been observed with large doses, as used for Parkinson disease, and has not been reported with lower doses (Drake, 2013; Caputo, 2014). It has been suggested that cardiac ultrasound be performed every 2 years in patients on chronic therapy of cabergoline at doses of less than 2 mg per week.

Outcomes of Treatment in Women with Prolactinomas

Although cabergoline is currently the dopamine agonist of choice, bromocriptine is preferred if use is required in pregnancy because of its longer experience of use during pregnancy. Various incidence reports of use of bromocriptine or cabergoline in the first trimester have not shown any fetal defects or pregnancy complications. If pregnancy occurs after ovulation is induced with a dopamine agonist, therapy is usually discontinued, although there is no evidence that the drug is teratogenic or adversely affects pregnancy outcome.

When bromocriptine or cabergoline is used to treat hyperprolactinemia, therapy is usually continued for at least 12 months, after which it should be discontinued for a few weeks. Most women with microadenomas have recurrence of hyperprolactinemia, amenorrhea, and galactorrhea, although approximately 10% to 20% have permanent remission after discontinuation.

Moriondo and associates have reported that after 1 year of bromocriptine treatment, 11% of women with microadenomas

have persistent normalization of PRL levels, with return of regular menses after the drug is discontinued (Moriondo, 1985) (Fig. 39.7). This incidence of permanent remission reached 22% after 2 years of treatment.

For macroadenoma, Kharlip and coworkers have suggested that the recurrence rate after cabergoline for macroadenomas was 50% to 60% within the first 18 months (Kharlip, 2009). The reduction in size of macroadenomas usually occurs rapidly. Figure 39.8 shows the reduction in size during bromocriptine therapy. Within a few weeks after starting treatment, size reduction occurs, but following withdrawal of drug the tumor size may increase just as rapidly. Thus the drug should be withdrawn cautiously. In contrast to the frequent occurrence of pituitary insufficiency, including diabetes insipidus, after surgical or radiologic treatment of large tumors, dopamine agonist treatment is not accompanied by any pituitary insufficiency.

Because permanent remission rarely occurs following withdrawal of treatment from individuals with large tumors, long-term treatment is usually necessary. Drug therapy has been maintained for over 10 years in many patients without any long-term sequelae or loss of efficacy.

Because of the excellent results of medical therapy and the poor initial results of surgery, particularly for large tumors with the high recurrence rates, it may be concluded that dopamine agonist therapy, specifically cabergoline, should be used as the initial management of those with PRL-secreting macroadenomas. After maximal shrinkage of tumor, medical therapy can be continued or operative treatment initiated. If surgery is elected medical therapy should be continued until the time of operation to prevent tumor expansion. The rates of success after operation are no different in those who received or did not receive medication prior to surgery.

OPERATIVE APPROACHES FOR PROLACTINOMA

Trans-sphenoidal microsurgical resection of prolactinoma has been widely used for therapy, and numerous reports of large series of individuals treated by this technique have been published. In general, trans-sphenoidal operations have minimal risk, with a mortality of less than 0.5%. However, most deaths have been reported to occur after treatment of macroadenomas. The risk of temporary postoperative diabetes insipidus is 10% to 40%, but the risk of permanent diabetes insipidus and iatrogenic hypopituitarism is less than 2%. The initial cure rate, with normalization of PRL levels and return of ovulation, is relatively high for microadenomas (65% to 85%) but less so with macroadenomas (20% to 40%). Vision can return to normal in 85% of patients with loss of acuity and visual field defects.

The initial cure rate is related to the pretreatment PRL levels. Those tumors with PRL levels less than 100 ng/mL have an excellent prognosis (85%), and those with levels higher than 200 ng/mL have a poor prognosis (35%). Operative treatment of tumors in individuals older than 26 years with amenorrhea for longer than 6 months carries a poorer prognosis than tumors in younger women with a shorter duration of amenorrhea. Nevertheless, long-term follow-up of patients after operation has indicated that late recurrence of hyperprolactinemia is common. Serri and colleagues followed 28 women with microadenomas and 16 with macroadenomas for 6 years after operation. PRL levels normalized and menses resumed in 24 (85%) of those with microadenomas and 5 (31%) of those with macroadenomas. However, hyperprolactinemia recurred in 50% of those with microadenoma and 4 of 5 with macroadenomas after a mean period of 4 and 2.5 years, respectively (Serri, 1983) (Fig. 39.9). There was no

Figure 39.9 Cumulative recurrence rate in patients with microprolactinoma (group 1) or macroadenoma (group 2) after initially successful operation. Figures in parentheses indicate the number of patients who were seen at each yearly interval. (From Serri O, Rasio E, Beauregard H, et al. Recurrence of hyperprolactinemia after selective transsphenoidal adenomectomy in women with prolactinoma. *N Engl J Med*. 1983;309[5]:280-283.)

significant difference in recurrence rates for those who conceived and those who did not. Rodman and coworkers have reported a lower postoperative recurrence rate (~20% for both microadenomas and macroadenomas) following initial cure rates of 85% and 37%, respectively (Rodman, 1984). The risk of recurrence in both series appeared to be related to the immediate postoperative PRL levels being greater in those with a PRL level >10 ng/mL.

Overall, it can be concluded that after surgery, recurrence rates for microadenomas or macroadenomas are similar (21% and 19.8%, respectively). Long-term surgical cure rates are 58% for microadenomas but only 26% for macroadenomas using a normal PRL level as a criterion.

Because of the good results with medical therapy, surgery is recommended only for women with macroadenoma who fail to respond to medical therapy or have poor compliance with this regimen. It is best to reduce the size of macroadenomas maximally with bromocriptine before surgical removal of these extrasellar tumors.

RADIATION THERAPY FOR MACROADENOMAS

External radiation with cobalt, proton beam, or heavy particle therapy and brachytherapy with yttrium-90 rods implanted in the pituitary have all been used to treat macroadenomas but are not the primary mode of treatment. The current method of choice is probably the gamma knife and linear accelerator. Results have been inconsistent, and damage to normal pituitary tissue may occur, leading to abnormal anterior pituitary function and diabetes insipidus. Damage to the optic nerves may also occur, which led to the more precise technique of the gamma knife. Thus radiation therapy should be used only as adjunctive management following incomplete operative removal of large tumors.

PREGNANCY AND TREATMENT OF PROLACTINOMAS

Many women with hyperprolactinemia, with or without adenomas, wish to become pregnant. A small percentage of these

Figure 39.10 Coronal and sagittal magnetic resonance imaging scans of an intrasellar prolactin secreting macroadenoma in a woman prior to conception (*above*) and at 7 months of gestation (*below*). Note the marked tumor enlargement at the latter point, at which time the patient was complaining of headaches. (From Molitch ME. Medical treatment of prolactinomas. *Endocrinol Metab Clin North Am*. 1999;28[1]:143-169.)

women conceive spontaneously, but most require treatment to induce ovulation. Barbieri and Ryan have compiled a literature review of the pregnancy courses of 275 women with adenomas, most of whose conceptions had been induced by bromocriptine (Barbieri, 1983). They reported that of 215 women with microprolactinomas, less than 1% had changes in visual fields, radiologic evidence of tumor enlargement, or neurologic signs. Approximately 5% developed headaches during pregnancy. Of 60 women with macroprolactinomas, 20% developed adverse changes in their visual field and polytomographic or neurologic signs during pregnancy, and some of them required bromocriptine or operative treatment during pregnancy or shortly postpartum. The pituitary gland normally increases in size during pregnancy, and macroadenomas are at risk for enlarging to the point of causing symptoms (Fig. 39.10), particularly if they did not receive treatment prior to pregnancy. Molitch reported that if no treatment occurred before pregnancy, 2.7% of women with a microadenoma became symptomatic, whereas 22.9% of women with a macroadenoma were symptomatic (Molitch, 2011). However, with prepregnancy treatment, only 4.8% of women with a macroadenoma became symptomatic during pregnancy.

Women with a microadenoma do not require treatment during pregnancy, whereas women with macroadenoma only require treatment if they become symptomatic. Testing of visual fields every 3 months should be carried out in all women with a macroadenoma. Routine measurements of PRL during pregnancy have been controversial because of the wide range of values in pregnancy. However, it has been suggested that if PRL exceeds 400 ng/mL, this level should prompt visual field testing in women with an adenoma.

Although cabergoline is the dopamine agonist of choice for hyperprolactinemia, bromocriptine is used in pregnancy because there is a greater experience with bromocriptine, whereas there is no evidence of an adverse effect with cabergoline (Glezer, 2014). Using bromocriptine, Turkalj found there was a spontaneous abortion rate of 11%, an ectopic pregnancy rate of 0.7%, and a twin pregnancy rate of 1.8%. The incidence of minor (2.5%) and major (1%) congenital defects was similar to pregnancy outcomes in untreated populations of women (Turkalj, 1982). The mean amount of drug ingested and duration of postconception treatment were similar in mothers who had normal children and those who had children with defects. Thus ingestion of bromocriptine during pregnancy does not appear to increase the risk of congenital abnormalities, spontaneous abortion, or multiple gestations. Postnatal surveillance of more than 200 children born in this series has revealed no adverse effects to date.

Ruiz-Velasco compiled the obstetric histories of almost 2000 pregnancies occurring in hyperprolactinemic women that have been reported in the literature. Most of these pregnancies were induced with bromocriptine. There was a full-term delivery rate of 85%, an abortion rate of 11%, a prematurity rate of 2%, and a multiple pregnancy rate of 1.2% (Ruiz-Velasco, 1984). Although PRL levels increased during pregnancy, after delivery the levels returned to pretreatment values in approximately 85% of these women. A postpartum increase over pretreatment levels was uncommon (3%), and PRL levels returned to normal in 13%. Similarly, among women who had a postpartum radiologic examination, 84% showed no change, 9% improved, and 7% worsened. Thus stopping treatment during pregnancy only occasionally results in tumor growth.

Breastfeeding may be initiated without adverse effects on the tumors and may be initiated after delivery unless there have been visual field defects during pregnancy (Auriemma, 2013; Domingue, 2014). Treatment before conception and during pregnancy does not affect the incidence of persistent lactation following discontinuation of nursing. The incidence of menstrual abnormalities and degree of galactorrhea appear to be similar to the state that existed before starting medical therapy.

Women with Hyperprolactinemia Who Do Not Wish to Conceive

For women who do not wish to conceive and for whom galactorrhea is not a problem, no therapy is necessary unless estrogen levels are low. Thus to prevent osteoporosis in this clinical situation, estrogen-progestogen hormone replacement or oral contraceptives should be given, regardless of whether an adenoma is present (Corenblum B, 1993). Long-term evaluation of all women with hyperprolactinemia should be carried out. Unless a macroadenoma is present, measurement of PRL levels once a year is advisable. Repeat imaging studies are unnecessary unless symptoms of headaches or visual disturbances occur or PRL levels increase substantially.

During medical treatment of macroadenomas, MRI or CT and occasional visual field examination should be performed to determine the effect of medication on the tumor. At these intervals, a decision can be made about whether to continue long-term treatment or to remove the tumor surgically.

KEY POINTS

- The main symptoms of hyperprolactinemia are galactorrhea and amenorrhea, the latter caused by alterations in normal GnRH release.
- Pathologic causes of hyperprolactinemia include pharmacologic agents (e.g., tranquilizers, narcotics, antihypertensive drugs), hypothyroidism, chronic renal disease, chronic neurostimulation of the breast, hypothalamic disease, and pituitary tumors (e.g., prolactinoma, acromegaly, Cushing disease).
- Autopsy studies reveal that prolactinomas are present in approximately 10% of the population.
- Approximately 70% of women with hyperprolactinemia, galactorrhea, and amenorrhea with low estrogen levels will have a prolactinoma.
- Most macroadenomas enlarge with time; almost all microadenomas do not.
- The initial operative cure rate for microadenomas is approximately 80% and 30% for macroadenomas, but the long-term recurrence rate is at least 20% for each.
- In women with hyperprolactinemia and no macroadenoma, bromocriptine or cabergoline treatment returns PRL levels to normal in 90%, induces ovulatory cycles in 80%, and eradicates galactorrhea in 60%.
- The dopamine agonist of choice is cabergoline, because of increased efficacy and fewer side effects.
- Without prior treatment, 2.7% of women with microadenomas develop symptoms, whereas 22.9% of women with a macroadenoma will develop symptoms. Estrogen therapy or oral contraceptives will not stimulate the growth of PRL-secreting microadenomas and can be used for treatment of hyperprolactinemia and hypoenestrogenism.
- Surgical treatment of prolactinomas is recommended only for patients who fail to respond or do not comply with medical management.

Hyperandrogenism and Androgen Excess Physiology, Etiology, Differential Diagnosis, Management

Roger A. Lobo

Hyperandrogenism in women is often referred to as **androgen excess**. Although most women with hyperandrogenism will have hyperandrogenemia (elevated androgen levels in blood) as well as skin manifestations (e.g., **acne**, **hirsutism**, or **alopecia**), many women exhibit only skin manifestations without demonstrable findings in blood, and women can have no clinical signs of hyperandrogenism despite hyperandrogenemia. This chapter begins with a discussion of physiology, which will help explain this paradox.

The clinical signs associated with excessive androgen production in women are related to findings in skin and include acne, hirsutism, alopecia and, rarely, **virilization**. It is these complaints that warrant an evaluation and possible treatment. Hyperandrogenemia, per se, should not be the target of any treatment.

These skin disorders may be understood by understanding the **pilosebaceous unit (PSU)**. The PSU is composed of a sebaceous component and pilary component from which the hair shaft arises. Abnormalities of the sebaceous component lead to acne, and abnormalities of the pilary unit lead to excessive growth (hirsutism) or excessive shedding (alopecia). There are two types of hair; vellus hair is soft, fine, and unpigmented, whereas terminal hair is coarse, thick, pigmented, and undergoes cyclic changes. Anagen is the growth phase of hair. It is followed by the transitional catagen phase and, finally, by a resting, or telogen, phase, after which the hair sheds (Ebling, 1988). Androgen is necessary to produce development of terminal hair, and the duration of the anagen phase is directly related to the levels of circulating androgen (Rosenfield, 2005b). The duration of anagen also determines the length of hair, which varies in different parts of the body. For facial hair it is approximately 4 months, which has implications for the treatment of facial hirsutism, described later.

There are several steroidogenic enzymes in the hair follicle, but the activity level of the enzyme **5 α -reductase** most directly influences the degree of androgenic effect on hair growth. With elevated levels of circulating androgen or increased activity of 5 α -reductase, terminal hair appears where normally only vellus hair is present. With these alterations, the length of the anagen phase is prolonged and the hair becomes thicker. Excessive 5 α -reductase activity also may lead to acne as well as scalp hair loss (alopecia).

The presence of hirsutism without other signs of virilization is associated with a milder increase in androgenic activity, compared to what is observed with virilization, and it has a longer, more

gradual onset. The amount and location of hair growth found in women with hirsutism varies. In the milder forms, hair is found only on the upper lip and chin, whereas with increasing severity it appears on the cheeks, chest (intermammary), abdomen (superior to the umbilicus), inner aspects of the thighs, lower back, and intergluteal areas. The severity of the hirsutism can be roughly quantified by a modified scoring system of Ferriman and Gallwey (Ferriman, 1961; Hatch, 1981) (Fig. 40.1, Table 40.1). Examples of this scoring system may be found in Figure 40.2. Although a score greater than 7 or 8 has generally been considered to be consistent with hirsutism, this only pertains to the Caucasian or African-American population. In Asian women the threshold for an abnormal score is much lower at >3 (Escobar-Morreale, 2012). Increased hair growth only on the extremities or in isolated areas is called **hypertrichosis** and should not be confused with hirsutism.

Virilization is a relatively uncommon clinical finding and its presence is usually associated with markedly elevated levels of circulating testosterone (≥ 2 ng/mL). In contrast to the gradual development of hirsutism, signs of virilization usually occur over a relatively short period. These signs are caused by the masculinizing and defeminizing (antiestrogenic) actions of testosterone and include temporal balding, clitoral hypertrophy, decreased breast size, dryness of the vagina, and increased muscle mass. Women with virilization are almost always amenorrheic. The presence of androgen-secreting neoplasms should always be suspected in any woman who develops signs of virilization, particularly if the onset is rapid.

PHYSIOLOGY OF ANDROGENS IN WOMEN

Androgen production in women is best understood by the concept of production from glandular tissues, namely the ovaries and adrenals, and from nonglandular tissues. This third compartment of production and modification of androgens includes many peripheral tissues and, for our discussion of hyperandrogenism, principally means the PSU itself, which not only responds to androgen but can modify it by enzymatic modifications. From a quantitative perspective, the major androgen produced by the ovaries is **testosterone** and that of the adrenal glands is **dehydroepiandrosterone sulfate (DHEAS)**. Measurement of the amount of these two steroids in the circulation provides clinically relevant information regarding the presence and source of increased androgen

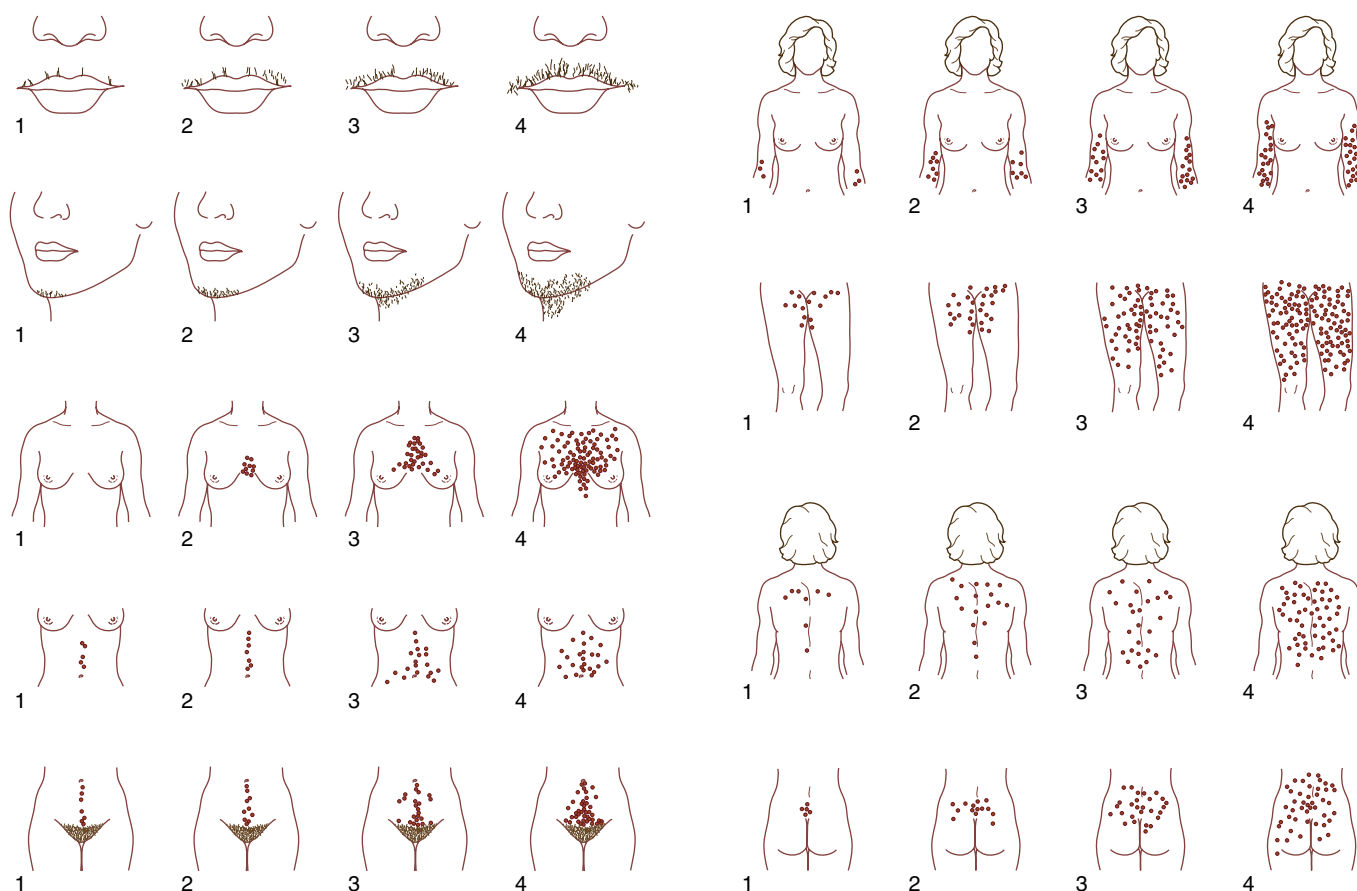

Figure 40.1 Modified Ferriman Gallwey score. (Modified from Hatch R, Rosenfield RL, Kim MH, et al. Hirsutism: implications, etiology and management. *Am J Obstet Gynecol.* 1981;140[7]:815-830.)

Table 40.1 Definition of Hair Gradings at 11 Sites*

Site	Grade	Definition
Upper lip	1	Few hairs at outer margin
	2	Small mustache at outer margin
	3	Mustache extending halfway from outer margin
	4	Mustache extending to midline
Chin	1	Few scattered hairs
	2	Scattered hairs with small concentrations
	3, 4	Complete cover, light and heavy
Chest	1	Circumareolar hairs
	2	With midline hair in addition
	3	Fusion of these areas, with 75% cover
	4	Complete cover
Upper back	1	Few scattered hairs
	2	Rather more, still scattered
	3, 4	Complete cover, light and heavy
Lower back	1	Sacral tuft of hair
	2	With some lateral extension
	3	75% cover
	4	Complete cover
Upper abdomen	1	Few midline hairs
	2	Rather more, still midline
	3, 4	Half- and full cover
Lower abdomen	1	Few midline hairs
	2	Midline streak of hair
	3	Midline band of hair
	4	Inverted V-shaped growth
Arm	1	Sparse growth affecting not more than 25% of limb surface
	2	More than this; cover still incomplete
	3, 4	Complete cover, light and heavy
Forearm	1-4	Complete cover of dorsal surface; two grades of light and two of heavy growth
Thigh	1-4	As for arm
Leg	1-4	As for arm

From Ferriman D, Gallwey JD. Clinical assessment of body hair growth in women. *J Clin Endocrinol Metab.* 1961;21:1440-1447.

*Grade 0 at all sites indicates absence of terminal hair.

Figure 40.2 Examples of scoring for hirsutism using the Ferriman Gallwey method in [Figure 40.1](#). (Photographs of women without use of any method to remove body hair; obtained with personal confidentiality and institutional review board permission.) Panels A-I depict the 9 different body areas as listed on each panel. (Modified from Yildiz BO, Bolour S, Woods K, et al. Visually scoring hirsutism. *Hum Reprod Update*. 2010;16[1]:51-64.)

Figure 40.2, cont'd

production. In addition to glandular production of androgens, conversion of androstenedione and Dehydroepiandrosterone (DHEA) to testosterone occurs in peripheral tissues.

The ovaries secrete only approximately 0.1 mg of testosterone/day, mainly from the thecal and stroma cells. Other androgens secreted by the ovary are androstenedione (1 to 2 mg/day) and DHEA (<1 mg/day). The adrenal glands, in addition to secreting large quantities of DHEAS (6 to 24 mg/day), secrete approximately the same daily amount of androstenedione (1

mg/day) as the ovaries and less than 1 mg of DHEA/day. The normal adrenal gland secretes little testosterone, although some adrenal tumors have the ability to produce testosterone directly.

Androstenedione and DHEA do not have strong androgenic activity but are peripherally converted at a slow rate to the biologically active androgen, testosterone. Only approximately 5% of androstenedione and a smaller percentage of DHEA are converted to testosterone. The total daily production of testosterone in women is normally approximately 0.35 mg. Of this, 0.1

Table 40.2 Origin of Testosterone in Women

Origin	Amount (mg/day)
Ovarian secretion	0-1
Peripheral conversion	
Androstenedione → testosterone	0.2
Dehydroepiandrosterone → testosterone	0.05
Total testosterone production	0.35

From Lobo RA. Androgen excess. In: Mishell DR Jr, Davajan V, Lobo RA, eds. *Infertility, Contraception and Reproductive Endocrinology*. 3rd ed. Cambridge, MA: Blackwell Scientific; 1991.

Table 40.3 Plasma Concentrations of Androgens During Menstrual Cycle Same

Steroid Hormone	Phase of Cycle	PLASMA CONCENTRATION	
		Mean	Range
Androstenedione (ng/mL)	*	1.4	0.7-3.1
Testosterone (ng/mL)	*	0.35	0.15-0.55
Dehydroepiandrosterone (ng/mL)	*	4.2	2.7-7.8
Dehydroepiandrosterone sulfate (μg/mL)	*	1.6	0.8-3.4

From Goebelsmann U. Steroid hormones. In: Mishell DR Jr, Davajan V, eds. *Infertility, Contraception and Reproductive Endocrinology*. 2nd ed. Oradell, NJ: Medical Economics Books; 1986.

*Unspecified; no major changes during menstrual cycle.

mg comes from direct ovarian secretion, 0.2 mg from peripheral conversion of androstenedione, and 0.05 mg from peripheral conversion of DHEA (Table 40.2). Because the ovaries and adrenal gland secrete approximately equal amounts of androstenedione and DHEA, approximately two thirds (0.22 mg) of the daily testosterone produced in a woman originates from the ovaries. Thus increased circulating levels of testosterone usually indicate abnormal ovarian androgen production. Normal circulating levels of these androgens in women of reproductive age are shown in Table 40.3. For practical purposes, circulatory levels of DHEAS reflect an adrenal source of production, and in women more than 95% is adrenal derived. Occasionally, in women who have increased production of ovarian DHEA, such as some with polycystic ovary syndrome (PCOS), the elevated levels of DHEAS might have an ovarian component because DHEA may be converted to DHEAS in the circulation. Another specific marker of adrenal androgen production, used for research purposes, is 11β-hydroxyandrostenedione (Stanczyk, 1991), because the adrenal primarily has the ability to 11-hydroxylate androstenedione, whereas the ovary has a limited ability to do so.

Although DHEAS serves as a good marker of adrenal hyperandrogenism, several guidelines for the evaluation of hyperandrogenism in women omit this measurement, because DHEAS itself is a “weak” androgen and may not contribute much to the overall androgenicity. Nevertheless it is our perspective that the measurement of DHEAS gives a more complete picture of androgen production.

Most testosterone in the circulation (≈85%) is tightly bound to sex hormone-binding globulin (SHBG) and is believed to be biologically inactive. An additional 10% to 15% is loosely bound to albumin, with only approximately 1% to 2% not bound to any protein (**free testosterone**). Both the free and albumin-bound

Figure 40.3 Peripheral androgen metabolism and markers of this activity. Ao G, Androsterone glucuronide; DHT, dihydrotestosterone; 3α-diol G, 3α-androstane-3α,17β-diol glucuronide; (S), serum. (From Lobo RA. Androgen excess. In: Mishell DR Jr, Davajan V, Lobo RA, eds. *Infertility, Contraception and Reproductive Endocrinology*. 3rd ed. Cambridge, MA: Blackwell Scientific; 1991.)

fractions (often called *unbound*) are biologically active. Serum testosterone can be measured as the total amount, the amount that is believed to be biologically active (unbound, or non-SHBG bound), and as the free form. As discussed later, because commercial laboratory measurements of “free” testosterone are not accurate, it may be useful to measure the ratio of testosterone and SHBG.

To exert a biologic effect, testosterone is metabolized peripherally in target tissues to the more potent androgen **5α-dihydrotestosterone (DHT)** by the enzyme **5α-reductase**. 5α-reductase activity is important for testosterone action peripherally (as in the PSU) as well as in the genitalia (Serafini, 1985a). It is not necessary for testosterone action in other areas such as in muscle or bone. After further 3-keto reduction, DHT is converted to another metabolite, 5α-androstane-3α,17β-diol (3α-diol). 3α-Diol is conjugated to the sulfate or glucuronide. The glucuronide, **5α-androstane-3α,17β-diol glucuronide (3α-diol-G)**, is a stable, irreversible product of intracellular 5α-reductase activity and reflects this activity in blood (Fig. 40.3).

Even with normal circulatory levels of androgen, increased 5α-reductase activity in the PSU results in increased androgenic activity, producing hirsutism (Serafini, 1985a; Paulson, 1986) (Fig. 40.4). Measurements of 5α-reductase activity in skin biopsies have found that the level of activity correlated well with the degree of hirsutism present (Serafini, 1985b). The degree of 5α-reductase activity can be measured in skin biopsies by a variety of methods. This technique is only used for investigational purposes; if necessary for diagnostic reasons, 3α-diol-G levels can be directly measured in serum. We have found that the measurement of this metabolite is the most accurate indicator of the degree of peripheral androgen metabolism in women, as long as the level of glandular production (testosterone) is appreciated. Although serum levels of total testosterone are similar in normal and hirsute women, there are significant differences in 3α-diol-G (Lobo, 1983) (Fig. 40.5). In general, whereas non-SHBG-bound testosterone has been found to be

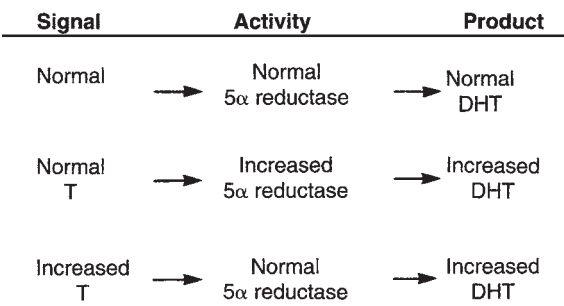

Figure 40.4 Influence of androgen substrate (signal; e.g., testosterone or androstenedione) and 5α-reductase activity (in pilosebaceous units) on local production of biologically active androgens. T, Testosterone; DHT, dihydrotestosterone. (From Lobo RA. Androgen excess. In: Mishell DR Jr, Davajan V, Lobo RA, eds. *Infertility, Contraception and Reproductive Endocrinology*. 3rd ed. Cambridge, MA: Blackwell Scientific; 1991.)

Figure 40.5 Plasma total testosterone, unbound testosterone (free T) and 5α-androstane-3α,17β-diol glucuronide (3α-diol-G) in normal and hirsute women. Note insignificant elevation with overlap for testosterone and free T testosterone and highly significant increase in 3α-diol-G without overlap between two groups of women. (From Horton R, Hawks D, Lobo RA. 3α,17β-androstanediol glucuronide in plasma: a marker of androgen action in idiopathic hirsutism. *J Clin Invest*. 1982;69:1203-1206.)

elevated in approximately 60% to 70% of hirsute women, levels of 3α-diol-G have been found to be elevated in more than 80% of women in this setting.

In summary, there are three markers of androgen production in serum, one for each compartment in which androgens are produced (Table 40.4). These measurements best reflect the area of interest, although it is clear that each compartment also produces other hormones. Interpretation of levels of 3α-diol-G is controversial because these levels are highly dependent on

Table 40.4 Markers of Androgen Production

Source	Marker
Ovary	Testosterone
Adrenal gland	DHEAS
Periphery	3α-diol-G

DHEAS, Dehydroepiandrosterone sulfate; 3α-diol-G, 5α-androstane-3α,17β-diol glucuronide.

circulating levels of precursor androgens, such as testosterone and also androstenedione. A reasonable argument may be that if testosterone and DHEAS are normal but there is significant hirsutism, then measuring 3α-diol-G may not be necessary and one may merely assume a peripheral source of androgen excess.

CAUSES OF ANDROGEN EXCESS OR HYPERANDROGENISM

Although most causes will result in hirsutism, each of the diagnostic categories can lead to any of the manifestations of androgen excess: acne, hirsutism, or alopecia. One frequent causative factor of signs of androgen excess is the administration of androgenic medication. In addition to testosterone itself, various anabolic steroids, 19-norprogesterogens, and danazol have androgenic effects. Thus a careful history of medication intake is important for all women with hirsutism.

Hirsutism or virilization can also be associated with some forms of abnormal gonadal development. With this cause, individuals have signs of external sexual ambiguity or primary amenorrhea, in addition to findings of androgen excess, and a Y chromosome is often present. These conditions are discussed further in Chapter 38.

Signs of androgen excess during pregnancy can be caused by increased ovarian testosterone production. This is usually caused by a luteoma of pregnancy or hyperreactio luteinalis. The former is a unilateral or bilateral solid ovarian enlargement; the latter is bilateral cystic ovarian enlargement. After pregnancy is completed, the excessive ovarian androgenic production resolves spontaneously and the androgenic signs regress.

A diagnosis of these three causes of androgen excess can usually easily be made by means of a careful history and physical examination. The remaining causes of androgen excess, together with the origin of hyperandrogenism, are listed in Table 40.5. Details of each of these causes will be described. Idiopathic hirsutism and PCOS are the most common disorders, together making up more than 90% of cases. PCOS is the most frequent disorder, and because of its overall prevalence and importance among reproductive women, it is covered in detail in a separate chapter.

IDIOPATHIC HIRSUTISM (PERIPHERAL DISORDER OF ANDROGEN METABOLISM)

Idiopathic hirsutism is diagnosed when there are signs of hirsutism and regular menstrual cycles in conjunction with normal circulating levels of androgens (both testosterone and DHEAS). Because this type of disorder is frequently present in several individuals in

Table 40.5 Differential Diagnosis of Hirsutism and Virilization*

Source	Diagnosis
Nonspecific	Exogenous, iatrogenic Abnormal gonadal or sexual development
Pregnancy	Androgen excess in pregnancy, luteoma or hyperreactio luteinalis
Periphery	Idiopathic hirsutism
Ovary	Polycystic ovary syndrome [†] Functional or idiopathic hyperandrogenism [‡] Stromal hyperthecosis
Adrenal gland	Ovarian tumors Adrenal tumors Cushing syndrome Adult-onset congenital adrenal hyperplasia

*Idiopathic hirsutism and polycystic ovary syndrome do not present with virilization.

[†]The hyperandrogenism in PCOS can also be of adrenal origin, at least in part.

[‡]Functional hyperandrogenism may well be a type of PCOS, but without clearly defined polycystic ovaries on ultrasound, and can also have an adrenal source of hyperandrogenism.

the same family, particularly those of Mediterranean descent, it has also been called *familial*, or *constitutional*, *hirsutism*. Because neither ovarian nor adrenal androgen production is increased, the cause of the androgen excess has been called *idiopathic hirsutism*. Several studies have been done, where it has been documented that some women so diagnosed have subtle increases in androgen production and metabolism. However, the more important way to characterize this disorder, where androgens are normal or very slightly increased, is that there is an enhancement of androgen action in the PSU (i.e., an increased androgen sensitivity), which also has a familial predisposition. We have found that approximately 80% of these women have increased levels of 3α -diol-G, indirectly indicating that the cause of hirsutism is largely the result of increased 5α -reductase activity (Paulson, 1986) (Fig. 40.6). Also, we have directly measured the percentage conversion of testosterone to DHT in genital skin as an assessment of the 5α -RA level in the skin of women with idiopathic hirsutism. The amount of 5α -RA was increased in hirsute women as compared with normal women and correlated well with the degree of hirsutism and levels of serum 3α -diol-G (Serafini, 1985b). Thus idiopathic hirsutism is actually a disorder of the peripheral compartment and is possibly genetically determined, although it is also possible that early exposure to androgens can program increased 5α -RA. Anti-androgens that block peripheral testosterone action or interfere with 5α -RA are effective therapeutic agents for this disorder.

POLYCYSTIC OVARY SYNDROME

Polycystic ovary syndrome (PCOS) is the most common disorder diagnosed in women presenting with symptoms and signs of androgen excess. A survey taken in 2012 suggested that it accounts for 71% of women presenting with hirsutism (Escobar-Morreale, 2012).

PCOS was originally described in 1935 by Stein and Leventhal as a syndrome consisting of amenorrhea, hirsutism, and obesity in association with enlarged polycystic ovaries (Stein, 1935). The classic definition of PCOS includes women who are anovulatory and have irregular periods as well as hyperandrogenism, as determined by signs such as hirsutism or elevated blood levels of androgens, testosterone, or DHEAS. The diagnosis should only be made in the absence of other known disorders, including enzymatic

Figure 40.6 Serum 3β -diol-G in premenopausal nonhirsute women (Pre), hirsute women, normal men, and postmenopausal nonhirsute women (Post). The asterisks denote $P < .05$, as compared with Pre. (From Paulson RJ, Serafini PC, Catalino JA, Lobo RA. Measurements of $3\alpha, 17\beta$ -androstenediol glucuronide in serum and urine and the correlation with skin 5α -reductase activity. *Fertil Steril*. 1986;46:222-226.)

disorders (e.g., 21-hydroxylase deficiency), Cushing syndrome, or tumors (The Rotterdam ESHRE/ASRM-sponsored PCOS consensus workshop group, 2004; Azziz, 2006).

As will be discussed in Chapter 41, PCOS is also diagnosed in women with normal menstrual cycles, who are presumably ovulating, and in its widest spectrum of diagnostic categories is the most common reproductive disorder, occurring in 5% to 20% of all women of reproductive age (Fauser, 2012).

For the purposes of understanding the interaction of androgen excess and PCOS, it should be appreciated that the most important feature of PCOS is that it is a hyperandrogenic disorder (Azziz, 2006). Although the majority of women will have an ovarian source of hyperandrogenism (i.e., an elevation in testosterone), adrenal hyperandrogenism (elevations in DHEAS) may be found in up to 50% of women (Carmina, 1992). In some women with PCOS and signs of hyperandrogenism (acne, hirsutism, or alopecia), blood levels of androgens may be “normal.” This most likely relates to the lack of sensitivity of current assays.

Because there are important aspects of PCOS that are prevalent (metabolic disease, fertility concerns, cancer risk, etc.) and because this disorder is extremely common in women of reproductive age, even though it may not be accurately diagnosed, a separate chapter (Chapter 41) is devoted to this discussion.

Serum testosterone levels usually range from 0.7 to 1.2 ng/mL, and androstenedione levels are usually from 3 to 5 ng/mL. In addition, approximately 50% of women with this syndrome have elevated levels of DHEAS, suggesting adrenal androgen involvement. However, in some countries, the prevalence of this putative adrenal involvement is lower. Evidence also exists for adrenal hyperactivity to stimulation in at least one third of women with PCOS. Because of the hyperandrogenic state, and the frequent hyperinsulinemia and overweight status in PCOS (discussed in Chapter 41), sex hormone binding globulin (SHBG)

Figure 40.7 Scheme depicting the possible role of adrenal-derived androgen in initiating androgen excess and anovulation. A_2 , Androstenediol; E_2 , estradiol; LH , luteinizing hormone; $SHBG-BC$, sex hormone-binding globulin binding capacity; T , testosterone. (From Lobo RA, Goebelsmann U. Effect of androgen excess on inappropriate gonadotropin secretion as found in polycystic ovary syndrome. *Am J Obstet Gynecol.* 1982;142:394-401.)

is decreased, leading to an increase in the unbound fraction of testosterone, thus heightening the androgenicity (Lobo, 1982) (Fig. 40.7). Although almost all women with PCOS have elevated levels of circulating androgens, the presence or absence of hirsutism depends on whether those androgens are converted peripherally by 5α -reductase to the more potent androgen DHT, as reflected by increased circulating levels of 3α -diol-G. Nonhirsute women with PCOS have elevated circulatory levels of testosterone, unbound testosterone, or DHEAS, but not 3α -diol-G (Lobo, 1983).

FUNCTIONAL OR IDIOPATHIC HYPERANDROGENISM

This category is included because it may be found in other reviews in the literature and is more commonly diagnosed by European clinicians; it is considered to occur in up to 15% of women presenting with hirsutism (Escobar-Morreale, 2012). It is diagnosed when androgens are elevated (either ovarian or adrenal) and menstrual cycles are regular and ovulatory. There is also no evidence on ultrasound for polycystic ovaries, making this an “idiopathic” state. However, it is our view that this category is really a variant of PCOS, in which women may be ovulatory. Because ovarian morphology in women with PCOS is variable, this category may essentially be merged with PCOS.

STROMAL HYPERTHECOSIS

Stromal hyperthecosis is an uncommon benign ovarian disorder in which the ovaries are typically bilaterally enlarged to approximately 5 to 7 cm in diameter. Histologically, there are nests of luteinized theca cells within the stroma (Fig. 40.8). The capsules of these ovaries are thick, similar to those found in PCOS but, unlike PCOS, subcapsular cysts are uncommon. The theca cells produce large amounts of testosterone, as determined by retrograde ovarian vein catheterization. The ultrasound picture of stromal hyperthecosis may be variable (Brown, 2009). Like PCOS, this disorder has a gradual onset and is initially associated with anovulation or amenorrhea and hirsutism. However, unlike PCOS, with increasing age the ovaries secrete steadily increasing amounts of testosterone. Thus when women with this disorder reach the fourth decade of life, the severity of the hirsutism

Figure 40.8 Surgical specimen of ovarian stromal hyperthecosis. Note fleshy appearance, without cystic activity.

increases and signs of **virilization**, such as temporal balding, clitoral enlargement, deepening of the voice, and decreased breast size, appear and gradually increase in severity. By this time, serum testosterone levels are usually higher than 2 ng/mL, similar to levels found in ovarian and adrenal testosterone-producing tumors. However, with the latter conditions, the symptoms of virilization appear and progress much more rapidly than with ovarian hyperthecosis, in which symptoms progress gradually over many years.

ANDROGEN-PRODUCING TUMORS

Tumors are rare, occurring less than 1% of the time in women presenting with hyperandrogenism, but they represent the most important reason for evaluating women with androgen excess in order to rule out the diagnosis.

Ovarian Neoplasms

It is possible for almost every type of ovarian neoplasm to have stromal cells that secrete excessive amounts of testosterone and cause signs of androgen excess. Thus on rare occasions, excess testosterone produced by benign and malignant cystadenomas, Brenner tumors, and Krukenberg tumors have caused hirsutism, virilization, or both. Certain germ cell tumors contain many testosterone-producing cells. The testosterone produced by two of these neoplasms, **Sertoli-Leydig cell tumors** and **hilus cell tumors**, almost always causes virilization. In addition, lipoid cell (adrenal rest) tumors can produce increased amounts of testosterone, DHEAS, or both. Rarely, granulosa/theca cell tumors can also produce testosterone in addition to increased levels of estradiol.

Androgen-producing ovarian tumors usually produce rapidly progressive signs of virilization. Sertoli-Leydig cell tumors usually develop during the reproductive years (second to fourth decades) and, by the time they produce detectable signs of androgen excess, the tumor is almost always (>85% of the time) palpable during bimanual examination. These tumors are uncommon. Less than 1% of solid ovarian neoplasms are Sertoli-Leydig cell tumors. Hilus cell tumors usually occur after menopause. They are usually small and not palpable during bimanual examination; however, the history of rapid development of signs of virilization and the presence of markedly elevated levels of testosterone

(more than 2.5 times the upper limits of the normal range), with normal levels of DHEAS, usually facilitate the diagnosis.

Adrenal Tumors

Almost all the androgen-producing adrenal tumors are adenomas or carcinomas that generate large amounts of the C19 steroids normally produced by the adrenal gland—DHEAS, DHEA, and androstenedione. Although these tumors do not usually secrete testosterone directly, testosterone is produced by extraglandular conversion of DHEA and androstenedione. Women with these tumors usually have markedly elevated serum levels of DHEAS ($>8 \mu\text{g/mL}$). Women with these laboratory findings and a history of rapid onset of signs of androgen excess should undergo a computed tomography (CT) scan or magnetic resonance imaging (MRI) of the adrenal glands to confirm the diagnosis. In addition to these uncommon tumors, a few testosterone-producing adrenal adenomas have been reported. The cellular patterns of these tumors resemble those of ovarian hilus cells, and the tumors secrete large amounts of testosterone. Because adrenal adenomas also secrete DHEAS, an adrenal adenoma is highly likely when DHEAS levels are greater than $8 \mu\text{g/mL}$ and testosterone levels are more than 1.5 ng/mL .

LATE-ONSET 21-HYDROXYLASE DEFICIENCY

Congenital adrenal hyperplasia (CAH) is an inherited disorder caused by an enzymatic defect (usually 21-hydroxylase [21-OHase] or, less often, 11 β -hydroxylase), resulting in decreased cortisol biosynthesis. As a consequence, adrenocorticotrophic hormone (ACTH) secretion increases and adrenal cortisol precursors produced proximal to the enzymatic block accumulate. These are converted mainly to 17-hydroxyprogesterone and androstenedione, and androstenedione in turn is converted to testosterone, which produces signs of androgen excess. Late or adult onset CAH occurs in no more than 3% of women presenting with hirsutism (Escobar-Morreale, 2012).

Because the enzymatic defects are congenital, the classic severe form (complete block) usually becomes clinically apparent in fetal life by producing masculinization of the female external genitalia. The severe form of CAH is the most common cause of sexual ambiguity in the newborn. The more attenuated (mild) block of 21-hydroxylase activity usually does not produce the physical signs associated with increased androgen production until after puberty. Thus this condition, known as **late-onset 21-hydroxylase deficiency (LOHD)** or late-onset congenital adrenal hyperplasia (LOCAH), is associated with the development of signs of hyperandrogenism in a woman in the second or early third decade of life.

Although the incidence of classic CAH is only 1 in 14,500 live births worldwide, Speiser and coworkers, using histocompatibility locus antigen (HLA)-B genotyping of families with LOHD-affected individuals, have concluded that the incidence of LOHD varies among different ethnic groups but, overall, is probably the most frequent autosomal genetic disorder in humans. The incidence of LOCAH was estimated to be 0.1% in a diverse white population; in Yugoslavians, Hispanics, and Ashkenazi Jews, however, the incidence was 1.6%, 1.9%, and 3.7%, respectively (Speiser, 1985) (Fig. 40.9). Both classic CAH and LOCAH are transmitted in an autosomal recessive manner at the *CYP21B* locus and are linked to the HLA-B locus.

The molecular basis of the disease is complex. The gene for *CYP21* is located on 6p near the HLA complex. In proximity to this

Figure 40.9 Relative frequencies of Nonclassical 21-hydroxylase deficiency, classical 21-hydroxylase deficiency, and other autosomal recessive disorders. (From Speiser PW, Dupont B, Rubenstein P, et al. High frequency of nonclassical steroid 21-hydroxylase deficiency. *Am J Hum Genet.* 1985;37:650-657.)

gene is a nonfunctional or pseudogene (*CYP21P*). Depending on the population, 20% to 25% of individuals with classic CAH have a deletion of the *CYP21* locus or a rearrangement between *CYP21* and *CYP21P*. Current molecular techniques of genotyping can pick up well over 95% of these abnormalities, with most cases being 1 of 10 common mutations. A spectrum of mutations results in the enzymatic defects and clinical presentations shown in Table 40.6.

LOCAH is a phenotype that is symptomatic after adolescence and does not define the genotype. Affected individuals may be homozygous for alleles, yielding mildly abnormal enzymatic activity, or compound heterozygotes with a combination of defective alleles. The so-called *cryptic 21-hydroxylase deficiency*, on the other hand, represents mild or asymptomatic individuals with biochemically identified defects that, with the advent of molecular diagnostic techniques, have been redefined as belonging to several different clinical presentations.

New and coworkers have proposed a schema for identifying and classifying the clinical spectrum of disease shown in Table 40.6. Because there are three possible manifestations of *CYP21Y* alleles (normal, mildly defective, or severely defective), there are six possible genotypes representing three clinical phenotypes (asymptomatic, LOCAH, and classic CAH). Individuals with LOCAH may be compound heterozygotes, with one mildly and one severely defective allele, or homozygous, with two mildly defective alleles. There is no perfect correlation between genotypes and phenotypes and—because the genetics are complex, with many possible abnormalities, particularly in diverse populations—it has been recommended that for clinical purposes, diagnosis and treatment of CAH should be based on

Table 40.6 Genotypic Characterization of the Forms of 21-Hydroxylase Deficiency

Form of 21-Hydroxylase Deficiency	Clinical Phenotype	Hormonal Phenotype (in Response to ACTH)	Genotype
Classic (CAH)	Prenatal virilization, fully symptomatic	Marked elevation of precursors (serum 17-hydroxyprogesterone and Δ -androstenedione)	21-OH-def ^{severe}
Nonclassic (LOHD)	Symptomatic: later development of virilization; milder symptoms Asymptomatic: no virilization or other symptoms	Moderate elevation of precursors	21-OH-def ^{severe}
			21-OH-def ^{mild}
			21-OH-def ^{mild}
			21-OH-def ^{mild}
Carrier	Asymptomatic	Precursor level greater than normal	21-OH-def ^{severe}
			21-OHase (normal)
			21-OH-def ^{mild}
			21-OHase (normal)
			21-OHase (normal)
Normal	Asymptomatic	Lowest levels—some overlap seen with carriers	21-OHase (normal)

From New MI, White PC, Pang S, et al. The adrenal hyperplasias. In: Scriver CR, Beaudet AL, Sly S, Valle D, eds. *Metabolic Basis of Inherited Diseases*. 6th ed. New York: McGraw-Hill; 1989.

biochemical findings. Carriers can be identified among family members who are heterozygous, with one normal allele. They have normal basal 17-hydroxyprogesterone levels, a mild degree of hirsutism, if present, and smaller increases of 17-hydroxyprogesterone after ACTH stimulation, usually between 3.5 and 10 ng/mL. Molecular genotyping is primarily used for prenatal testing when there is a known severe mutation to determine the risk of having a severely affected child.

LOCAH is also usually associated with menstrual irregularity. It has been hypothesized that the mechanism for anovulation is similar to that which occurs with PCOS. The increased levels of androgen lower SHBG levels, thus increasing the amount of biologically active circulating estradiol. The increased estradiol stimulates tonic LH release, which increases ovarian androgen production and locally inhibits follicular growth and ovulation. Thus women with this disorder present with postpubertal onset of hirsutism and oligomenorrhea or amenorrhea, similar to women with PCOS. However, women with LOCAH, unlike those with PCOS, commonly have a history of prepubertal accelerated growth (at 6 to 8 years of age), with later decreased growth and a short ultimate height. A history of this growth pattern, a family history of postpubertal onset of hirsutism, and findings of mild virilization are indicators of the presence of CAH.

To differentiate LOCAH from PCOS, measurement of basal (early morning) serum 17-hydroxyprogesterone levels should be performed. If basal levels are greater than 8 ng/mL, the diagnosis of LOCAH is established. If 17-hydroxyprogesterone is above normal (2.5 to 3.3 ng/mL) but less than 8 ng/mL, an ACTH stimulation test should be performed. A baseline 17-hydroxyprogesterone level should be measured and 0.25 mg of synthetic ACTH infused as a single bolus. One hour later, another serum sample of 17-hydroxyprogesterone should be measured. If the level increases more than 10 ng/mL, the diagnosis of LOCAH is established (Baskin, 1987) (Fig. 40.10).

Corticosteroid treatment is normally reserved for patients wishing to conceive to restore ovulatory function. In other women, treatment is more efficient and safer using oral contraception (OC) pills, as in PCOS and other functional states described later.

It is important to measure 11-desoxycortisol during the ACTH stimulation when the diagnosis is being evaluated, because of the possibility of 11-hydroxylase deficiency. This

Figure 40.10 Means and ranges of 17 α -hydroxyprogesterone levels before and after cosyntropin administered intramuscularly in normal subjects, suspected heterozygotes, patients with late-onset congenital adrenal hyperplasia (CAH), and one patient with adrenal carcinoma. (From Baskin HJ. Screening for late-onset congenital adrenal hyperplasia in hirsutism or amenorrhea. *Arch Intern Med*. 1987;147:847-848.)

disorder is much more rare, but it also has an incomplete, adult form and may also be associated with hypertension. Women with this incomplete form also have increases in 17-hydroxyprogesterone and thus require the measurement of 11-desoxycortisol to differentiate it from 21-hydroxylase deficiency.

CUSHING SYNDROME

Excessive adrenal production of glucocorticoids caused by increased ACTH secretion (Cushing disease) or adrenal tumors produces the signs and symptoms of Cushing syndrome. These findings include hirsutism and menstrual irregularity in addition to the classic findings of central obesity, dorsal neck fat pads, abdominal striae, and muscle wasting and weakness. The latter catabolic effect of glucocorticoid excess differs from the anabolic effects of testosterone excess, but some women with PCOS may have other clinical findings similar to those found with Cushing syndrome. Women with Cushing syndrome are more likely to present with other symptoms and signs of glucocorticoid excess, rather than because of hirsutism; but this has been found to occur in fewer than 1% of cases.

Cushing syndrome can be easily excluded by performing an overnight dexamethasone suppression test. To perform this test, 1 mg of dexamethasone is ingested at 11 PM, and the plasma cortisol level is measured the following morning, at 8 AM. If the cortisol level is less than 5 µg/100 mL, Cushing syndrome is ruled out. If the cortisol level fails to suppress to this degree, the diagnosis of Cushing syndrome is not established. It is necessary to perform a complete dexamethasone suppression test (Liddle test) or measure the urinary free cortisol and plasma ACTH levels to determine whether Cushing syndrome exists.

Depression and other conditions can cause failure to suppress with the dexamethasone screening test just described. Accordingly, many endocrinologists prefer to depend on measurement of the 24-hour urinary free cortisol level or salivary cortisol. A creatinine level is also measured to gauge completeness of urine collection. Values above 100 µg/24 hours in urine are abnormal, and values greater than 240 µg are almost diagnostic of Cushing syndrome. Late night salivary cortisol is now considered to be the most accurate method. Samples are usually obtained on two separate nights; values above 0.4 µg/dL are diagnostic for Cushing syndrome (Sakihara, 2010).

Cushing syndrome may result from a pituitary tumor producing ACTH (Cushing disease), an ectopic tumor in the body, adrenal neoplasms, or hyperplasia. Various algorithms have been developed for this differential diagnosis.

DIFFERENTIAL DIAGNOSIS

Women with androgen excess/hyperandrogenism will present with acne, hirsutism or alopecia, and some women will have more than one of these three complaints. All women with these complaints should have a careful history encompassing a physical exam, laboratory assessment of circulating androgens, and often some sort of imaging.

Measurements of total testosterone, free (unbound) testosterone, or the free androgen index have all been advocated to assist in the diagnosis of hyperandrogenism. In a clinical setting, commercial assays for testosterone are insensitive and cannot discriminate reliably between normal and abnormal values, unless values are very high (tumor or male range). Several organizations are addressing this factor, including the Endocrine Society, Centers for Disease Control and Prevention (CDC), Androgen Excess and PCOS Society (AE-PCOS) Society, American Society for Reproductive Medicine (ASRM), and American Congress of Obstetricians and Gynecologists (ACOG), and accurate assays will be soon be standardized (Rosner, 2010). Increasingly laboratories are using a chromatography/mass spectrometry analysis, and clinicians should make themselves familiar with the particular lab assays they use, and their normal ranges. Although the free androgen index or non-SHBG-bound testosterone level is a better discriminator of hyperandrogenism than total testosterone, an accurate measurement of total testosterone may be all that is necessary. It is not clinically important whether a hirsute woman has a total testosterone level in the highest portion of the normal range or a mildly elevated level of non-SHBG-bound testosterone. Thus to determine the magnitude of elevated androgens, as well as their source, measurement of total testosterone is more cost effective than the other assays and provides the clinician with the information necessary to establish the diagnosis. *To summarize, the laboratory workup should include an accurate measure of testosterone (unbound testosterone or the free androgen index [testosterone/SHBG is optional]), DHEAS, and 17-hydroxyprogesterone*

when LOCAH is suspected (younger individuals, family history of androgen excess, and in high prevalent ethnic groups).

As noted, androgen excess caused by iatrogenic causes, sexual ambiguity, or pregnancy-associated ovarian tumors can usually be easily determined by the history and physical examination. Masculinizing ovarian or adrenal tumors are associated with rapidly progressive signs of hirsutism and virilization. Serum testosterone levels higher than 2 ng/mL, with normal DHEAS levels, indicate the probable presence of an ovarian tumor. The diagnosis can be confirmed by bimanual pelvic examination and ultrasonography, CT, or MRI. Women with a rapid progression of virilization and DHEAS levels greater than 8 µg/mL most likely have an androgen-producing adrenal adenoma; CT or MRI can confirm the diagnosis. A long history of gradually increasing hirsutism, even if accompanied by virilization, is not consistent with the diagnosis of adrenal or ovarian tumors. The diagnosis of ovarian stromal hyperthecosis should be suspected for women with these signs and testosterone levels greater than 1.5 ng/mL. Women with physical findings consistent with Cushing syndrome should have the diagnosis ruled out. PCOS, LOHD, and idiopathic hirsutism or those women diagnosed with functional hyperandrogenism may be associated with a similar history and findings at physical examination. Women with LOHD commonly have a family history of androgen excess and often belong to an ethnic group with a higher gene frequency for an abnormality. The diagnosis of LOHD is established by measurement of 17-hydroxyprogesterone, either by testing of an early morning serum sample or following ACTH stimulation.

Apart from tumors (requiring surgery), LOCAH, and Cushing syndrome (all of these being relatively rare disorders), the other disorders causing the androgen excess are functional disorders, in which the treatment is the same as discussed later. Women presenting with only acne or alopecia should still be evaluated as described previously, but each disorder will be discussed separately as well because of some of their unique features.

TREATMENT OF ANDROGEN EXCESS/HYPERANDROGENISM

The success of treatment of hyperandrogenic disorders requires patience and persistence. The nature of the PSU and the hair cycle requires a longer time for improvement to be witnessed. In general, among the disorders, the most successful disorder to treat is acne with approximately 90% of women showing benefit; this is followed by hirsutism with an approximate 70% response rate, and finally alopecia, which only has a 30% response rate.

SPECIFIC DISORDERS

Ovarian and Adrenal Tumors

Tumors are best identified by high-grade imaging techniques. In the past, selective vein catheterization has been used, but this is seldom necessary today. Suppression/stimulation tests have not been beneficial because many tumors are LH responsive and androgens will be suppressed somewhat with oral contraceptives or GnRH agonists.

Almost all Sertoli-Leydig cell tumors are unilateral. If the woman has not completed her family and these tumors are well differentiated and confined to one ovary, the tumors may be treated by unilateral salpingo-oophorectomy. Because most hilus

cell tumors occur after menopause, they are best treated by bilateral salpingo-oophorectomy and total abdominal hysterectomy. Adrenal adenomas and carcinomas should also be treated by operative removal. Adrenal carcinomas frequently have metastasized to the liver by the time the androgenic signs have developed. Despite chemotherapy, the prognosis is poor after metastases have occurred. Stromal hyperthecosis is also best treated by bilateral salpingo-oophorectomy. After removal of the ovaries of women with stromal hyperthecosis or any of the androgen-producing tumors, the acne and oiliness of the skin disappear, breast size increases, and clitoral size decreases. The excess central hair becomes finer and grows less rapidly but does not disappear. Electrolysis or laser treatment can remove the body hair more effectively once the source of PSU stimulation has been removed.

Late-Onset 21-Hydroxylase Deficiency (Congenital Adrenal Hyperplasia)

The treatment of women with LOCAH depends on their primary complaint. The androgen excess and menstrual irregularity can be treated as in women with PCOS, usually with an oral contraceptive. However, if women wish to conceive, it is preferable to use glucocorticoids such as hydrocortisone (15 to 20 mg), prednisone (5 to 7.5 mg), or dexamethasone (0.5 to 0.75 mg) in divided doses. Doses as low as 2.5 mg of prednisone or 0.25 mg dexamethasone may be used initially. The aim of treatment is to suppress androstenedione and bring 17-hydroxyprogesterone and progesterone levels into the normal range. Ovulation usually resumes rapidly.

Polycystic Ovary Syndrome

As is discussed in [Chapter 41](#), because of the metabolic and other concerns in women with PCOS, lifestyle management has an important role in any treatment plan. It has been established that lifestyle measures and weight loss will assist in the treatment of hyperandrogenism in PCOS ([Moran, 2011](#)).

Treatment of Skin Manifestations of Androgen Excess

Although ovarian or adrenal androgen excess increases the likelihood of these complaints, enhancement of these effects because of increased 5 α -reductase activity largely explains the abnormalities. Thus a successful strategy usually requires an antiandrogen added to suppression therapy, usually with an OC. Although it is reasonable to begin with monotherapy (OC), particularly if the disorder is relatively mild, in women with more significant complaints and findings, an antiandrogen can be used initially. It is important to use antiandrogens in conjunction with an OC because of the concerns of exposure during pregnancy.

In women who have "idiopathic" hirsutism and very mild and localized complaints, it is also reasonable not to use medical therapy and to use hair removal alone, as described later.

Oral Contraceptive Steroids

Oral contraceptive steroids (usually prescribed orally, but the effect would be similar with transdermal or vaginal preparations) suppress ovarian androgens by inhibiting LH stimulation of the ovary. They also decrease adrenal androgens (DHEAS) by about 30% ([Klove, 1984](#)); and inhibit 5 α -reductase activity ([Cassidenti, 1991](#)). In addition, the potency of ethinyl estradiol in contraceptives increases SHBG, which results in lower free or unbound testosterone.

Among the various preparations, it would seem logical to use a less androgenic progestogen (norgestimate, desogestrel, drospirenone) than more potent ones (levonorgestrel). However, there

are no randomized trial data to support this assertion. There are some data to support the superiority of cyproterone acetate (CPA), which has significant antiandrogen activity, but CPA is not available in the United States. Randomized data have shown, however, that there is no difference in efficacy in using a 20 μ g or 30/35 μ g preparation ([Zimmerman, 2014](#)) and therefore lower estrogen dose contraceptives should be used. Some evidence has suggested that the newer progestogens, which are less androgenic, as well as CPA, may increase the risk of thrombosis, compared to contraceptives containing levonorgestrel or norethindrone. If true, this effect is relatively small, and the absolute risk of thrombosis in young women is small and less than that of normal pregnancy. It is important, however, to use lower-dose estrogen products (20 μ g). Also obesity is an additional risk factor for thrombosis, and thus lifestyle management is important, particularly in women with PCOS, who may be at greater risk for thrombosis.

Antiandrogens

Peripheral androgen blockade with antiandrogens is dose related. Receptor blockade with [spironolactone](#) and [flutamide](#) and a specific 5 α -2 inhibitor, [finasteride](#), are the agents most commonly used. Cyproterone acetate (2 mg), which is a progestogen is most frequently used in combination with ethinyl estradiol as an OC, although larger doses have been used as well. Drospirenone in the doses used in contraceptives (3 mg) does not have appreciable antiandrogenic activity.

Spironolactone has been used and studied extensively and should be considered the treatment of choice in the United States for women with idiopathic hirsutism, as well as many with PCOS ([Lobo, 1985](#); [Swiglo, 2008](#); [Martin, 2008](#)). In addition to being an androgen receptor blocker, it also decreases ovarian testosterone production and inhibits 5 α -RA. Various dosages, from 50 to 200 mg daily, have been used. We have found that a dose of 200 mg/day of spironolactone is more effective than 100 mg/day ([Lobo, 1985](#)). Barth and associates have found a clinically evident response of decreased hair after 3 months of spironolactone, 200 mg/day ([Barth, 1989](#)). After 1 year of treatment, a 15% to 25% reduction was seen in hair shaft diameter and linear growth rate at all body sites. With the higher dose of spironolactone, liver function test results and plasma electrolyte levels are usually unchanged, and side effects occur infrequently, except for irregular uterine bleeding. The latter can be controlled with concomitant use of OCs. Electrolytes and blood pressure should be monitored for the first few weeks of therapy to ensure that hypotension and hyperkalemia do not occur.

Flutamide is a pure androgen blocker that has shown efficacy in the treatment of hirsutism. There is a dose-response relationship (250 to 750 mg/day), and even lower doses have some efficacy ([Cusan, 1994](#); [Inal, 2005](#)). However, the major concern is hepatic toxicity ([Bruni, 2012](#)), which may lead to death. Most guidelines have advised against the use of flutamide for this reason ([Martin, 2008](#)), and if it is used it should be used with caution at lower doses and with close monitoring of hepatic function. As with other antiandrogens, contraception should be used.

Finasteride, a 5 α -reductase inhibitor (5 mg/day), is an effective treatment for hirsutism, and 5 mg has similar efficacy as 100 mg of spironolactone ([Wong, 1995](#); [Bayram, 2002](#)). Because finasteride is a specific 5 α -2 inhibitor (there are two isoenzymes for 5 α reductase: 1 and 2) and hirsutism is likely a combination of both types 1 and 2, a better inhibitor may be preferable, but it is unavailable at present. Finasteride is used currently as a second-line treatment when there are side effects or problems with using spironolactone.

Other Agents for Treatment

In severe cases, use of a **GnRH agonist** with estrogen or an OC add-back has been shown to be successful (Andreyko, 1986; Bayhan, 2000). However, this is expensive and cannot be used for long-term therapy. It has been used in women with high levels of circulating androgens.

Ketoconazole, which blocks adrenal and gonadal steroidogenesis by inhibiting cytochrome P450–dependent enzyme pathways, has been used in dosages of 200 mg, twice daily, to treat hyperandrogenism associated with PCOS and idiopathic hirsutism. This potent drug effectively decreases hair growth and acne, but major side effects and complications (including hepatitis) occur in most women so treated. These problems limit the use of ketoconazole to select women, who require careful monitoring. In these severe cases, it is probably preferable to use a GnRH agonist.

Glucocorticoids have been used for the treatment of androgen excess for many years. Although it is logical to suppress the adrenal gland in women who have adrenal androgen excess, and low doses have been used with some degree of success, the benefit is relatively modest (Carmina, 1998) compared with other agents such as antiandrogens. Because of its potential for serious side effects, glucocorticoids are not recommended for treating androgen excess but may be considered as an adjunct to ovulation induction in some women.

Insulin sensitizers have been proposed as agents to treat androgen excess and have been used in women with PCOS. Although some agents have shown some minor beneficial effects, they are not recommended as a primary therapy for manifestations of androgen excess (Cosma, 2008).

Eflornithine cream 13.9% is a topical treatment that has been approved by the U.S. Food and Drug Administration (FDA) for facial hirsutism. Eflornithine is an inhibitor of ornithine decarboxylase, which is an enzyme necessary for the growth and development of the hair follicle. It was originally developed for the treatment of trypanosomal sleeping sickness. It is approved only for facial hirsutism and its mechanism is such that it affects all hair follicles and is not specific for hirsutism; it has been used for older women with nonterminal hair growth (Wolf, 2007). Its application twice a day results in a modest improvement in about 8 weeks. Thus for isolated facial hirsutism it may have an adjunctive role in that it can hasten the overall response, which takes much longer with traditional suppressive therapy. Side effects are minimal and include some local irritation; it is also expensive.

Follow-up for Treatment of Hirsutism

Because of the length of the hair growth cycle, responses to treatment should not be expected to occur within the first 3 months of therapy, and it usually takes about 6 months to see a response. Objective methods of assessing changes of hair growth, such as photographs, are useful. With the use of various therapies, a successful response for hirsutism should occur in approximately 70% of women within 1 year of therapy. Remaining excess hair can be removed by electrolysis or laser techniques. Treatment should be continued for 3 years and then stopped to determine whether hirsutism recurs. If so, therapy can be reinitiated.

Hair Removal Techniques

These cosmetic measures can be used as a primary treatment for mild isolated hirsutism or should be initiated after adequate suppressive therapy to remove unwanted hair once the growth rate has been inhibited by therapy.

Many depilatory methods have been used, but more definitive therapies are available such as the use of electrolysis and lasers, although these therapies may be expensive.

Electrolysis uses electrical energy through a wire electrode. Destruction of hair follicles results in its permanent removal. A “blended” technique has been thought to be more effective (Richards, 1995) although electrolysis is somewhat painful and can only be used for small areas at a given time.

Photoepilation uses lasers that apply heat to pigmented hair follicles. There are four types of lasers: Nd:Yag, diode, alexandrite, and ruby, and a meta-analysis suggested superiority of the diode laser (Sadighha, 2009). In general, long wavelength, long pulse duration lasers such as the Nd:Yag or diode are recommended for pigmented darker hair. For women with light or blond hair, electrolysis is recommended (Harris, 2014).

Acne

Acne vulgaris is considered to be a manifestation of androgen excess, although it need not be, and particularly in adolescents it merely reflects the physiologic responses of the PSU to the changing hormonal status and alterations in the bacteriologic flora. In general, however, androgens stimulate sebum production, and high doses of estrogen can inhibit it. There are many scoring systems for acne vulgaris, and the most common is the method presented by Cook, although it is primarily used for research purposes (Cook, 1979). Among hyperandrogenic disorders, acne vulgaris is the disorder that is most successfully treated, with response rates of close to 90%.

Among women who present with acne, 52% can be found to have androgen excess, with increases in unbound testosterone being the most frequently encountered (Lucky, 1983). Thus in women who present with significant acne, particularly if they have not responded to routine dermatologic measures, an evaluation of androgen excess is warranted. An enhancement of 5 α -reductase, mostly type 1, is a large part of the androgen abnormalities in acne (Carmina, 1991).

Treatment is usually with combination oral contraceptives (Arowojola, 2012), which is at least as effective as chronic antibiotic therapy (Koo, 2014). Among oral contraceptives, less androgenic progestogens have been preferred (Jaisamrarn, 2014), although there is limited evidence for superiority over androgenic progestogens (Kelly, 2010). The estrogen component of the contraceptive pill is particularly important for inhibiting sebum production, although it usually does not require increasing ethynyl estradiol above the 35 μ g dose. Although most antiandrogenic agents are effective (Fig. 40.11), oral contraceptives and pure antiandrogens are superior to finasteride (Carmina, 2002a). If oral contraceptives alone are not completely successful, as with hirsutism, the addition of antiandrogens are beneficial (Carmina, 2002b; Zouboulis, 2010).

Alopecia

Alopecia in women is a major source of stress and fear. Previously called androgenic alopecia, the preferred term currently is **female pattern hair loss (FPHL)**. This may or may not be associated with androgen excess. Hair loss is usually on the frontal scalp and vertex, with relative sparing of the occipital scalp. It is important to rule out dermatologic diseases such as alopecia areata and specific scalp dermatologic diseases. Absent this, although it is important to rule out androgen excess, with hormonal evaluation as suggested previously, the prevalence of

Figure 40.11 Percentage reduction in Cook scores after 1 year of treatment with either Diane (contraceptive pill with CPA/EE2), high-dose CPA, flutamide 250 mg/day, finasteride 5 mg/day. The asterisk signifies reduction at $P < .01$; the cross at $P < .05$. (Modified from Carmina E, Lobo RA. A comparison of the relative efficacy of antiandrogens for the treatment of acne in hyperandrogenic women. *Clin Endocrinol [Oxf]*. 2002;57[2]:231-234.)

androgen abnormalities is low, with elevations occurring in only 39% of women (Futterweit, 1988). Androgen excess, perhaps estrogen abnormalities, and genetics play into the etiology. With androgen excess, exaggerated 5 α -reductase activity has been implicated in women with alopecia (Legro, 1994). There are several scoring systems for FHPL, with the method presented by Ludwig being the most commonly used, but mainly for research purposes (Ludwig, 1977).

Figure 40.12 Percentage decrease in Ludwig scores in four groups of women with hyperandrogenic alopecia. Only flutamide (-21%) showed a significant decrease in scores, $P < .05$. (Modified from Carmina E, Lobo RA. Treatment of hyperandrogenic alopecia in women. *Fertil Steril*. 2003;79[1]:91-95.)

Antiandrogen therapy is the mainstay of treatment. In women, spironolactone and flutamide (to be used with caution) have efficacy (Carmina, 2003) and of importance, finasteride, which is used widely in men, is not effective in women (Price, 2000; Carmina, 2003) (Fig. 40.12). Many dermatologists advocate local injections and applications of various products to the scalp, but there are few data to support this strategy. Minoxidil is also used to stimulate hair growth with limited effectiveness. In general the response rate to all treatments does not exceed 30%. Ultimately genetic manipulations and stem cell therapy may prove to be beneficial.

KEY POINTS

- The major androgen produced by the ovaries is testosterone and that of the adrenal glands is DHEAS.
- There are three markers of androgen production, one for each compartment in which androgens are produced. In the ovary, it is testosterone; in the adrenal gland, DHEAS; and in the periphery, 3 α -diol-G.
- Approximately 85% of testosterone is bound to SHBG and is biologically inactive, 10% to 15% is bound to albumin, and 1% to 2% is unbound. Both of the latter fractions are biologically active.
- Commercial assays for testosterone and unbound testosterone in women may be inaccurate; more detailed assays should be requested, and unbound testosterone is best assessed by the ratio of testosterone and SHBG.
- Women with idiopathic hirsutism have increased 5 α -RA.
- There are three criteria to diagnose PCOS; the diagnosis is based on clinical criteria, not laboratory values.
- The most frequently used diagnostic criteria for PCOS (called the *Rotterdam criteria*) require finding any two of the following: menstrual irregularity, hyperandrogenism, or polycystic ovaries on ultrasound.
- Women with ovarian neoplasms have testosterone levels more than 2.5 times the upper limits of the normal range.
- The diagnosis of LOHD is established if the basal (early morning) serum 17-hydroxyprogesterone levels are greater than 2 to 3 ng/mL or if the level 1 hour after infusion of 0.25 μ g ACTH is more than 10 ng/mL.
- Women with LOHD have a block in cortisol biosynthesis of 11 β -hydroxylase or 21-hydroxylase, resulting in increased circulating levels of 17-hydroxyprogesterone.
- Because of the length of the hair growth cycle, response should not be expected until after 3 months of therapy.
- The best treatment for hirsutism is with an oral contraceptive, often together with an antiandrogen, with spironolactone being the preferred agent. Response rates are approximately 70%.
- Acne vulgaris is often a manifestation of androgen excess and may be effectively treated with oral contraceptives and sometimes with the addition of an antiandrogen. The response rate is approximately 90%.
- Female pattern hair loss (androgenic alopecia) may be due to enhanced scalp androgen action (5 α -reductase activity). It is best treated with antiandrogen therapy, but the response rate is poor at $\sim 30\%$.
- Excessive hair removal should be carried out once excessive androgen action (if present) has been suppressed. Laser treatment is more effective than electrolysis, although the latter is preferred for light-colored hair.

Polycystic Ovary Syndrome

Roger A. Lobo

POLYCYSTIC OVARY SYNDROME DEFINITION

Polycystic ovary syndrome (PCOS)—originally described in 1935 by Stein and Leventhal as a syndrome consisting of amenorrhea, hirsutism, and obesity in association with enlarged polycystic ovaries (Stein, 1935)—is the most common hormonal disorder in reproductive-aged women. The “classic” features occur in 3% to 7% of the population and with its broadest definition may occur in 15% to 20% of women (Fauser, 2012). The classic definition of PCOS includes women who are anovulatory and have irregular periods as well as hyperandrogenism, as determined by signs such as hirsutism or elevated blood levels of androgens. This should occur in the absence of enzymatic disorders (e.g., 21-hydroxylase deficiency), Cushing syndrome, or tumors. Usually, in the United States, the diagnosis does not require findings on ultrasound (US) of characteristic polycystic ovaries. This U.S.-based definition has been referred to as the National Institutes of Health (NIH) consensus definition because it followed an NIH conference in 1989, but this was not a consensus conference, and there was no true consensus among attendees (Zawadzki, 1992). However, there have been two other definitions used for PCOS, and a conference convened at NIH attempted to reconcile all these definitions (NIH Evidence-based Methodology Workshop, 2012) (Table 41.1).

In recognition that some women with PCOS may *not* have menstrual irregularity, and stressing the importance of the U.S. findings, the “Rotterdam” criteria emerged following a European Society for Human Reproduction and Embryology/American Society for Reproductive Medicine (ESHRE/ASRM) conference in 2004 (Rotterdam ESHRE/ASRM-Sponsored PCOS Consensus Workshop Group, 2004). Menstrual irregularity, symptoms or findings of hyperandrogenism, and polycystic ovaries on US are the three criteria used in the definition; but only two of these three criteria are required for the definition. Thus several phenotypes are possible, including hyperandrogenism and polycystic ovaries in ovulatory women (so-called *phenotype C*) and irregular cycles and polycystic ovaries in the absence of documented hyperandrogenism (phenotype D). The latter is the most controversial phenotype, which some investigators in the field have rejected.

Because hyperandrogenism is deemed to be an important feature of PCOS, the Androgen Excess and Polycystic Ovary Syndrome (AEPCOS) Society has offered a third definition of PCOS, which stresses hyperandrogenism as a key feature and then recognizes that women with PCOS can have polycystic ovaries on US or menstrual irregularity (anovulation) (Azziz, 2006).

A workshop at NIH in December 2012 attempted to draw consensus among the various definitions. It was concluded among independent panelists that the Rotterdam criteria should be adopted for convention and familiarity (it is the most commonly used definition worldwide) but that it is not ideal, and investigators should strive to find a more appropriate name for the disorder (NIH Evidence-based Methodology Workshop, 2012). Table 41.1 lists the four definitions with various phenotypes.

OVARIAN MORPHOLOGY

As discussed previously, ultrasound morphology has become an important parameter in the diagnosis of PCOS. Figures 41.1 and 41.2 depict the typical appearance of the polycystic ovary (gross specimen) and by US in a sagittal plane. However, there is heterogeneity in ovarian morphology in women with PCOS and the lack of standard criteria for the minimum requirements for the US diagnosis of polycystic ovaries. According to Rotterdam criteria, any one ovary having 12 or more cystic structures (2 to 8 mm) or an ovarian volume >10 cc is sufficient. Although originally thought to be important, according to Rotterdam the orientation of the cysts is not important; these are typically peripherally oriented around a dense stroma, thus showing an increased stromal/peripheral area ratio. Others have found that the stromal/peripheral area ratio is the most important diagnostic criterion and correlates well with the androgen status of the woman (Fulghesu, 2007) (Fig. 41.3). Most recently, Christ has suggested that the cutoff should be 26 follicles throughout the ovary, or a volume >10 cc. The stromal/peripheral ratio was considered important, but it was second in diagnostic accuracy to the finding of 26 follicles, which eliminated the overlap in ovarian findings between normal women and those with PCOS (Christ, 2014). Although the criterion of 26 follicles represents the visualization of the entire ovary (and requires high-grade imaging capabilities), most have used the number of small follicles (2 to 8 mm) in a single sonographic plane that adequately depicts the increased cystic activity within the ovary. *Thus, although the US diagnosis is rather subjective and is in the “eyes of the beholder” with many US units not being able to make a specific diagnosis, in our view, bilateral cystic ovaries (10 or more in a single sonographic plane of an ovary, arranged peripherally) with a volume >10 cc should provide a practical way to make the US diagnosis.*

It is also important to note that 10% to 25% of the normal reproductive age population (no symptoms or signs of PCOS)

Table 41.1 Criteria for Diagnosis of Polycystic Ovary Syndrome

Study*	Criteria
National Institute of Child Health and Human Development 1990	Menstrual irregularity Hyperandrogenism (clinical or biochemical)
ESHRE-ASRM 2003 “Rotterdam criteria”	Menstrual irregularity Hyperandrogenism (clinical or biochemical) Polycystic ovaries on ultrasound (two of three required)
AECOS 2006	Hyperandrogenism (clinical or biochemical) and menstrual irregularity Polycystic ovaries on ultrasound (either or both of the latter two)
NIH Workshop 2012	Endorsement of Rotterdam criteria, acknowledging its limitations, and suggesting the name PCOS should be changed

*All required the exclusion of other underlying hormonal disorders or tumors.

Figure 41.1 Surgical specimen of polycystic ovaries.

Figure 41.2 Typical color Doppler ultrasound of a polycystic ovary showing increased blood flow. (From Strauss JF, Barbieri RL, eds. *Yen and Jaffe's Reproductive Endocrinology*. 6th ed. Philadelphia: Elsevier; 2009:822.)

may have polycystic ovaries found on US. These ovaries have been called *polycystic-appearing ovaries (PAO)* or *polycystic ovarian morphology (PCOM)* in the literature (Wong, 1995). This isolated finding should not be confused with the diagnosis of PCOS, but it may be a risk factor for other features of PCOS (e.g., insulin resistance, cardiovascular risk factors) discussed later.

Figure 41.3 Example of calculating the ovarian cystic area (A1) and the stromal area (A2). (Modified from Fulghesu AM, Angioni S, Frau E, et al. Ultrasound in polycystic ovary syndrome—the measuring of ovarian stroma and relationship with circulating androgens: results of a multicentric study. *Hum Reprod*. 2007;22[9]:2501-2508.)

MENSTRUAL IRREGULARITY

Menstrual irregularity includes oligomenorrhea (cycles over 35 days) as well as a menstrual frequency of every few months and frank amenorrhea (over 6 months missed). Though the majority of women with PCOS have irregular cycles, signifying problems with ovulation, the ovulatory phenotype (“C”) reporting regular cycles occurs with variable frequencies in different populations: from 3% in Korea to 30% in Italy among women diagnosed with PCOS (Chae, 2008; Carmina, 2007). The ovulatory phenotype has less metabolic and cardiovascular risks as will be discussed later. It has been reported that menstrual irregularity is the best correlate of having insulin resistance in women with PCOS (Chae, 2008; Carmina, 2007). Additionally, although the subfertility of women with PCOS is predominantly due to problems of anovulation, many women with PCOS with ovulatory function will present with subfertility as well.

HYPERANDROGENISM/ANDROGEN EXCESS

Often considered to be the cardinal feature of women with PCOS, androgen excess may be difficult to diagnose. As discussed in Chapter 40, production of androgens in excess may emanate from the ovary, adrenal, or the periphery. Although symptoms of androgen excess, particularly of hirsutism, is sufficient for the inclusion of this parameter in the diagnosis of PCOS, blood measurements of testosterone may not always be accurate and often are “normal” in women with symptoms.

The androgen excess has been implicated in contributing to abnormalities in LH secretion, weight gain and adipose deposition, and the metabolic derangements of PCOS, discussed later.

DIAGNOSIS OF POLYCYSTIC OVARY SYNDROME IN ADOLESCENTS

An early diagnosis of PCOS in a teenager is not easy and should be made with caution. This is because in using Rotterdam criteria, all parameters for the diagnosis (menstrual irregularity, findings of androgen excess, and ovarian morphology) change and evolve during the postpubertal years. We have argued that a firm diagnosis of PCOS should only be made if all three Rotterdam criteria are present at least 3 years postmenarche (persistence of irregular menstruation, hirsutism and elevated testosterone, ovarian volume >10 cc) (Carmina, 2010). Adolescents for whom a firm diagnosis cannot be made are considered to be at risk and should be followed and merely treated for their specific complaint, if warranted. This prevents the burden of unnecessarily labeling an adolescent at an early age with a diagnosis that may not be correct.

CHARACTERISTIC ENDOCRINE FINDINGS IN POLYCYSTIC OVARY SYNDROME

Characteristic endocrinologic features include abnormal gonadotropin secretion caused by increased gonadotropin-releasing hormone (GnRH) pulse amplitude or increased pituitary sensitivity to GnRH. These abnormalities result in tonically elevated levels of luteinizing hormone (LH) in approximately two thirds of the women with this syndrome (Fig. 41.4). After a bolus of GnRH, there is usually an exaggerated response of LH, but not of follicle-stimulating hormone (FSH; see Fig. 41.4). Because of issues of metabolic clearance, typically the more obese women with PCOS will be found to have normal LH levels, while thin women with PCOS often have elevated levels. The high tonic levels of LH, often referred to as “inappropriate gonadotropin secretion” is due to elevated androgen and unbound estradiol or hypothalamic/pituitary functional abnormalities related to neurotransmitters such as dopamine.

Because FSH levels in women with PCOS are normal or low, an elevated LH/FSH ratio has been used to diagnose PCOS. However, only 70% of women with a clinical diagnosis of PCOS have an elevated level of immunoreactive LH or an immunologic LH/FSH ratio greater than 3, although almost all women with PCOS had elevated serum levels of biologically active LH (Lobo, 1983) (Fig. 41.5). *However, an elevated LH level or an elevated LH/FSH ratio is neither specific for, nor required for, the diagnosis of PCOS.*

In addition to increased levels of circulatory androgens, women with PCOS have increased levels of biologically active (non–sex hormone-binding globulin [SHBG]–bound) estradiol, although total circulating levels of estradiol are not increased (Fig. 41.6). The increased amount of non–SHBG-bound estradiol is caused by a decrease in SHBG levels, which is brought about by the increased levels of androgens and obesity, with high insulin levels present in many of these women. Estrone is also increased because of increased peripheral (adipose) conversion of androgen. The tonically increased levels of biologically active estradiol may

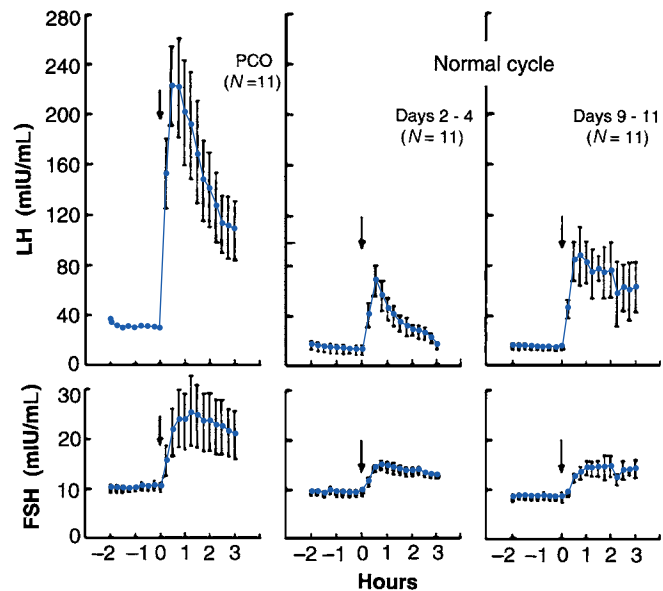

Figure 41.4 Comparison of quantitative luteinizing hormone (LH) and follicle-stimulating hormone (FSH) release in response to a single bolus of 150 µg of gonadotropin-releasing hormone (GnRH) in patients with polycystic ovarian syndrome (PCO) and in normal women during low-estrogen (early follicular) and high-estrogen (late follicular) phases of their cycles. (From Rebar R, Judd HL, Yen SSC, et al. Characterization of the inappropriate gonadotropin secretion in polycystic ovary syndrome. *J Clin Invest.* 1976;57[5]:1320-1329.)

stimulate increased GnRH pulsatility and produce tonically elevated LH levels and anovulation. In addition, the lowered SHBG level increases the biologically active fractions of androgens in the circulation. The importance of the decreased levels of SHBG is shown schematically in Figure 41.7 (Lobo, 1982). This relative hyperestrogenism (elevated levels of estrone and non–SHBG-bound estradiol), which is unopposed by progesterone because of anovulation, increases the risk of endometrial hyperplasia.

Androgens from a variety of sources are elevated in women with PCOS (Fig. 41.8). Serum testosterone levels usually range from 0.7 to 1.2 ng/mL, and androstenedione levels are usually from 3 to 5 ng/mL. In addition, approximately 50% of women with this syndrome have elevated levels of dehydroepiandrosterone sulfate (DHEAS), suggesting adrenal androgen involvement. However, in some countries, this prevalence of putative adrenal involvement is lower. Evidence also exists for adrenal hyperactivity to stimulation in at least one third of women with PCOS. Although almost all women with PCOS have elevated levels of circulating androgens, the presence or absence of hirsutism depends on whether those androgens are converted peripherally by 5 α -reductase to the more potent androgen dihydrotestosterone (DHT), as reflected by increased circulating levels of 3 α -androstane diol glucuronide (3 α -diol-G) (see Chapter 40). Nonhirsute women with PCOS have elevated circulatory levels of testosterone, DHEAS, or both, but not 3 α -diol-G (Lobo, 1983).

Approximately 20% to 30% of women with PCOS also have mildly elevated levels of prolactin (20 to 35 ng/mL), possibly related to the increased pulsatility of GnRH, due to a relative dopamine deficiency or to tonic stimulation from unopposed estrogen. In this setting, if the diagnosis of PCOS is clear, these mild elevations in prolactin level only should be followed.

Figure 41.5 Serum measurements of immunoreactive luteinizing hormone (LH), immunoreactive LH-to-follicle-stimulating hormone (FSH) ratios, and bioactive LH in control subjects (C), women with chronic anovulation (CA), and women with polycystic ovary syndrome (PCO). Boxes represent the mean \pm 3 standard deviation (SD) of control levels. (From Lobo RA, Kletzky OA, Campeau JD, et al. Elevated bioactive luteinizing hormone in women with the polycystic ovary syndrome. *Fertil Steril*. 1983;39[5]:674-678.)

INSULIN RESISTANCE

It is well established that some degree of insulin resistance (IR) occurs in most women with PCOS, even in those of normal weight. Insulin and insulin-like growth factor 1 (IGF-1) enhance ovarian androgen production by potentiating the stimulatory action of LH on ovarian androstenedione and testosterone secretion. High levels of insulin bind to the receptor for IGF-1 as a

Figure 41.6 Serum estrogen concentrations in 13 non-PCOS patients and 22 PCOS patients (shaded areas). (From Lobo RA, Granger L, Goebelsmann U, et al. Elevation in unbound serum estradiol as a possible mechanism for inappropriate gonadotropin secretion in women with PCOS. *J Clin Endocrinol Metab*. 1981;52[1]:156-158.)

Figure 41.7 Scheme depicting the possible role of adrenal-derived androgen in initiating androgen excess and anovulation. A₂, Androstenediol; E₂, estradiol; LH, luteinizing hormone; SHBG-BC, sex hormone-binding globulin binding capacity; T, testosterone. (From Lobo RA, Goebelsmann U. Effect of androgen excess on inappropriate gonadotropin secretion as found in polycystic ovary syndrome. *Am J Obstet Gynecol*. 1982;142[4]:394-401.)

result of the significant homology of the IGF-1 receptor with the insulin receptor. The granulosa cells also produce IGF-1 and IGF-binding proteins (IGFBPs). This local production of IGF-1 and IGFBP may result in paracrine control and enhancement of LH stimulation and production of androgens by the theca cells in women with PCOS. Because IGFBP levels are lower in women with PCOS, there is increased bioavailable IGF-1, which increases stimulation of the theca cells in combination with LH to produce higher levels of androgen production. In addition, elevated insulin levels (as well as androgen) stimulate adipocyte production of adipokines (adipocytokines), which interfere with the metabolism and breakdown of adipose tissue and further enhance IR (Fig. 41.9). IR in PCOS is primarily characterized by an insulin resistance in peripheral tissues, manifest primarily in muscle and adipose and minimally at the level of ovary or adrenal (Sam, 2003). Figure 41.10 reflects these events with the less efficient serine phosphorylation (rather than tyrosine phosphorylation) resulting in less efficient insulin action (metabolic

Figure 41.8 Basal levels of various androgens in hyperandrogenic women with polycystic ovary syndrome (PCOS) versus matched controls. All androgens, dehydroepiandrosterone (DHEA), DHEA sulfate (DHEAS), androstenedione (A), total testosterone (tT), and unbound testosterone (uT), are significantly elevated.

Figure 41.10 Mechanism of insulin resistance (IR) in women with polycystic ovary syndrome. At specific sites, IR is due to serine phosphorylation affecting metabolic, but not mitogenic, actions of insulin. (From Sam S, Dunaif A. Polycystic ovary syndrome: syndrome XX? *Trends Endocrinol Metab.* 2003;14[8]:365-370.)

Figure 41.9 Diagrammatic depiction of the relationship among androgens, insulin, and body fat (release of adipokines). (From Escobar-Morreale HF, San Milan JL. Abdominal adiposity and the polycystic ovary syndrome. *Trends Endocrinol Metab.* 2007;18[7]:266-272.)

effect), but with no effects on the production of androgens (intact mitogenic effect) (Sam, 2003).

The cause of IR in PCOS is unknown; it is not caused by insulin receptor defects but by signaling abnormalities as noted previously. It is likely that genetic factors contribute to these findings. Most women with PCOS will be found to have euglycemia with peripheral IR; in more severe cases, there is also evidence of beta cell (secretory) dysfunction, which increases the risk of type 2 diabetes. In a prospective evaluation of 254 women with PCOS who had an oral glucose tolerance test, it was found that 31% had impaired glucose tolerance and 7.5% had undiagnosed diabetes. In nonobese women with PCOS, 10% had impaired glucose tolerance and 1.5% had diabetes (Legro, 1999). Norman

and coworkers have shown that over a mean follow-up period of 6.2 years, 9% of women with PCOS in Australia progressed to having impaired glucose tolerance and 8% became diabetic (Norman, 2001). Thus the negative effects of obesity and PCOS on insulin resistance are additive. Although clinicians may assume most women with PCOS have some degree of IR, particularly those who are older and who are overweight or obese, it is recommended that testing should be directed at ruling out diabetes and glucose intolerance, rather than diagnosing IR (Fausser, 2012).

Fasting glucose levels are a poor predictor of diabetes in PCOS. More recently, it has been suggested that measuring the level of hemoglobin A1C (HbA1C; normal <6%) is the most efficient means of ruling out glucose intolerance or frank diabetes, but there is still disagreement about its role as a screening test.

Various techniques have been used to diagnose IR in women with PCOS. These include fairly complicated but more accurate measures used only in a research setting, such as the clamp test, intravenous frequent sampling glucose tolerance test, or the insulin tolerance test. Using fasting glucose and insulin measurements and calculating the quantitative insulin sensitivity check index (QUICKI) or homeostasis model assessment of insulin resistance (HOMA) have been useful and correlate well with the more invasive techniques (Table 41.2). However, as stated earlier, from a treatment standpoint, it may not be necessary to compute these parameters in routine practice; clinicians should assume that overweight or obese women with PCOS are insulin resistant and should be treated as such. An oral glucose tolerance test should be carried out to rule out impaired glucose tolerance or diabetes, which cannot be assumed or discounted. Figure 41.11 depicts the prevalence of abnormal testing parameters in women with PCOS (Carmina, 2004).

Acanthosis nigricans (AN) has been found in approximately 30% of hyperandrogenic women. Approximately 50% of the hyperandrogenic women who had PCOS and were obese had AN. Although it has been suggested that the presence of hyperandrogenism, IR, and AN constitutes a special syndrome (the HAIR-AN syndrome), most investigators believe that many women with PCOS have some degree of AN, particularly when obese, and do

Table 41.2 Measurements of Insulin Sensitivity

Test	Measurement	Normal Value*
Hyperinsulinemic clamp	M/1 (mean glucose use/mean plasma insulin concentration)	$>1.12 \times 10^{-4}$
Homeostasis model assessment of insulin resistance (HOMAIR)	[Fasting insulin ($\mu\text{U/mL}$) \times fasting glucose (mmol/L)]/22.5	<2.77
Glucose-to-insulin ratio	Fasting glucose (mg/dL)/fasting insulin ($\mu\text{U/mL}$)	>4.5
Quantitative insulin sensitivity check index (QUICKI)	$1/[\log \text{fasting insulin } (\mu\text{U/mL}) + \log + \text{fasting glucose (mg/dL)}]$	>0.357
Fasting insulin	—	Assay dependent

*Normal values may vary depending on the insulin assay used.

Figure 41.11 Percentage of 129 obese women with polycystic ovary syndrome (PCOS) with insulin resistance (IR) based on fasting basal insulin (white), glucose/insulin (G/I) ratio (red), homeostasis model assessment of insulin resistance (HOMA) (yellow), or quantitative insulin sensitivity check index (QUICKI) (light blue). * $P < .01$ compared with G/I ratio. (From Carmina E, Lobo RA. The use of fasting blood to assess the prevalence of insulin resistance in women with polycystic ovary syndrome. *Fertil Steril*. 2004;82[3]:661-665.)

Figure 41.12 Elevated levels of anti-müllerian hormone (AMH) in women with polycystic ovary syndrome (PCOS) decrease with time, and levels are lower in ovulatory women. Data from a 20-year longitudinal study in women with PCOS. (From Carmina E, Campagna AM, Mansuet P, et al. Does the level of serum antimüllerian hormone predict ovulatory function in women with polycystic ovary syndrome with aging? *Fertil Steril*. 2012;98[4]:1043-1046.)

not have another distinct endocrine disorder. The combination of increased insulin and IGF-1 enhances the development of AN.

Müllerian-inhibiting substance (MIS) or anti-müllerian hormone (AMH) is a glycoprotein produced by the granulosa cells of preantral follicles. Because of the larger number of preantral follicles in PCOS, the MIS or AMH level is significantly elevated in women with PCOS (Dewailly, 2014). Physiologically, AMH or MIS attenuates a sensitivity of FSH in stimulating granulosa cells; the levels are higher in clomiphene-resistant women and in those who are chronically anovulatory compared to those with more regular cycles, even as they age (Fig. 41.12) (Carmina, 2012a). It has been suggested that AMH is involved in the pathophysiology of anovulation in PCOS and, because it reflects at least in part ovarian morphology, that AMH may be used as a blood test for PCOS without needing to perform US. One review suggested a cutoff value of about 4.7 ng/mL, (Iliodromiti, 2013); although the degree of overlap in values of AMH between PCOS and normal women precludes its routine use (Casadei, 2013).

PATHOPHYSIOLOGIC CONSIDERATIONS

It is clear that there is a genetic predisposition to PCOS. However, it is likely that several genes are involved, and these are **susceptibility genes** that predispose the women affected to develop PCOS. A review by Kosova and Urbanek pointed out the many difficulties in finding a direct genetic linkage, which are related to the nature of the disorder, its heterogeneity, and the large sample size required to find meaningful associations (Kosova, 2013). There are also multiple family studies of sisters, brothers, and daughters of affected women all showing some traits associated with aspects of PCOS.

Environmental factors are clearly involved as well, based on twin studies, in which PCOS is not always concordant on a genetic basis (Vink, 2006). Maternal exposure to androgen has been shown in a monkey model to contribute to the development of PCOS (Abbott, 2005).

Most recently, genome-wide association studies in Han Chinese and European families have pointed out certain susceptibility genes with some consistency. These include loci at

Figure 41.13 Genome-wide association studies in 8226 women with polycystic ovary syndrome (PCOS) diagnosed by Rotterdam criteria and 7578 controls, with several loci identified for susceptibility genes of interest. (From Shi Y, Zhao H, Shi Y, et al. Genome-wide association study identifies eight new risk loci for polycystic ovary syndrome. *Nat Genet.* 2012;44[9]:1020-1027.)

2p16.3, 2p21, and 9q 33.3, involving the LH/human chorionic gonadotropin (hCG) receptor, a thyroid adenoma locus, and DENND1A, potentially affecting function of the endoplasmic reticulum (Chen, 2010). This was confirmed in subsequent studies with the addition of other potential loci (Shi, 2012; Zhao, 2012) (Fig. 41.13). The 2p16.3 locus was confirmed in a U.S. study (Mutharasan, 2013). It has been long established that a vicious cycle propagates the disorder in PCOS, regardless of how it begins (Strauss, 2009) (Fig. 41.14). Thus it was attractive to postulate that dopamine deficiency in the hypothalamus might give rise to the exaggerated LH responses in PCOS, and there are several similar hypotheses. However, it has been observed that morphologically identifiable polycystic ovaries are seen in children (Bridges, 1993). This occurrence predicts puberty and other normal endocrinologic events, suggesting a central role for altered polycystic ovarian morphology in the disorder.

Furthermore, not all women with isolated polycystic ovaries have PCOS as stated earlier. Thus a pathophysiologic model can be put together as follows. An ovary is polycystic in up to 20% of girls, according to data from Bridges and colleagues. Thus the ovary transitions early in life from normal to polycystic-appearing (PAO). This influence occurs in a specific way by genetic factors or environmental factors, or it is induced by other endocrine disturbances (Lobo, 1996) (Fig. 41.15). The woman who develops PAO may have normal menses, normal androgen levels, and normal ovulatory function and parity. However, if subjected to various susceptibility factors (likely genetic) or environmental or other challenges or insults, with varying degrees of severity, women with PAO may develop a full-blown syndrome (PCOS) (see Fig. 41.15). The syndrome, if full-blown, exhibits the full extent of hyperandrogenism and anovulation, with the most extreme form of this menstrual disturbance being amenorrhea (the type A or B phenotype according to Rotterdam criteria). However, in this spectrum of disorders, the androgen disturbances may also be near normal. Similarly, the menstrual disturbance may be mild.

This model requires that normal homeostatic factors may be able to ward off stressors or insults in some women who can go through life without PCOS but have PAO, which does not change morphologically. Alternatively, with varying degrees of success, a woman's homeostatic mechanisms may at any time, early or later

Figure 41.14 Pathophysiologic concept of polycystic ovary syndrome (PCOS). Increased luteinizing hormone (LH) secretion, together with enhanced theca cell responsiveness, drives the production of excess ovarian androgen. Increased androgen production may inhibit steroid negative feedback effects on hypothalamic gonadotropin-releasing hormone pulse generation to account for the rapid LH pulse frequency observed in women with PCOS. In addition, increased androgen levels are associated with android obesity, visceral fat deposition, and dyslipidemia, all of which may contribute to insulin resistance. Independently, hyperandrogenemia, obesity, and hyperinsulinemia may decrease sex hormone-binding globulin, thereby increasing bioactive testosterone. Finally, increased androgen may have direct effects on the ovary to increase follicle number and follicle size and possibly enhance granulosa cell responsiveness to follicle-stimulating hormone (FSH). E2, Estradiol. (From Strauss JF, Barbieri RL, eds. *Yen and Jaffe's Reproductive Endocrinology*. 6th ed. Philadelphia: WB Saunders; 2009:509.)

in reproductive life, allow symptoms of PCOS to emerge with varying degrees of severity. Two of the major insults are thought to be weight gain and psychological stress. Therefore the typical teenager born with PAO may develop PCOS fairly quickly, but a PCOS picture may only develop later in life in some women, even after having children, with weight gain, for example.

CONSEQUENCES OF POLYCYSTIC OVARY SYNDROME

The importance of diagnosing PCOS is that there are known long-term consequences of the diagnosis warranting lifelong

surveillance. These include metabolic and cardiovascular risks as well as the risk of certain cancers with aging.

There have been several consensus meetings for the diagnosis and treatment of PCOS as mentioned earlier. The first two dealt with the diagnosis of PCOS (Rotterdam ESHRE/ASRM Sponsored PCOS Consensus Workshop Group, 2004) and the treatment of infertility (Thessaloniki ESHRE/ASRM-Sponsored PCOS Consensus Workshop Group, 2008). The third and most recent of these was held in Amsterdam and addressed the “long-term” consequences of PCOS (Fauser, 2012). Figure 41.16 depicts the shift in emphasis with aging, requiring a multidisciplinary approach. With aging, concerns

PCOS: changing women's health paradigm

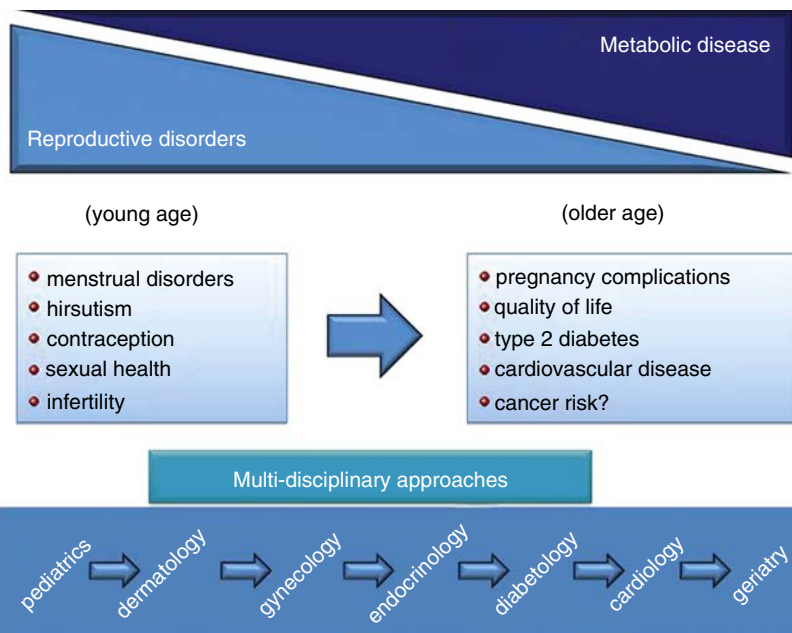

Figure 41.16 Schematic representation of the change in emphasis from early age reproductive disorders to long-term metabolic and cardiovascular health. (From Fauser B, Tarlatzis B, Rebar RW, et al. Consensus on women's health aspects of polycystic ovary syndrome [PCOS]: the Amsterdam ESHRE/ASRM-sponsored 3rd PCOS Consensus Workshop Group. *Fertil Steril*. 2012;97[1]:28-38.e25.)

for cardiovascular disease including hypertension, metabolic syndrome, diabetes, and cancer (endometrial and ovarian) become more prominent.

WEIGHT GAIN/OBESITY AND METABOLIC SYNDROME

Weight gain as women age is a major predictor of abnormal metabolic findings and the emergence of cardiovascular (CV) disease risks; indeed all the symptoms of PCOS are worse with increasing body weight. The prevalence of obesity varies widely in different countries. It is lowest in countries such as China and Japan (<10%) and highest in the United States and some other Western countries (~70%). There is increased abdominal and visceral fat in women with PCOS, and this has been correlated to IR and metabolic dysfunction (Lord, 2006). Therefore lifestyle management has to be a priority for women with PCOS and must be maintained lifelong.

Metabolic syndrome, which is largely driven by obesity and leads to diabetes and CVD, has a prevalence during the reproductive years. The prevalence of metabolic syndrome in the United States is approximately 60% in young (20 to 39 years) obese women with PCOS (Apridonidze, 2005). The diagnosis is made using Adult Treatment Panel III criteria (three of five of the following: waist circumference >88 cm, high-density lipoprotein <50 mg/dL, triglycerides >150 mg/dL; blood pressure >130/85 mm Hg, fasting blood sugar >110 mg/dL). In other countries in which obesity is less prevalent, the prevalence of metabolic syndrome in PCOS is still increased but is much lower (5% to 9%) (Carmina, 2006). The constellation of risk factors that make up metabolic syndrome will place women with PCOS at increased risk for CV disease and diabetes, but there is nothing specific of more significance regarding metabolic syndrome in PCOS.

DIABETES

Type 2 diabetes mellitus is more prevalent (two to three times higher) in women with PCOS of reproductive age (Legro, 1999). This is driven by IR, which in turn is worsened by overweight status and menstrual irregularity. In prospective follow-up studies, there is a high conversion rate in women with PCOS from euglycemia toward impaired glucose tolerance, and in women followed for 6 years who had impaired glucose tolerance the conversion rate to frank diabetes was 54% (Norman, 2001). Thus it is extremely important to screen for diabetes in the overweight population with PCOS. It has been suggested that this is best done with an oral glucose tolerance test (Fauser, 2012). Lack of precision in the screening for diabetes with hemoglobin A1C measurements has precluded the recommendation of using hemoglobin A1C as a screening tool, although it has proven to be useful in the follow-up of women as they are being treated. Diet and exercise remain the mainstays of treatment, and metformin has a significant role to play. In at risk women and those with glucose intolerance and prediabetes, metformin is often used with doses of 1500 mg per day. Doses are often higher in the presence of diabetes.

QUALITY-OF-LIFE ISSUES

Although the data are not completely consistent, it is generally stated that there is poor quality of life among women with PCOS. This is most likely related to their burden of being overweight, having irregular cycles, decreased fertility, and skin concerns such as acne and hirsutism, albeit not all women have the same number or degree of these symptoms. Depression is a factor, which may play a major role in women with PCOS seeking care and being compliant with diet, lifestyle, and various treatments. In a meta-analysis, Dokras found a fourfold increase in the prevalence of depression among women with PCOS (Dokras, 2011). A strong argument has been made for screening women with PCOS for depression. It has also been found that interventions, such as weight loss, are able to improve quality of life (Thomson, 2010).

CARDIOVASCULAR CONCERNS

Women with PCOS have characteristic lipid and lipoprotein abnormalities (Wild, 1988) (Fig. 41.17), including the presence of abnormal lipoprotein particles, which adds to a long list of abnormalities that tend to increase cardiovascular (CV) risk. Table 41.3 depicts several CV risk factors, including the development of hypertension and diabetes as women approach menopause. Figure 41.18 depicts data that have been generated from retrospective observations, and although it is yet not definitively established that these risks pertain to all women with PCOS, it provides evidence suggesting concern. (Dahlgren, 1992). It is unlikely that these risks occur in women with “milder” phenotypes. Data have largely been obtained from women with more classic features of PCOS, particularly obesity. There is evidence that the milder phenotypes diagnosed using the Rotterdam criteria have fewer CV risk factors. Figure 41.19 depicts a hypothetical scheme for increasing CV risk in women with PCOS with various phenotypes (Jovanovic, 2010).

It is important to note, however, that there are no definitive data on whether PCOS increases CV mortality (Fauser, 2012). Although multiple risk factors are present (IR, lipids, adipocytokines, inflammatory markers, surrogate markers of atherosclerosis on imaging), (Fauser, 2012), retrospective analyses have shown no increase in mortality, except among diabetic women (Pierpoint, 1998; Wild, 2000; Fauser, 2012). There has been some consideration that the older retrospective studies focused on a younger population of women and may not have been sufficiently rigorous to establish whether there is, or is not, an increased CV risk in PCOS. However, a more recent study following a postmenopausal cohort presumed to have PCOS earlier in life has shown a lower CV event-free survival with time (greater CV mortality) in PCOS (Shaw, 2008) (Fig. 41.20). Although the conclusions are as yet unclear, women with PCOS should be counseled regarding CV risk factors and preventing hypertension, dyslipidemias, and diabetes by lifestyle modification and other means, as reviewed by the AEPCOS Society (Wild, 2010).

CANCERS IN POLYCYSTIC OVARY SYNDROME

As depicted in [Figure 41.21](#), there is an age-specific onset for some of the consequences of PCOS. All cancers increase with aging, but endometrial cancer can begin at a younger age because of long-term anovulation and unopposed estrogen stimulation of the endometrium. It is likely that there are other susceptibilities as well, which contribute to the diagnosis of cancer at a younger age. Although breast cancer does not seem to be increased in women with PCOS ([Chittenden, 2009](#)), both endometrial and ovarian cancer are

increased ([Fauser, 2012; Chittenden, 2009](#)). The data for these reports are negatively affected by the heterogeneity of the patient population and their retrospective nature. Most of the data pertain to women diagnosed with "classic" PCOS. It is likely that women with milder phenotypes may have little or no increased risk.

Endometrial cancer is increased at least two- to threefold, even when controlling for weight. Apart from unopposed estrogen being a risk factor, there may also be a defect in progesterone signaling in the endometrium among cancer patients ([Savaris, 2011](#)). The data are less strong for ovarian cancer, but the risk is thought to be about 2.5 times increased ([Chittenden, 2009](#)).

This level of risk for endometrial and ovarian cancer can be brought down to a normal rate with the use of oral contraceptives (OCs). The decreased risk of these cancers with the use of OCs for about 5 years is well known ([Grimbizis, 2010](#)) and translates into a good strategy for normalizing cancer risk in women with PCOS, particularly because many women normally would be treated with OCs in any event for other symptoms. Also of interest, is that there is a growing body of evidence that metformin, which may also be used for women with PCOS, has inhibitory effects on various cancers; the data are strongest for endometrial and breast cancer ([Col, 2012; Tan, 2011](#)).

OVARIAN AGING: POLYCYSTIC OVARY SYNDROME AND MENOPAUSE

As all women age, the ovaries decrease in size and androgen levels decrease; this is true for those with PCOS as well. It is logical to assume therefore that at some juncture in time, the phenotype of PCOS may change or disappear. An interesting phenomenon, which has been well documented, is that as women with PCOS age, their menstrual cycles, if irregular when younger, become more regular and ovulatory ([Elting, 2003; Carmina, 2012b](#)).

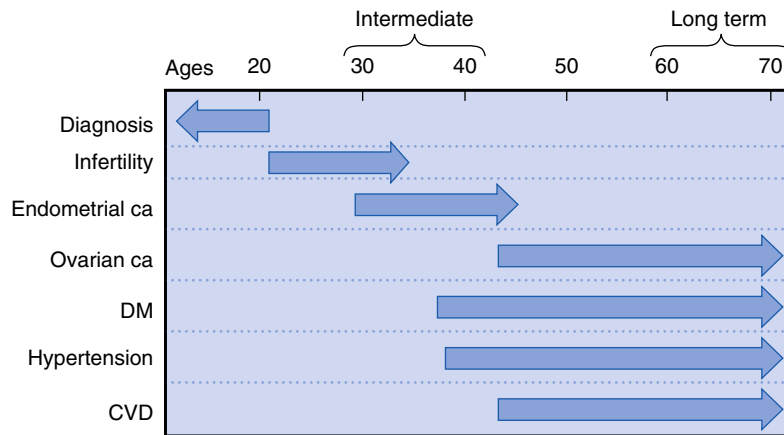

Figure 41.21 Consequences of polycystic ovary syndrome (PCOS) as a function of age. *ca*, Cancer; *CVD*, cardiovascular disease; *DM*, diabetes mellitus.

This is because of a decrease in the total follicular cohort and subsequently lower levels of AMH (Carmina, 2012a). In our longitudinal studies of women with PCOS, followed for 20 years, by the fourth decade nearly half of the women had evidence of ovulatory function, and in 8% the diagnosis of PCOS could no longer be made (Carmina, 2012b).

Although with aging the follicular cohort is decreased, compared to other women of the same age, there are still more follicles, and typically higher levels of AMH. This leads to the notion that there may be preserved fertility in women with PCOS as they age. This has been confirmed in one retrospective study in an IVF model, in which the live birth rate was higher at an older age compared to women with tubal disease (Mellembakken, 2011). As women enter menopause, which is likely to be at a later age (although not well documented [Fauser, 2012]), despite lowered androgen levels, hirsutism may still be prevalent (Schmidt, 2011). There is also evidence that there is a persistence of the metabolic issues that existed at an earlier age (Puurunen, 2011), thus requiring continued vigilance in managing and following these women.

ISOLATED POLYCYSTIC OVARIES

We have found that normal ovulatory women with PAO or PCOM have a subtle form of ovarian hyperandrogenism when stimulated with gonadotropins or human chorionic gonadotropin (hCG) (Wong, 1995). We have also found subtle changes in insulin sensitivity and altered lipoproteins (Chang, 2000). Therefore, although many women with isolated PAO or PCOM may not have any problems, this finding may be considered as a risk factor for developing the consequences of PCOS.

TREATMENT OF POLYCYSTIC OVARY SYNDROME

Treatment of women with PCOS should be directed at the specific complaint. These concerns fall into three main categories: androgen excess and symptoms of hyperandrogenism; irregular bleeding (in this setting often called dysfunctional uterine bleeding) and risks of endometrial disease due to unopposed estrogen stimulation from anovulation; fertility concerns and subfertility, mostly due to anovulation. In addition, a common complaint

is weight gain or the inability to lose weight. This is also related to IR and metabolic concerns discussed previously. Accordingly, regardless of the complaint, lifestyle management is an extremely important component of any treatment regimen.

Androgen excess (acne, hirsutism, and alopecia) occurs in the majority of women with PCOS, but not in all women. At times the symptoms are sufficiently mild that the treatment focus is on other concerns such as subfertility. Specific treatment for androgen excess symptoms is covered in Chapter 40 and usually involves the use of an OC, with or without an anti androgen.

Treatment of irregular bleeding should be directed at supplying the missing progesterone in anovulatory women. This potentially can lead to endometrial hyperplasia or cancer if not treated. Women who are overweight and older are a higher risk group, and endometrial biopsy may be indicated, although there are no validated guidelines as to when a biopsy should be carried out (Fauser, 2012). It is important to remember that it is the women with PCOS along with menstrual irregularity who have IR and are more likely to have metabolic dysfunction. OCs are the most logical and effective treatment, particularly because it is known that they reduce the risk of endometrial cancer. OCs may also be indicated for treatment of symptoms of androgen excess. In other women, progestogen therapy alone may be used at 2- to 3-month intervals to shed the endometrium in chronically anovulatory women. Medroxyprogesterone acetate (5 to 10 mg) or norethindrone acetate (2.5 to 10 mg) may be used in this setting. More complicated cases of menometrorrhagia are treated, as would other patients, as discussed in Chapter 26.

Treatment of subfertility in PCOS is predominantly due to anovulation. Even women with the ovulatory phenotype “C” may have subtle ovulatory disturbances, and it is known that some women have endometrial defects in progesterone and insulin signaling (DuQuesnay, 2009). Prior to treatment with ovulation induction, it is important to rule out other fertility factors, specifically male factors by obtaining a semen analysis (see Chapter 42).

TREATMENT OF SUBFERTILITY IN POLYCYSTIC OVARY SYNDROME

Before ovulation induction, it is necessary to normalize overt abnormalities in glucose tolerance and to encourage weight loss for overweight women. Ovulation induction may be accomplished by a variety of agents, including metformin, clomiphene,

Figure 41.22 Kaplan-Meier curves for live birth, according to study group (**A**) or by BMI, body mass index (**B**) (From Legro RS, Barnhart HX, Schlaff WD, et al. Clomiphene, metformin, or both for infertility in the polycystic ovary syndrome. *N Engl J Med.* 2007;356[6]:551-566.)

letrozole, gonadotropins, and pulsatile GnRH, as well as ovarian diathermy or drilling. Adjunctive measures include the use of dexamethasone, dopamine agonists, thiazolidinediones, and various combinations of these options, although today, these agents are rarely used. In vitro fertilization (IVF; stimulated or unstimulated) may be indicated in difficult-to-manage cases or if other infertility factors are present (Thessaloniki ESHRE/ASRM-Sponsored PCOS Consensus Workshop Group, 2008).

Although metformin had been used as a first-line treatment for infertility, with supportive evidence for some effectiveness including data from a Cochrane review (Tang, 2013), more recent randomized trials with a focus on live births as an end point have suggested that clomiphene is superior to metformin for first-line therapy (Legro, 2007) (Fig. 41.22). Metformin should be used for overweight and obese women to achieve better metabolic control prior to pregnancy and for those who may have a more casual approach to their fertility, in that metformin takes longer to become effective and may not induce ovulation in some women. Even when metformin cannot induce ovulation, its continued use may be beneficial when combined with clomiphene or gonadotropins. An improvement in oocyte quality with metformin has been suggested, but the effect has not been proved. It may decrease the risk of ovarian hyperstimulation syndrome (OHSS) in women with PCOS undergoing IVF (Tso, 2009; Palomba, 2011).

Clomiphene has been the mainstay for ovulation induction. Most pregnancies occur within the first few cycles. Accordingly,

Figure 41.23 Results of a prospective randomized trial in women with polycystic ovary syndrome (PCOS) comparing the live-birth rates of the administration of letrozole versus clomiphene (Kaplan-Meier curves). Letrozole performed significantly better. (Data from Legro RS, Brzyski RG, Diamond MP, et al. Letrozole versus clomiphene for infertility in the polycystic ovary syndrome. *N Engl J Med.* 2014;371[2]:119-129.)

it is reasonable to use clomiphene, with or without metformin, as an initial approach, after obtaining a semen analysis, but not for more than three or four ovulatory cycles before a more comprehensive workup is undertaken. Letrozole (2.5 to 5 mg/day, 5 days) has proved to be efficacious as an alternative to clomiphene, and it is particularly suited for women who have side effects with clomiphene. In a randomized head-to-head comparison of clomiphene and letrozole in women with PCOS, letrozole was found to be superior (Legro, 2014) (Fig. 41.23). This was also confirmed in a Cochrane review (Frank, 2015), and a cost analysis has also shown letrozole to be more cost effective as a first-line treatment, thus establishing its place as first-line treatment for women with PCOS. Low-dose gonadotropin therapy is highly effective as a second-line treatment (for failure with oral agents and for the occasional patient who may have transitory low estrogen status); there is no evidence that any one gonadotropin preparation is better than another (Thessaloniki ESHRE/ASRM-sponsored PCOS Workshop Group, 2008).

Currently, pulsatile GnRH therapy is rarely used, primarily because its use is cumbersome and less effective in PCOS compared with its use for hypothalamic amenorrhea. Ovarian drilling (diathermy) is a reasonable second-line therapy, particularly in clomiphene failures and when gonadotropin therapy has proved difficult. In randomized trials against standard gonadotropin therapy, ovarian drilling resulted in similar pregnancy rates but with a lower rate of multiple pregnancies (Thessaloniki ESHRE/ASRM-sponsored PCOS Workshop Group, 2008). However, in the United States, ovarian “drilling” or “diathermy” is rarely carried out, in part because of cost concerns.

For women who fail to conceive with ovulation induction over six cycles and in those with other infertility factors, IVF is the next step. Details of this treatment may be found in Chapter 43. The only caveat to IVF treatment in women with PCOS is the higher-than-normal risk of OHSS. This should always be kept in mind in treating women with PCOS, with significant dose adjustments in the treatment regimen, and using antagonist cycles, possibly metformin (when indicated) and the GnRH agonist trigger (see Chapter 43).

METABOLIC AND WEIGHT CONCERNS

The key management strategy should be directed at altering lifestyle variables. Exercise regimens, particularly when coordinated with a group of similar women, have been shown to be beneficial. Details of these approaches may be found elsewhere. However, this approach should be part of all therapies for PCOS, acknowledging that some thin and normal-weight women with PCOS probably already have a healthy lifestyle.

Metabolic syndrome (MBS), driven largely by weight in the United States, is usually treated by a combination of diet and metformin. Six- to 12-month therapy has been shown to reduce weight by 5% to 7%, as well as to reduce insulin resistance and improve metabolic parameters. Positive results also have been reported with the use of bariatric surgery in obese women with PCOS, where most of the symptoms of PCOS were found to disappear after surgery (Escobar-Morreale, 2005). Nevertheless, this approach carries risks and should not be considered as first-line therapy.

Some data suggest that the use of antiandrogens (specifically flutamide) may also be efficacious for reducing body weight and visceral fat in women with PCOS (Gambineri, 2006). A combination of drospirenone and 17 α -ethinylestradiol (EE₂) with flutamide and metformin also has been used successfully in adolescents (Ibanez, 2005). However, this multidrug regimen

Table 41.4 Treatment for Women with Polycystic Ovary Syndrome

Complaint	Treatment Options
Infertility	Letrozole, clomiphene, with or without metformin, gonadotropins, ovarian cautery (“drilling”)
Skin manifestations	Oral contraceptive + antiandrogen (spironolactone, finasteride), GnRH agonists
Abnormal bleeding	Cyclic progestogen, oral contraceptives
Weight, metabolic concerns	Diet/lifestyle management, metformin

GnRH, Gonadotropin-releasing hormone.

has not been tested in an adult population. Although therapy for women with PCOS should be directed at a woman’s specific complaint, improvement of lifestyle variables, including weight reduction and fitness, should be the mainstay of all treatments. Metformin has an important role for metabolic concerns, particularly when MBS is present, and may aid in cases of subfertility.

A summary of various treatments for specific complaints in PCOS is provided in Table 41.4. Resources for patients may be found at Australia AEPCOS (jeanhailes.org.au/health-a-z/pcos), Endo Society (www.ae-society.org), and American Society for Reproductive Medicine (www.asrm.org).

KEY POINTS

- There are three criteria to diagnose PCOS; the diagnosis is based on clinical criteria, not laboratory values.
- The most frequently used diagnostic criteria for PCOS (called the *Rotterdam criteria*) require finding any two of the following: menstrual irregularity, hyperandrogenism, or polycystic ovaries on ultrasound.
- The disorder is heterogeneous and is not a single gene disorder, although several susceptibility genes have been identified; environmental influences are most likely involved as well.
- If untreated, women with PCOS have an increased risk of developing diabetes mellitus and hypertension after menopause; women with the disorder may have increased cardiovascular disease, although whether cardiovascular mortality is increased has not been confirmed.
- Treatment of women with PCOS should be directed at the specific complaint: menstrual function, skin disorders of androgen excess, or subfertility. Typically, more than one complaint exists and can be dealt with concomitantly unless the woman is trying to conceive.
- Weight gain and metabolic concerns (particularly insulin resistance, prediabetes, etc.) are extremely common and should be treated aggressively (usually with lifestyle management), particularly before pregnancy.
- Long-term consequences of PCOS include cardiovascular and metabolic concerns and the increased risks of endometrial and ovarian cancer, unless OCs have been used. With ovarian aging, cycles may become more regular, and some but not all the symptoms of PCOS may disappear as women approach menopause. The age of menopause may be later.
- Women with PCOS who desire fertility should be treated with agents that stimulate ovulation. Letrozole and clomiphene are first-line agents, with the former being more successful. Gonadotropins and ovarian “drilling” are second-line treatments, which are less commonly used today in the United States, with an approach of progressing women to IVF more quickly.

Infertility

Etiology, Diagnostic Evaluation, Management, Prognosis

Roger A. Lobo

The term *infertility* is generally used to indicate that a couple has a reduced capacity to conceive as compared with the mean capacity of the general population. In a group of normal fertile couples, the monthly ability to get pregnant, or *fecundability*, is approximately 20%. This figure is important for all couples seeking fertility to know, because it will alleviate unrealistic expectations of immediate success with various therapies, which can only approach 20%/cycle (with the exception of *in vitro fertilization–embryo transfer* [IVF-ET]). For most couples, the correct term should be *subfertility*, suggesting a decreased capacity for pregnancy but not an impossible feat.

The Centers for Disease Control and Prevention (CDC) also distinguishes between *infertility*, which uses a more strict definition of only married couples having trouble getting pregnant, and *impaired fecundity*, which is a more general term applying to all women who have difficulty conceiving or carrying a pregnancy to term (CDC, 2015).

The definition of infertility is the inability of a couple to conceive after one year of trying. This timeline is relevant to help determine when an infertility investigation should begin. In women older than 35 years, this timeline should be after 6 months of trying. An early investigation is also warranted if any of the following is present: oligo/amenorrhea; known tubal obstruction, uterine disease, or severe endometriosis; or known male factor (Practice Committee ASRM, 2012a).

The World Health Organization (WHO) has defined infertility as a disease and a significant cause of disability (warranting evaluation and treatment) (www.who.int/reproductivehealth/topics/infertility/definitions). Clearly, infertility is a cause of major distress for couples and should be assessed thoroughly and not neglected; and as with other disorders, counseling and support groups should be available in the clinical setting.

INCIDENCE OF SUBFERTILITY AND INFERTILITY

Results from the three U.S. National Surveys of Family Growth performed under the direction of U.S. government agencies have provided information about infertility in this country. Analyses of the data obtained from the surveys performed in 1982, 1988, and 1995 have indicated that the proportion of U.S. women

ages 15 to 44 years with impaired fecundity increased from 8% in 1982 and 1988 to 10% in 1995, a 20% rise. It was estimated that the number of women with impaired fecundity in the United States increased from 4.6 million to 6.2 million between 1982 and 1995, a 35% rise. Most of this increase occurred among nulliparous women in the oldest age group (35 to 44) because women of the Baby Boom generation were reaching this age. Many in this group had delayed childbearing. According to data from the CDC, in 2002, 7.4% of all women aged 15 to 44 in the United States had infertility, using the CDC's strict definition; and in the latest 2006-2010 survey, this occurred in 6% of the population. Impaired fecundity occurred in 10.9% of the reproductive age group in the 2006-2010 survey. The number of women in the reproductive age group who have ever received any infertility services has remained constant between the 2002 and 2006-2010 surveys: 7.4 million women, or 11.9% of the population (CDC, 2015).

INFERTILITY AND AGE

Data from both older and more recent studies have indicated that the percentage of infertile couples increases with increasing age of the female partner. Analysis of data from three national surveys in the United States has revealed that the percentage of presumably fertile married women not using contraception who failed to conceive after 1 year of trying steadily increased from ages 25 to 44 years (Menken, 1986) (Table 42.1). Data from a study of presumably fertile nulliparous women married to husbands with azoospermia who underwent donor artificial insemination revealed that the percentage who conceived after 12 cycles of insemination declined substantially after age 30 (Schwartz, 1982) (Table 42.2). This older, classic study used fresh semen; currently, only frozen donor sperm is used, which does not achieve as favorable pregnancy rates. Decreasing fecundability with age is even more pressing in this context. With IVF, data from the Society for Assisted Reproductive Technology (SART) in the United States providing information on 165,172 cycles in 2012 has shown that the percentage of deliveries per oocyte retrieval procedure is 43.4% in women younger than 35, 25.4% by ages 38 to 40, and 14% by ages 41 to 42 years, and only 5% in women over 42 years (www.sart.org/find_frm.html).

In general terms, approximately one in seven couples are infertile if the wife is 30 to 34, one in five is infertile if she is 35 to 40, and one in four is infertile if she is 40 to 44 years of age. Another way to interpret these data is to state that as compared with women aged 20 to 24 years, fertility is reduced by 6% in the next 5 years, by 14% between ages 30 and 34, by 31% between ages 35 and 39, and to a much greater extent after age 40. Of interest is the finding that the most common diagnostic category among women undergoing IVF in the United States in the most recent survey (2012) cited previously is diminished ovarian reserve: 17% of cycles; which is a characteristic of older women undergoing treatment (www.sart.org/find_frm.html).

Table 42.1 Married Women Who Are Infertile, by Age*

Age (yr)	Infertile (%)
20-24	7.0
25-29	8.9
30-34	14.6
35-39	21.9
40-44	28.7

From Menken J, Trussell J, Larsen U. Age and infertility. *Science*. 1986;233:1389-1394.
*From three national U.S. surveys.

Table 42.2 Pregnancy Rates by Age at 1 Year in Normal Women with Azoospermatic Husbands after Donor Insemination

Age (yr)	Pregnancy Rate (%)
<25	73.0
26-30	74.1
31-35	61.5
36-40	55.8

From Schwartz D, Mayaux MJ. Female fecundity as a function of age: results of artificial insemination in 2193 nulliparous women with azoospermic husbands. *N Engl J Med*. 1982;306(7):404-406.

FECUNDABILITY: THE ABILITY TO CONCEIVE

Analysis of data from presumably fertile couples who stop using contraception to conceive has shown that approximately only 50% of the couples will conceive in 3 months, 75% will conceive in 6 months, and by 1 year approximately 90% will have conceived (Hull, 1985) (Fig. 42.1). Statistical analysis of these data indicates that the normal monthly fecundability is approximately 0.2 (20%).

This information is extremely important when analyzing data concerning the results of various treatment methods applied to a group of infertile couples. This group includes those with hypofertility from presumed causes (e.g., mild endometriosis) as well as those with idiopathic (unexplained) infertility. For example, it has been estimated that if the mean fecundability of the population is 0.2 (a 20% monthly rate), this rate decreases over time (Leridon, 1984) (Table 42.3). Analysis of these statistical tables reveals that after 2 years of trying to conceive, approximately 4% of these couples will not have conceived. Their mean monthly fecundability is approximately 0.08, and 57% will conceive in the next year. Of the 2% still not pregnant at this time, after 3 years after trying to conceive, the monthly fecundability drops to approximately 0.06, 0.05, and 0.04 in the next 3 years, respectively. Thus in the fourth, fifth, and sixth years of attempting to conceive, only 48%, 42%, and 37% of nonpregnant women should conceive without treatment.

Several studies have reported the incidence of spontaneous conception among infertile couples without a specifically diagnosed cause of infertility (unexplained infertility). A live birth rate among 873 infertile couples in several Canadian centers has been observed without treatment. The cumulative live conception rate at 3 years was 38.2% and was 45% after 7 years (Collins, 1995b) (Fig. 42.2). Among the total group with the diagnosis of unexplained infertility who received no treatment, one third had a live birth during the first 3 years of observation without treatment.

Figure 42.1 Curve of theoretic time to pregnancy in women with a monthly fecundability of 0.2 (open circles) and curve of actual time to pregnancy in fertile women discontinuing contraception (solid line). (Open circle data from Hull MG, Glazener CM, Kelly NJ, et al. Population study of causes, treatment, and outcome of infertility. *Br Med J*. 1985;291[6510]:1693-1697. Solid line data from Murray DL, Reich L, Adashi EY. Oral clomiphene citrate and vaginal progesterone suppositories in the treatment of luteal phase dysfunction: a comparative study. *Fertil Steril*. 1989;51[1]:35-41.)

Thus in order to determine that any method of treatment for infertility is superior to no treatment, the treatment results on the incidence of pregnancy over time must be statistically analyzed. Ideally, these results should be compared with an untreated control group. At the least, these pregnancy rates should be compared with the rates of the untreated women with a normal diagnostic evaluation (discussed later). Various statistical formulas for performing these analyses based on a life table analysis have been described. This statistical approach is necessary to determine whether treatment methods are beneficial.

CAUSES OF INFERTILITY

The exact incidence of the various factors causing infertility varies among different populations and cannot be precisely determined. Collins reported that among 14,141 couples in 21 publications, ovulatory disorders occurred 27% of the time; male factors, 25%; tubal disorders, 22%; endometriosis, 5%; other, 4%; and unexplained factors, 17% (Collins, 1995a). It has not been shown that other abnormalities, such as antisperm

antibodies, luteal phase deficiency, subclinical genital infection, or subclinical endocrine abnormalities such as hypothyroidism or hyperprolactinemia in ovulatory women are true causes of infertility. No prospective randomized studies have demonstrated that treatment of these latter entities results in greater fecundability than without treatment. If any of these do cause infertility, they do so infrequently. With current techniques of investigation, it is impossible to diagnose the cause of infertility in up to 20% of couples, and they are considered to have unexplained infertility. After a rigorous investigation, other reports have suggested this figure to be as low as 10%. However, it is unclear if subtle abnormalities, as noted, have much to do with infertility. Also, most couples with unexplained infertility are hypofertile (subfertile), and some are able to conceive without treatment, although it may take several years and with a diminishing probability of this occurrence over time.

DIAGNOSTIC EVALUATION

The diagnostic evaluation of infertility should be thorough and completed as rapidly as possible. During the initial interview, the couple should be informed about normal human fecundity and how these probabilities decrease with increasing age of the female partner and with the duration of infertility. The various tests in the diagnostic evaluation and why they are performed should be thoroughly explained. The available therapies and prognosis for treatment of the various causes of infertility should also be included in the dialogue. The couple should be informed that after a complete diagnostic infertility evaluation, the cause for infertility cannot be determined in a large group of couples. For many couples, the reduced fecundability can be suggested to be age related. Methods to increase the fecundity of couples with a normal diagnostic evaluation, such as *controlled ovarian stimulation* (COS) and intrauterine insemination, as well as the possibility of *in vitro fertilization* (IVF) should also be covered.

Each couple should be instructed about the optimal time in the cycle for conception to occur and should be encouraged to have intercourse on the day before ovulation. Unless the husband has oligozoospermia (oligospermia), daily intercourse for 3 consecutive days at midcycle should be encouraged. When ovulation is more precisely determined, as with luteinizing hormone (LH) monitoring (discussed later), intercourse should occur for 2 consecutive days around the LH surge. Because the egg disintegrates less than 1 day after it reaches the ampulla of the oviduct, it is best that sperm be present in this area when the egg arrives so that fertilization can occur. Because normal sperm retain their fertilizing ability for up to 72 hours, it is preferable to have sperm in the oviduct prior to the arrival of the oocyte.

A study was performed by Wilcox and coworkers of fertile couples who stopped contraception to conceive and recorded the cycle day when they had sexual intercourse. Hormone analysis was performed to determine the day of ovulation. None of the women became pregnant in the group of couples who had intercourse after ovulation occurred. The pregnancy rate was approximately 30% if intercourse occurred on the day of ovulation, as well as 1 and 2 days prior to ovulation. The pregnancy rate was approximately 10% if coitus occurred 3, 4, or 5 days before ovulation. No pregnancies occurred when intercourse took place 6 days or more before ovulation (Wilcox, 1995)

Table 42.3 Incidence of Conception Over Time among Nonsterile Couples with Mean Fecundability of 0.2

Months without Conception	COUPLES NOT YET HAVING CONCEIVED		
	Proportion (%)	Mean Fecundability	Proportion (%) of Couples Who Will Conceive (within 12 mo)
0	100.0	0.20	86.0
6	31.9	0.14	77.0
12	14.0	0.11	69.2
24	4.3	0.08	57.0
36	1.9	0.06	48.2
48	1.0	0.05	41.7
60	0.6	0.04	36.7

Modified from Leridon H, Spira A. Problems in measuring the effectiveness of infertility therapy. *Fertil Steril*. 1984;41(4):580-586.

Figure 42.2 Cumulative rate of conceptions leading to live birth. Couples (873) who remained untreated throughout follow-up; cumulative rate of live birth conception at 36 months was 38.2% (95% CI, 34.2-42.3). (Modified from Collins JA, Burrows EA, Wilan AR. The prognosis for live birth among untreated infertile couples. *Fertil Steril*. 1995;64[1]:22-28.)

Figure 42.3 Probability of conception on specific days near the day of ovulation. The bars represent probabilities calculated from data on 129 menstrual cycles in which sexual intercourse was recorded to have occurred on only a single day during the 6-day interval ending on the day of ovulation (day 0). The solid line shows daily probabilities based on all 625 cycles, as estimated by the statistical model. (From Wilcox AJ, Weinberg CR, Baird DD. Timing of sexual intercourse in relation to ovulation: effects on the probability of conception, survival of the pregnancy, and sex of the baby. *N Engl J Med*. 1995;333:1517-1521.)

(Fig. 42.3). It is therefore considered optimal to perform insemination or have sexual intercourse on the day before ovulation.

Because peak levels of LH occur 1 day before ovulation, measurement of LH by urinary LH immunoassays is the best way to determine the optimal time to have intercourse or an insemination. Tests that measure LH in a random daily urine specimen are usually more convenient for planning natural or artificial insemination than tests that detect LH in the first morning urine specimen. Ovulation most commonly occurs on the day following the detection of LH in a random specimen (12 to 24 hours later), and it occurs on the day when LH is detected in the first morning specimen, which contains urine formed during the prior night. Several types of commercial kits are available for determining peak LH, so women who find it difficult to determine a hormone change using one type can try another system or kit. Basal body temperature (BBT) charts are not as precise for determining ovulation, with ovulation occurring over a span of several days of the thermogenic shift.

In some cases, women produce less than adequate amounts of vaginal lubricant. Various vaginal lubricants and chemicals, as well as saliva, used to improve coital satisfaction may interfere with sperm transport. Some men experience midcycle impotence because of the pressure of performing intercourse on demand. In such cases, the intercourse schedule should be less rigorous. The couple should also be told that among fertile couples, there is only approximately a 20% chance of conceiving in each ovulatory cycle, even with optimally timed coitus, and that it takes time to become pregnant. Thus the terms *time* and *timing* should be emphasized during the initial counseling session. Couples should also be advised to cease smoking cigarettes and drinking caffeinated beverages in excess. Cigarette smoking and caffeine consumption have been shown independently in several studies to decrease the chances of conception. The common practice of vaginal douching also reduces the chance of conception by approximately 30%.

All couples should have a complete history taken, including a sexual history, and a physical examination. After this initial evaluation, tests should be undertaken to determine if the woman is ovulating and has patent fallopian tubes and if a semen sample of the male partner is normal.

DOCUMENTATION OF OVULATION

Preliminary information that the woman is ovulatory is provided by a history of regular menstrual cycles. If the woman has regular menstrual cycles, a serum progesterone level should be measured in the midluteal phase to provide indirect evidence of ovulation as well as normal luteal function. Although serum progesterone levels vary in the normal luteal phase in a pulsatile manner, a serum progesterone level above 3 to 5 ng/mL suggests some ovulatory function, but it cannot indicate the adequacy of normal ovulation. Progesterone levels of 10 ng/mL or higher are found during at least 1 day of the luteal phase of normal ovulatory cycles in which conception occurred (Hull, 1982). Measurement of the daily BBT provides indirect evidence that ovulation has taken place but does not give as precise information about ovulation timing as the LH kit, or the quality of ovulation, by progesterone. The BBT graph also provides information about the approximate day of ovulation and duration of the luteal phase. The BBT should be taken shortly after awakening, only after at least 6 hours of sleep and prior to ambulating, with sublingual placement of a special thermometer with gradients between 96° and 100° F.

Women with oligomenorrhea (menses at intervals of 35 days or longer) or amenorrhea who wish to conceive should be treated with agents that induce ovulation, regardless of whether they have occasional ovulatory cycles. Therefore for these women, direct or indirect measurement of progesterone is unnecessary until after therapy is initiated.

The endometrial biopsy is sometimes considered as a diagnostic method for the adequacy of ovulation and luteal function. *We feel that an endometrial biopsy is not indicated in this setting.* It is invasive and painful, and it does not provide accurate information in terms of “endometrial dating” of the luteal phase, as was carried out in the past (Coutifaris, 2004).

SEMEN ANALYSIS

Although information about ovulation is being obtained, the male partner's reproductive system should be evaluated by means of a semen analysis. Abnormalities in the semen analysis (male factor) occurs in approximately 20% of couples with infertility as the sole factor and may be involved in 30% to 40% of cases overall. The male partner should be advised to abstain from ejaculation for 2 to 3 days before collection of the semen sample. It is best to collect the specimen in a clean (not necessarily sterile) wide-mouthed jar after masturbation. It is important that the entire specimen be collected, because the initial fraction contains the greatest density of sperm. Ideally, collection should take place in the location where the analysis will be performed. The degree of sperm motility should be determined as soon as possible after liquefaction, which usually occurs 15 to 20 minutes after ejaculation. Sperm motility begins to decline 2 hours after ejaculation, and it is best to examine the specimen within this period. Semen should not be exposed to marked changes in temperature and,

if collected at home during cold weather, the specimen should be kept warm during transport to the laboratory.

Parameters used to evaluate the semen include volume, viscosity, sperm density, sperm morphology, and sperm motility. The last parameter should be evaluated in terms of percentage of total motile sperm as well as quality of motility (rapidity of movement and amount of progressive motility). Sperm morphology is an extremely important parameter, which is correlated to fertilizing ability. Using strict criteria (Kruger), only approximately 4% or more of the sperm in an ejaculate may be considered normal according to the most recent WHO criteria (WHO, 2010). It should be remembered that the sperm analysis is a subjective test and that there is a fair degree of variability from test to test in the same man. Also, the semen profile reflects sperm production that occurred 3 months earlier, which is important to note if there were illness at that time. Table 42.4 lists the parameters that are generally considered normal for a semen analysis, according to the latest WHO study. It is beyond our scope here to discuss fully the causes and diagnostic evaluation of semen abnormalities. In broad terms, the various causes of semen abnormalities are cited in Table 42.5.

When semen analyses were performed on a group of men whose wives had conceived within the past 4 months, approximately 75% had at least one abnormal characteristic and 25% had two abnormalities. These results confirm that there is normally a wide variability in the parameters used to characterize semen. Because the characteristics of semen may vary over time and undergo normal biologic variability, it is best to repeat the test at least once if an abnormality is found. If abnormalities persist, the male should have a urologic exam. It is important not to miss a rare abnormality, such as a testicular tumor; in addition it has been appreciated that male factor infertility is associated with other medical conditions and subsequent problems (Eisenberg, 2015).

The comprehensive evaluation should include a history of physical exam (occasionally with ultrasound); hormonal evaluation (LH, follicle-stimulating hormone [FSH], testosterone, estradiol, prolactin [PRL], and thyroid-stimulating hormone [TSH]); and genetic abnormalities (karyotype, and defects such as cystic fibrosis mutations and Y-chromosome microdeletions), particularly with severe sperm abnormalities (Practice Committee ASRM, 2012a).

EVALUATION AND LABORATORY TESTS

Aspects of the woman's medical history that should be highlighted include the following: any pregnancy complications if previously pregnant; previous pelvic surgery of any type; significant dysmenorrhea; dyspareunia or sexual dysfunction; abnormal cervical cytology or procedures to treat cervical abnormalities; and use of medication, drugs, and tobacco. Family history should be explored for genetically related illnesses, birth defects and, most importantly, the history of age of menopause in female family members. Finally, any symptoms suggestive of endocrine disorders should be solicited (e.g., weight changes, skin changes).

The physical examination should focus on extremes of body mass, skin changes, thyroid abnormalities, breast secretion, abnormal pain on abdominal or pelvic examination, and assessment of the vagina and cervix. In addition, if available, vaginal ultrasound performed at the same time may be extremely

Table 42.4 Lower Fifth Percentile Values in Fertile Men*

valuable in picking up abnormalities of the uterus (e.g., fibroids) endometrial thickness, pelvic masses, and ovarian morphology (e.g., polycystic appearance, unusually small). These may provide a guide for further testing.

In a healthy asymptomatic woman, only a complete blood count (CBC), blood type, Rh factor, and rubella status are needed, together with a Pap smear obtained within 12 months of the previous test.

Increasingly it is recommended (although not mandatory) to screen for genetic carrier status. Comprehensive screening for carrier status including Fragile X and other abnormalities such as cystic fibrosis is easily carried out at the time of routine blood testing. There are several laboratories that can do such screening. We use the Family Prep Screen offered by Counsyl (www.counsyl.com), in which more than 100 diseases may be screened for free; Counsyl also offers follow-up consultation.

Infectious disease screening (for chlamydia and gonorrhea) is carried out routinely in most practices at the time of the Pap smear. Further infectious disease screening (e.g., syphilis, HIV, hepatitis) is warranted, particularly for couples undergoing insemination or IVF.

In most women, and particularly in women older than 35 years, serum follicle-stimulating hormone (FSH) and estradiol (E_2) levels should be obtained on cycle day 2 or 3. Elevated FSH values (>10 mIU/mL), suggest decreased ovarian reserve, which reflects the pool of viable oocytes remaining in the ovary. Levels over 20 mIU/mL afford a particularly poor prognosis. However,

although FSH levels tend to fluctuate from cycle to cycle, once the FSH level has been elevated in a given cycle, the overall prognosis is reduced. E_2 levels, if elevated on days 2 and 3 (>70 pg/mL), do not allow for a valid interpretation of FSH values and may independently suggest a decreased prognosis regarding ovarian reserve (Evers, 1998).

Antimüllerian hormone (AMH) or müllerian-inhibiting substance (MIS) has become a valuable standard for assessing ovarian reserve. MIS, which is produced by the granulosa cells of small growing follicles, physiologically suppresses FSH stimulation of sustained follicular growth. Levels are highest in young women and lower with reproductive aging; various nomograms by age have been established (Seifer, 2011) (Fig. 42.4). Serum AMH/MIS decreases with aging, and when levels reach 0.05 ng/mL (essentially undetectable levels), menopause occurs within 4 to 5 years (Sowers, 2008). Levels are higher in women with polycystic ovary syndrome (PCOS) (Iliodromiti, 2013). In terms of ovarian reserve, higher levels (>2 ng/mL) suggest a larger cohort of small available follicles and low levels (<0.5 ng/mL) suggest a decreased ovarian reserve, with the levels of AMH reflecting the sensitivity of the ovary to gonadotropic stimulation, and thus the choice of treatment when ovarian stimulation is desired (La Marca, 2014).

Unlike FSH, AMH/MIS values are fairly constant and stable throughout the menstrual cycle, particularly in the low ranges. Higher values, however, exhibit more variability in the early to midfollicular phase. It is now established that use of oral contraceptive pills decreases values by 15% to 20%.

Figure 42.4 AMH age-specific median values with mean \pm standard deviation values for women ages 24 to 50, $n = 17120$, obtained at 1-year intervals. Note values are from a single laboratory using reagents from the older Beckman/Diagnostic Systems Laboratories (DSL) Generation 1 assay; thus assays systems will vary for the absolute numbers but not for the trend of declining values with age. (From Seifer D, Baker VL, Leader B. Age specific serum AMH values for 17120 women presenting to fertility centers within the United States. *Fertil Steril*. 2011;95[2]:747-750.)

From a clinical perspective, assays for AMH and MIS have not been standardized (several different assays have been used), requiring each clinician to establish his or her own normative data and receiver operating characteristic (ROC) curves, as our group has done, reflecting the values quoted earlier.

Use of Ultrasound in the Diagnostic Evaluation

It is most common to carry out a pelvic ultrasound evaluation as part of the investigation. By so doing, significant pathology such as fibroids, endometriosis, and other pathology can be uncovered. In addition polycystic ovaries, which are prevalent, can be appreciated; and finally an antral follicle count (AFC) can be obtained, which is similar in value to the measurement of AMH, in the assessment of ovarian reserve. An age-related nomogram for AFCs has also been reported (Almog, 2011) (Fig. 42.5). For standardization it has been suggested that the AFC be obtained on cycle days 2 to 4 (Broekmans, 2010).

Other Blood Testing

Some specialists obtain antibody titers for *Chlamydia trachomatis*, which if elevated may signify the possibility of tubal disease. It has been suggested that if the immunoglobulin G (IgG) antibody titer is greater than 1:32, 35% of patients have evidence of tubal damage. Whether this type of evaluation is routinely warranted as a focus for the infertility investigation continues to be debated.

Although not proven to be of major benefit in normal ovulatory women, most clinicians will measure TSH and prolactin at the screening visit. TSH values in the normal range (<4.4 $\mu\text{U/mL}$), but higher than 2.5 mIU/mL are often considered to be abnormal in women presenting with infertility. This is because normal values in the first trimester of pregnancy should be <2.5 $\mu\text{U/mL}$. However, there is no evidence that values between 2.5

to 4 $\mu\text{U/mL}$ affect fertility status or outcomes of pregnancy (Practice Committee ASRM, 2015).

If an abnormality is found in one of the first two noninvasive diagnostic procedures (documentation of ovulation and semen analysis), it should be treated before proceeding with the more costly and invasive procedures, unless there is a history or findings suggestive of tubal disease. For example, if the woman has oligomenorrhea and does not ovulate each month, after a normal semen analysis is observed, ovulation should be induced with clomiphene citrate for two to three cycles before performing the other diagnostic measures. Provided that no other infertility factors are present, most anovulatory women (80%) conceive after induction of ovulation with therapeutic agents, and half the couples will conceive during the first three ovulatory cycles (Gysler, 1982).

If these initial diagnostic tests are normal, the more uncomfortable and costly hysterosalpingography (HSG) should be performed in the follicular phase of the next cycle.

Hysterosalpingography

It is best to schedule the HSG during the week following the end of menses to avoid a possible pregnancy and also get better definition of the uterine cavity when the endometrium is still thin. The HSG should be avoided if there has been a history of salpingitis in the recent past or if there is tenderness on pelvic examination. As noted, most practices routinely screen for chlamydia and gonorrhea during the initial examination. However, we routinely prescribe prophylactic antibiotics at the time of HSG: doxycycline (100 mg twice daily for 3 days, starting 1 day before the procedure), but this recommendation is not universally followed. If a hydrosalpinx is seen with HSG, doxycycline should be continued for 1 week. The examination should be performed with use of a water-soluble contrast medium and

Figure 42.5 Age-related nomogram for antral follicle count depicted by various percentiles showing a biphasic decline and with a poor antral follicle count defined by a value under eight. (From Almog B, Shehata F, Shalom-Paz E, et al. Age-related nomogram for antral follicle count: McGill reference guide. *Fertil Steril*. 2011; 95[2]:663-666.)

image-intensified fluoroscopy. A water-soluble contrast medium enables better visualization of the tubal mucosal folds and vaginal markings than an oil-based medium. It is important to be able to evaluate the appearance of the intratubal architecture to determine the extent of damage to the tube (Fig. 42.6, A and B). A meta-analysis, including four randomized trials, has indicated that a therapeutic benefit is more likely to occur when oil-soluble contrast media are used in an HSG performed for the diagnostic evaluation of infertility (Watson, 1994). The odds of pregnancy occurring after the procedure were twofold higher when oil-soluble media were used compared with water-soluble media. These results differ from those of a large randomized trial by Spring and colleagues that found no difference in pregnancy rates when the HSG was performed with oil-soluble or water-soluble contrast media (Spring, 2000). Thus the therapeutic benefit of oil-soluble contrast media remains inconclusive.

Because oil-soluble contrast media have more complications than water-soluble media, including pain resulting from peritoneal irritation and formation of granulomas, it is probably best to perform routine HSGs with water-based media. The diagnostic HSG will not only determine whether the tubes are patent but also, if disease is present, will help determine the magnitude of the disease process and provide information about the lining

of the oviduct, and uterine cavity in particular, that cannot be obtained by laparoscopic visualization. The procedure can also determine whether salpingitis isthmica nodosa is present in the interstitial portion of the oviduct (Fig. 42.6, C). When an HSG shows lack of patency in one tube, this has been shown to be falsely positive, approximately 50% of the time at laparoscopy. Therefore it is not necessary to perform tubal reconstructive surgery on a woman with one patent tube. However, a diagnostic laparoscopy may be considered to detect the presence of peritubal adhesions. The finding of a normal endometrial cavity at the time of HSG obviates the need for hysteroscopy. If severe tubal disease, such as a large hydrosalpinx, is found at the time of HSG (Fig. 42.6, D), based on success rates, it is preferable for the couple to undergo IVF-ET than for the woman to have tubal surgery. If the hydrosalpinx is large and clearly visible on ultrasound, it is preferable to perform laparoscopic salpingectomy prior to IVF-ET because the pregnancy rate with IVF-ET may be decreased by as much as 40% (Zeyneloglu, 1998).

Quite frequently one or both tubes may show proximal obstruction. This may be the result of uterine spasm (contractions) due to the discomfort of the procedure, or due to true obstruction; the latter may be only a mild obstruction due to tubal debris. It has become common to attempt fluoroscopic-controlled

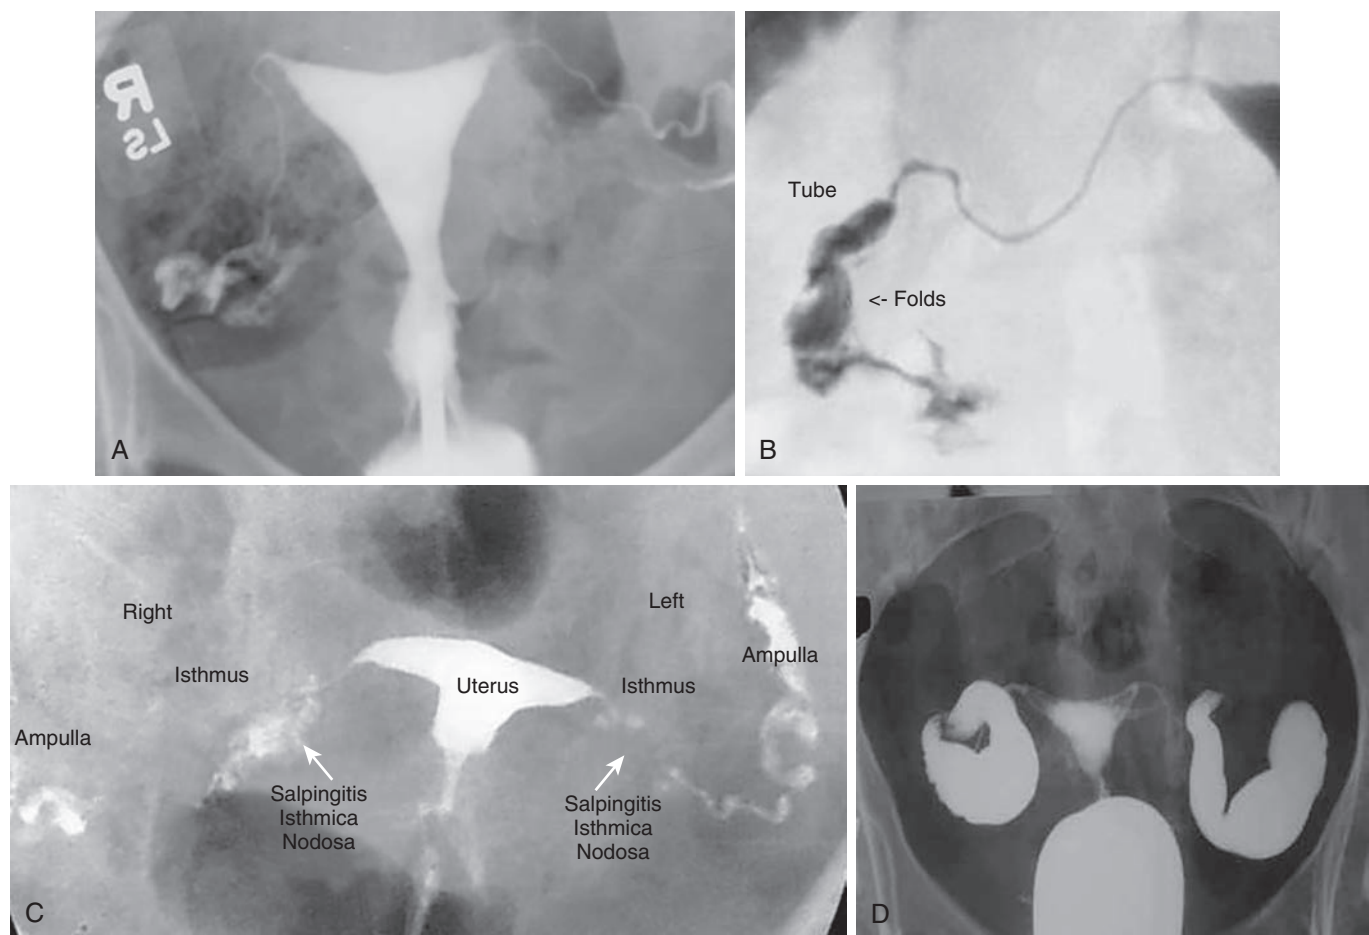

Figure 42.6 Representative hysterosalpingograms showing a normal study (A), normal ampullary folds (B), bilateral salpingitis isthmica nodosa (proximal disease) (C), and bilateral hydrosalpinges (distal disease) (D).

selective cannulation of the proximal tube, either immediately or at a subsequent visit (Thurmond, 2008) (Fig. 42.7). This can be successful in up to 90% of cases, and if successful it alleviates either unnecessary concern or the need for laparoscopy or IVF.

When the extent of tubal disease is unclear or the couple prefers not to undergo IVF-ET, diagnostic laparoscopy should be carried out in the follicular phase of the cycle. In general, the goal should be to have all tubal reconstruction carried out laparoscopically (discussed later).

Postcoital Test (No Longer Routine)

Although important from a physiologic standpoint (cervical mucus being important for sperm transport), the postcoital test (PCT) is now rarely indicated as a necessary part of the infertility investigation. It is a very subjective test. A normal PCT is one in which at least five motile sperm are visible in normal cervical mucus obtained from the upper canal just prior to ovulation. A suboptimal test can be the result of technique, timing of the test, and problems with cervical mucus or with sperm. Although a good PCT has been correlated with a better prognosis for pregnancy, sperm have been recovered at laparoscopy when there was a poor PCT. Moreover, because the suggested treatment for a poor PCT is intrauterine insemination after ovarian stimulation, this is the exact next step taken, even if the PCT is normal, in the setting of unexplained infertility. Occasionally, as may happen with an orthodox Jewish couple, a semen analysis cannot be obtained. Here, a PCT provides a surrogate for visualizing motile, normal-appearing sperm.

Laparoscopy: Is It a Routine Part of the Investigation?

In the past, this was an obligatory final step in the infertility investigation when all other test results were normal. Data have shown that in 20% to 40% of cases, some minor abnormalities

may be found (e.g., endometriosis, adhesions), which may have a bearing on fecundability. Obviously, if there is something suspicious on ultrasound or examination, there has been prior pelvic surgery or appendicitis, or there is pelvic pain or dyspareunia, the index of suspicion is increased. The probability that peritubal adhesions of sufficient severity to cause infertility will be found at the time of laparoscopy is less than 5% in a woman with no history of salpingitis or symptoms of dysmenorrhea, a normal bimanual pelvic examination, and normal antibody titers (if obtained) (Fatum, 2002). Provided the woman is younger than 40 years and is having ovulatory cycles, and there is an acceptable semen analysis and an age-appropriate marker of ovarian reserve such as AMH, several cycles of controlled ovarian stimulation and intrauterine insemination may be undertaken before performing diagnostic laparoscopy or going directly to IVF-ET. At this juncture, a decision can be revisited about whether performing a laparoscopy should be considered, although many couples usually prefer to proceed with IVF-ET, particularly if they have insurance coverage for IVF.

ADDITIONAL TESTING FOR COUPLES PRESENTING WITH INFERTILITY?

Significance of a Diagnosis of Luteal Deficiency (Is This a True Diagnosis?)

Although suggested for many years, it has never been established that luteal phase defects cause infertility. The diagnosis of luteal deficiency used to be made upon finding serum progesterone levels consistently below 10 ng/mL 1 week before menses or finding consistent evidence for a histologic delay (>3 days) in the pattern of the normal secretory endometrium, indicating an inadequate effect of progesterone on the endometrium. This endometrial defect had to be found in two consecutive cycles. Erroneous diagnoses of this

Figure 42.7 Technique of tubal cannulation using a vacuum cup on the cervix, the introduction of a 5.5-French catheter into the tubal ostium under fluoroscopy; followed by a 0.015-inch guidewire into the fallopian tube for dislodgement of debris (**A**). **B** shows injection of contrast through a 3-French catheter into the tube confirming successful cannulation and a normal-appearing patent tube. (From Thurmond AS. Fallopian tube catheterization. *Semin Intervent Radiol.* 2008;25[4]:425-431.)

entity occur because of cycle variability and the subjective interpretation of histologic dating criteria. There is at least a 10% disagreement of more than 2 days when the same observer dated the specimens on two separate occasions, and even more interobserver variability. As noted earlier, more recent studies have confirmed the lack of efficacy of the endometrial biopsy (Coutifaris, 2004). *Routine endometrial biopsies for the diagnosis of infertility should not be carried out.*

As noted regarding the PCT, ovarian stimulation with intra-uterine insemination (IUI) is often the first empirical treatment for unexplained infertility. This essentially treats the luteal inadequacy, if it exists, preempting the need for invasive and imprecise endometrial biopsies.

Immunologic Factors in Subfertility?

Substantial evidence from animal studies has indicated that antibodies can be induced in females from antigens obtained from organs in the male reproductive tract, and that these antibodies interfere with normal reproduction. Both sperm-agglutinating and sperm-immobilizing antibodies have been found in the serum of some infertile women, but also in the serum of fertile control subjects. Agglutinating antibodies are found more frequently than immobilizing antibodies in most series and, in some reports, the incidence of sperm-agglutinating antibodies in infertile women is similar to that in the control group. Even with the finding of sperm agglutination or immobilization in interactions with serum (in vitro), it has not been demonstrated that a similar degree of sperm inactivation occurs in the lower genital tract. Thus there is no definitive evidence that sperm agglutination or immobilization in the serum of infertile women is the cause of their infertility. One of the reasons for this discrepancy is that both serum assays measure mainly IgM and IgG antibodies, whereas the antibodies locally produced in the genital tract are mainly IgA. Thus some investigators have measured antisperm antibodies in cervical mucus and found a correlation between their presence and infertility. However, no data have shown that the finding of antibodies against sperm in the male or female partner is a cause of infertility. In addition, corticosteroid treatment of the male or female partner does not significantly increase the pregnancy rate compared with no therapy.

Autoimmunity to sperm in semen and serum has been found in some infertile men, particularly those who have had testicular infection, injury, or a surgical procedure such as vasectomy reversal. Men with these antibodies have been treated with corticosteroid therapy and sperm-washing techniques. Nevertheless, the effectiveness of such treatment remains to be established.

Four prospective studies have reported the incidence of fertility occurring after a diagnostic infertility evaluation was performed in which the presence of antisperm antibodies was documented (Collins, 1993). These studies were performed in four different laboratories in three different countries. Several different techniques were used for the antibody tests. All four studies showed no correlation between the presence of antisperm antibodies in either member of the couple and the chance of conception. Pregnancy rates over time were similar in couples who had or did not have antisperm antibodies. Therefore tests to detect these antibodies as part of the diagnostic infertility evaluation are not justified because their presence does not affect fecundity.

Significance of Infectious Diseases in Subfertility

Some researchers have suggested that asymptomatic, or occult, infection of the upper female genital tract and male genital tract is a cause of infertility. As early as 1973, it was suggested that infection with what was then called *T-mycoplasma* in the male could interfere with normal sperm function, and infection of the female reproductive tract could interfere with normal sperm transport. The current name now used for these organisms is *Ureaplasma urealyticum*. Two other microorganisms found in the female genital tract are *Mycoplasma hominis* and *M. fermentans*. Although it has been reported that treatment of infertile couples with antibiotics, such as tetracycline or doxycycline, that eradicate these organisms result in high pregnancy rates, controlled studies have reported no difference in pregnancy rates between couples treated with antibiotics and those not treated. Harrison and colleagues have studied 88 infertile couples with no demonstrable cause of infertility. One third were treated with doxycycline, one third received placebo, and one third received no treatment. *T-mycoplasma* was isolated from approximately two thirds of the couples in each group and was eradicated only in the group treated with doxycycline. Nevertheless, conception rates were similar in each group (Harrison, 1975) as was also reported by Matthews and coworkers (Matthews, 1978) (Table 42.6). Other investigators have suggested that asymptomatic *Chlamydia trachomatis* infection may also cause infertility, but the dosage of doxycycline used in the randomized studies cited earlier would also have eradicated these organisms. Thus there is no evidence that asymptomatic infection of the genital tract of the human male or female causes infertility.

Are Other Tests of Sperm Function Indicated?

In that the semen analysis is subjective and variable, it has long been suggested that other more functional tests would improve the evaluation of the male partner (Oehninger, 2014). The zona-free hamster egg penetration test originally described by Yanagimachi and associates was a test developed to predict the fertilizing ability of sperm and provides an additional, perhaps more sensitive, parameter for assessing sperm function than routine semen analysis. However, many variables factors affect the test results. It has been shown that this test does not correlate well with IVF of human eggs. The sensitivity and specificity of the hamster egg penetration assay (sperm penetration assay) is considered to be too low to justify its routine use as part of the infertility investigation.

Table 42.6 Controlled Studies of Outcome of Therapy of Couples with Unexplained Infertility and *Urea urealyticum* Infections

Study*	Treatment	No. of Couples	No. of Pregnancies	Conceptions (%)
Harrison et al	Doxycycline	30	5	17
	Placebo	28	4	14
	None	30	5	17

*From original source.

Other functional tests of sperm (such as the hypo-osmotic swelling test) assess the integrity of the sperm cell membrane, and others (the zona pellucida binding test, acrosome reaction, and the hyaluronan binding assay) assess maturity and viability (Oehninger, 2014). However, there is no evidence, at present, that these tests add information to the infertility investigation or affects treatment. The DNA fragmentation test in sperm has become popular. This test, which is carried out by flow cytometry

or direct microscopy, determines the rate of DNA fragments; a DNA fragmentation index of more than 30% has been suggested to indicate a poorer rate of fertilization and therefore suggests the need for IVF with intracytoplasmic sperm injection (ICSI). However, at present, there is no evidence that this correlates with the success of IVF, and it cannot be advocated as a routine test (Practice Committee ASRM, 2014).

Figure 42.8 Effect of various treatments on fecundability: ovulatory, tubal, and male factors. (Modified from Hull MG, Glazener CM, Kelly NJ, et al. Population study of causes, treatment, and outcome of infertility. *Br Med J.* 1985;291[6510]:1693-1697.)

PROGNOSIS OF VARIOUS DIAGNOSES UNCOVERED BY THE INFERTILITY INVESTIGATION

Before discussing the specific treatments for abnormalities uncovered by the investigation, it is useful to frame a prognosis for the couple depending on what factor(s) have been found.

The highest probability of conception with treatment other than with IVF-ET occurs among couples in whom anovulation is the only abnormality, with substantially lower probabilities of pregnancy in couples with tubal disease and sperm abnormalities (Hull, 1985) (Fig. 42.8). Although these data are older, this information from Hull still provides the best available comparisons. Among a group of infertile couples with unexplained infertility who were followed for 2 years without treatment after the evaluation was completed, it was found that the chances of becoming pregnant were greater in women younger than 35 years (~75%) than in women older than 35 (50%) (Hull, 1985) (Fig. 42.9). The cumulative conception rate at the end of 2 years without therapy for those couples was much greater for those who had tried to conceive for less than 3 years before evaluation (~75%)

Figure 42.9 Cumulative rates of conception from first attendance at clinic in couples with unexplained infertility related to age of woman. Rates for each age group are shown as solid squares, <25 years; blue triangles, 25 to 29 years; solid triangles, 30 to 34 years; blue squares, >35 years. Standard errors of proportions are given at 6, 12, 18, and 24 months. (From Hull MG, Glazener CM, Kelly NJ, et al. Population study of causes, treatment, and outcome of infertility. *Br Med J.* 1985;291[6510]:1693-1697.)

Figure 42.10 Cumulative pregnancy rates in unexplained infertility without treatment related to duration of infertility. (From Hull MG. Effectiveness of infertility treatments: choice and comparative analysis. *Int J Gynaecol Obstet.* 1994;47[2]:99-108.)

than those who had tried to conceive for more than 3 years (~30%) (Hull, 1994) (Fig. 42.10). In three of the four studies of infertile couples who received no therapy mentioned earlier, more than 50% of the couples who eventually conceived did so in the first year after completing the infertility evaluation. It has been suggested that certain couples have a better prognosis for spontaneous conception after the initial investigation, based on age and the time of trying to conceive. This has been defined as >30% within a year of the evaluation (Hunault, 2004), and it has been suggested that in these couples, it may not be necessary to start empiric treatment (discussed later). Generally, for couples presenting with the inability to conceive, even if no factors have been found (unexplained infertility), in order to increase their chances of conception or to shorten the time interval until conception takes place, various empiric treatments have been advocated. This generally increases the fecundity rate from a baseline of around 4% to 9% to 10% per cycle as will be discussed later in the Unexplained Infertility section.

OUTCOMES OF PREGNANCY IN WOMEN UNDERGOING VARIOUS TREATMENTS

Ovulation-inducing drugs and reconstructive tubal surgery have independently been shown to be associated with an *increased incidence of ectopic pregnancy* compared with the normal population (see Chapter 17). Use of ovulation-inducing drugs alone has been shown to increase the incidence of multiple gestations. With IVF the chances of multiple gestations is better controlled based on the decision to transfer one or more embryos (see Chapter 43). However, IVF does increase the risk of ectopic pregnancies, with a higher rate based on the number of embryos transferred (Perkins, 2015). There is also an increase in the risk of heterotopic pregnancies. Therefore if conception occurs after treatment with ovulation induction or tubal reconstructive surgery, monitoring of early gestation with serial human chorionic gonadotropin (HCG) levels and ultrasonography assists in determining whether the pregnancy is intrauterine and how many gestational sacs are present. However, infertile couples who conceive do not

have a higher rate of spontaneous abortion or perinatal mortality than normal couples. In older women, nevertheless, there is a higher loss rate because of aneuploidy.

TREATMENT OF THE CAUSES OF INFERTILITY

The management of the various causes of infertility will be presented here in the order generally followed in an infertility investigation.

MEDICAL TREATMENT FOR ANOVULATION

Therapeutic agents currently available to induce ovulation are clomiphene citrate, letrozole, and urinary and recombinant gonadotropins. Adjunctive treatments include gonadotropin-releasing hormone (GnRH) agonist and antagonists, as well as HCG, which is used to trigger ovulation. In addition, as discussed in Chapter 39, if anovulation is caused by hyperprolactinemia, dopamine agonists are an effective means of inducing ovulation. As noted in Chapter 40, ovulation may be induced by corticosteroid therapy in women with congenital adrenal hyperplasia.

Clomiphene Citrate

Clomiphene citrate (CC) is the usual first-line pharmacologic agent for treating women with oligomenorrhea and those with amenorrhea who have sufficient ovarian estrogen production. CC is a racemic mixture of en- and zu-clomiphene, which act as estrogen antagonists. The former has a shorter half-life and is more active than the zu-clomiphene isomer, which has a much longer half-life and is more estrogen agonistic than antagonistic. CC acts by competing with endogenous circulating estrogens for estrogen-binding sites on the hypothalamus, thereby blocking the negative feedback of endogenous estrogen. GnRH is then released in a normal manner, stimulating FSH and LH, which in turn cause oocyte maturation, with increased E_2 production. The drug is usually given daily for 5 days, beginning 3 to 5 days after the onset of spontaneous menses or withdrawal bleeding induced with a progestogen.

During the days when the drug is ingested, serum levels of LH and FSH rise, accompanied by a steady increase in serum E_2 level. After ingestion of CC is discontinued, E_2 levels continue to increase and the negative feedback on the hypothalamic-pituitary axis causes a decrease in FSH and LH levels, similar to the change seen in the late follicular phase of a normal ovulatory cycle. Approximately 5 to 9 days (mean, 7 days) after the last CC tablet has been ingested, the exponentially rising level of E_2 from the dominant follicle has a positive feedback effect on the pituitary or hypothalamus, producing a surge in LH and FSH levels, which usually results in ovulation and luteinization of the follicle.

Presumptive evidence of ovulation can be obtained by observation of a sustained rise in BBT or measurement of an elevation of serum progesterone level. It is best to obtain the serum sample for progesterone approximately 2 weeks after the last CC tablet, because this will usually be in the middle of the luteal phase, approximately 1 week after ovulation. A rise in serum progesterone level above 3 ng/mL correlates well with the finding of a secretory endometrium, but it has been reported that the maximal midluteal progesterone levels in CC-induced ovulatory conception cycles are consistently above 15 ng/mL (Hammond, 1983).

These levels are higher than the 10 ng/mL level, which is the minimum concentration of progesterone found in spontaneous ovulatory conception cycles (Hull, 1982) because following ovulation induction with CC, more than one follicle usually matures and undergoes luteinization.

Various treatment regimens have been advocated for the use of CC. Most start with an initial dosage of 50 mg/day for 5 days, beginning on the fifth day of spontaneous or induced menses. If presumptive evidence of ovulation occurs with this dosage, the same dosage of clomiphene citrate is taken in subsequent cycles until conception occurs. If ovulation fails to occur with the initial dosage, a sequential, graduated, increasing dosage regimen has proven to be effective, with a minimum of side effects. With this regime, if ovulation does not occur with the 50-mg dose, the dosage of drug is increased in the next treatment cycle to 100 mg/day for 5 days. If ovulation does not occur with 100 mg/day in subsequent cycles, the dosage is sequentially increased to 150 mg. In the past, we have used doses up to 250 mg, with and without HCG (Lobo, 1982). In the 10 years' experience with this treatment regimen as reported by Gysler and associates, approximately half of the women who ovulated and half of those who conceived did so following treatment with the 50-mg/day regimen, and an additional 20% ovulated with the 100-mg/day dosage (Gysler, 1982). However, approximately 25% of all women who ovulated or conceived did so following treatment with a higher dosage regimen, indicating the value of the individualized sequential treatment regimen. However, from a practical standpoint, it is unusual to use doses higher than 150 mg, particularly when adjuncts are available, such as metformin in overweight women with PCOS or switching to letrozole.

A more recently used regimen, the stair-step regimen, does not wait for menses after a failed response before moving to the next dose (Hurst, 2009). Thus if there is no follicular development on ultrasound 5 days after the last clomiphene tablet, the patient is immediately placed on 100 mg for 5 days and subsequently to 150 mg for 5 days in the same cycle if follicular development does not occur. Although preliminary retrospective reports have shown that this is a reasonable approach to hasten therapy, prospective randomized trials are still in progress.

With the dosage regimen of CC up to 250 mg, more than 90% of women with oligomenorrhea and 66% with secondary amenorrhea and normal estrogen status will have presumptive evidence of ovulation. Although only approximately 50% of patients who ovulate with this treatment will conceive, Gysler and associates have reported that 85% of those with no other causes of infertility conceive after such treatment (Gysler, 1982). The fecundability during several months of treatment with CC, if no other causes of infertility are present, are similar to those of a normal fertile population. Using life table analysis, the monthly pregnancy rate (fecundability) of women treated with CC who had no other infertility factor was 22% compared with a rate of 25% for women discontinuing diaphragm use (Messinis, 1997). The monthly fecundability remained constant throughout almost 1 year of treatment. Almost all the anovulatory women without other infertility factors in this series, as well as other women with correctable infertility factors, had conceived after 10 cycles of treatment. This rate is also similar to the use of gonadotropins (Messinis, 1997) (Fig. 42.11).

These data indicate that discontinuation of therapy is the major reason for the reported difference in ovulation and

Figure 42.11 Cumulative pregnancy rate of 60% at 6 months with clomiphene. (From Messinis IE, Milingos SD. Current and future status of ovulation induction in polycystic ovary syndrome. *Hum Reprod Update*. 1997;3[3]:235-253.)

conception rates in anovulatory women treated with CC. However, despite these data, many investigators believe that pregnancy rates are lower with CC than might be expected based on ovulation rates, and other factors (in some women), such as cervical mucus and endometrial problems, explain this discrepancy. In ovulatory women who respond to CC, HSG should be performed if a pregnancy does not occur after 3 months. A semen analysis should be done before starting CC. When conception occurs after ovulation has been induced with CC, the incidence of multiple gestation is increased to approximately 8%, with almost all being twin gestations. However, when the drug is used in normally ovulating women with unexplained infertility, the rate increases to almost 20%. The incidence of clinical spontaneous abortion ranges between 15% and 20%, similar to the rate in the general population. The rates of intrauterine fetal death and congenital malformation are also not significantly increased. Animal data have shown that if the drug is given in high dosages during the time of embryogenesis, there is an increased incidence of fetal anomalies. However, limited human data have indicated that if the drug is ingested during the first 6 weeks after conception has occurred, the incidence of fetal malformation, although higher (5.1%) than in the normal noninfertility population, it is not significantly increased. Although no definitive data have shown that the drug is teratogenic in humans, it is best that the woman be tested for pregnancy before each course of treatment. It is also important to determine that the ovaries have not become enlarged, because formation of ovarian cysts is the major side effect of CC treatment. If cysts are present, they will regress spontaneously without therapy, but if additional CC is given and further gonadotropin release is induced, stimulation and further enlargement of the cyst may occur. Clinically palpable ovarian cysts occur in approximately 5% of women treated with CC but in less than 1% of treatment cycles. The cysts usually range in size from 5 to 10 cm and do not require surgical excision, because they almost always regress spontaneously. Cysts can occur in any treatment cycle with any dosage, and the incidence is not increased with the higher dosages of drug.

Recurrence of cyst formation with the same dosage is uncommon. Other side effects, which occur in less than 10% of women treated with this drug, include vasomotor flushes, blurring of vision, abdominal pain or bloating, urticaria, and a slight degree of hair loss.

Up to 10% of women treated with CC fail to ovulate with the highest dosage. Older data have suggested that this so-called resistance is not caused by the inability of the hypothalamic-pituitary axis to respond, but to the lack of the ovarian response to raised gonadotropin levels. Contributors of CC resistance include body mass index, free androgen and insulin; higher values all contributing to this resistance (Imani, 2002). Although various prediction models have been generated to determine the CC response, none has proven to be useful prospectively. Findings in women with PCOS also suggest that higher levels of AMH may contribute to CC resistance as well as the dosage required for gonadotropins in women with PCOS; AMH inhibits FSH action in the ovary (Mahran, 2013).

Some data suggest that in women with elevated levels of androgen, particularly dehydroepiandrosterone sulfate (DHEAS), the use of low doses of dexamethasone may enhance the ovulation-inducing effect of CC. This approach is less frequently used today. Other adjuncts that have been tested, but that lack validation, include adding a dopamine agonist such as bromocriptine and antiandrogens. Metformin and insulin sensitizers have also been used as adjunctive treatments.

Metformin and Other Insulin Sensitizers

Metformin, a biguanide used to control blood sugar in diabetics, has a role in ovulation induction in women with PCOS and has been shown to be superior to placebo. Although not a true insulin sensitizer, it decreases hepatic glucose production and has some minor peripheral action, leading to some decrease in insulin resistance. It also has a direct role in inhibiting ovarian androgen steroidogenesis and acts on the endometrium, which are probably the major mechanisms that help with ovulation and pregnancy.

Studies have confirmed the efficacy of metformin over placebo in inducing ovulation in women with PCOS. However, in direct comparisons with clomiphene, it was inferior to clomiphene in terms of live birth rates in women with PCOS (Legro, 2007) (Fig. 42.12). Therefore although not necessarily a first-line choice in women with PCOS, it is clearly an adjunct and may be helpful in women who exhibit some degree of insulin resistance. However, it should be considered as a preliminary option in heavy or obese women and for those with impaired glucose tolerance or significant insulin resistance prior to ovulation induction with other agents.

The typical dosage of metformin is 1500 mg/day. It is preferable to use long-acting tablets (extended release or extra strength) available in 500- and 750-mg tablet form and to ingest them all at the same time during a meal, preferably at dinner. However, it should be initiated only at 500 mg and titrated up over several weeks. This is because of gastrointestinal effects (e.g., nausea, vomiting, and diarrhea), which is the primary concern with metformin and precludes its use in up to 20% of women.

Lactic acidosis is a rare complication that occurs primarily in older individuals. However, checking blood levels after 3 months of metformin is good practice, and women also should be reminded not to drink alcohol heavily, although the occasional

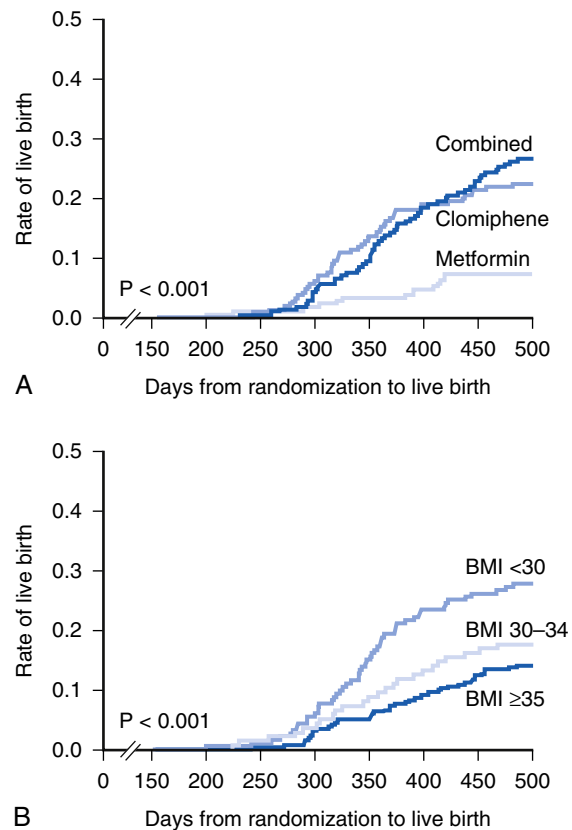

Figure 42.12 Kaplan-Meier curves for live birth, according to study group Panel **A**: all three groups; Panel **B**: groups divided by BMI. (From Legro RS, Barnhart HX, Schlaff WD, et al. Clomiphene, metformin, or both for infertility in the polycystic ovary syndrome. *N Engl J Med*. 2007;356[6]:551-566.)

drink is acceptable. Many endocrinologists advocate a dose of 2000 mg/day for heavier women.

When metformin alone is prescribed for anovulatory women who wish to conceive, the ovulation rate is approximately 60% in adherent women. In CC-resistant patients, those who fail to ovulate with 150 mg/day (although the data are mixed), approximately 25% of women will respond to CC with metformin. Metformin is a category B substance for pregnancy and has been continued through the first trimester and beyond in select patients (see Chapter 41).

Letrozole

Aromatase inhibitors are efficacious as primary agents for ovulation induction. Most of the experience is with letrozole. The mechanism of action is that of inhibition of E_2 production during the 5 days of administration, with a negative feedback causing an increase in FSH levels, much like the response to CC. Intraovarian androgen levels are also increased, which may enhance FSH sensitivity. Letrozole (2.5 or 5 mg; there is no good evidence for a dose difference) is administered for 5 days like clomiphene, beginning on cycle days 3 to 5.

Because letrozole is short acting, the problems of thick cervical mucus or a thin endometrium associated with clomiphene have not been reported with letrozole. However, E_2 levels are usually lower at ovulation. Pregnancy rates are comparable to those with

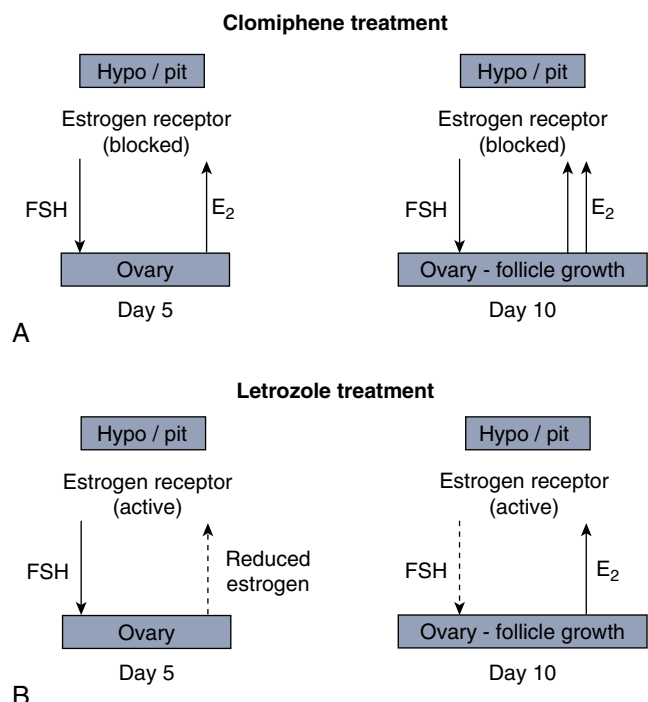

Figure 42.13 Clomiphene citrate (Panel A) and letrozole treatment (Panel B). (From Casper RF, Mitwally MF. Review: aromatase inhibitors for ovulation induction. *J Clin Endocrinol Metab.* 2006;91[3]:760-771.)

Figure 42.14 Live birth rates in a randomized trial of letrozole versus clomiphene in women with polycystic ovary syndrome. (Data from Legro RS, Brzyski RG, Diamond MP, et al. Letrozole versus clomiphene for infertility in the polycystic ovary syndrome. *N Engl J Med.* 2014;371[2]:119-129.)

CC alone, and there has been a suggestion for a reduced incidence of multiple pregnancies because of its shorter half-life and lack of stimulation of gonadotropins beyond the early follicular phase (Casper, 2006) (Fig. 42.13). A randomized trial comparing letrozole and CC in women with PCOS showed the superiority of letrozole in terms of live births (Legro, 2014) (Fig. 42.14). In this trial there were no differences in adverse effects or congenital anomalies, and the multiple rates were comparable. Including this trial, a meta-analysis from Cochrane also confirmed the superiority of letrozole (Franik, 2014). In that it has also been deemed to be cost effective, letrozole should be considered the first-line treatment (over CC) in women with PCOS, although to date it still

has not been approved by the U.S. Food and Drug Administration (FDA) for ovulation induction.

There is little information about the effects of letrozole in CC-resistant patients, but anecdotally it has been found to be effective in this regard in many women. Letrozole with gonadotropins has also been used for COS. It has been suggested that it can reduce the gonadotropin dose needed when used as a sequential regimen (letrozole priming followed by gonadotropins), and it may be used in combination with gonadotropins in poor responders for IVF.

Gonadotropins

Gonadotropin therapy is indicated for ovulation induction when estrogen levels are low and when there is no repose to CC or letrozole. Low serum E_2 levels (usually <30 pg/mL) or lack of withdrawal bleeding after progestogen administration signifies a state that will be unresponsive to oral therapies (CC, letrozole) that are dependent on a negative feedback system. Apart from this indication in usually amenorrheic women, it is appropriate to use gonadotropins when there is resistance to CC or letrozole. Gonadotropins have also been used when there has been the inability to conceive after several (four to six) cycles of CC or letrozole, although this indication is not as frequently applied today.

The original gonadotropin preparations were extracts of postmenopausal urine. Although purified, they contained large amounts of protein contaminants. These preparations are used less often today but are still available worldwide (Pergonal, Humegon). More recent preparations with additional purification have allowed them to be administered subcutaneously (SC) rather than intramuscularly (IM). These preparations are titrated to provide an equal quantity of LH (75 IU) and FSH (75 IU) in one ampule.

Further modifications of these urinary products have eliminated most of the LH activity and provided a relatively pure FSH urinary preparation (Bravelle, Metrodin, containing 75 IU FSH/ampule). All nonrecombinant preparations, because they are extracted from human sources, have batch to batch variability in terms of biologic activity.

Recombinant pure FSH preparations (from Chinese hamster ovarian cells) are currently available for SC administration (Gonal-F, Follistim, 75 IU FSH). Recombinant pure LH has also become available as a supplement (Luvris, 75 IU LH), although it is unclear if the addition of LH is really necessary in most cases.

Because each woman responds individually to the dosage of gonadotropins, even the same woman in different treatment cycles, it is essential to monitor treatment carefully with frequent measurements of estrogen levels and ovarian ultrasonography. Close monitoring (US and E_2) is important to assess the adequacy of the response and to avoid ovarian hyperstimulation.

There is a different concept regarding induction of ovulation with gonadotropins when the problem is anovulation or when gonadotropins are used in the setting of unexplained infertility or for the purposes of IVF (discussed later). Many practitioners often lose this concept, which then leads to a high rate of hyperstimulation and multiple pregnancies. It is for these reasons that gonadotropins are often avoided in the setting of failure to conceive after several ovulatory cycles of CC or letrozole, favoring an approach of going directly to IVF.

The goal of therapy in anovulatory women is to produce one mature follicle, sometimes two. In women with low estrogen status, cycle fecundability approaches the ideal (~20%/cycle) if there are no other infertility factors. It is a little lower, however, in women who are CC failures or have PCOS (Lunenfeld, 1995) (Fig. 42.15). In these patients, the risk of hyperstimulation is greatest, and great care has to be used when monitoring these women (discussed later).

By injecting gonadotropins, the physiology behind this approach is to increase the serum FSH level above a critical threshold level, which is an unknown at the outset. The window for this therapeutic threshold is fairly wide in normal and hypoestrogenic women, but it is extremely narrow in PCOS, increasing the risk of hyperstimulation. A starting dose of 150 IU with FSH is used (as a recombinant preparation of pure

Figure 42.15 **A**, Cumulative pregnancy rates for hypogonadotropic anovulatory women (WHO group I) treated with gonadotropins. *Solid circles* represent the cumulative pregnancy rate in women younger than 35 years. *Open circles* represent the cumulative pregnancy rate in women older than 35 years. **B**, Cumulative pregnancy rates following gonadotropin treatment for anovulatory women who did not respond to clomiphene induction of ovulation (WHO group II). *Solid circles* represent the cumulative pregnancy rate in women younger than 35 years. *Open circles* represent the cumulative pregnancy rate in women older than 35 years. (From Lunenfeld B, Insler V. Human gonadotropins. In: Wallach EE, Zacur HA, eds. *Reproductive Medicine and Surgery*. St. Louis: Mosby; 1995:617.)

FSH or a combination of LH and FSH in a urinary preparation). The E_2 level is determined and ultrasound is performed after approximately 5 days and then approximately every other day until a follicle reaches a diameter of at least 18 mm. The serum E_2 level should be at least in the range of 200 pg/mL for a mature follicle. At this point, 5000 to 10,000 IU of HCG is administered IM (or pure recombinant HCG, 250 μ g SC) to trigger ovulation. Timed intercourse is usually advised if there is a normal semen analysis and good cervical mucus. Ovulation should occur between 36 and 48 hours after the trigger of HCG. Particularly in women with hypothalamic amenorrhea and low estrogen status, vaginal progesterone supplementation (100 mg/day) is usually prescribed, although this addition is not completely evidence based.

In women with PCOS in whom the ovary is extremely sensitive to gonadotropin, a starting dose of only 50 to 75 IU is used. A slow step-up regimen is usually preferred, increasing the dose slowly only after 7 days (Macklon, 2009) (Fig. 42.16). Although there have been advocates for the use of a step-down approach (higher initial dose and then a rapid decrease), randomized trials in PCOS have suggested the preference for using the traditional step-up approach, which has better outcomes.

The pregnancy rate per cycle should be similar to that following CC therapy (~20%). With sufficient duration of treatment and no other infertility factors, cumulative pregnancy rates are excellent. It has been reported that the cumulative pregnancy rate after nine cycles of gonadotropin therapy is approximately 77%. These effects are influenced by age and type of anovulation as noted previously (see Fig. 42.15). The incidence of spontaneous abortion after gonadotropin therapy is higher than the normal rate (25% to 35%), and the overall multiple pregnancy

Figure 42.16 Schematic representation of serum follicle-stimulating hormone (FSH) levels and daily dose of exogenous FSH during low-dose step-up or step-down regimens for ovulation induction. (From Macklon NS, Bart CJ. Medical approaches to ovarian stimulation for infertility. In: Strauss JF, Barbieri RL, eds. *Yen and Jaffe's Reproductive Endocrinology*. 6th ed. Philadelphia: WB Saunders; 2009:701.)

rate (usually twins) is in the range of 15%, but there is a risk of this being much higher.

Ovarian Hyperstimulation Syndrome

Although enlarged ovaries are frequently encountered after gonadotropin administration, significant ovarian hyperstimulation syndrome (OHSS) occurs in approximately 0.5% of women receiving gonadotropins. OHSS can be life threatening, causing massive fluid shifts, ascites, pleural effusion, electrolyte disturbances, and thromboembolism (Tan, 2013). The cause has not been completely elucidated but is related to the large cystic ovaries, high E_2 levels, and the ovarian elaboration of substances such as vascular endothelial growth factor (VEGF), which increase vascularity and vascular permeability. Several investigators have classified OHSS into mild, moderate, and severe forms. A representative categorization may be found in Box 42.1 (Navot, 1992). HCG triggers the syndrome, and blood levels of HCG continue to stimulate the ovaries in OHSS. Therefore the syndrome is worse if pregnancy occurs and abates within 1 week in the absence of pregnancy. For this reason, if severe OHSS is anticipated, HCG injection should be withheld. In IVF cycles, the embryos may be frozen rather than replaced to avoid pregnancy.

Treatment of OHSS is largely supportive, with judicious use of fluids and prevention of thrombosis. Correction of electrolyte disturbances and maintenance of urine output are of greatest

importance. Occasionally, admission for intensive care unit (ICU) monitoring is necessary.

Avoidance of excessive stimulation is the primary approach for preventing OHSS. Lowering or withholding the dose of HCG is also advisable. An alternative approach is to use a GnRH agonist instead of HCG to trigger ovulation (as long as there is a normal pituitary able to release LH) because LH is much shorter acting and will clear from the circulation soon after ovulation, unlike HCG. An experimental approach being studied to treat OHSS is the use of a dopamine agonist such as cabergoline, which interferes with the action of VEGF.

The majority of studies and meta-analyses have not shown a statistically significant increased risk of ovarian or breast cancer in women receiving gonadotropin therapy (Diergaarde, 2014).

Gonadotropin-Releasing Hormone

An alternative to the administration of gonadotropins is gonadotrophin-releasing hormone (GnRH) treatment, particularly in estrogen-deficient women. Because continuous administration of GnRH will saturate the receptors and thus inhibit gonadotropin release to induce ovulation, GnRH must be administered in a pulsatile manner at intervals of 1 to 2 hours. GnRH is a peptide, so it cannot be administered orally; the two methods of administration in current use are the IV and SC routes. More drugs must be administered by the SC route than by the IV route; however, the SC route avoids use of an IV catheter, with its accompanying problems. The success rates, however, are better with IV delivery. The medication is given by means of a small portable pump, which is usually worn attached to an article of clothing. Ovulation rates of approximately 75% to 85% per treatment cycle have been reported. However, this approach is cumbersome, requiring a continuous line and a portable pump 24 hours a day. Currently, it is not frequently used.

OTHER THERAPEUTIC MODALITIES

Weight and Lifestyle Management

Particularly in women who are clomiphene-resistant, weight loss will often ameliorate the situation. In overweight women, it is important to ensure that abnormalities in glucose and lipid metabolism are normalized as much as possible, before induction of ovulation. There is evidence that lifestyle changes in diet and exercise may improve overall fitness and metabolic parameters, as well as ovulatory responses, even in the absence of true weight loss, although there could be a redistribution of body fat with lifestyle changes.

Ovarian Electrocauterization

At an ESRE/Adolescent Sexual and Reproductive Health (ASRH) consensus meeting for the treatment of infertility in PCOS, it was concluded that a possible alternative to gonadotropin therapy in clomiphene-resistant women with PCOS is the use of ovarian electrocautery, which has similar efficacy (Thessaloniki European Society for Human Reproduction and Embryology/American Society for Reproductive Medicine consensus meeting, 2008) (Fig. 42.17).

Laparoscopic electrical or laser-generated burn holes through the ovarian cortex have been associated with improving ovulation rates, as was described many years ago with ovarian wedge resection, which is no longer performed. The major advantage of this more invasive method of ovarian electrocauterization is that it

Box 42.1 Classification of Ovarian Hyperstimulation Syndrome

Mild

Ovarian enlargement (5 cm or less)
Abdominal discomfort

Moderate

Ovarian enlargement (6–10 cm)
Nausea or gastrointestinal symptoms
Abdominal discomfort
Normal laboratory evaluation
Mild ascites, not clinically evident

Severe

Symptoms as above and other symptoms, such as respiratory distress
Ovarian enlargement
Severe ascites (clinically evident)
Hydrothorax
Elevated hematocrit (>45%)
Elevated WBC count (>15,000/ μ L)
Elevated creatinine
Electrolyte abnormalities (hyponatremia, hyperkalemia)
Elevated liver function tests

Critical (as a subcategory of severe)

Severe end-organ dysfunction
Oliguria, creatinine >1.6 mg/dL
Severe respiratory distress
Thrombotic complications
Infection
Severe hemoconcentration
Hematocrit >55%
WBC count >25,000/ μ L

Footnotes: Test for heterogeneity: $\chi^2 = 0.35$, $df = 3$ ($p = 0.91$), $I^2 = 0\%$

Test for overall effect: $Z = 2.89$ ($p = 0.01$)

B

Figure 42.17 Results from the meta-analysis of the randomized control trial of laparoscopic ovarian surgery versus gonadotrophins for live birth rate (A) and multiple pregnancy rate (B). (From Thessaloniki ESHRE/ASRM-Sponsored PCOS Consensus Workshop Group. Consensus on infertility in PCOS. *Fertil Steril*. 2008;89:505-522.)

decreases the risk of hyperstimulation and multiple pregnancies. In addition to a concern of surgical complications, excessive destruction of the ovarian cortex can lead to premature ovarian failure. Only a limited number of burn holes (~10) should be made.

Figure 42.17 compares the pregnancy rates after electrocauterization and gonadotropin therapy. It has been reported that the endocrine changes may persist for at least 10 years (Gjonnaess, 1998). A Cochrane review has also reported an overall term pregnancy rate of 50% after surgery and a low multiple pregnancy rate (Farquhar, 2005).

Nevertheless, ovulation induction in women with PCOS should still be a medical treatment, particularly with the use of adjuncts, if necessary. In our view, ovarian electrocauterization should be reserved for patients who have difficulties with gonadotropin stimulation (failure of dominant follicle selection or hyperstimulation risk) even in the setting of IVF, which is usually the next step in women who tend to have hyperstimulation with gonadotropin induction of ovulation.

DEALING WITH A MALE CAUSE OF INFERTILITY

All gynecologists who care for infertile couples should understand how to interpret a semen analysis and how to offer a prognosis for a disorder of abnormal semen. Although gynecologists usually do not perform a diagnostic evaluation or treat the man with a reproductive disorder, they should be able to provide counsel regarding the use of intrauterine insemination with the husband's or donor's semen, as well as with treatment by ICSI, testicular sperm extraction (TESE), or microsurgical epididymal serum aspiration (MESA).

Male Partner Evaluation

If the semen analysis is abnormal and has been repeated, it is important that the man be evaluated by an andrologist, usually a urologist. Important medical conditions must be ruled out, and occasionally an abnormality is found that can be treated. Blood should be obtained for hormone and other testing, as needed, and a careful urologic examination can diagnose problems such

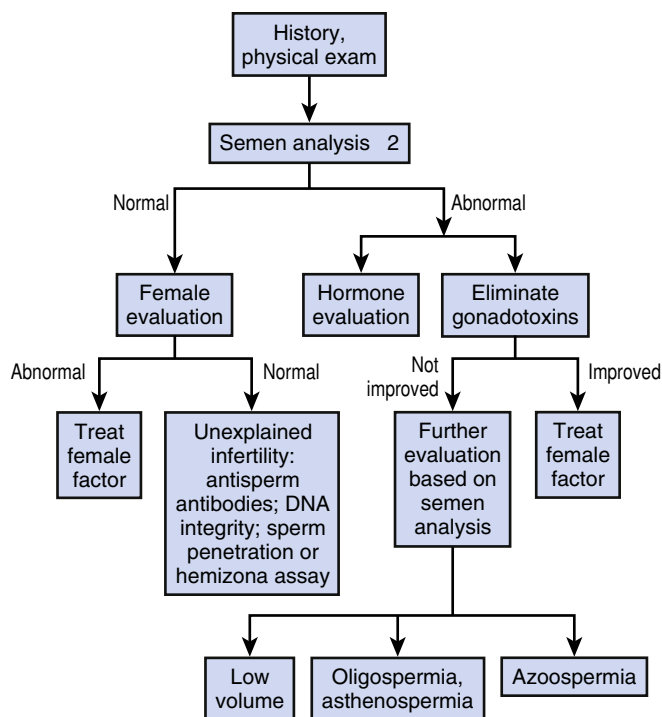

Figure 42.18 General algorithm for the diagnostic evaluation of male infertility. (From Turek PJ. Practical approaches to the diagnosis and management of male infertility. *Nat Clin Pract Urol*. 2005;2:226-238.)

as testicular abnormalities and infection (Fig. 42.18). The more treatable conditions are hormonal abnormalities (apart from an elevated FSH level, signifying end-organ seminiferous failure), as well as infection. Varicocele repair remains somewhat controversial, and the decision must be individualized based on the ages of the couple, other factors that may be involved, and whether the *varicocele* is symptomatic, or at least clinically detected (palpable). Although a varicocele has been shown to correlate with poor sperm characteristics, there is often a variable response to surgery. It is important to note that improvement may not be evident for 6 months, given that the cycle of spermatogenesis is approximately 3 months in length (Practice Committee ASRM, 2014).

If the evaluation is nondiagnostic or if no treatment is possible or indicated, the best therapy should be directed at improving the ejaculate for intrauterine insemination or to carry out IVF with ICSI. A general algorithm for treatment is shown in Figure 42.19.

Intrauterine insemination has been used to treat oligospermia and abnormalities of semen volume or viscosity to enhance fecundability. The limitation of successful IUI is when there is significant oligospermia or motility problems (<5 million motile sperm available) or with very poor morphology. Data, however, have suggested that abnormal morphology alone may not affect the success of IUI treatment (Devenau, 2014).

The procedure of IUI (after washing and centrifugation of the ejaculate) is associated with higher pregnancy rates if combined with COS than when used in natural ovulatory cycles. IUI is also of benefit to women with variable degrees of cervical stenosis. Ideally, insemination should take place on the day of, or just prior to ovulation. It is advisable to use a urinary LH enzyme-linked

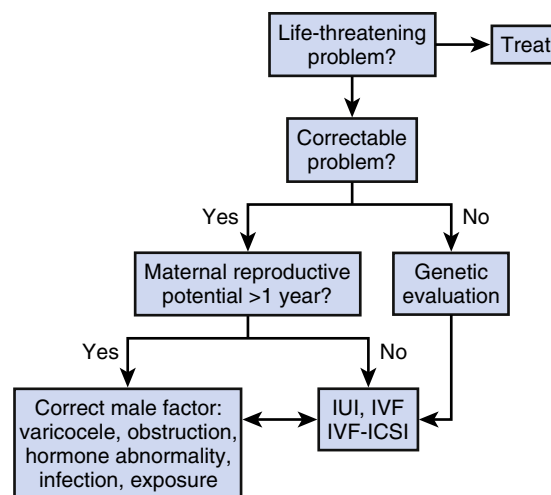

Figure 42.19 General algorithm for treatment of male infertility. ICSI, Intracytoplasmic sperm injections; IUI, intrauterine insemination; IVF, in vitro fertilization. (From Turek PJ. Practical approaches to the diagnosis and management of male infertility. *Nat Clin Pract Urol*. 2005;2:226-238.)

immunosorbent assay (ELISA) kit to determine the optimal date to perform insemination because the urinary LH peak occurs on the day prior to ovulation. Insemination should be scheduled for the morning after LH is initially detected in an afternoon urine specimen. In women who have difficulty with LH kits, ovulation may be “triggered” with HCG injection (typically 250 µg of recombinant HCG subcutaneously), as long as follicular development is adequate (typically at least a 20-mm follicle on ultrasound).

Separation of sperm from the seminal fluid by double centrifugation, the swim-up technique, or use of a density gradient should be performed before IUI. This enhances sperm motility and is thought to increase capacitation (membrane changes in sperm that facilitate fertilization). IUI of unwashed seminal fluid should not be used because it may cause infection and can produce severe uterine cramps as a result of prostaglandin content in seminal fluid.

Until rather recently, if there were severe abnormalities in the semen analysis, the prognosis for fertility was less than that for any other cause of infertility (see Fig. 42.8), even with the use of IVF techniques. Attempts to enhance fertilization rates of aspirated oocytes with the technique of subzonal insemination of sperm were unsuccessful because fertilization rates remained low, approximately 15%. After Van Steirteghem and associates developed the technique of ICSI, fertilization rates of oocytes injected with a single normal sperm obtained from men with severe abnormalities in their semen analysis increased above 50% (Van Steirteghem, 1993). Pregnancy rates per embryo transfer are now similar after ICSI compared with other indications for IVF. When there is very low or no sperm in the ejaculate, IVF/ICSI can be carried out using testicular sperm (see Chapter 43).

Some couples, particularly those whose male partner has azoospermia, may choose to use donor sperm insemination. If they choose this option, the attitudes of both partners regarding the use of donor semen and the stability of the marriage must be thoroughly discussed before the procedure is performed. Donors

from sperm banks are carefully screened for infectious diseases, and all semen samples are quarantined for at least 6 months because of the long time it takes for positive antibodies to HIV to appear after infection. The American Society for Reproductive Medicine has published a set of guidelines for semen donor insemination. These guidelines provide information regarding indications for donor insemination, as well as suggested procedures for selection and screening of possible semen donors.

Freezing of sperm is the only way that donor insemination should be done because of the time necessary to quarantine samples to rule out infectious diseases, but freezing sperm affects fecundability. A cumulative pregnancy rate after insemination of approximately 50%, and a monthly fecundity rate of only 9% has been reported after 6 months of treatment. However, the range is variable and may be as high as a fecundity rate of 18%, with a 45% cumulative pregnancy rate at 3 months. There is a known variability of semen quality after thawing, even in normal fertile sperm donors.

UTERINE CAUSES OF INFERTILITY

In the evaluation of the uterus by HSG, a number of “filling defects” may be appreciated. These are usually polyps, submucous fibroids, or intrauterine adhesions. Each of these may affect the woman’s ability to get pregnant or lead to miscarriage and should be corrected.

Intrauterine Adhesions

In addition to menstrual abnormalities and recurrent abortion, some women may not be able to conceive because of the presence of intrauterine adhesions (IUA). As noted in [Chapter 16](#), most women with IUAs have had a previous curettage of the uterine cavity, usually during or shortly following a pregnancy. If the only abnormal finding in the infertility investigation is the presence of IUAs, the prognosis for conception after hysteroscopic lysis of the adhesions is good. March and Israel have reported that of 69 infertile women with IUAs and no other infertility factors, 52 (75%) conceived after hysteroscopic treatment.

Leiomyoma

Congenital uterine defects rarely cause infertility, and the uterine anomalies associated with maternal ingestion of diethylstilbestrol (DES) have not been shown in randomized studies to be a cause of infertility. It is also difficult to assess the effect of leiomyomas on conception, because many women with leiomyomas have no difficulty conceiving. However, depending on their location, fibroids may decrease the chance of conception or increase the miscarriage rate. Data indicate a global change in endometrial receptivity, even with intramural fibroids ([Rackow, 2010](#)). If no other cause of infertility is found and myomas of moderate size and position are present, a myomectomy is justified. More recent data from the IVF literature point to a decreased pregnancy rate with submucous fibroids, and larger intramural fibroids (>4 cm), but in those (intramural and subserosal fibroids) that do not distort the cavity the pregnancy rate is not affected ([Sunkara, 2010](#)). *The overall pregnancy rate after myomectomy in women with no other causes of infertility has been found to be significantly improved in retrospective studies; surprisingly there are no prospective studies showing a benefit of myomectomy.*

Tuberculosis

Although rare in the United States, genital tuberculosis should be kept in mind. If HSG reveals findings consistent with pelvic tuberculosis, endometrial biopsy and culture should be performed to confirm the diagnosis. The radiographic features of pelvic tuberculosis that are almost diagnostic include the following: (1) calcified lymph nodes or granulomas in the pelvis; (2) tubal obstruction in the distal isthmus or proximal ampulla, sometimes resulting in a pipe stem configuration of the tube proximal to the obstruction; (3) multiple strictures along the course of the tube; (4) irregularity to the contour of the ampulla; and (5) deformity or obliteration of the endometrial cavity without a previous curettage ([Fig. 42.20](#)). Appropriate antituberculosis medication should be initiated, but women with pelvic tuberculosis should be considered sterile, because pregnancies after therapy are rare. Tubal reconstructive surgical procedures are therefore not indicated. If tuberculosis is present in the tube but not in the uterus, pregnancies have been reported following IVF ([Parikh, 1997](#)).

Figure 42.20 Tuberculous salpingitis in 37-year-old nulligravida with primary infertility for 15 years. Right tube is obstructed in the zone of transition between the isthmus and the ampulla. Arrows indicate multiple strictures in both tubes. Nodular contour of endometrial cavity may also be related to tuberculosis and is analogous to the pattern found in the ampulla in other cases. Small diverticulum near internal os probably represents adenomyosis. Diagnosis of tuberculosis was confirmed by endometrial culture. (From Richmond JA. Hysterosalpingography. In: Mishell DR Jr, Davajan V, Lobo RA, eds. *Infertility, Contraception and Reproductive Endocrinology*. 3rd ed. Cambridge, MA: Blackwell Scientific; 1991.)

Tubal Causes of Infertility

Since the 1980s, the incidence of infertility caused by damage to the fallopian tube has increased because of an increased incidence of salpingitis. Obstructions occur at the distal or proximal portion of the tube and sometimes in both regions. Distal obstruction, leading to a hydrosalpinx (Fig. 42.21) is much more common than proximal obstruction. The prognosis for fertility after surgical tubal reconstruction depends on the amount of damage to the tube, as well as the location of the obstruction. If there is extensive damage, the chances for conception after tubal reconstruction are unlikely. Women with extensive tubal disease have a greater chance of conceiving with an IVF procedure, so the extent and location of the intrinsic and extrinsic tubal disease should be ascertained by HSG and possibly laparoscopy in an effort to determine whether tubal reconstruction or IVF offers the better prognosis (Practice Committee ASRM, 2012b). As noted, if a large hydrosalpinx is seen at the time of HSG, it is best to suggest that the woman have IVF rather than undergo tubal reconstructive surgery. It is recommended that the hydrosalpinx be excised before IVF if it is large and visible by ultrasound. If proximal and distal obstructions of the tube exist, the damage to the tube is usually so extensive that the tube cannot function normally. Therefore although it is possible to achieve tubal patency after surgical repair with proximal and distal blockage, subsequent intrauterine pregnancy is uncommon and surgical reconstruction should not be performed in such cases. In general, infertility surgery for tubal disease is a dying art—the pregnancy rates with IVF are far superior, and most women would prefer to avoid surgery as long as they have insurance coverage for IVF.

Distal Tubal Disease

HSG can help to determine whether the tubal obstruction is complete or partial, the size of the distal sacculization, and the appearance of the mucosal folds and rugal pattern of the endosalpinx (see Fig. 42.21). Laparoscopy will assist in determining

Figure 42.21 Hysterosalpingography showing bilateral hydrosalpinges with dilation, clubbing, and obstruction at fimbriated ends. Patient was 32-year-old woman with 10-year history of primary infertility. (From Richmond JA. Hysterosalpingography. In: Mishell DR Jr, Davajan V, Lobo RA, eds. *Infertility, Contraception and Reproductive Endocrinology*. 3rd ed. Cambridge, MA: Blackwell Scientific; 1991.)

the size of the hydrosalpinx, amount of muscularis, and thickness of the wall of the tube after distention with dye. Laparoscopic examination will determine whether pelvic adhesions are present and the extent of these adhesions. Women with fimbrial obstruction are not a homogeneous group, and the prognosis for intrauterine pregnancy following distal tubal reconstruction is related to the extent of the disease process. Therefore it is important to perform HSG and laparoscopy before surgical reconstruction to provide an individualized prognosis.

If the fimbriae of the distal end of the tube are relatively normal, with only partial occlusion by adhesions or fimbrial bridges, removal of these adhesions by means of a fimbrioplasty procedure will result in higher conception rates (~60%) than if the distal end is completely occluded and a cuff salpingostomy procedure is required. Overall conception rates following salpingostomy are in the 30% range, with a high percentage (~25%) being tubal pregnancies. Although microsurgical techniques had been used for all tubal infertility surgery, all procedures are currently carried out via laparoscopy. The incidence of ectopic pregnancy after surgical reconstruction for distal tubal disease is directly related to the amount of tubal damage existing before the operative procedure.

The results of tubal reconstruction correlate with the degree of tubal damage according to the severity of five factors: (1) extent of adhesions, (2) nature of adhesions, (3) diameter of the hydrosalpinx, (4) appearance of the endosalpinx, and (5) thickness of the tubal wall. Using these criteria, prognostic categories have been identified: good, with a cumulative pregnancy rate of approximately 75%; intermediate, approximately 20%; and poor, less than 5%. In the good category, only 1 of 22 pregnancies may be ectopic, but in the intermediate group 50% of the pregnancies may be expected to be tubal. In the poor prognostic group, most of the pregnancies will be ectopic. Accordingly, in women with fixed adhesions, with absent rugal folds and a thick, fixed tubal wall, distal tubal reconstructive surgery probably should not be performed.

The degree of distal tubal occlusion can be divided into four categories on the basis HSG findings (Donnez, 1986) (Fig. 42.22). Following microscopic tubal reconstruction, the cumulative pregnancy rate is directly related to the degree of occlusion. If the distal tubal ostium is completely normal but peritubal adhesions are present, lyses of these adhesions by salpingolysis have resulted in a 64% intrauterine pregnancy rate, similar to that obtained with a fimbrioplasty for partial obstruction. Approximately 50% of women who underwent salpingostomy for degree II occlusion conceived, with no ectopic pregnancies, but only approximately 25% of those with degree III or IV occlusions had subsequent intrauterine pregnancies, and the ectopic pregnancy rate was approximately 10% (Donnez, 1986) (Fig. 42.23; Table 42.7). Thus following operation for more extensive distal tubal disease, almost one third of the pregnancies that occurred were ectopic.

In all studies, the best prognostic factor was the thickness of the tubal wall. If there was a hydrosalpinx more than 2 cm in diameter, with a thick tubal wall, the prognosis for a term pregnancy following distal tubal reconstruction was extremely poor.

Rock and coworkers have classified women with distal fimbrial occlusion into three categories based on the extent of tubal disease (Rock, 1978) (Box 42.2). A life table analysis of couples in these three categories with no other causes of infertility was performed after the female partner underwent neosalpingostomy

Figure 42.22 Classification of distal tubal occlusion based on degree of dilation seen on hysterosalpingography. **A**, Degree I, conglutination of the fimbrial folds (arrow) with tubal patency. **B**, Degree II, complete distal occlusion with normal ampullary diameter. **C**, Degree III, complete distal occlusion with ampullary dilation of 15 to 25 mm in diameter. **D**, Degree IV, occlusion with ampullary distention greater than 25 mm. (From Donnez J, Casanas-Roux F. Prognostic factors of fimbrial microsurgery. *Fertil Steril*. 1986;46[2]:200-204.)

(Hassiakos, 1990). Of those women, 80% with mild tubal disease conceived, whereas only 31% of those with moderate disease and 16% of those with severe disease conceived (Fig. 42.24). The ectopic pregnancy rate was higher in the latter two categories. This information should be given to the woman when she is counseled, and if the prognosis for term pregnancy is poor, she should be advised to undergo IVF instead of surgical tubal

reconstruction. Distal tubal reconstructive surgery should be carried out by operative laparoscopy. The results of a series of 65 consecutive distal tuboplasties, both fimbrioplasties and neosalpingostomies performed endoscopically, have shown that the intrauterine pregnancy rate is 26% after fimbrioplasty and 29% after neosalpingostomy, similar to the historical success rate after microsurgery. The prognoses for fertility after salpingostomy is correlated more with the extent of disease than with the type of surgical procedure. Basically, it can be expected that one third of the patients will have intrauterine pregnancies within 2 to 3 years if they have mild or moderate disease.

Proximal Tubal Blockage

If no dye enters the tube during HSG, the diagnosis of proximal tubal blockage is likely. However, because spasm of the uterus during the procedure may occlude the intrauterine portion of the tube, the diagnosis cannot be confirmed. Here, at least half of the time, the tube will be found to be patent on subsequent testing or at laparoscopy. Laparoscopy also allows examination of the distal portion of the tube, which cannot be visualized radiographically if there is proximal blockage.

Currently, it is preferred to attempt selective catheterization of the proximal portion of a tube at HSG under fluoroscopy if it does not fill with dye (Thurmond, 2008) (see Fig. 42.7). Cannulation of the proximal portion is also possible under direct guidance at hysteroscopy. Cannulation to open the putative obstruction is possible as long as there is no gross disease visible, such as salpingitis isthmica nodosa (SIN). Proximal tubal blockage may be caused by debris or endometriosis, but a significant occlusion is usually explained by prior infection or SIN.

In the past, proximal obstructions were best handled by microsurgical cornual tubal reanastomosis, with pregnancy rates in the range of 50% and ectopic rates of only 10%. Although this approach may still be considered on a selective basis, *most cases of obstruction not relieved by fluoroscopic or hysteroscopic selective cannulation are now treated by IVF*.

Adjunctive Therapy

Adjunctive procedures for surgical tubal reconstruction previously included prophylactic antibiotics, intraperitoneal corticosteroids, postoperative hydrotubation, and placement of tubal stents. Prospective studies have not demonstrated postoperative hydrotubation to have any benefit, and tubal stents should not be used because they may cause mucosal damage. Data from several studies have shown that intraperitoneal adjuncts are not effective.

It is important to stress surgical technique, attention to hemostasis, and irrigation of blood and debris away from the surgical site with Ringer's lactate solution. The only barriers currently used with some efficacy are an absorbable adhesion barrier (Gynecare Interceed, Ethicon), to be used only in areas that are dry and not bleeding, and barriers impregnated with hyaluronic acid (Septrafilm, Genzyme). The latter can be used as a slurry at the end of laparoscopy. Gore-Tex requires suturing and removal; therefore it is rarely used and is not applicable for tubal disease.

If pregnancy does not occur within 6 to 12 months after tubal reconstruction, HSG should be performed. If tubal obstruction has recurred, a repeat surgical procedure is not advised. In this setting, the pregnancy rates are less than 10%.

Figure 42.23 Cumulative pregnancy rates following microsurgical repair of these lesions. *Solid circles*, salpingolysis; *open circles*, fimbrioplasty; *squares*, salpingostomy (degree II); *black triangles*, salpingostomy (degree III); *blue triangles*, salpingostomy (degree IV). (From Donnez J, Casanas-Roux F. Prognostic factors of fimbrial microsurgery. *Fertil Steril*. 1986;46[2]:200-204.)

Table 42.7 Pregnancy Rate after Microsurgery and Ciliated Cell Percentage in Cases of Distal Tubal Occlusion

Type of Operation	No. of Patients	No. of Intrauterine Pregnancies	Ectopic Pregnancies
Fimbrioplasty			
Occlusion of degree I	132	79 (60%)	2 (2%)
Salpingostomy			
Occlusion of degree II	27	13 (48%)	0
Occlusion of degree III	16	4 (25%)	1 (6%)
Occlusion of degree IV	40	9 (22%)	5 (12%)
Total	83	26 (31%)	6 (7%)
Salpingolysis	42	27 (64%)	1 (2%)

Modified from Donnez J, Casanas-Roux F. Prognostic factors influencing the pregnancy rate after microsurgical cornual anastomosis. *Fertil Steril*. 1986;46(6):1089-1092.

ENDOMETRIOSIS

Some investigators have estimated that as many as 40% of infertile women have endometriosis. If endometriosis is found at the time of laparoscopy, the extent of the disease should be documented. The causes, diagnosis, and treatment of endometriosis are presented in detail in [Chapter 19](#).

Although endometriosis is frequently encountered in an infertility population (20% to 40%), the diagnosis may be subtle and may only be realized if a laparoscopy is carried out. As noted, laparoscopy is often currently bypassed in the investigative workup. Thus unless there is a strong component of pain as a presenting complaint, or a large endometrioma is seen on ultrasound, the diagnosis may not be appreciated. The treatment for pain is somewhat different and is reviewed in [Chapter 19](#).

If laparoscopy is carried out and mild lesions are seen, it makes sense to ablate them surgically by electrocauterization or laser. Although this may not have a major therapeutic value, the

Box 42.2 Classification of the Extent of Tubal Disease with Distal Fimbrial Obstruction

Mild

Absent or small hydrosalpinx <15 mm diameter
Inverted fimbriae easily recognized when patency is achieved
No significant peritubal or periovarian adhesions
Preoperative hystrogram reveals rugal pattern

Moderate

Hydrosalpinx = 15-30 mm in diameter
Fragments of fimbriae not readily identified
Periovarian or peritubular adhesions without fixation, minimal cul-de-sac adhesions
Absence of a rugal pattern on preoperative hystrogram

Severe

Large hydrosalpinx >30 mm diameter
No fimbriae
Dense pelvic or adnexal adhesions with fixation of the ovary and tube to the broad ligament, pelvic sidewall, omentum, or bowel
Obliteration of the cul-de-sac
Frozen pelvis (adhesion formation so dense that limits of organs are difficult to define)

From Rock JA, Katayama P, Martin EJ, et al. Factors influencing the success of salpingostomy techniques for distal fimbrial obstruction. *Obstet Gynecol*. 1978;52(5):591-596.

current thinking is that peritoneal endometriosis may release substances that could impair fertilization at various levels.

A new classification of endometriosis has been developed, with fertility as the hard end point (see [Chapter 19](#)). The components of this classification scheme are based on structured factors that contribute to the infertility of endometriosis. In general, women with endometriosis have a reduced fecundity in relation to the extensiveness of the disease, and women with extensive disease usually have a mechanical (obstructive) cause of infertility as well.

Figure 42.24 Life table analysis of pregnancy outcome after neosalpingostomy by extent of disease. (From Schlaff WD, Hassiakos DK, Damewood MD, et al. Neosalpingostomy for distal tubal obstruction: prognostic factors and impact of surgical technique. *Fertil Steril.* 1990;54[6]:984-990.)

Surgery in the setting of infertility is reserved for those patients with pain and if large endometriomas are present. Smaller, 2- to 4-cm endometriomas may be observed, particularly in older women, because of the concern of compromising ovarian reserve by ovarian cystectomy. Otherwise, women should be treated as if they have unexplained infertility (discussed later). Many women with unexplained infertility may have endometriosis that has not been diagnosed because laparoscopy was not performed. The lowered cycle of fecundity in endometriosis is similar to that of women with unexplained infertility (~4%). COS, generally with IUI, is the usual initial treatment. If pregnancy does not occur in three to six cycles, IVF is offered as the next step. When surgery has been offered as the primary treatment for moderate to severe disease, which is easily diagnosed, pregnancy rates of approximately 50% have been recorded with operative laparoscopy. This rate is similar to the rate after laparotomy (Chapter 19).

IVF pregnancy rates have been suggested to be reduced, but this mainly occurs with severe disease. In select cases, prior suppression of known causes of endometriosis (e.g., using a GnRH agonist for 2 to 3 months) has been shown to improve IVF pregnancy rates.

UNEXPLAINED INFERTILITY

This diagnostic category is relatively arbitrary and is probably never truly unexplained. Unexplained infertility is defined in couples with normal ovulation and pelvic evaluation with a normal uterus and patent tubes on hysterosalpingogram, as well as a normal semen analysis. In the past, the diagnosis also required a normal postcoital test and a laparoscopy. Laparoscopy is no longer carried out routinely unless there are clues to significant pelvic abnormalities. The rationale for omitting laparoscopy in the required diagnostic workup is that it is invasive and costly, and it is unlikely that the subtle abnormalities will change the outcome of treatment. Some studies have included couples into the category of unexplained infertility with mild abnormalities in the semen analysis and the suggestion of mild endometriosis.

Using the broad definition of unexplained infertility, approximately 20% of all couples will fall into this category. If exhaustive

Table 42.8 Randomized Trial of Treatments for Unexplained Infertility

Number of Initiated Cycles	CC/IUI	FSH/IUI	IVF
All subjects	1294	700	622
Live births per initiated cycle	7.6% (6.2-9.2)	9.8% (6.8-14)	30.7% (27.1-34.5)

Data from Reindollar RH, Regan MM, Neumann PJ, et al. A randomized clinical trial to evaluate optimal treatment for unexplained infertility: the fast track and standard treatment (FASTT) trial. *Fertil Steril.* 2010;94(3):888-899. CC, Clomiphene; IUI, intrauterine insemination; FSH, follicle-stimulating hormone; IVF, in vitro fertilization.

meticulous testing is carried out, including laparoscopy, this figure has been reported to be less than 5%. Additional testing for defects in sperm function and for endometrial histologic and biochemical variables has not been validated for routine use in making the diagnosis. Subtle defects may be overcome by standard empirical treatment for unexplained infertility.

The routine empirical treatment of unexplained infertility is ovarian stimulation with CC or gonadotropins, coupled with IUI. Prospective studies have shown that CC alone or IUI alone is not efficacious (Bhattacharya, 2008). Several European studies have also suggested that good prognosis patients, based on age and shorter duration of infertility, should undergo “expectant management,” meaning continued timed intercourse for another 6 months before proceeding to treatment. This scenario is usually unacceptable for the U.S. population for social and economic reasons. Also in Europe, the standard management of unexplained infertility with CC/IUI results in a lower pregnancy rate per cycle (closer to an expectant group) because of a more conservative approach to ovarian stimulation (Custers, 2012). The efficiency of COS/IUI is highly age dependent. In women in their 30s, the expected fecundity rate is 8% to 9% and is not much different with the use of CC or gonadotropins, a conclusion that has been based on prospective data (Reindollar, 2010) (Table 42.8).

In 1998, Guzick and associates published a review of data from 45 published studies of various therapies of unexplained infertility, including mild endometriosis. After adjustment for study quality, pregnancy rates per initiated treatment cycle were 1.3% to 4.1% for no treatment, 8.3% for CC plus IUI, 17.1% for gonadotropins plus IUI, and 20.7% for IVF. Although the pregnancy rate in this analysis of nonrandomized studies was higher with gonadotropins/IUI than with CC/IUI, prospective data have shown that the rates are similar as noted previously (Reindollar, 2010). Although the rate of approximately 9% per cycle may seem low, the background rate for unexplained infertility is no more than 4%, thus the fecundity is more than doubled. In terms of the choice of CC/IUI, whereas in a non-PCOS patient with unexplained infertility, letrozole/IUI may also be used, it appears that CC/IUI may be more effective (National Institutes of Health Reproductive network: data in preparation).

Unfortunately, even with monitoring, 20% or more of the pregnancies that occurred with the use of gonadotropins were multiple gestations, with approximately 8% being higher-order multiples (triplets or more). For this reason, gonadotropin/IUI is less frequently used in couples with unexplained infertility.

A large prospective trial was carried out by Reindollar and colleagues to assess whether it was reasonable to skip gonadotropin-IUI therapy and proceed to IVF after three cycles of CC/IUI (called *fast track*). The logical next step after CC or gonadotropin/IUI therapy is still proceeding to IVF. One of the concerns with unexplained infertility is that there may be failure to fertilize, even if there are normal ovulation and semen characteristics. IVF also has a higher cycle fecundity rate (discussed later). In the prospective trial, as shown in Figure 42.25, there was an increased pregnancy rate in the accelerated arm (100% to 156%; hazard ratio, 1.25). The median time to pregnancy was also shorter, 8 versus 11 months, and average charges per delivery were \$9800 lower. Individual per cycle pregnancy rates for CC/IUI, gonadotropin/IUI, and IVF were 7.6%, 9.8%, and 30%, respectively (Reindollar, 2010). The conclusion of these authors was that the gonadotropin/IUI step in the usual algorithm for unexplained infertility may be omitted. Age is a significant factor in terms of efficacy of treatment. Table 42.9 shows the results of a large retrospective study of the success of CC/IUI according to age (Dovey, 2008). It is clear that in older women, because of reduced efficacy (after age 42, cumulative pregnancy rates over 3 to 9 months are approximately 1.8%), couples should consider going directly to IVF. In a follow-up study by Reindollar in a slightly older population (38 to 42 years), it was concluded that in this group, going directly to IVF is probably a better option (Goldman, 2014).

Cycle fecundity may be reduced substantially, even in women younger than 40 years who have a low ovarian reserve. Accordingly, it is important to measure day 2 to 3 FSH levels as well as MIS/AMH and an antral follicle count. Low parameters will help dictate how aggressive treatment should be, with many couples being directed toward IVF as a primary treatment. Because of the importance of IVF as a treatment option in current infertility management, a separate chapter is devoted to IVF and newer therapies (Chapter 43).

COUNSELING AND EMOTIONAL SUPPORT

The diagnosis of infertility can be a devastating and life-altering event that affects many aspects of a woman's life. Infertility

Figure 42.25 Randomized clinical trial to evaluate optimal treatment for unexplained infertility: the fast track and standard treatment (FASTT) trial. (From Reindollar RH, Regan MM, Neumann PJ, et al. A randomized clinical trial to evaluate optimal treatment for unexplained infertility: the fast track and standard treatment [FASTT] trial. *Fertil Steril*. 2010;94[3]:888-899.)

Table 42.9 Realistic Chances of Pregnancy with Intrauterine Insemination: Age Dependency*

Age of Woman (yr)	Pregnancy Rate per Cycle (%)
<35	≈10-11.5
35-37	≈8.2-9.2
38-40	≈6.5-7.3
40-41	≈3.6-4.3
>42†	≈0.8-1.0

From Dovey S, Sneeringer RM, Penzias AS. Clomiphene citrate and intrauterine insemination: analysis of more than 4100 cycles. *Fertil Steril*. 2008;90(6): 2281-2286.

*Large cohort of 4100 cycles of CC IUI.†In women >42 years, cumulative pregnancy rates = 1.8% (1 in 55).

and its treatment can affect a woman and her spouse or partner medically, financially, socially, emotionally, and psychologically. Feelings of anxiety, depression, isolation, and helplessness are not uncommon in women undergoing infertility treatment. Strained and stressful relationships with spouses, partners, and other loved ones occur among patients undergoing infertility treatment as treatment gets under-way and progresses.

It is important that every program address the emotional and social needs of couples undergoing treatment. Individual counseling and support groups, as well as patient information

sessions, should be part of every infertility practice. National support groups such as the National Infertility Association (RESOLVE, www.resolve.org) and the American Fertility Association (www.theafa.org) are also available to provide assistance and information. The American Society for Reproductive

Medicine (ASRM) also has many educational resources, specifically designed for patients with a separate portal available at the society's website (www.asrm.org.) Patient-oriented videos are available regarding various aspects of infertility at www.reproductivefacts.org.

KEY POINTS

- Approximately 10% of all U.S. couples with women of reproductive age are infertile, approximately more than 7 million women, and the incidence of infertility steadily increases in women after age 30.
- Among fertile couples who have coitus in the week before ovulation, approximately 20% (monthly fecundability, 0.2) have a chance of developing a clinical pregnancy.
- In the United States, approximately 20% of cases of infertility are caused by anovulation, 30% to 40% by an abnormality of semen production, 30% to 40% by pelvic disease, and approximately 10% to 20% of cases are unexplained.
- A systematic evaluation of factors involved in infertility should be carried out rapidly, along with markers of ovarian reserve (antral follicle count, AMH); this will help frame the discussion with couples as to how best to proceed with treatment.
- Of all the causes of infertility, treatment of anovulation results in the greatest success with ovulation induction, if no other causes of infertility are present; conception rates over time are close to those of a normal fertile population.
- Letrozole for ovulation induction in women with polycystic ovary syndrome may be superior to the use of clomiphene.
- When conception occurs after clomiphene treatment in anovulatory women, the incidence of multiple gestation is increased to approximately 8%; almost all of them being twin pregnancies. The incidences of clinical spontaneous abortion, ectopic gestation, intrauterine fetal death, and congenital malformation are not significantly increased, although ectopic pregnancies are more common following assisted reproductive technology.
- The prognosis for fertility after tubal reconstruction depends on the amount of damage to the tube as well as the location of the obstruction. Mild abnormalities of the proximal tube may be treated with selective catheterization/cannulation under fluoroscopy. Large hydrosalpinges (distal disease) are best treated by salpingectomy and IVF.
- If both proximal and distal obstructions of the tube exist, intrauterine pregnancy is uncommon, and operative reconstruction should not be performed; IVF is the best therapy.
- In women with unexplained infertility, the use of COS and IUI with clomiphene/IUI or gonadotropins/IUI yields monthly fecundity rates of approximately 8% to 10% (at least doubling the baseline rate) and should be the initial treatment for unexplained infertility. Use of gonadotropins does not offer a major advantage over clomiphene and carries more risks in terms of hyperstimulation and multiple pregnancies.
- After three to six cycles of COS/IUI, IVF should be offered as the next step, and IVF should be the primary therapy in women around age 40.

In Vitro Fertilization

Janet Choi, Roger A. Lobo

Because of the central importance of in vitro fertilization (IVF) in the treatment of infertility as well as its potential to answer fundamental questions in reproductive biology, a separate chapter has been devoted to this topic. IVF is often used interchangeably with the term *assisted reproductive technologies* (ART), which the American Society for Reproductive Medicine (ASRM) has defined as the manipulation of sperm and egg outside of the body. However, some clinicians include ovarian stimulation cycles with the use of intrauterine insemination (IUI) in the definition of ART.

In 2010, Bob Edwards was awarded the Nobel Prize for physiology and medicine for his pioneering work in making IVF a reality (Stephens, 1978). IVF has revolutionized the field of reproduction. Not only has it opened many avenues of research and broadened our understanding of basic human reproductive physiology, but its successful clinical use has allowed millions of couples to conceive who might otherwise have been unable to do so. IVF has provided the ability to diagnose significant genetic defects before implantation and has led to the possibility of embryonic stem cell research. IVF has also opened possibilities for fertility preservation (Lobo, 2005). Reproductive-aged patients newly diagnosed with cancer can undergo ART to cryopreserve oocytes or embryos prior to embarking on their cancer therapy. More recently, healthy reproductive-aged women not yet ready to conceive but concerned about the normal age effect on their fecundity may pursue elective fertility preservation. Indications for IVF are listed in Box 43.1.

IVF was originally carried out for women with tubal disease. This is still a major indication for IVF, and over time with the success of IVF, reconstructive tubal surgery is much less frequently carried out in favor of a direct approach of IVF. As discussed in Chapter 42, a significantly dilated tube (hydrosalpinx) on ultrasound is an indication for salpingectomy before carrying out IVF. Endometriosis is also a major indication for IVF.

SPECIFIC INDICATIONS FOR IN VITRO FERTILIZATION

MALE FACTOR INFERTILITY

In the past, if there were severe abnormalities in the semen analysis, the prognosis for fertility was less than that for any other cause of infertility, even with the use of IVF. Attempts to enhance fertilization rates of aspirated oocytes with the

technique of subzonal insemination of sperm were unsuccessful because fertilization rates remained low at approximately 15%. After Van Steirteghem and associates developed the technique of intracytoplasmic sperm injection (ICSI) (Palermo, 1992), fertilization rates of oocytes injected with a single normal sperm obtained from men with severe abnormalities in their semen analysis increased above 50%. Pregnancy rates per embryo transfer are now similar after ICSI compared with other indications for IVF. Fertilization rates of approximately 60% of the oocytes injected may be achieved with sperm from semen samples containing no motile sperm, few motile sperm, and high numbers of motile sperm (Tsirigotis, 1994). In addition, a fertilization rate of approximately 60% was attained whether the sperm were freshly obtained by masturbation, by electro-ejaculation, or were previously frozen. A fertilization rate of oocytes of almost 50% was also achieved when the sperm were aspirated directly from the epididymal fluid.

The excellent results obtained with ICSI by the group that originally described the technique have been replicated in other centers. By using this technique, the pregnancy rate of couples whose male partner has an extremely low concentration of motile sperm in the semen samples (<100,000/mL) can reach a normal pregnancy rate for IVF, based on the age of the woman (discussed later). Studies of pregnancies resulting from ICSI and standard IVF have revealed a similar rate of pregnancy loss and multiple gestation. Therefore ICSI is now the treatment of choice for all causes of male infertility, as well as for couples with no known cause of infertility for whom fertilization has failed with standard IVF procedures. At present, ICSI is utilized in 60% to 70% of all cases of IVF. The number of ICSI cases has increased because ICSI has been used even for minor sperm abnormalities and in other cases such as unexplained infertility and in older women where there is a concern about the rate of fertilization (Fig. 43.1). (Also see the video of an ICSI procedure [Video 43.1].)

The clinical pregnancy rate is higher when testicular or epididymal sperm is retrieved from men with obstruction of the vas deferens (obstructive azoospermia) than when testicular sperm is retrieved from men with azoospermia without reproductive tract obstruction (nonobstructive azoospermia) (Palermo, 1999). Even if the sperm retrieved from the testes remain immotile, the pregnancy rate after ICSI is acceptable at 15% or higher. The likelihood of retrieval of spermatozoa from testicular tissue of men with azoospermia and normal follicle-stimulating hormone (FSH) levels is almost 100%.

Box 43.1 Indications for In Vitro Fertilization

Blocked or absent fallopian tubes
Low sperm counts or absent sperm (azoospermia requiring TESE)
Advanced reproductive age
Endometriosis
Unexplained infertility unresponsive to IUI therapy
Screening for aneuploid embryos and/or genetic disease
Fertility preservation

Figure 43.1 ICSI-intracytoplasmic sperm injection. (Courtesy of Center for Women's Reproductive Care at Columbia University.)

Even if the man's FSH levels are markedly elevated, there is at least a 50% likelihood that spermatozoa can be retrieved from the testes and used to perform an ICSI procedure (Jezek, 1998). Thus the presence of a combination of azoospermia and an elevated FSH level is not a contraindication for performing a testicular sperm extraction (TESE) procedure, although it is advantageous to carry out a diagnostic TESE prior to an IVF cycle. Diligence is required with the aid of microscopy to select the best sperm for use in ICSI, and several groups have advocated a surgical microdissection of the testicular tubules in order to obtain viable sperm (Schlegel, 1999).

UNEXPLAINED INFERTILITY/ADVANCED REPRODUCTIVE AGING

Patients with unexplained infertility may consider IVF treatment particularly if they fail to conceive following a few treatments with controlled ovarian stimulation and IUI. In fact, women of advanced reproductive age and infertility may be advised to consider moving directly to IVF, by-passing IUI therapy altogether (Donderwinkel, 2000).

A large prospective trial was carried out by Reindollar and colleagues to assess whether it was reasonable to skip gonadotropin-IUI therapy and proceed to IVF after three cycles of clomiphene-IUI (called "fast track") in women with unexplained infertility (Reindollar, 2010). The logical next step after clomiphene or gonadotropin-IUI therapy is still IVF. One of the concerns with unexplained infertility is that there may be failure to fertilize, even if there are normal ovulation and semen characteristics. IVF also has a higher cycle fecundity rate than IUI. In the prospective trial, which also included a cost analysis, conventional therapy included three months of clomiphene-IUI followed by three cycles of gonadotropin-IUI and then up to six cycles of IVF. The other arm of this randomized trial omitted the gonadotropin-IUI step and proceeded directly to IVF after clomiphene-IUI (Fig. 43.2).

Figure 43.2 Randomized clinical trial to evaluate optimal treatment for unexplained infertility: the fast track and standard treatment (FASTT) trial. (From Reindollar RH, Regan MM, Neumann PJ, et al. A randomized clinical trial to evaluate optimal treatment for unexplained infertility: the fast track and standard treatment [FASTT] trial. *Fertil Steril*. 2010;94[3]:888-899.)

As shown in Figure 43.2, there was an increased pregnancy rate in the accelerated arm (100% to 156%; hazard ratio, 1.25). The median time to pregnancy was also shorter, 8 versus 11 months, and average charges per delivery were \$9800 lower. Individual per cycle pregnancy rates for clomiphene-IUI, gonadotropin-IUI, and IVF were 7.6%, 9.8%, and 30%, respectively. The authors concluded that the gonadotropin-IUI step in the usual algorithm for unexplained infertility may be omitted. However, this remains an area of controversy and may not be applicable to couples who do not have insurance coverage for IVF, unlike in Massachusetts (where the study was carried out) where IVF coverage is mandated.

The extension of this study (the Forty and Over Treatment Trial [FORT-T]) in older women, 38 to 42 years, strongly suggested that infertile women in this age category should consider going directly to IVF (Goldman, 2014). In this study, patients who proceeded directly to IVF achieved significantly higher clinical pregnancy rates as compared with patients who tried two cycles of IUI treatment (with either clomiphene citrate or gonadotropin therapy). Additionally, the ratio of treatment cycles to live birth rates was significantly lower in patients who went straight to IVF versus patients who started with conservative treatment (Table 43.1).

Table 43.2 shows the results of a large retrospective study of the success of clomiphene-IUI (Dovey, 2008). Because of the age-related decline in Clomid/IUI pregnancy rates (after age 42, cumulative pregnancy rates over 3 to 9 months are approximately

Table 43.1 Clinical Pregnancy and Live Birth Rates per Couple, by Randomization Assignment for the First Two Treatment Cycles and at the End of All Treatment

Randomized Treatment Arm	No. of Couples (%)	FIRST TWO TREATMENT CYCLES		DURATION OF STUDY	
		No. of Clinical Pregnancies*† (%, 97.5% CI)	No. of Live Births‡ (%, 97.5% CI)	No. of Clinical Pregnancies§ (%, 97.5% CI)	No. of Live Births§ (%, 97.5% CI)
CC/IUI	51 (33.1)	11 (21.6, 10.2-37.3)	8 (15.7, 6.2-30.5)	38 (74.5, 58.4-86.9)	25 (49.0, 32.9-65.2)
Gonadotropin (FSH)/IUI	52 (33.8)	9 (17.3, 7.3-32.2)	7 (13.5, 4.9-27.6)	34 (65.4, 49.0-79.5)	22 (42.3, 27.1-58.7)
Immediate IVF	51 (33.1)	25 (49.0, 32.9-65.2)	16 (31.4, 17.7-47.9)	38 (74.5, 58.4-86.9)	24 (47.1, 31.2-63.4)
Total¶	154	45 (29.2, 21.3-38.2)	31 (20.1, 13.4-28.4)	110 (71.4, 62.5-79.3)	71 (46.1, 37.0-55.4)

From Goldman MB, Thornton KL, Ryley D, et al. A randomized clinical trial to determine optimal infertility treatment in older couples: the Forty and Over Treatment Trial (FORT-T). *Fertil Steril*. 2014;101(6):1574-1581.

Note: Includes treatment-dependent pregnancies.

CC, Clomiphene citrate; CI, confidence interval; FSH, follicle-stimulating hormone; IUI, intrauterine insemination; IVF, in vitro fertilization.

*Number of clinical pregnancies includes all ultrasound confirmed pregnancies, including pregnancy losses.

†For clinical pregnancy rate after first two treatment cycles. $P=.0067$ for comparison between CC/IUI and immediate IVF; $P=.0007$ for comparison between FSH/IUI and immediate IVF.

‡For live-birth rate after first two treatment cycles. $P=.101$ for comparison between CC/IUI and immediate IVF; $P=.035$ for comparison between FSH/IUI and immediate IVF.

§For clinical pregnancy and live-birth rates after all treatment, there are no statistically significant differences, reflecting subsequent IVF, treatment in all arms.

¶Of these, there were 5, 2, and 4 clinical pregnancies and 5, 1, and 3 live births in the CC/IUI, FSH/IUI and immediate IVF arms, respectively, that occurred before treatment was initiated or between treatment cycles one and two. Over the duration of the study there were 11, 3, and 9 clinical pregnancies and 7, 1, and 6 live births in the CC/IUI, FSH, IUI, and immediate IVF arms, respectively, that occurred outside of treatment cycles.

1.8%), couples in which the female partner is older should consider going directly to IVF. This recommendation is particularly suited for women age 40 or older, those with a borderline elevated day 2 to day 3 FSH level, and women with decreased antral follicle counts and antimüllerian hormone levels.

OOCYTE/EMBRYO CRYOPRESERVATION FOR FERTILITY PRESERVATION

This indication for pursuing ART procedures has been growing. Not only is it an important method to preserve fertility in young women with cancer about to undergo chemotherapy, but increasingly it is being used in healthy young women who electively wish to delay childbearing with the knowledge of the detrimental effects of aging on reproductive capacity. If the woman has a male partner and either is married or is in a stable relationship, use of sperm to fertilize the oocytes and then freeze embryos rather than oocytes is more successful in terms of ultimate pregnancy rates and therefore remains an option. This topic is discussed in more detail later in the chapter.

PRECONCEPTION GENETIC SCREENING AND DIAGNOSIS

Another indication for IVF is to screen embryos for aneuploidy or genetic disease (see “Preimplantation Genetic Diagnosis/Screening” presented later in the chapter). Couples suffering recurrent aneuploid pregnancy loss (due to a balanced translocation in a partner, for example) may consider IVF/preconception genetic screening (PGS) as a means of screening their embryos prior to conceiving again and potentially suffering another miscarriage. However, the most recent studies have not been able to demonstrate a statistical benefit, in part because of a relatively high rate of success with natural conception after two to three losses (Stray-Pedersen, 1984).

Couples who are found to carry mutations in life-threatening diseases (e.g., cystic fibrosis, Tay-Sachs disease, Huntington disease) may opt to do IVF with preconception genetic diagnosis

Table 43.2 Realistic Chances of Pregnancy with Intrauterine Insemination: Age Dependency*

Age of Woman (years)	Pregnancy Rate per Cycle (%)
<35	≈10-11.5
35-37	≈8.2-9.2
38-40	≈6.5-7.3
40-41	≈3.6-4.3
>42†	≈0.8-1.0

From Dovey S, Sneeringer RM, Penzias AS. Clomiphene citrate and intrauterine insemination: analysis of more than 100 cycles. *Fertil Steril*. 2008;90(6):2281-2286.

*Large cohort of 4100 cycles of CC IUI.

†In women >42 years, cumulative pregnancy rates = 1.8% (1 in 55).

(PGD) to eliminate the transmission of these diseases by excluding affected embryos using specific probes. Although controversial for ethical reasons, couples may also opt to undergo IVF/PGS for gender selection or “family balancing.”

IN VITRO FERTILIZATION PROCEDURE

The goal of a successful IVF treatment is the generation of good-quality embryos. IVF can be carried out in a natural cycle, which was the original approach used by Steptoe and Edwards that led to the birth of Louise Brown. However, here usually only one oocyte and one embryo can be expected, and the success rate is far lower than with conventional IVF, in which gonadotropins are administered to increase the number of oocytes retrieved. Although unstimulated IVF remains an option on an individual basis, its use is currently limited because of the lower pregnancy rates and the expectations of couples to become pregnant as efficiently as possible.

With conventional IVF, gonadotropin stimulation (75 IU to 600 IU of FSH or hMG) is administered, usually subcutaneously, for approximately 10 days. The starting daily dose typically ranges from 75 to 600 IU of FSH or hMG (human menopausal gonadotropin—i.e., preparations containing both 75 IU of FSH and 75 IU of LH). The starting dose is chiefly determined by

Egg retrieval is usually performed through the vagina with an ultrasound-guided needle.

Figure 43.3 Diagram of oocyte retrieval. (Modified from American Society for Reproductive Medicine: *Assisted reproductive technologies: a guide for patients*. American Society for Reproductive Medicine, Birmingham, AL: 2015.)

the patient's ovarian reserve and age, with higher doses used for older patients with decreased ovarian reserve and lower doses for patients with a more robust reserve and for women with PCOS. The traditional long cycle protocol begins with down-regulation using a gonadotropin-releasing hormone (GnRH) agonist for two weeks prior to gonadotropin administration. Once down-regulation is evidenced with estradiol levels <50 pg/mL, the patient is then started on gonadotropin stimulation while maintaining ovulation suppression with the daily use of the GnRH agonist. Increasingly, however, a GnRH antagonist is used to block spontaneous ovulation from occurring once follicular development occurs. With this "short protocol," gonadotropins are begun on cycle day 2, without prior down-regulation, and the antagonist is added around day 6 of stimulation. Data support an equal efficacy of the two approaches (Al-Inany, 2011).

When at least three mature follicles are seen on ultrasound (≈ 18 mm) with an appropriate rise of serum E_2 , human chorionic gonadotropin (HCG) is administered (5,000 to 10,000 IU). Vaginal ultrasound aspiration of the follicles is typically carried out 34 to 36 hours later (Fig. 43.3). This procedure is usually performed with the patient sedated, although it can be performed with local anesthetic use. Complications include infection, torsion, and internal bleeding, though rates are low ($<0.25\%$) (Roest, 1996).

The harvested oocytes are then combined with a sperm sample from a male partner or from donor sperm. One of two methods is used to fertilize the oocytes: insemination (where a high concentration of sperm is placed into a dish with an oocyte) or intracytoplasmic sperm injection (ICSI). On average, about 60%

Figure 43.4 Evidence of normal fertilization: 2pn (pronuclei). (Courtesy of Center for Women's Reproductive Care at Columbia University.)

to 70% of the mature oocytes should fertilize with insemination and normal-functioning sperm/oocytes. With ICSI, embryologists can select individual sperm and microinject a sperm into each mature (MII) oocyte. Approximately 12 to 18 hours later the oocytes are inspected for evidence of fertilization (Fig. 43.4). ICSI does not yield "better" fertilization rates than in the normal

Figure 43.5 Day 3 embryo.

situation; rather, it helps to produce “normal” fertilization rates in situations where fertilization may not occur or will occur at a low rate.

The embryology laboratory environment is the key factor in the success of IVF. Typically, 3 days after aspiration, six to eight cell cleavage stage embryos are obtained. Three-day-old embryos can be assessed for potential transfer using criteria assessing the blastomere morphology and symmetry as well as the degree of embryo fragmentation ([Fig. 43.5](#)). Fragmentation is felt to be the extracellular debris created by the dividing embryonic cells, and embryos with a high degree of fragmentation (i.e., >10% of the embryo) are associated with lower implantation and pregnancy rates ([Luke, 2014](#)).

At the time of a day 3 transfer, the embryologist may opt to utilize assisted hatching (AH). Using acid or a laser, the embryologist can drill a small hole in the zona pellucida of the embryo. A meta-analysis suggested improved implantation and clinical pregnancy rates with AH use but concluded that live birth rates were not improved ([Carney, 2012](#)). The authors concluded that AH may be most useful in older women (i.e., >37 years old) and in women with previously unexplained IVF failures. One downside to the use of AH is the slightly increased potential for monozygotic twinning (1% to 2%) ([Hershlag, 1999](#)).

Increasingly, with improved quality of sequential culture media, embryo culture is continued to days 5 to 6, when a blastocyst has developed ([Fig. 43.6](#)).

Fertilized oocytes that can be cultured on day 5/6 are usually of better quality and afford a higher pregnancy rate over day 3 embryos ([Glujovsky, 2012](#)). Typically, patients are awake for the embryo transfer, which is carried out with one of several specialized catheters (similar to those used for IUI) under ultrasound guidance ([Fig. 43.7](#)).

The decision regarding the number of embryos to transfer is key to optimizing success and reducing the chance of

Figure 43.6 Blastocyst (day 5 or 6 embryo).

multiple pregnancies. The American Society for Reproductive Medicine (ASRM) has published firm guidelines to assist in this decision-making process ([Practice Committee ASRM, 2013](#)) ([Table 43.3](#)). Implementation of these guidelines has proved to be successful in reducing the rate of high-order multiple pregnancies, although the rate of twins has not decreased substantially. In 2013, the Society for Assisted Reproductive Technologies (SART) reported a nearly 30% twin rate in patients under 35. In women with a good overall prognosis for pregnancy—such as women under the age of 35 or women with a history of a prior live pregnancy—elective single embryo transfer (eSET) can still lead to an acceptable pregnancy rate while minimizing the risk of multiples ([Luke, 2015](#)). Single embryo transfer does not totally eliminate the

Figure 43.7 Embryo transfer with catheter. (Copyright Lisa Clark, courtesy of Cook Medical, 2010.)

Table 43.3 American Society for Reproductive Medicine's Recommended Limits on the Numbers of Embryos to Transfer

Prognosis	AGE (YEARS)			
	<35	35-37	38-40	41-42
Cleavage-Stage Embryos*				
Favorable†	1-2	2	3	5
All others	2	3	4	5
Blastocysts*				
Favorable†	1	2	2	3
All others	2	2	3	3

From Practice Committees of the American Society for Reproductive Medicine and the Practice Committee of the Society for Assisted Reproductive Technology. Criteria for number of embryos to transfer: a committee opinion. *Fertil Steril*. 2013;99(1):44-46.

*See text for more complete explanations. Justification for transferring one additional embryo more than the recommended limit should be clearly documented in the patient's medical record.

†Favorable ¼ first cycle of IVF, good embryo quality, excess embryos available for cryopreservation, or previous successful IVF cycle.

risk for multiples, as there is a nearly 2% risk for monozygotic twinning following blastocyst transfer (Kanter, 2015). Transferring embryos on day 5 when the embryos are more developed and proportionately more “normal,” is becoming the trend for all IVF cycles. This means, however, that some women who have poor embryo quality may not have any good-quality embryos for transfer.

Several methods have been suggested to help in the selection of a normal embryo for transfer. This includes an analysis of the culture media for metabolic parameters and secreted proteins, as well as an analysis of time-lapse videos of the cultured embryos for normal developmental parameters (Krisher, 2015; Kirkegaard, 2015). However, none of these methods is currently the standard of practice in IVF.

Excess embryos of good quality that are not transferred may be cryopreserved by the use of several validated techniques, typically slow cooling or vitrification, with the latter being the preferred technique. The pregnancy rates from

thawed, good-quality embryos are almost equal to the rate of fresh cycles. No known increased fetal risks are associated with embryo cryopreservation.

IN VITRO FERTILIZATION SUCCESS RATES

What is important to couples is their overall chance of pregnancy resulting in a live birth. Clinical data published by SART may be found in Table 43.4. These rates are influenced by age and far less so by diagnosis of treatment. Live birth rates per cycle range from 40.1% in women <35 years to 4.5% at age >42. When a larger number of cycles have been studied over time, the overall optimistic chance of pregnancy after six cycles of IVF is 72% (95% confidence interval [CI], 70%-74%) (Dor, 1996).

Optimistic means continuous treatment without any dropouts; the conservative cumulative pregnancy rate, which includes some dropouts, is 51% (CI: 49%-52%) (Malizia, 2009) (Fig. 43.8). However, this is influenced by age, as noted previously (Fig. 43.9).

Pregnancy rates over six cycles are fairly constant over time and may continue to increase at the same rate, although some data suggest a plateau effect after six cycles (Fig. 43.10). This latter point is unclear because few IVF patients (<10%) exceed six cycles of treatment.

Most recently, patients can estimate their chance for IVF success using SART's interactive calculator—“Predict My Success”—found on the organization's home page (www.sart.org). This patient predictor is based on data obtained from nearly 500,000 treatment cycles performed in the United States and is based on the experience of all SART clinics. This calculator therefore gives an average expectation for success with cycles one, two, and so on, and for the number of embryos replaced. Patients merely enter demographic data and their infertility diagnosis in order to calculate their chance for IVF pregnancy.

GAMETE INTRAFALLOPIAN TRANSFER AND OTHER ALTERNATIVES TO “TRADITIONAL” IN VITRO FERTILIZATION

A modification of IVF, called *gamete intrafallopian transfer* (GIFT), can be used if the infertile woman has functional fallopian tubes. With this technique, both oocytes and sperm are placed into the tube through a catheter at the time of laparoscopy. Although IVF, embryo culturing, and embryo transfer into the uterus are avoided by this technique, controlled ovarian hyperstimulation and laparoscopy are still required. Because this technique requires a laparoscopy, GIFT is rarely done at present because pregnancy rates are similar or lower to those of routine in vitro fertilization and embryo transfer (IVF-ET) when matched for age and diagnosis (Leeton, 1987; Ranieri, 1995). Modifications of GIFT include pronuclear stage tubal transfer (PROST), or zygote intrafallopian transfer (ZIFT), and tubal embryo stage transfer (TEST). With ZIFT, the oocytes are fertilized in vitro and transferred 24 hours later. Tubal embryo transfer (TET) is similar to ZIFT except that the embryos are transferred 8 to 72 hours after fertilization. Again, because laparoscopy is required, these procedures are rarely performed today.

Another option for IVF is to aspirate immature eggs in a natural cycle, usually in anovulatory women with PCOS. No

Table 43.4 Society for Assisted Reproductive Technologies (SART)–Clinic Outcome Reporting System (CORS) IVF Clinic Success Rate, 2013

Treatment Type		Procedure Frequency		Diagnosis Frequency		
IVF	>99%	ICSI	67%	Tubal factor	6%	
GIFT	<1%	Unstimulated	1%	Ovulatory dysfunction	7%	
ZIFT	<1%	PGD	6%	Diminished ovarian reserve	18%

or minimal gonadotropin stimulation is used prior to oocyte aspiration. In vitro maturation (IVM) of the oocytes is then carried out, followed by ICSI. IVM may be most reasonable in women with PCOS, as their larger ovaries with multiple small follicles allow for easier aspiration of immature oocytes (vs. women with decreased ovarian reserve, for instance) (Walls, 2015). The main advantage of IVM is the elimination of hyperstimulation risk. However, even in specialized centers, the success rate for IVM is significantly lower than the rates seen with conventional IVF-ET, and it is currently not recommended for routine use (Practice Committees ASRM and SART, 2013a; Chian, 2009).

RISKS OF IN VITRO FERTILIZATION

OVARIAN HYPERSTIMULATION SYNDROME

Ovarian hyperstimulation syndrome (OHSS) is typically an iatrogenic complication of gonadotropin stimulation. Patients at highest risk of OHSS are those with polycystic ovary syndrome, normo-ovulatory patients with a high ovarian reserve, and patients who previously experienced OHSS in a prior IVF cycle. OHSS was discussed in Chapter 42.

Avoidance of excessive stimulation is the primary approach for preventing OHSS. However, even with careful monitoring of gonadotropin dosage and follicular response, OHSS can still

Figure 43.8 Expectations of live birth with IVF-ET. (From Malizia BA, Hacker MR, Penzias AS. Cumulative live-birth rates after in vitro fertilization. *N Engl J Med.* 2009;360[3]:236-243.)

Figure 43.9 Expectations of live birth with IVF-ET by age. (From Malizia BA, Hacker MR, Penzias AS. Cumulative live-birth rates after in vitro fertilization. *N Engl J Med.* 2009;360[3]:236-243.)

Figure 43.10 Overall cumulative pregnancy rate in IVF treatment (95% CI). (From Dor J, Seidman DS, Ben-Shlomo I, et al. Cumulative pregnancy rate following in vitro fertilization: the significance of age and infertility aetiology. *Hum Reprod.* 1996;11[2]:425-428.)

develop. Coasting (withholding daily gonadotropin treatment while monitoring follicular development toward the end of the IVF cycle) may help decrease OHSS risk, although suboptimal pregnancy rates have been noted with more than 3 days of coasting (Nardo, 2006). GnRH antagonist cycles have been associated with lower OHSS rates as opposed to GnRH agonist “long” cycles (Xiao, 2014). Deferring embryo transfer immediately post retrieval and cryopreserving the embryos for a future frozen embryo transfer cycle helps decrease the duration of OHSS by (temporarily) avoiding pregnancy.

Administration of a daily dopamine agonist for starting immediately post-hCG trigger administration for up to 8 days following the hCG trigger has been shown in some studies to decrease OHSS development (Leitao, 2014).

To date the most effective means of decreasing OHSS risks with conventional IVF is using a GnRH agonist trigger. Using doses of 1 to 4 mg of GnRH agonist in lieu of hCG has dramatically (though not entirely) reduced OHSS development in the most high-risk patients. Lower pregnancy rates likely due to luteal phase insufficiency limited the use of this method until recent years. This defect likely occurs for the same reason that the GnRH agonist trigger successfully limits OHSS risks—the shorter half-life of the GnRH agonist versus hCG minimizes the cascade of events leading to prolonged OHSS. By combining the agonist trigger with a greatly reduced dose of hCG (i.e., 1000 IU or 1500 IU) and with the addition of supplemental estrogen/progesterone in the luteal phase, pregnancy rates are similar to those found with the conventional hCG trigger (Griffin, 2012).

IN VITRO FERTILIZATION PREGNANCY COMPLICATIONS

The major pregnancy concerns after IVF are related to multiple gestations resulting in prematurity and other sequelae (Schieve, 1999). Because of the risks of prematurity with high-order multiples, couples may elect to undergo selective fetal reduction early in pregnancy. This is considered a safe procedure but carries an overall risk of pregnancy loss of approximately 1%.

However, there are some pregnancy-related risks that occur, even with singletons (Table 43.5). Therefore careful obstetric care is extremely important. Congenital anomaly risks in IVF pregnancies may be slightly increased (3% to 4%) compared with the natural rate of birth defects in the normal population (2% to 3%) but not when compared with an infertility population not undergoing IVF.

Although controversial, there may be a slightly increased risk of chromosomal structural defects in children born after ICSI. In a study of 8319 live births, Van Steirteghem and coworkers found a rate of sex chromosomal aneuploidy of 0.6% in the ICSI offspring versus 0.2% in the general neonatal population and structural autosomal abnormalities in 0.4% versus 0.07%, as well as an increase in structural aberrations related to the infertile fathers (Van Steirteghem, 2002). Increasingly data have suggested that although there may be a slightly increased rate of birth defects with IVF compared with the general population, it is not increased when compared with an infertile population that did not use IVF to conceive (Rimm, 2011). Similarly the latest meta-analysis to date has suggested no difference in risk between IVF with and without ICSI (Wen, 2012). Also there

Table 43.5 Potential Risks in Singleton In Vitro Fertilization Pregnancies

Perinatal Risks	Absolute Risk in IVF Pregnancies (%)	Relative Risk (vs. Non-IVF Pregnancies)
Preterm birth	11.5	2.0 (1.7-2.2)
Low birth weight (<2500 g)	9.5	1.8 (1.4-2.2)
Very low birth weight (<1500 g)	2.5	2.7 (2.3-3.1)
Small for gestational age	14.6	1.6 (1.3-2.0)
Neonatal ICU admission	17.8	1.6 (1.3-2.0)
Stillbirth	1.2	2.6 (1.8-3.6)
Neonatal mortality	0.6	2.0 (1.2-3.4)
Cerebral palsy	0.4	2.8 (1.3-5.8)
Genetic Risks		
Imprinting disorder	0.03	17.8 (1.8-432.9)
Major birth defect	4.3	1.5% (1.3-1.8)
Chromosomal Abnormalities (after ICSI)		
Of a sex chromosome	0.6	3.0
Of another chromosome	0.4	5.7

Modified from Reddy UM, Wapner RJ, Rebar RW, et al. Infertility, assisted reproductive technology, and adverse pregnancy outcomes. Executive Summary of a National Institute of Child Health and Human Development Workshop. *Obstet Gynecol.* 2007;109(4):967-977.

In this table, the absolute risk is the percentage of IVF pregnancies in which the risk occurred. The relative risk is the risk in IVF versus the risk in non-IVF pregnancies; for example, a relative risk of 2.0 indicates that twice as many IVF pregnancies experience this risk as compared with non-IVF pregnancies. The numbers in parentheses (confidence interval) indicate the range in which the actual relative risk lies.

is no direct evidence of ICSI increasing the risk of imprinting disorders, which was suggested previously (Vermeiden, 2013). Follow-up of the children, however, does suggest an increased rate of urogenital abnormalities, which may be related to the male subfertility. Counseling of patients before ICSI about these findings is important. The uncertainty surrounding these issues is that it is likely that the infertile population also carries some risks (independent of IVF) when compared with the normal fertile population (Simpson, 2014).

OVARIAN AND BREAST CANCER RISKS AFTER IN VITRO FERTILIZATION

Most studies do not show an increased risk for ovarian and breast cancer in patients previously exposed to IVF treatment (Brinton, 2013). Overall, IVF complication rates are low, with the most recent survey of ART complications (i.e., OHSS, hospitalizations, infections, maternal deaths) in the United States revealing rates far below 1% (Kawwass, 2015).

PREIMPLANTATION GENETIC DIAGNOSIS/SCREENING

A variety of genetic tests can help clinicians screen for heritable diseases or aneuploidy prior to embryo transfer. Preimplantation genetic diagnosis (PGD) identifies specific genetic mutations that are known to cause disease. A common use of PGD is to screen for the presence of autosomal recessive diseases such as cystic fibrosis (CF). If both potential parents are CF

Figure 43.11 Trophectoderm biopsy. (Courtesy of Center for Women’s Reproductive Care at Columbia University.)

carriers, PGD can identify embryos that are homozygous for CF genes. Parents may elect to use PGD to avoid implanting these embryos. Preimplantation genetic selection (PGS) refers to screening embryos for aneuploidy. Because aneuploid pregnancy rates increase with maternal age, PGS may be offered to older women (above age 37 to 38) to select for euploid embryos. This may increase the chance for a live birth with IVF (Forman, 2014). Although ethically controversial (ASRM Ethics Committee, 2004), PGS can be used for gender selection and family balancing.

PGD/PGS can be conducted on the polar body of unfertilized oocyte, blastomeres from cleavage-stage (day 3) embryos or the trophectoderm of day 5/6 blastocysts. Because polar body biopsy cannot detect genetic errors occurring postfertilization, PGD/PGS is most commonly conducted on embryos. Until recently, PGD/PGS most commonly occurred with day 3 embryos with the removal of one to two blastomeres per embryo. Fluorescence in situ hybridization (FISH) was then conducted on the biopsied cells. Results could return within 24 to 48 hours at which point only the euploid embryos could be selected for transfer on blastocyst (embryo day 5 or 6). Because of false-positive and false-negative test risks (Hanson, 2009) as well as the risk of embryonic mosaicism leading to incomplete biopsy results, researchers sought more sensitive screening tests. With the development of array comprehensive genetic hybridization (aCGH) and blastocyst biopsy techniques, more accurate results could be obtained with trophectoderm biopsy of day 5/6 blastocysts (Fig. 43.11). Biopsy at the later blastocyst stage does not seem to impair embryonic survival in contrast to embryos biopsied on day 3 (Scott, 2013).

A variety of genetic screening techniques can be used to test embryonic cells: FISH (fluorescence in situ hybridization), single nucleotide polymorphism microarray, aCGH, real-time polymerase chain reaction, and next-generation sequencing. Currently, aCGH is most commonly used, as it allows analysis of all 23 chromosome pairs (unlike FISH, which can only screen a few chromosomal pairs at a time). However, comparative genomic hybridization cannot detect certain chromosomal issues such as balanced translocations, uniparental disomy, polyploidy, or point

mutations. Eventually, next-generation sequencing, which allows for aneuploidy and genetic mutations at the same time, may become the screening tool of choice for PGS/PGD.

Studies (Franasiak, 2014) have shown that PGS for aneuploidy screening of embryos may help maintain consistently high live birth rates for those patients fortunate enough to undergo embryo transfer post-PGS even with advancing reproductive age. Compared with age-matched controls undergoing IVF without PGS, women who underwent IVF/PGS and embryo transfer were found to achieve higher live birth rates. However, fewer patients undergo transfer, as PGS leads to the diagnosis of abnormal embryos, which are not transferred.

RISKS OF PREIMPLANTATION GENETIC DIAGNOSIS/SCREENING

False-positive results may stem from mosaicism within the biopsied embryo leading to the discard of a potentially normal embryo. False-negative results can lead to the transfer of an affected embryo and the conception of a disease-affected pregnancy. Because of this small risk (1% to 2%), patients are still advised to undergo antenatal genetic testing (i.e., chorionic villus sampling or amniocentesis) even post-PGS. Compared with standard IVF, PGD/PGS does not seem to be associated with an increased risk for obstetrical complications or congenital anomalies in resultant offspring (Eldar-Geva, 2014; Beukers, 2013).

DONOR IN VITRO FERTILIZATION

Donor IVF enables fertilization in patients who are unable to conceive using their own oocytes due to decreased ovarian reserve or menopausal changes occurring naturally or post gonadotoxic therapy for cancer. A known or anonymous oocyte donor undergoes controlled ovarian stimulation. Once her oocytes are retrieved, they can then be fertilized with sperm (patient's partner or donor sperm). Resultant embryos are then transferred into the "recipient" patient's uterus following estrogen/progesterone priming to promote endometrial receptivity (see the "Frozen Embryo Transfer" section). Because of age-related effects on declining oocyte quality, pregnancy rates using oocytes from younger age oocyte donors (20 to 30) are typically in the 60% to 70% rate. The rate is relatively independent of the age of the recipient as long as her uterus is normal. Egg donation cycles can safely be carried out in healthy women into their 50s. Pregnancy rates may slightly decline in recipients over the age of 40, but live birth rates of close to 50% per donor cycle can be expected in women into their 50s. Obstetrical complication rates increase, however, in the extremes of advanced maternal age with higher incidences of gestational diabetes and preeclampsia (Paulson, 2002; Kort, 2012).

FROZEN EMBRYO TRANSFER

Estrogen therapy (administered via oral, transdermal, or intramuscular routes) is administered typically over a 2-week period to "prime" the endometrium, readying it for embryo transfer. Monitoring of patient response to the hormone therapy can be done with vaginal ultrasound measurement of endometrial thickness as well as blood measurements of estradiol. Once an endometrial

thickness of 6 to 8 mm or more is attained, progesterone supplementation (via either vaginal or intramuscular injection route) is begun 4 to 6 days before the scheduled embryo transfer.

Embryos are thawed on the day of the scheduled transfer. Survival rates of frozen embryos vary from clinic to clinic. The freezing method (most commonly vitrification at the present time) as well as the baseline quality of the embryos prior to cryopreservation impact embryo survival rates. Thawed embryos are then transferred into the patient's uterus.

The number of thawed embryos to transfer depends on the age of the woman at the time of freezing and on ASRM guidelines. Because implantation/pregnancy rates decline with female age and oocyte quality, the recommended number to transfer will increase with the age of the woman at the time of freeze. For instance, women who froze embryos prior to turning age 35 would be counseled to transfer just one to two embryos. Women freezing embryos at age 40 and above might be advised to transfer three or more. As with fresh IVF transfer, there is an increasing trend toward transferring exclusively at the blastocyst (day 5/6) stage over the day 3 stage.

Some studies now suggest improved pregnancy rates with the use of frozen embryo transfer versus a fresh cycle in certain patient populations. Proponents of frozen embryo transfer over fresh point to better endometrial receptivity and synchronization with the implantation window in programmed frozen cycles (Roque, 2013). Because not all frozen embryos survive the thawing process, however, some women may not be able to undergo a frozen embryo transfer.

FERTILITY PRESERVATION

Patients at risk for future infertility due to gonadotoxic therapy for cancer or an immunologic disorder have several fertility preservation (FP) options. ART to harvest and cryopreserve mature oocytes or embryos is the most well-established method of fertility preservation. Oocyte biology leads to generally lower pregnancy rates with cryopreserved oocytes over embryos. Improvements in oocyte cryopreservation methods have led to improved freeze/thaw survival rates of oocytes and hence pregnancy rates. Nevertheless, even in younger (i.e., <37 years old) women, the pregnancy rate per frozen oocyte has ranged from 4% to 12% with a rapid decline occurring with older patients (Practice Committee ASRM, 2013). To date, only a few thousand live births have been reported from cryopreserved/thawed oocytes, whereas millions of pregnancies have resulted from cryopreserved embryos (Noyes, 2009).

ASRM has long stated that FP should be discussed with any reproductive-aged woman at risk for iatrogenic premature ovarian failure. However, it was not until 2013 that ASRM finally reversed its opinion that elective fertility preservation be considered "experimental." However, ASRM has still not endorsed its routine use for storing or "banking" embryos for the purpose of delaying pregnancy (Practice Committee ASRM, 2013). Although IVF and embryo cryopreservation has led to millions of pregnancies in infertile populations of women, few studies exist demonstrating cryopreservation pregnancy rates in women undergoing FP electively. Concern that the ART process may endanger a woman's future fertility potential—for instance, due to a postprocedure infection leading to pelvic adhesions—is an area of concern and for discussion when counseling women seeking to electively freeze oocytes/embryos. Additionally, concern remains that a woman might receive false hope

through a FP cycle, leading her to further delay child-bearing to an age when ART may no longer be able to assist her should she develop infertility.

OVARIAN TISSUE CRYOPRESERVATION

Research is ongoing in the area of ovarian tissue cryopreservation. For patients unable to go through an ART procedure, surgical removal of a whole or part of an ovary for cryopreservation may offer another way to preserve future fertility potential. The frozen tissue can then be thawed and orthotopically or heterotopically transplanted back into the patient's body at a future date if the need arises. To date, few live births ([Donnez, 2013](#)) have been reported following this process. Ovarian tissue cryopreservation is currently available at a limited number of centers in the United States and requires Institutional Review Board (IRB) approval. Ovarian tissue cryopreservation is not advised for patients suffering from hematologic cancers such as leukemia. Metastatic sites have been found in ovarian tissue harvested from patients with leukemia, leading to concern that transplantation of such tissue may lead to reseeded of malignant cells ([Bastings, 2013](#)).

GnRH agonist use may confer some ovarian protection against the gonadotoxic effect of certain chemotherapeutic agents ([Del Mastro, 2014](#)). GnRH agonists may work in one of several possible ways to protect the ovaries: suppression of the hypothalamic-pituitary gonadal axis leading to decreased blood flow to the ovaries, thereby minimizing ovarian exposure to chemotherapy; suppression of FSH-driven follicular recruitment; and activation of factors within the ovaries that might work directly to protect ovarian reserve ([Blumenfeld, 2007](#)). GnRH agonist administration initially leads to a transient increase in endogenous gonadotropin secretion, potentially stimulating the maturation of a "wave" of oocytes and thereby exposing more oocytes to the gonadotoxic agent. Because of this flare effect, it is important to administer the agonist 7 to 10 days prechemotherapy exposure. This sequence allows for the flare effect to fade and the agonist's suppressive/protective effect to come to the forefront. A study in reproductive-age breast cancer patients showed

that GnRH agonist administration before and during chemotherapy significantly improved ovarian function as well as pregnancy potential following cancer therapy when compared with the control patients who received no agonist ([Moore, 2015](#)).

Patients facing impending pelvic radiation therapy may consider ovarian transposition via laparoscopy or laparotomy; the ovaries can be lifted above the pelvic brim and fixed to the anterior abdominal wall. Fixing the ovaries out of the field of radiation may help shield them from injury, thus helping patients to maintain their ovarian function ([Gubbala, 2014](#)).

FUTURE DEVELOPMENTS

IVF and PGS have opened opportunities for stem cell research. Somatic cell nuclear transfer into oocytes has led to the development of pluripotent stem cell lines. Research into inducing somatic cells transformation into pluripotent stem cells may allow for tissue development for organ transplantation and repair of injured tissue. This technology may translate into repairing injured cardiac myocytes following an infarction, repairing damaged retinal tissue, or possibly generating oocytes for patients diagnosed with ovarian failure. Nuclear transfer into an enucleated donor cell has paved the way for treating rare mitochondrial diseases ([Paull, 2013](#)). All of these areas are still experimental, conducted under IRB approval where appropriate ([Trownson, 2013](#)).

To date, more than 5 million babies have resulted from IVF since Louise Brown was conceived via IVF in 1978. In the United States, 1% of babies are conceived via IVF, whereas in Europe, up to 3% are conceived with IVF. With improvements in PGS and IVF technology, goals include improving pregnancy rates particularly in women of advanced reproductive age while minimizing the risk for multiple pregnancies. In the future, advances in stem cell research may allow for innovative treatments for rare genetic and more common medical disorders while also offering possibilities for extending reproductive opportunities for patients with gonadal failure.

KEY POINTS

- For IVF with and without ICSI, the delivery rate per cycle in which ova are retrieved is as high as 50%, depending on the age of the woman. The rate of pregnancy following IVF is directly related to the number of embryos placed in the uterine cavity. The rate of pregnancy is inversely related to the age of the female patient.
- Strict guidelines set forth by ASRM, which limit the number of embryos transferred, has reduced the rate of high-order multiple pregnancies in the United States.
- Preimplantation genetic selection and diagnosis allow for screening of embryos for aneuploidy or genetic disease prior to embryo transfer. Because advancing reproductive age is associated with higher rates of aneuploid embryos, PGS may help improve pregnancy rates in older women.
- Donor in vitro fertilization offers women who cannot conceive with their own oocytes the opportunity to experience pregnancy.
- Oocyte and embryo cryopreservation gives women the possibility of maintaining their future fertility potential even when faced with the possibility of premature menopause due to gonadotoxic medical treatments. Though still experimental, ovarian tissue freezing is another possible method of fertility preservation. Oocyte cryopreservation is available for healthy females who are interested in elective fertility preservation, but they need to be carefully counseled about the low pregnancy rates associated with cryopreserved oocytes.
- IVF technology has helped to expand research into stem cell therapy, which may further improve treatments for infertility as well as other medical conditions in the near future.

Key Points

CHAPTER 1: FERTILIZATION AND EMBRYOGENESIS

KEY POINTS

- Oocyte meiosis is arrested at the prophase I from the fetal period until the time of ovulation.
- Fertilization occurs in the ampulla of the fallopian tube before the second polar body is cast off.
- After fertilization, first cell division leading to the two-cell embryo takes about 26 hours.
- The human embryo enters the uterus somewhere between 4 and 5 days after conception at the blastocyst stages of development.
- Implantation occurs when trophoblastic cells contact endometrium and burrow beneath the surface. This generally takes place 3 days after the embryo enters the uterus.
- Twinning due to embryo splitting may occur at any time until the formation of the blastocyst, after which time each cell is no longer pluripotent.
- The earliest fetal epithelium to develop is the ectoderm, the second is the endoderm, and the third is the mesoderm.
- hCG is secreted by the syncytiotrophoblast at about the time of implantation. It doubles in quantity every 1.2 to 2 days until 7 to 9 weeks' gestation.
- Angiogenesis is seen by day 15 or 16. Embryonic heart function begins in the third week of gestation.
- Organogenesis is complete by postconception day 56.
- The mesonephric duct system gives rise in the male to the epididymis, vas deferens, and seminal vesicles. Remnants of the mesonephric duct system in the female remain as parovarian cysts and the Gartner duct.
- The paramesonephric duct system develops in the female to give rise to the fallopian tube, uterus, and cervix. Remnants give rise to the hydatid of Morgagni at the end of the fallopian tubes. Remnants in the male remain as the appendix of the testes and prostatic utricle. This duct system is suppressed in the male by the action of AMH.
- The vagina develops from the sinovaginal bulbs, which are outgrowths of the urogenital sinus. Failure of these bulbs to form leads to agenesis of the vagina.
- The adult kidney develops from the metanephros, and its collecting system (ureter and calyceal system) develops from the metanephric (ureteric) bud from the mesonephric duct.
- The urinary bladder develops from the urogenital sinus.
- The *SRY* gene on the Y chromosome is responsible for the development of testes. Without the presence of this gene, the gonadal development is ovarian. With the absence of Sertoli cells, AMH is not produced, the paramesonephric duct system develops into a phenotypic female configuration, and the mesonephric duct system is suppressed.
- The genital tubercle elongates to form the penis in the male and the clitoris in the female.
- Two functional X chromosomes are necessary for optimal development of the ovary.

CHAPTER 2: REPRODUCTIVE GENETICS

KEY POINTS

- Virtually all human diseases have an underlying genetic component. All health care professionals need a basic level of familiarity with genetics and genomics, as this is an integral part of mainstream medicine.
- Genetic variation between healthy individuals exists in the form of SNPs and CNVs providing different “doses” of a large repeated DNA sequence at a given genetic locus, or alterations in three-dimensional DNA structures called *epigenetic modification*.
- Naturally occurring variations in genetic sequence, such as SNPs, may mediate an individual’s susceptibility to disease or responsiveness to a particular medication.
- The human genome contains about 3 billion base pairs, of which only about 1.5% makes up the exome, or protein-coding portion. The remaining 98.5% of the human genetic sequence encodes biologically active nucleic acid molecules, which are an active area of molecular biology research.
- Genetic pathology can arise from alteration in the sequence of a gene, changes in the normal amount of a gene product, or sequence changes in regulatory regions, which prevent the cell from expressing the intended gene product.
- When a heterozygous individual who has an autosomal dominant trait mates with a normal individual, 50% of their offspring will have the trait.
- When two individuals who carry an autosomal recessive trait mate, 25% of their offspring will demonstrate the trait and 50% will be carriers.
- X-linked recessive characteristics are transmitted from maternal carriers to male offspring and will affect 50% of the male offspring.
- The mechanism of trinucleotide repeat disorders is DNA misalignment during meiosis, which leads to unstable dynamic expansion of the number of three-nucleotide repeats within the gene as it is passed from generation to generation, causing progressively more severe manifestations of disease.
- Prader-Willi and Angelman syndromes demonstrate the concept that certain regions of genetic material are imprinted and depend on dose and inheritance from two separate gametes for normal function.
- The phenotype and severity of disorders that affect the mitochondria are determined by the source of the genetic material (nuclear or mitochondrial DNA), the proportion of affected mitochondria inherited by the cell, as well as the threshold for energy production needed in the affected cell.
- In general, if a couple produces an offspring with a multifactorial defect and the problem has never occurred in the family, it can be expected to be repeated in 2% to 5% of subsequent pregnancies.
- Individuals who carry balanced rearrangements of genetic material are phenotypically normal, but their gametes are at risk for unbalanced genetic content, which may lead to infertility or recurrent pregnancy loss.
- Nondisjunctional events have been described in every autosome except chromosomes 1 and 17. Live births can result from nondisjunctional events involving chromosomes 21, 18, 13, or 22, and these occur more commonly with advancing maternal age.
- There are screening and diagnostic tests available for prenatal diagnosis of a large number of genetic diseases and syndromes. Indications for testing may include family history of a specific disease or recurrent clinical phenotype, ethnic background with increased carrier frequency of a certain disease, poor obstetric outcome history, increased maternal age, or population-based prevalence risk.
- In genetic counseling, the role of the care providers (genetic counselors and physicians) is to conduct nondirectional counseling of screening and diagnostic options in order to provide prospective parents with information to optimize pregnancy outcomes based on their personal values and preferences. Before screening or testing, the patient needs to understand the options that may ensue from a positive test result.
- Genetic screening based on cell-free fetal DNA is currently recommended only for women with increased risk of fetal aneuploidy.
- Definitive diagnosis of a genetic disease in the prenatal period requires tissue diagnosis obtained through invasive testing methods such as preimplantation genetic diagnosis, chorionic villus sampling, or amniocentesis.
- With next-generation sequencing, it is possible to determine the complete sequence data for an individual exome (protein-coding region) or genome (complete genetic material). However, accurate interpretation of these data is limited by unknown function of natural genetic variation and noncoding DNA regions, which make up the majority of the sequence.
- All cancer is genetic. However, most cancer is not inherited. For a normal cell line to be transformed into a malignant cell line, several genetic mutations in that somatic cell line must occur that alter cell growth and differentiation.
- In 5% to 10% of families with cancer, there is a germline (inherited) mutation that predisposes certain tissues to become malignant.
- Types of genes and genetic mechanisms involved in malignancy may be grouped into four categories: oncogenes, tumor suppressor genes, DNA repair genes, and epigenetic mechanisms of aberrant DNA packaging.
- Oncogenes (gain of function) behave as growth-promoting genes, and they act in a genetically dominant manner. In other words, only one abnormal copy of the gene will produce a clinically relevant phenotype due to increased gene function.
- Tumor suppressor genes restrain cell growth in damaged cells; therefore loss of the tumor suppressor gene through mutation leads to increased cell proliferation of abnormal cells and cancer development. They account for the majority of autosomal dominant cancer syndromes.

KEY POINTS—cont'd

- DNA repair genes identify and mend DNA replication errors made during replication. When they are nonfunctional, replication errors can lead to cancer development.
- Epigenetic mechanisms involve alterations in patterns of DNA methylation or DNA packaging (3D structure determined by histone interaction and nucleosome positioning).
- Lynch syndrome has a prevalence of 3% to 5% in all patients with newly diagnosed endometrial cancer.
- In patients with endometrial cancer, the actual tumor tissue can be screened for Lynch syndrome using IHC for the four mismatch repair proteins (MLH1, MSH2, MSH6, and PMS2), MSI analysis, and MLH1 hypermethylation testing.

CHAPTER 3: REPRODUCTIVE ANATOMY

KEY POINTS

- The labia majora are homologous to the scrotum in the male. The labia minora are homologous to the penile urethra and a portion of the skin of the penis in males.
- The clitoris is the female homologue of the penis in the male. Skene glands are homologous to the prostate gland in the male.
- The average length of the clitoris is 1.5 to 2 cm. Clinically, in determining clitoromegaly width is more important and should be less than 1 cm, for it is difficult to actually measure the length of the clitoris.
- The female urethra measures 3.5 to 5 cm in length. The mucosa of the proximal two thirds of the urethra is composed of stratified transitional epithelium, and the distal one third is stratified squamous epithelium.
- When a woman is standing, the axis of the upper portion of the vagina lies close to the horizontal plane, with the upper portion of the vagina curving toward the hollow of the sacrum.
- The vaginal length increases with weight and height, and it decreases with age.
- The lower third of the vagina is in close anatomic relationship to the urogenital and pelvic diaphragms.
- The middle third of the vagina is supported by the levator ani muscles and the lower portion of the cardinal ligaments.
- The primary lymphatic drainage of the upper third of the vagina is to the external iliac nodes, the middle third of the vagina drains to the common and internal iliac nodes, and the lower third has a wide lymphatic distribution, including the common iliac, superficial inguinal, and perirectal nodes.
- Descriptive terms for pelvic organs are derived from the Latin root, whereas terms relating to surgical procedures are derived from the Greek root.
- The length and width of the endocervical canal vary. The width of the canal varies with the parity of the woman and changing hormonal levels. It is usually 2.5 to 3 cm in length and 7 to 8 mm at its widest point.
- The fibromuscular cervical stroma is composed primarily of collagenous connective tissue and ground substance. The connective tissue contains approximately 15% smooth muscle cells and a small amount of elastic tissue.
- The major arterial supply to the cervix is located in the lateral cervical walls at the 3 and 9 o'clock positions.
- The pain fibers from the cervix accompany the parasympathetic fibers to the second, third, and fourth sacral segments.
- The transformation zone of the cervix encompasses the border of the squamous epithelium and columnar epithelium. The location of the transformation zone changes on the cervix depending on a woman's hormonal status.
- The uterus of a nulliparous woman is approximately 8 cm long, 5 cm wide, and 2.5 cm thick and weighs 40 to 50 g. In contrast, in a multiparous woman each measurement is approximately 1.2 cm larger and normal uterine weight is 20 to 30 g heavier. The maximal weight of a normal uterus is 110 g.
- In the majority of women, the long axis of the uterus is both anteverted in respect to the long axis of the vagina and anteflexed in relation to the long axis of the cervix. However, a retroflexed uterus is a normal variant found in approximately 25% of women.
- The uterine and ovarian arteries provide the arterial blood supply of the uterus. The uterine arteries are large branches of the anterior division of the hypogastric arteries, whereas the ovarian arteries originate directly from the aorta.
- Afferent nerve fibers from the uterus enter the spinal cord at the eleventh and twelfth thoracic segments.
- The oviducts are 10 to 14 cm in length and are composed of four anatomic sections. Closest to the uterine cavity is the interstitial segment, followed by the narrow isthmic segment, then the wider ampullary segment, and distally the trumpet-shaped infundibular segment.
- The right oviduct and appendix are often anatomically adjacent. Clinically it may be difficult to differentiate inflammation of the upper portion of the genital tract and acute appendicitis.
- During the reproductive years, the ovaries measure approximately 1.5 cm × 2.5 cm × 4 cm.
- The ovary in nulliparous women rests in a depression of peritoneum named the *fossa ovarica*. Immediately adjacent to the ovarian fossa are the external iliac vessels, the ureter, and the obturator vessels and nerves.

Continued

KEY POINTS—cont'd

- Three prominent ligaments determine the anatomic mobility of the ovary: the mesovarian, the ovarian ligament, and the infundibulopelvic ligament.
- The arterial supply of the pelvis is paired, bilateral, and has multiple collaterals and numerous anastomoses.
- The extent of collateral circulation after hypogastric artery ligation depends on the site of ligation and may be divided into three groups: branches from the aorta, branches from the external iliac arteries, and branches from the femoral arteries.
- The internal iliac nodes are found in an anatomic triangle whose sides are composed of the external iliac artery, the hypogastric artery, and the pelvic sidewall. This rich collection of nodes receives channels from every internal pelvic organ and the vulva, including the clitoris and urethra.
- The femoral triangle is the anatomic space lying immediately distal to the fold of the groin. The boundaries of the femoral triangle are the sartorius and adductor longus muscles and the inguinal ligament.
- The pudendal nerve and its branches supply the majority of both motor and sensory fibers to the muscles and skin of the vulvar region.
- The femoral nerve may be compromised by pressure on the psoas muscle during abdominal surgery and by hyperflexion of the leg during vaginal surgery.
- The pelvic diaphragm is important in supporting both abdominal and pelvic viscera and facilitates equal distribution of intraabdominal pressure during activities such as coughing. The levator ani muscles constitute the greatest bulk of the pelvic diaphragm.
- The major function of the urogenital diaphragm is to support the urethra and maintain the urethrovesical junction.
- Contained within the broad ligaments are the following structures: oviducts, ovarian and round ligaments, uterers, ovarian and uterine arteries and veins, parametrial tissue, embryonic remnants of the mesonephric duct and Wolffian body, and two secondary ligaments.
- The cardinal ligaments provide the major support to the uterus.
- A congenital anomaly of a double, or bifid, ureter occurs in 1% to 4% of females.
- When the urinary bladder is empty, the ureteral orifices are approximately 2.5 cm apart. This distance increases to 5 cm when the bladder is distended.
- The distal ureter enters into the cardinal ligament. In this location the ureter is approximately 1 to 2 cm lateral to the uterine cervix and is surrounded by a plexus of veins. In approximately 12% of women, the cervix will be less than 0.5 cm from the cervix.
- Two ways of distinguishing the ureter from pelvic vessels are (1) identification of peristalsis after stimulation with a surgical instrument and (2) identification of Auerbach plexuses.
- Surgical compromise of the ureters may occur during clamping or ligating of the infundibulopelvic vessels, clamping or ligating of the cardinal ligaments, or wide suturing in the endopelvic fascia during an anterior repair.
- The following three important axioms should be in the forefront of decision making during difficult gynecologic surgery: (1) do not assume that the anatomy of the left and right side of the pelvis are invariably identical mirror images; (2) during difficult operations with multiple adhesions, operate from known anatomic areas into the unknown; and (3) from the sage advice of a distinguished Canadian gynecologist, Dr. Henry McDuff: "If the disease be rampant and the anatomy obscure, and the plans of dissection not pristine and pure, do not be afraid, nor faint of heart, try the retroperitoneum, it's a great place to start."

CHAPTER 4: REPRODUCTIVE ENDOCRINOLOGY

KEY POINTS

- GnRH analogues are synthesized by substitution of amino acids in the parent molecule at the 6 and 10 positions. The various agonists have greater potencies and longer half-lives than the parent GnRH.
- LH and FSH have the same α subunit of thyroid-stimulating hormone (TSH) and human chorionic gonadotropin (HCG). The β subunits of all these hormones have different amino acids and carbohydrates, which provide specific biologic activity.
- LH acts on the theca cells to produce androgens, which are then transported to the granulosa cells, where they are aromatized to estrogens.
- Pregnenolone, 17-hydroxypregnenolone, progesterone, 17-hydroxyprogesterone, and corticosteroids have 21 carbon atoms; androgens (testosterone and androstenedione) have 19 carbon atoms; estrogens have 18 carbon atoms and a phenolic ring A.
- Kisspeptin (KISS1) plays a key role in the regulation of GnRH release.
- Because the ovaries lack 21-hydroxylase, 11- β -hydroxylase, and 18-hydroxylase reductase activity, they are unable to synthesize mineralocorticoids or glucocorticoids.
- Sex hormone-binding globulin (SHBG) primarily binds dihydrotestosterone, testosterone, and estradiol. About 65% of circulating testosterone is bound to SHBG and 30% to albumin. Approximately 2% remains unbound or free.
- Estrogen stimulates the synthesis of both estrogen and progesterone receptors in target tissues, and progestins inhibit the synthesis of both estrogen and progesterone receptors.

KEY POINTS—cont'd

- With ultrasound it has been found that there is a steady increase in follicular diameter and volume that parallels the rise in estradiol. The dominant follicle has a maximal mean diameter of about 19.5 mm, with a range of 18 to 25 mm just before ovulation. The mean maximal follicular volume is 3.8 mL, with a range of 3.1 to 8.2 mL.
- Ovulation occurs about 24 hours after the estradiol peak, as well as 32 hours after the initial rise in LH, and about 12 to 16 hours after the peak of LH levels in serum.
- Progesterone levels in serum are less than 1 ng/mL before ovulation and reach midluteal levels of 10 to 20 ng/mL.
- After menstruation, regeneration of the endometrium comes from cells in the spongiosum that were previously a portion of the secretory endometrium and not from the stratum basale as previously believed.
- Enzyme-linked immunosorbent assay (ELISA), or “sandwich,” techniques have been developed to measure protein hormones (e.g., LH, FSH, HCG) with the use of monoclonal antibodies against the α and β subunits. The end point is a color reaction and can be read in a spectrophotometer.
- There are four characteristics of hormone assays that establish their reliability: sensitivity, specificity, accuracy, and precision.

CHAPTER 5: EVIDENCE-BASED MEDICINE AND CLINICAL EPIDEMIOLOGY

KEY POINTS

- Evidence-based medicine seeks to improve the care of patients and the delivery of care to patients.
- Descriptive-observational studies, including cross-sectional studies and case series, help generate hypotheses and characterize the context of disease.
- Cohort studies allow us to study many outcomes over time.
- Case-control studies allow us to study rare diseases and evaluate for a wide range of exposures.
- RCTs are considered to be the gold standard of experimental clinical study design.
- PCTs are designed to study the effectiveness of an intervention in the real world.
- CER encompasses patient-centered research, PCTs, meta-analyses, systematic reviews, evidence-based guidelines, and health services research to study the benefits and harms of an intervention to improve patient care on the individual and population level.
- Estimating the value of health care involves an assessment of the quality and integration of care, as well as the overall cost to provide all services included in that care.

CHAPTER 7: HISTORY, PHYSICAL EXAMINATION, AND PREVENTIVE HEALTH CARE

KEY POINTS

- Strive to become a culturally sensitive and aware physician with a nonjudgmental approach to women regardless of race or ethnicity, age, faith, disabilities, profession, sexual orientation, or activities.
- Menstrual history includes age of menarche, number of days of cycle, number of days of flow, presence of bleeding between menstrual periods, the date of the last menstrual period, and the date of the previous menstrual period.
- A complete gynecologic evaluation should always include a sexual history, contraceptive history, and history of physical or sexual abuse.
- The specific components of the annual exam will be based on patient age, health concern, and risk factors. Whether to perform breast or pelvic exams is a joint decision between individual providers and their patients.
- Cervical cytology screening should begin at age 21 regardless of the onset of sexual activity.
- Pap smears should be performed every 3 years until age 29, then either every 3 or 5 years, depending on the addition of HPV testing. Screening should continue until between age 65 and 70, at which time adequately screened women and those with negative screening can stop undergoing cervical cancer screening.
- Sexually active women should be evaluated at appropriate intervals for sexually transmitted diseases, with annual chlamydia screening for women age 26 and under. Counseling women on safe sex practices to avoid contracting sexually transmitted diseases is important.
- Goals of preventive medicine include maintaining good health and function and promoting high-quality longevity.
- The physician should maintain an immunization record for each patient and offer appropriate vaccinations as recommended by public health guidelines.

CHAPTER 8: THE INTERACTION OF MEDICAL DISEASES AND FEMALE PHYSIOLOGY

KEY POINTS

- LARC methods are safe, effective, and have minimal risk of user error, thus they have become the recommended option for most women with complicated chronic illnesses.
- The severity of asthma symptoms increases around the time of menses.
- Many women with IBS and IBD will have exacerbations of symptoms with menses.
- Women with chronic renal disease often experience menorrhagia.
- Estrogen-containing contraceptives are not recommended in women with hypertension who are over 35, use tobacco, have poorly controlled disease, or are on medications for hypertension.
- Progesterone stabilizes red cell membranes and significantly decreases the frequency of sickling crises.
- Withdrawal of progesterone (even in small amounts such as periovulatory) leads to a significant decline in the seizure threshold and an increase in seizure frequency and severity.
- Women who have migraines with aura are more susceptible to stroke, and thus the use of ECC in women with migraines with aura is contraindicated.
- Early referral of women with cancer to a reproductive endocrinologist with expertise in potential therapies to preserve fertility is important.

CHAPTER 9: EMOTIONAL ASPECTS OF GYNECOLOGY

KEY POINTS

- Depression, anxiety disorders, obsessive-compulsive disorder, and posttraumatic stress disorder are treatable with medications or psychotherapy.
- A history of manic or hypomanic symptoms increases the risk for a “switch” into mania with antidepressant treatment.
- Close follow-up, in 1 to 2 weeks, is recommended to monitor for increases in suicidal thoughts with antidepressants, especially in adolescents and young adults.
- Active suicidal thoughts and plans are a psychiatric emergency.
- Eating disorders are life-threatening conditions that are often unrecognized.
- Girls or women presenting with amenorrhea, menstrual dysfunction, low bone density, sexual dysfunction, infertility, anxiety, depression, or hyperemesis gravidarum should be screened for eating disorders.
- Women with anxiety disorders, especially panic disorder and posttraumatic stress disorder, are at increased risk for suicide and should be asked about suicidal thoughts or plans.
- Anxiety disorders respond well to reassurance, education, and treatment with psychotherapy and medications (especially SSRI antidepressants).
- Many substance use disorders, such as alcoholism, have a more rapidly progressive course in women than in men (“telescoping”).
- More than two drinks per day on average is considered heavy drinking for a woman.
- Motivational interviewing is a highly effective, brief intervention that increases women’s engagement in substance abuse treatment and other behavior change.
- In cases of misuse of potentially habit-forming medications, a formal treatment agreement may be necessary.
- Understanding attachment styles can help providers to work effectively with “difficult” patients.
- Nonpharmacologic treatments for hypoactive sexual desire disorder include lifestyle changes for reducing stress and fatigue, recognizing and treating depression, increasing quality time with the partner, improving body image, and bringing novelty into the sexual repertoire.
- Lesbian and bisexual women require routine gynecologic care, have a high rate of mental health and substance use problems, and prefer female, preferably lesbian, health care providers.
- Lesbian and bisexual women have an elevated rate of mental health problems, substance use disorders, and suicide attempts, especially during adolescence.
- Intimate partner violence crosses all ethnic, racial, educational, age, and socioeconomic lines and has a large burden of social, physical, mental, and public health implications.
- The physician has a responsibility to screen and acknowledge intimate partner violence and abuse, identify the community resources for immediate referrals, assess safety, assist with reporting if necessary or desired, document appropriately using medicolegal tools, and provide ongoing clinical care.
- Gynecologists are often called on to provide or refer women for counseling related to grief; losses such as miscarriage, perinatal loss, and infertility; and end-of-life issues.
- Women suffering losses as a result of miscarriage, perinatal loss, unplanned pregnancy, or infertility benefit from support, counseling, and screening for depression and posttraumatic stress disorder.
- Complicated grief and grief accompanied by symptoms of depression benefit from antidepressant medication treatment in addition to psychotherapy.
- Women with terminal illness benefit from an engaged, genuine relationship with physicians and other health care providers, treatment of depression and anxiety states, psychological interventions and psychotherapy, and early integration of palliative care into treatment.

CHAPTER 10: ENDOSCOPY: HYSTEROSCOPY AND LAPAROSCOPY**KEY POINTS**

- The most frequent problem in performing endometrial sampling is cervical stenosis or spasm; it is also a problem for hysteroscopy, and this increases the risk of uterine perforation.
- Major indications for hysteroscopy include abnormal uterine bleeding, removal of endometrial polyps or submucous myomas, endometrial ablations, retained IUDs, desire of no incision sterilization, intrauterine adhesions diagnosis and treatment, infertility, resection of a uterine septum, and recurrent pregnancy loss.
- The endometrial lining may be ablated through the hysteroscope in women with abnormal bleeding or menorrhagia who have a normal uterine cavity and are poor surgical candidates, those who wish to retain their uterus, and those who do not desire further childbearing.
- Older resectoscopic and second-generation nonresectoscopic endometrial ablation devices appear to be equivalent with respect to successful reduction in menstrual flow and patient satisfaction at 1 year.
- Vaginal misoprostol administration the night before the hysteroscopic procedure can aid in cervical softening.
- A paracervical block with local anesthetic is the best method of pain control for outpatient hysteroscopy compared with topical or intracervical anesthesia.
- Complications of hysteroscopy include uterine perforation with risk of injury to the surrounding vascular and visceral structures, pelvic infection, bleeding, and absorption of the distending media.
- The primary laparoscopic trocar placement leads to the >50% of vascular and bowel injuries in gynecologic laparoscopy.
- Absolute contraindications to laparoscopy include a hemoperitoneum that has produced hemodynamic instability, bowel obstruction, advanced malignancy, large abdominal masses, severe cardiovascular disease, and tuberculous peritonitis.
- The incidence of complications with operative laparoscopy varies from 0.2% to 2%. Thermal bowel injuries often go unrecognized intraoperatively, and diagnostic delays can be life threatening.

CHAPTER 11: CONGENITAL ABNORMALITIES OF THE FEMALE REPRODUCTIVE TRACT**KEY POINTS**

- Gender identification in a newborn infant has emotional and psychological implications and should be performed as accurately as possible. However, in the setting of ambiguous genitalia, gender assignment should not be made without definitive testing and multidisciplinary participation.
- Congenital adrenal hyperplasia is an autosomal recessive condition, most commonly the result of an inborn error of metabolism involving the enzyme 21-hydroxylase. Homozygous individuals occur in 1 of every 490 to 67,000 births, averaging 1 in 14,000, and are at risk of moderate-to-severe manifestations. Heterozygotes (carriers) are present in 1 in 20 to 1 in 250 individuals and can have a more mild presentation. Differences in incidence depend on ethnic background of the population tested.
- Up to 75% of female neonates with ambiguous genitalia may develop a sodium-wasting adrenal crisis.
- The hymen develops at the junction of the sinovaginal bulb with the urogenital sinuses and is derived from endoderm, and multiple variants of hymenal anatomy exist.
- Vaginal agenesis is most often associated with Mayer-Rokitansky-Küster-Hauser syndrome or müllerian agenesis. Up to 50% of these women will have urologic abnormalities, and approximately one in eight will have skeletal abnormalities as well.
- Anomalies of the uterus and cervix demonstrate a polygenic or multifactorial pattern of inheritance and occur in approximately 2% to 3% of the female population.
- Approximately 15% of women with a history of first-trimester recurrent miscarriage and 25% of those with a second-trimester miscarriage may have a uterine anomaly.
- The uterine septum is the only uterine anomaly that can be easily corrected with a surgical procedure. In women with poor reproductive outcomes, surgery can normalize their chances of miscarriage and live birth.

CHAPTER 12: PEDIATRIC AND ADOLESCENT GYNECOLOGY

KEY POINTS

- It is important to give the child a sense that she will be in control of the examination process. Emphasize that the most important part of the examination is just “looking” and that there will be conversation during the entire process.
- Many gynecologic conditions in children can be diagnosed by inspection alone.
- The vaginal epithelium of the prepubertal child appears redder and thinner than the vaginal epithelium of a woman in her reproductive years.
- The prepubertal vagina is also narrower, thinner, and lacks the ability to distend like that of the vagina of a reproductively mature woman.
- The vagina of a child is 4 to 5 cm long and has a neutral pH.
- During the physical examination and rectal examination of the prepubertal child, no pelvic masses except the cervix should be palpable. The normal prepubertal uterus and ovaries are nonpalpable. The relative size ratio of cervix to uterus is 2 to 1 in a child.
- Many female adolescents do not want other observers, such as mothers, in the examining room.
- It is estimated that 80% to 90% of outpatient visits of children to gynecologists involve the classic symptoms of vulvovaginitis: introital irritation and discharge.
- Positive identification of gonorrhea, or chlamydia in a child with premenarcheal vulvovaginitis, is considered diagnostic of sexual abuse. However, many infants are infected with *Chlamydia trachomatis* during birth and remain infected for up to 2 to 3 years in the absence of specific antibiotic therapy.
- The major factor in childhood vulvovaginitis is poor perineal hygiene.
- A vaginal discharge that is both bloody and foul smelling strongly suggests the presence of a foreign body.
- In the period surrounding the time of puberty, children often develop a physiologic discharge secondary to the increase in circulating estrogen levels.
- The foundation of treating childhood vulvovaginitis is the improvement of local perineal hygiene.
- The majority of cases of persistent or recurrent nonspecific vulvovaginitis respond to improved hygiene and treatment of irritation resulting from trauma or irritating substances.
- The classic symptom of pinworms (*Enterobius vermicularis*) is nocturnal vulvar and perianal itching, the treatment for which is the antihelminthic agent, mebendazole.
- The most common vaginal foreign body in preadolescent females is a wad of toilet tissue.
- Persistent vaginal bleeding is an extremely rare symptom in a preadolescent female. However, it is important to do a thorough workup because of the serious sequelae of some of the causes of vaginal bleeding.
- Labial adhesions do not require treatment unless they are symptomatic or voiding is compromised. If necessary, small amounts of daily topical estrogen to the labia may be used for treatment.
- The usual cause of genital trauma during childhood is an accidental fall. Most such traumas involve straddle injuries.
- Accidental genital trauma often produces extreme pain and overwhelming anxiety for the child and her parents. Because of compassion and empathy, the gynecologist may underestimate the extent of the anatomic injuries.
- Small follicular cysts in preadolescent females are usually self-limiting.
- Ovarian tumors constitute approximately 1% of all neoplasms in premenarcheal children. In preadolescent females, both benign and malignant ovarian tumors are usually unilateral. Routine biopsy of the normal-appearing contralateral ovary should be avoided.
- Approximately 75% to 85% of ovarian neoplasms necessitating surgery are benign, with cystic teratomas being the most common.
- The most common malignancy in preadolescent females is a germ cell tumor.
- Even though ovarian neoplasms are rare in children, this diagnosis must be considered in a young girl with abdominal pain and a palpable mass.
- The surgical therapy of an ovarian neoplasm in a child should have two goals: the appropriate surgical removal of the neoplasm and the preservation of future fertility.
- Ovarian torsion should be managed conservatively with untwisting and preservation of the adnexa, regardless of the appearance.
- Presence or absence of Doppler flow on the ovary on ultrasound is not diagnostic of ovarian torsion, and the decision for surgical intervention should be based on the level of clinical suspicion.

CHAPTER 13: FAMILY PLANNING**KEY POINTS**

- Half of all pregnancies in the United States are unintended, and among women who experience unintended pregnancy, more than half are not using contraception.
- By the age of 45, at least half of U.S. women will experience an unintended pregnancy, and one in three will have had an abortion.
- Failure rates in the first year of contraceptive use are highest for coitus-related methods (e.g., withdrawal, periodic abstinence, condoms, barrier methods) followed by combined contraceptives (pill, patch, ring) and the progestin injection. The IUD, implants, and sterilization have typical use failure rates of less than 1%, similar to that of sterilization.
- The copper IUD can increase bleeding with menses, whereas the LNG-IUS is likely to decrease bleeding with menses or lead to amenorrhea. The primary mechanism of action for the LNG-IUS is thickening of the cervical mucus.
- The contraceptive implant has an effectiveness that is equal to or superior to that of sterilization and IUDs. It inhibits ovulation and may cause irregular bleeding patterns.
- The DMPA injection completely inhibits ovulation and is likely to cause amenorrhea. Return to fertility after cessation of use can be delayed, and some DMPA users may experience weight gain.
- Combined hormonal contraceptives increase a woman's risk of VTE by about threefold to about 1/1000 per year. Women with multiple risk factors for VTE or cardiovascular disease (e.g., obesity, age >35, smoking, a personal or family history of clotting disorder) should use effective birth control methods without estrogen.
- The most effective method of emergency contraception is the copper IUD, followed by a single dose of oral ulipristal acetate (Ella). Plan B, or an oral dose of levonorgestrel, is somewhat less effective.
- First- and second-trimester medical and surgical abortion is safe and effective. Overall, abortions have a lower complication risk than carrying a pregnancy to term. Access to legal and safe abortion is a cornerstone of maternal health.

CHAPTER 14: MENOPAUSE AND CARE OF THE MATURE WOMAN**KEY POINTS**

- The average age of menopause in the United States is 51.3 years, and it is younger in certain ethnic groups.
- Age at menopause is genetically predetermined and is not related to the number of ovulations, race, socioeconomic conditions, education, height, weight, age at menarche, or age at last pregnancy.
- Stages of menopause have been established, and the earliest clinical sign is menstrual alterations.
- The initial endocrinologic change signaling the onset of menopause is decreased AMH and ovarian inhibin-B production accompanied by an increase in FSH.
- Estradiol does not begin to significantly diminish until approximately 1 year before menopause. The rise in FSH occurs before this and stabilizes about 2 years after menopause.
- Because most diseases in women occur after menopause, the onset of menopause heralds an important opportunity to institute prevention strategies for prolonging and improving the quality of life for women.
- Bothersome vasomotor symptoms or hot flashes may persist for 10 or more years, with the mean duration of 4.5 years.
- Estrogen is the best therapy for the hot flush; other effective therapies are progestogens, selective serotonin reuptake inhibitors (SSRIs), gabapentin, clonidine, some phytoestrogens, acupuncture, and stellate ganglion blockade.
- About 1% to 1.5% of bone mass is lost each year after menopause in nonobese white and Asian women. Fractures begin to occur about age 60 to 65 in trabecular bone, such as the vertebral spine, and by age 60, 25% of these women develop spinal compression fractures. Hip fractures begin to increase after age 70.
- Dual-energy x-ray absorptiometry (DEXA) is the most accurate method to measure bone density. The bone mineral density is usually expressed as T scores and Z scores. Bone density does not completely reflect bone strength, which is what determines risk of fracture.
- In addition to estrogen (with and without progestogen), alendronate, risedronate, ibandronate, zoledronic acid, raloxifene, calcitonin, denosumab, and teriparatide will reduce postmenopausal bone loss, and some agents will stimulate bone formation as well.
- The primary indication for estrogen therapy is symptoms of menopause (hot flashes as well as quality-of-life issues); bone health may also be an indication in some women.
- In younger postmenopausal women who are receiving hormonal therapy for symptoms, the benefits outweigh risks with standard doses; lowering doses further decreases risks.

Continued

KEY POINTS—cont'd

- There is no risk of coronary disease and possibly some benefit with early treatment; there are small risks of venous thrombosis and possibly of ischemic stroke, which can be minimized or eliminated with lower doses or transdermal therapy.
- There are consistent data for a reduction in all-cause mortality of 20% to 30% in younger women who initiate estrogen therapy at the onset of menopause. These data are mostly with the use of estrogen. Estrogen/progestogen therapy shows the same trend, but the data are less robust.
- These findings suggest a potential role of estrogen as a prevention therapy after menopause, although the primary indication is for symptom control and osteoporosis prevention.
- Breast cancer risk is related to dose, duration of use, and progestogen exposure. Estrogen alone and possibly the use of natural progestogen do not substantially increase the risk.
- There is no proved cognitive benefit (although this has been shown in observational studies), but there is also no evidence for harm if initiated in symptomatic women at the onset of menopause.

CHAPTER 15: BREAST DISEASES

KEY POINTS

- The breast consists of approximately 20% glandular tissue and 80% fat and connective tissue; increasing proportions of fibroglandular to fatty tissues are the mark of denser breasts. Breast density is associated with increased risks of malignancy.
- Lymph drainage of the breast usually flows toward the most adjacent group of nodes. This concept represents the basis for sentinel node mapping in breast cancer. In most instances, breast cancer spreads in an orderly fashion within the axillary lymph node basin based on the anatomic relationship between the primary tumor and its associated regional (sentinel) nodes.
- The breast undergoes normal maturational changes throughout a woman's lifetime. The normal maturation involves a gradual increase in fibrous tissue around the lobules; with time the glandular elements are completely replaced by fibrous tissue.
- The incidence of benign breast disorders begins to rise during the second decade of life and peaks in the fourth and fifth decades. In malignant diseases, the incidence continues to increase after menopause.
- Fibroadenomas are the most common benign breast neoplasm and are most frequently present in adolescents and women in their 20s.
- Approximately 35% of fibroadenomas will disappear, and 10% will become smaller after many years.
- Over two thirds of women will experience breast pain at some time during their reproductive years, most commonly in the perimenopausal years. Approximately 90% of conditions that cause breast pain are benign.
- Cyclic bilateral breast pain is the classic symptom of fibrocystic breast change. The signs of fibrocystic changes include increased engorgement and density of the breasts, excessive nodularity, rapid change and fluctuation in the size of cystic areas, increased tenderness, and occasionally spontaneous nipple discharge.
- The majority of nipple discharge complaints have a benign etiology; however, 55% present with a coexisting mass of which 19% are malignant. An underlying malignancy is more likely when the discharge is spontaneous (vs. induced with nipple pressure), arises from a single duct, is blood stained, and is unilateral and persistent (occurring more than twice weekly).
- Intraductal papilloma and fibrocystic changes are the two most common causes of spontaneous nonmilky nipple discharge.
- Lactational mastitis commonly occurs in the first pregnancy during the first 6 weeks of breast-feeding. Continued breast-feeding or manual pumping of the affected breast is recommended to decrease engorgement.
- One out of eight women (12.5%) in the United States will develop carcinoma of the breast over the course of her lifetime.
- Approximately 50% of newly diagnosed breast cancers are attributable to known risk, whereas 10% are associated with a positive family history.
- Approximately 5% to 10% of breast cancers have a familial or genetic link. Genetic predisposition to develop breast carcinoma has been recognized in some families. In these families, breast cancer tends to occur at a younger age, and there is a higher prevalence of bilateral disease.
- Mutations in the *BRCA* family of genes have been identified that confer a lifetime risk of breast cancer that approaches 85%. *BRCA1* and *BRCA2* genes are involved in the majority of inheritable cases of breast cancer. These genes function as tumor suppressor genes, and several mutations have been described on each of these genes.
- Once a woman has developed carcinoma of one breast, her risk is approximately 1% per year of developing cancer in the other breast.
- Both tamoxifen and raloxifene significantly decrease the relative risk of developing breast carcinoma. AIs are a reasonable alternative to SERMs for postmenopausal women.

KEY POINTS—cont'd

- Screening mammography is the primary imaging technique for breast cancer detection. The sensitivity of mammography ranges from 80% to 90% and decreases in women with dense breasts.
- The incidence of carcinoma in biopsies corresponds directly with the patient's age. Approximately 20% of breast biopsies in women age 50 are positive, and this figure increases to 33% in women age 70 or older.
- Breast cancer is usually asymptomatic before the development of advanced disease. Breast pain is experienced by only 10% of women with early breast carcinoma. The classic sign of a breast carcinoma is a solitary, solid, three-dimensional, dominant breast mass. The borders of the mass are usually indistinct.
- Microscopic metastatic disease occurs early via both hematogenous and lymphatic routes. For example, 30% to 40% of women without gross adenopathy in the axilla will have positive nodes discovered during histologic examination. With the additional assessment tools of immunohistochemical staining for the presence of cytokeratin and serial sectioning of axillary nodes, 10% to 30% of patients considered to have negative nodes by standard histologic analysis are found to be node positive.
- The initial size of the breast carcinoma is the single best predictor of the likelihood of positive axillary nodes. The presence and number of axillary node metastasis are the best predictors of survival.
- Carcinomas make up the majority of breast malignancies and originate in the epithelium of the collecting ducts (ductal) or the terminal lobular ducts (lobular). Invasive ductal carcinoma is the most common, constituting approximately 70% to 80% of malignancies.
- A multidisciplinary team approach is necessary in the treatment of breast cancer. Determination of local or systemic treatment is based on several prognostic and predictive factors including tumor histology, tumor hormone receptor status (estrogen/progesterone), tumor HER2 status, multigene testing, axillary lymph node status, evaluation of metastatic disease, patient age, comorbidities, and menopausal status.
- The primary therapy for the majority of women with stages I and II breast cancer is conservative surgery, which preserves the breast, followed by radiation therapy.
- Gynecologists should actively address the psychosexual problems that breast cancer causes in women, early in the evaluation of the disease and for several years.

CHAPTER 16: SPONTANEOUS AND RECURRENT ABORTION

KEY POINTS

- About 15% to 20% of all human pregnancies end in a clinically recognized miscarriage, with 80% occurring in the first trimester; the incidence decreases with increasing gestational age.
- If embryonic cardiac activity is seen sonographically at 6 weeks' gestation, then the subsequent abortion rate is about 6% to 8%. If the embryo is viable at 8 weeks, then the subsequent abortion rate is 2% to 3%.
- For a woman with a reproductive history of three pregnancy losses with no live births, her chance of having a miscarriage in a subsequent pregnancy is about 45%; if she has had at least one live birth and three spontaneous abortions, the chance that her next pregnancy will result in a miscarriage is only about 30%.
- The major cause of early pregnancy loss is chromosomal. About 56% of these abnormalities are trisomic, 20% are polyploid, 18% will be chromosome X monosomies, and 4% will represent unbalanced translocations.
- Uterine anomalies can be observed in approximately 12.6% of women with recurrent pregnancy loss. Women with uterine septa have the highest risk of miscarriage.
- Women at risk of cervical insufficiency should be monitored with serial ultrasound examinations from 16 weeks to the end of 24 weeks. If strict criteria are used to diagnose cervical incompetence, fetal survival rates after cerclage have been reported to increase from 20% to 80%.
- Untreated overt hypothyroidism and subclinical hypothyroidism as well as hyperprolactinemia and uncontrolled diabetes are all potential causes of miscarriage.
- The incidence of antiphospholipid syndrome is between 15% and 20% in women with recurrent pregnancy loss. The treatment is both 81 mg of aspirin daily and prophylactic heparin initiated with a positive pregnancy test.
- The prevalence of major chromosomal abnormalities present in either partner of a couple with two or more pregnancy losses is about 3%, five to six times higher than in the general population. Abnormalities occur in the female parent about twice as frequently as in the male, with balanced reciprocal translocations occurring in half of these individuals.
- Studies that have followed women who had medical, surgical, and expectant management of miscarriage have noted no difference in subsequent pregnancy rates.
- Trending B-hCG levels and serial ultrasound examinations should be used to confirm a failed pregnancy. Care should be taken to avoid a single data point to diagnose an early pregnancy loss.
- Approximately 50% of women with recurrent pregnancy loss will not have an identifiable factor to explain their loss. The majority of these women will ultimately achieve a successful pregnancy without any intervention.

CHAPTER 17: ECTOPIC PREGNANCY

KEY POINTS

- The rate of ectopic pregnancy in the United States has remained fairly constant since the early 2000s and is approximately 6.6/1000 pregnancies in women aged 15 to 24.
- The mortality rate has decreased over time and is approximately 0.5 deaths per 1000 per year.
- Risks of ectopic pregnancy include age, pelvic inflammatory disease, prior tubal surgery, smoking, and infertility.
- About 85% of women with an ectopic pregnancy have serum HCG levels lower than in normal pregnancy; the normal HCG doubling time is 1.4 to 3 days in early pregnancy. In 85% of pregnancies, there is a 66% increase every 48 hours; a rise less than 53% in 48 hours is 99% sensitive for an abnormal pregnancy.
- An intrauterine sac should be seen in a normal pregnancy when HCG levels reach 1500 to 2500 mIU/mL. The so-called discriminatory zone is a gestational age over 38 days.
- Progesterone levels below 5 ng/mL indicate an abnormal pregnancy, and levels above 25 ng/mL indicate a normal pregnancy.
- Overall, the subsequent conception rate in women with an ectopic pregnancy is about 60%. A little less than half of these pregnancies terminate in another ectopic pregnancy or spontaneous abortion; so only about one third of women with an ectopic pregnancy have a subsequent live birth.
- In women with one remaining tube, when an unruptured ectopic pregnancy is treated by salpingostomy, the conception rate is 81% with an IUP rate of 56% and a subsequent ectopic gestation rate of 24%.
- Randomized trial data suggest there is no difference in overall subsequent pregnancy outcomes between women who are treated by salpingostomy versus salpingectomy.
- The overall risk of ectopic pregnancy if a pregnancy occurs after tubal sterilization is about 30%, reaching 50% if the sterilization technique was bilateral tubal fulguration.
- The incidence of heterotopic ectopic pregnancy is about 1% of all pregnancies and is more likely to occur after ART or in vitro fertilization.
- Asymptomatic persistent ectopic pregnancy can be treated expectantly or with methotrexate (MTX). Several regimens are in use, and at least one third of women with ectopic pregnancies can be treated medically. The success of MTX depends on the size/age of the gestation and the initial HCG level. The HCG level should fall at least 15% between days 4 and 7 after the methotrexate injection and at least 15% weekly thereafter.

CHAPTER 18: BENIGN GYNECOLOGIC LESIONS

KEY POINTS

- The most common large cyst of the vulva is a cystic dilation of an obstructed Bartholin duct, with a lifetime risk estimated to be 2%. These cysts occur most often during the third decade. Inflamed cysts may be treated with oral antibiotics or incision and drainage.
- The vulva contains 1% of the skin surface of the body, but 5% to 10% of all malignant melanomas in women arise from this region. Melanoma is the second most common malignancy arising in the vulva and accounts for 2% to 3% of all of the melanomas occurring in women.
- Ideally, all vulvar nevi should be excised and examined histologically. Special emphasis should be directed toward the flat junctional nevus and the dysplastic nevus, for they have the greatest potential for malignant transformation. The dysplastic nevus is characterized by being more than 5 mm in diameter, with irregular borders and patches of variegated pigment.
- The management of nonobstetric vulvar hematomas is usually conservative unless the hematoma is greater than 10 cm in diameter or rapidly increasing.
- In adult women, 50% of cases of chronic vulvovaginal pruritus are due to allergic and irritant contact dermatitis. The most common causes of vulvar contact dermatitis are cosmetic and local therapeutic agents. Initial treatment of severe lesions is removal of all irritants or potential allergens and application of topical steroids until the skin returns to normal.
- Women usually develop psoriasis during their teenage years, with approximately 3% of adult women being affected. Approximately 20% of these have involvement of the vulvar skin. The margins of psoriasis are better defined than the common skin conditions in the differential diagnosis, including candidiasis, seborrheic dermatitis, and eczema.
- Psoriasis does not involve the vagina, only the vulva.
- Lichen sclerosus does not involve the vagina, whereas lichen planus may involve the vagina.
- Vulvar pain, vulvodynia, is one of the most common gynecologic problems, reported by up to 16% of women in the general population; 30% of women will have spontaneous relief of their symptoms without any treatment.

KEY POINTS—cont'd

- Classically, the symptoms associated with the urethral diverticulum are extremely chronic in nature and have not resolved with multiple courses of oral antibiotic therapy.
- Cervical stenosis may occur following loop electrocautery excision procedures (LEEPs). The volume of tissue removed and repeat excisional procedures have been reported to increase the risk for cervical stenosis.
- Endocervical polyps are smooth, soft, red, fragile masses. They are found most commonly in multiparous women in their 40s and 50s. After the endocervical polyp is removed, endometrial sampling should be performed to diagnose a coexisting endometrial hyperplasia or carcinoma.
- Endometrial polyps are noted in approximately 10% of women when the uterus is examined at autopsy. Approximately one in four women with abnormal bleeding will have an endometrial polyp.
- Leiomyomas are the most common benign neoplasms of the uterus. The lifetime prevalence of leiomyomas is greater than 80% among African-American women and approaches 70% among white women.
- Cytogenetically, leiomyomas are chromosomally normal and arise from a single cell (they are clonal). All the cells are derived from one progenitor myocyte.
- Abnormal bleeding is experienced by a third of women with myomas, the most common pattern being intermenstrual spotting. Women with myomas and abnormal bleeding should be thoroughly evaluated for concurrent causes of bleeding.
- Adenomyosis is frequently asymptomatic. If multiple serial sections of the uterus are obtained, the incidence may exceed 60% in women 40 to 50 years of age.
- Adenomyosis rarely causes uterine enlargement greater than a size that corresponds to 14 weeks' gestation unless there is concomitant uterine pathology.
- The initial management of a suspected follicular cyst is conservative observation. The majority of follicular cysts disappear spontaneously by either reabsorption of the cyst fluid or silent rupture within 4 to 8 weeks of the initial diagnosis.
- The practice of aspirating cysts laparoscopically should be limited to cysts that are completely simple and associated with normal CA-125 levels. The intraoperative spillage of malignant cystic tumors should be avoided if possible, although the true risk that spillage poses is unknown.
- The differential diagnosis of a woman with acute pain and a suspected ruptured corpus luteum cyst includes ectopic pregnancy, a ruptured endometrioma, and adnexal torsion.
- The treatment of unruptured corpus luteum cysts is conservative. However, if the cyst persists or intraperitoneal bleeding occurs, necessitating operation, the treatment is cystectomy.
- Drainage or fenestration is effective for follicular cysts and poorly effective for cystadenomas. They will tend to recur. When cysts are drained, it is essential to remember that the cytologic examination of cyst fluid has poor predictive value and poor sensitivity in differentiating benign from malignant cysts.
- Theca lutein cysts arise from either prolonged or excessive stimulation of the ovaries by endogenous or exogenous gonadotropins or increased ovarian sensitivity to gonadotropins. The condition of ovarian enlargement secondary to the development of multiple luteinized follicular cysts is termed *hyperreactio luteinalis*. Approximately 50% of molar pregnancies and 10% of choriocarcinomas have associated bilateral theca lutein cysts.
- Benign ovarian teratomas vary from a few millimeters to 25 cm, may be single or multiple, and are bilateral 10% to 15% of the time. Dermoids are believed to arise during fetal life from a single germ cell. They are 46,XX in karyotype.
- Operative treatment of benign cystic teratomas is via cystectomy with preservation of as much normal ovarian tissue as possible.
- Fifty percent of patients with an ovarian fibroma will have ascites if the tumor is greater than 6 cm. The incidence of associated ascites is directly proportional to the size of the tumor.
- Transitional cell tumors (Brenner tumors) are small, smooth, solid, fibroepithelial tumors of the ovary. They usually occur in women between the ages of 40 and 60 and are predominantly unilateral.
- Adnexal torsion occurs most commonly in the reproductive years, with the average age of patients being in the mid-20s. Pregnancy predisposes to adnexal torsion.
- Ovarian tumors are discovered in 50% to 60% of women with adnexal torsion.
- Abnormal color Doppler flow is highly predictive of torsion of the ovary. However, approximately 50% of women with surgically confirmed adnexal torsion will have a normal Doppler flow study.
- Conservative surgery, either through the laparoscope or via laparotomy, entails gentle untwisting of the pedicle, possibly cystectomy, and stabilization of the ovary with sutures. De-torsion and fixation of the ovary is a safe procedure that reduces the risk of recurrence.
- The risk of pulmonary embolus with adnexal torsion is approximately 0.2%. The risk is similar regardless of whether the condition is managed by conservative surgery with untwisting or adnexal removal without untwisting.

CHAPTER 19: ENDOMETRIOSIS

KEY POINTS

- Endometriosis is a benign, usually progressive, and sometimes recurrent disease that invades locally and disseminates widely.
- Possible causal factors of endometriosis include retrograde menstruation, coelomic metaplasia, vascular metastasis, immunologic changes, iatrogenic dissemination, and a genetic predisposition.
- Endometriosis lesions produce estrogen locally and have increased secretion of prostaglandins and inflammatory cytokines, which can cause pain and contribute to infertility. There is also a relative resistance to progesterone in endometriosis lesions.
- Grossly, endometriosis appears in many forms, including red, brown, black, white, yellow, pink, or clear vesicles and lesions. Red, blood-filled lesions are in the most active phase of endometriosis.
- Approximately 10% of teenagers who develop endometriosis have associated congenital outflow obstruction.
- The two primary short-term goals in treating endometriosis are the relief of pain and the promotion of fertility. The primary long-term goal in the management of a woman with endometriosis is attempting to prevent progression or recurrence of the disease process.
- There are several established treatments for endometriosis (such as oral contraceptives and GnRH agonists and danazol) and some novel therapies undergoing trials such as the use of oral antagonists, aromatase inhibitors, progesterone receptor modulators, and cytokine inhibitors.
- The recurrence rate following medical therapy is 5% to 15% in the first year and increases to 40% to 50% in 5 years.
- The side effects associated with GnRH agonist therapy are primarily those associated with estrogen deprivation, similar to menopause. The three most common symptoms are hot flushes, vaginal dryness, and insomnia. A decrease in bone mineral content of trabecular bone has been demonstrated in the cortical bone on the lumbar spine by quantitative computed tomography.
- Many clinicians “add back” very low doses of estrogen, low doses of progestins, or both in combination with chronic GnRH agonist therapy.
- The incidence of endometriosis is 30% to 45% in women with infertility. There is probably some benefit to abrading endometriosis lesions when seen at laparoscopy. In patients with endometriosis, the success of IVF-ET decreases only in women with severe disease.
- Classic symptoms of endometriosis of the large bowel include cyclic pelvic cramping and lower abdominal pain and rectal pain with defecation, especially during the menstrual period.
- Endometriosis of the bladder is discovered most often in the region of the trigone or the anterior wall of the bladder. Bladder endometriosis produces midline, lower abdominal, and suprapubic pain, dysuria, and, occasionally, cyclic hematuria.

CHAPTER 20: ANATOMIC DEFECTS OF THE ABDOMINAL WALL AND PELVIC FLOOR

KEY POINTS

- In the female, large hernias, hernias that continuously have intraabdominal contents, hernias that cause continuing discomfort, and hernias that have been incarcerated should be operatively repaired.
- Pelvic organ prolapse is defined as the descent of one or more compartments of the vagina: the anterior vaginal wall, posterior vaginal wall, uterus (cervix), or apex (vaginal vault or cuff scar after hysterectomy).
- Pelvic organ prolapse is more likely to be symptomatic when the leading edge protrudes past the hymen; it can be managed expectantly if asymptomatic.
- Renal function should be evaluated in women with advanced pelvic organ prolapse if the patient declines treatment to reduce the prolapse.
- Vaginal delivery is a major risk factor for the development of pelvic organ prolapse.
- The cardinal and uterosacral ligaments hold the uterus and upper vagina in the proper location.
- Pessaries should be offered to all women with symptomatic pelvic organ prolapse.
- Pelvic organ prolapse often includes a mixture of anterior, posterior, and apical prolapse, and each compartment should be evaluated under strain prior to determining the appropriate operative treatment.
- Surgery for pelvic organ prolapse is usually effective at decreasing a vaginal bulge, but the effects on urinary, bowel, and sexual function can vary. It is important to elicit a patient's goals before surgery.
- Vaginal vault prolapse can be repaired abdominally or vaginally. An abdominal sacral colpopexy with synthetic mesh appears to have a higher long-term success rate for the vaginal apex, but at the risk of more surgical complications.

CHAPTER 21: UROGYNECOLOGY

KEY POINTS

- As many as 30% of all women may suffer from some degree of urinary incontinence during their lifetime.
- Continence is determined by the balance between forces that maintain urethral closure and those that affect detrusor function. Parasympathetic nervous system activity via the neurotransmitter acetylcholine stimulates receptors in the bladder wall to activate detrusor contraction. Sympathetic nervous system activation leads to bladder relaxation.
- The highest pressure zone in the urethra is approximately midpoint in the functional urethra, which is roughly 0.5 cm proximal to the urogenital diaphragm.
- Approximately 50% of all women will develop urinary infections at some point in their lifetime and, by age 70 years, as many as 10% of women will have recurrent UTIs.
- Painful bladder syndrome–interstitial cystitis is a painful, chronic bladder condition that is not related to infection and is associated with symptoms of bladder and pelvic pain, urinary frequency, urgency, or nocturia, and often dyspareunia.
- The midurethral synthetic tape slings (retropubic and transobturator midurethral) appear to have similar efficacy for the surgical treatment of stress incontinence, with a shorter surgery and recovery time than a Burch colposuspension.
- Retropubic and transobturator midurethral slings have similar success rates for stress incontinence, although with different risk profiles. The retropubic approach has a significantly higher risk of bladder perforation, bleeding, and voiding dysfunction, and the obturator approach has a higher risk of groin and leg pain.
- Approximately 20% of women with urinary incontinence suffer from detrusor overactivity. Behavioral changes and oral medications are first-line treatments, although often they have disappointing cure rates. Neuromodulation and surgical procedures are available and effective for refractory symptoms.
- Being obese or overweight increases the risk of urinary incontinence, and weight loss can reduce stress incontinence significantly.

CHAPTER 22: ANAL INCONTINENCE

KEY POINTS

- Estimates of fecal incontinence range from 11% to 15% of community-dwelling women older than 64 years.
- Over 30% of women reporting urinary incontinence also report fecal incontinence, known as *dual incontinence*.
- The IAS, under autonomic control, maintains the high-pressure zone or continence zone and, along with the EAS, keeps the anal canal closed.
- The EAS provides the voluntary squeeze pressure that prevents incontinence with increasing rectal or abdominal pressure. The EAS is innervated by the hemorrhoidal branch of the pudendal nerve from the S2-S4 nerve roots.
- A common cause of fecal incontinence is damage to the anal sphincter at the time of vaginal delivery, with or without neuronal injury. Prevention of these injuries is critical.
- The incidence of occult external anal sphincter disruption after vaginal delivery determined by endoanal ultrasound ranges from 11% to 35%. The chance of muscular injury is increased with midline episiotomy, instrumented delivery, and vaginal delivery of larger infants.
- Approximately 1 in 10 women will develop some fecal incontinence or fecal urgency after one vaginal delivery.
- At a tertiary colorectal referral clinic, a prospective study showed that further evaluation, including radiologic and physiologic tests, altered the final diagnosis or the cause of fecal incontinence in 19% of cases.
- Biofeedback for patients with fecal incontinence shows a similar reduction in incontinence episodes after intense education with a nurse specialist on the subjects of bowel care, medications, and dietary and fluid management. This highlights the importance of conservative management techniques.
- Overlapping anterior anal sphincteroplasty provides symptomatic control of incontinence in 60% to 80% of patients initially, but long-term outcomes are not nearly as successful.

CHAPTER 23: INFECTIONS OF THE LOWER AND UPPER GENITAL TRACTS

KEY POINTS

- The CDC regularly revises its treatment protocols for STIs. This information may be accessed online at www.cdc.gov/publications.
- Pediculosis pubis, an infestation by the crab louse *Phthirus pubis*, is characterized by constant itching, predominantly vulvar involvement, and the finding of eggs and lice by visual inspection. It may be treated by topical application of 1% permethrin cream rinse (Nix) or 1% lindane shampoo (Kwell).
- Scabies, an infection by the itch mite *Sarcoptes scabiei*, is characterized by intermittent pruritus, most commonly in the hands, wrists, breasts, vulva, and buttocks. It may be treated by a topical application of 5% permethrin cream (Nix) or 1% lindane lotion or 30 g of cream.
- Genital herpes is a recurrent incurable STI. Approximately 80% of individuals are unaware that they are infected. It is usually transmitted by individuals who are asymptomatic and unaware that they have the infection at the time of transmission.
- Nonspecific tests for syphilis, the VDRL and RPR, have a 1% false-positive rate. Therefore specific tests such as the *Treponema pallidum* immobilization (TPI), FTA-ABS, and MHA-TP must be used when a positive nonspecific test result is encountered.
- In women in the reproductive age range, bacterial vaginosis represents approximately 50% of vaginitis cases and candidiasis and *Trichomonas* infection represent approximately 25% each. HIV acquisition is increased in women with bacterial vaginosis and *T. vaginalis* infection.
- *T. vaginalis* infection is a highly contagious STI. It is the most prevalent nonviral, nonchlamydial STI of women. An asymptomatic female who has *Trichomonas* identified in the lower female genital urinary tract should definitely be treated.
- Symptoms that suggest cervical infection include vaginal discharge, deep dyspareunia, and postcoital bleeding. Most women who have lower reproductive tract infections caused by *C. trachomatis* or *N. gonorrhoeae* do not have mucopurulent cervicitis. The corollary is that most women who have mucopurulent cervicitis are not infected by *C. trachomatis* or *N. gonorrhoeae*.
- Acute PID is usually caused by a polymicrobial infection of organisms ascending from the vagina and cervix, traveling along the mucosa of the endometrium to infect the mucosa of the oviduct. It should be diagnosed with a minimum of suspicion with the knowledge that overtreatment is preferable to missed diagnosis.
- Approximately one in four women with acute PID experiences further medical sequelae, including recurrent acute PID, ectopic pregnancy, and chronic pelvic pain.

CHAPTER 24: PREOPERATIVE COUNSELING AND MANAGEMENT

KEY POINTS

- Optimal preparation for an operation facilitates a successful result and protects the patient and physician.
- The most significant risk factors for postoperative morbidity are preoperative conditions. They may affect the operation, anesthesia, and postoperative course and may preclude the procedure altogether.
- Approximately 0.5% of the general population and 1.5% of women older than 55 years are receiving continuous glucocorticoids.
- Latex allergy is directly responsible for 12% of the perioperative anaphylactic reactions in adult women and for 70% in children. Health care workers, women with spinal cord injuries, or those who have had to perform self-catheterization are at higher risk for latex allergy.
- The preoperative physical examination should answer three basic questions:
 - Has the primary gynecologic disease process changed since the initial diagnosis?
 - What is the effect of the primary gynecologic disease on other organ systems?
 - What deficiencies in other organ systems may affect the proposed surgery and hospitalization?
- An exam while the patient is under anesthesia may provide additional information, help avoid intraoperative surprises, and affect the surgical plan.
- It is estimated that 60% of routinely ordered tests would not have been performed if tests had been ordered only for an indication discovered by history or physical examination.
- The American Society of Anesthesiologists (ASA) Practice Advisory for Preanesthesia Evaluation states that routine preoperative tests, defined as a test ordered in the absence of a clinical indication or purpose, should not be ordered.
- A preoperative complete blood count and blood type and antibody screen should be performed prior to most gynecologic surgeries.
- Other individualized preoperative laboratory testing should be determined based on the age of the woman, extent of the surgical procedure, and findings at the time of complete history and physical examination.

KEY POINTS—cont'd

- Determining the preoperative creatinine or blood urea nitrogen (BUN) level is especially important if the woman is going to be treated with antibiotics excreted by the kidneys.
- A pregnancy test may be appropriate, depending on contraceptive and sexual history, but it should almost always be performed if the patient is a teenager, as menstrual history is at best an imperfect indication of an early pregnancy.
- Serum electrolyte levels are ordered for women taking diuretics or those with a history of renal disease or heart disease. Also, serum electrolyte levels should be evaluated in women with vomiting, diarrhea, ileus, bowel obstruction, or any condition that affects electrolyte balance.
- Routine chest x-rays on all patients often do not impact perioperative management in elective gynecologic surgery, but they should be ordered for women who are 20-pack/year smokers, women with cardiac or pulmonary symptoms, immigrants who have not had a recent chest film, and women older than 70 years.
- A baseline preoperative ECG has been found to be cost effective in asymptomatic women ≥ 60 years without a history of cardiac disease or significant risk factors.
- In the present medicolegal climate, the absence of informed consent is cited as a major problem in many lawsuits.
- Preoperative orders should be standardized to avoid omissions, and electronic order sets are standard at most institutions.
- If an enhanced recovery pathway is being utilized, the patient can usually eat solid food up until midnight and clear liquids until 30 minutes prior to presenting to the hospital.
- To avoid hypoglycemia, most enhanced recovery after surgery protocols allow patients to eat solid food up to 6 hours before surgery.
- Anesthesiologists classify surgical procedures according to the patient's risk of mortality using the ASA risk class stratification (classes 1-5).
- An emergency operation doubles the mortality risks for ASA classes 1, 2, and 3; produces a slightly increased risk in class 4; and does not change the risk in class 5.
- Enhanced recovery refers to a bundled process with the aim of attenuating pathophysiologic changes and the stress response occurring with surgery. These processes replace traditional but untested practices of perioperative care with the primary goal of hastening recovery.
- Adoption of enhanced recovery has resulted in an average reduction in length of stay of 2.5 days and a decrease in complications by as much as 50%.
- Enhanced recovery achieved the greatest benefit in patients undergoing complex cytoreduction for ovarian cancer, of whom 57% underwent colonic or small bowel resection.
- The popularity of TEA following major open gynecologic surgery is due to its effectiveness in controlling pain and the quicker return of bowel function seen in patients with epidural anesthetics.
- The role of TEA in an ERAS care plan is less clear, as it can compete at times with some of the ERAS goals and its use. TEA has been associated with more interventions to treat hypotension, longer length of hospital stay, and more complications in one series of early stage endometrial cancer patients.
- An SSI is one of the most common complications after surgery. SSIs dissatisfy patients and providers, but they also increase the cost of surgical care, increase morbidity, and can increase mortality.
- SSIs are categorized into three classifications by the CDC and the ACS NSQIP: (1) superficial incisional, (2) deep incisional, and (3) organ/space.
- Elements shown to decrease SSI that are often included in reduction bundles include preoperative nicotine cessation, preoperative antiseptic showering and chlorhexidine preparation, using hair clippers instead of a razor, appropriate preoperative antibiotic selection, normothermia, and glycemic control.
- There is abundant literature supporting the use of prophylactic antibiotics in gynecology. The incidence of febrile morbidity may be reduced from 40% to 15% and the incidence of pelvic infection decreased from 25% to 5%.
- The current guidelines for antimicrobial prophylaxis for vaginal or abdominal hysterectomy include the first- or second-generation cephalosporins of cefazolin, cefotetan, cefoxitin, or ampicillin-sulbactam.
- Among women with a β -lactam allergy, the recommended combinations are (1) clindamycin or vancomycin plus an aminoglycoside, or (2) aztreonam, or (3) a fluoroquinolone, metronidazole, and aminoglycoside, or (4) a fluoroquinolone alone.
- Comparative studies have documented that single-dose therapy is as effective as 24 hours of antibiotics. No advantage exists to continuing prophylactic antibiotics beyond the immediate operative period.
- Vaginal surgery continues to carry the lowest risks of SSI and should remain the preferred surgical approach when feasible. However, when minimally invasive approaches to hysterectomy replace laparotomy, the risk of SSI can be reduced by up to 16-fold.
- Multiple studies have documented a two- to threefold increase in the SSI rate directly related to perioperative shaving; if the hair is mechanically in the way, it should be clipped just before the operation.
- The use of chlorhexidine gluconate with 70% isopropyl alcohol as a skin preparation demonstrated a 40% reduction in SSIs in clean contaminated (type II) wound types compared with a 10% povidone-iodine solution.
- The risk of an SSI is significantly increased in the setting of smoking, and patients should be encouraged to stop as patients in a smoking cessation program had perioperative complication rates of 21% versus 41% in controls.
- Hypothermia has been shown to increase the incidence of wound infections, postoperative myocardial events, and perioperative blood loss; impair drug metabolism; and prolong postoperative recovery. Preventing intraoperative hypothermia improves surgical outcomes.

Continued

KEY POINTS—cont'd

- Glucose levels >180 mg/dL among diabetics and nondiabetics increase the risk of SSI by twofold. Perioperative blood glucose levels should be maintained at <200 mg/dL for all patients.
- Category 1A evidence has demonstrated that strict glucose control (80 to 130 mg/dL) in both diabetics and nondiabetics does not improve SSI rates over glucose levels <200 mg/dL. Strict control may have detrimental effects on postoperative outcomes.
- Approximately 25% of all SSIs are caused by *Staphylococcus aureus*.
- Approximately 40% of deaths following gynecologic surgery are related to pulmonary emboli. Although the initial venous injury most often occurs at the time of the operation, approximately 15% of symptomatic emboli do not present until the first week following discharge from the hospital.
- Using the “Caprini score,” women in the very low risk group have less than a 3% risk of VTE, women in the moderate group have a 10% to 30% risk, and women in the high risk groups have a more than 30% risk of a VTE.
- LMWH is superior to standard unfractionated heparin because it has a longer half-life, almost 100% bioavailability, dose-independent clearance, and a more consistent anticoagulation effect from dose to dose.
- A meta-analysis of studies evaluating high-risk procedures found perioperative and postoperative LMWH administration to be equally effective.
- In general, warfarin should be held for at least 5 days prior to surgery and the INR should be <1.5 prior to incision.
- Therapeutic dose aspirin should be held for 7 days prior to surgery. Once-daily dosing of baby aspirin (81 mg/day) can usually be continued.
- Factor Xa inhibitors should be held for 2-3 days before surgery, depending on the individual drug's half-life.
- Direct thrombin inhibitors should be held for 2-4 days prior to surgery, depending on renal function.
- Patients with bleeding disorders usually present early in their lives with bleeding. It is estimated that approximately 1% to 2% of patients in the United States have some type of bleeding diathesis, the most common of which is von Willebrand disease.
- Steroid use for longer than a 2-week period within the year prior to surgery necessitates augmented steroid administration during the perioperative period.
- Pulmonary function tests of lung volumes and flow rates are only indicated to evaluate women with a history or physical findings suggestive of restrictive or obstructive pulmonary disease.
- Predisposing factors that increase the incidence of atelectasis include morbid obesity, smoking, pulmonary disease, and advanced age. Increased pain, the supine position, abdominal distention, impaired function of the diaphragm, and sedation also contribute to decreased lung volumes and reduced dynamic measurements of pulmonary function postoperatively.
- The excessive mortality rate associated with a noncardiac operative procedure within 3 months of an acute myocardial infarct is 27% to 37%. Following a 6-month interval, the chance of a reinfarction is 4% to 6% with elective operations.
- The routine use of beta-blockers perioperatively to reduce the risk of nonfatal myocardial infarction is no longer practiced due to the increased risk of death, nonfatal stroke, hypotension, and bradycardia. As a result, the common practice of perioperative beta-blockade has given way to its selective use.
- The administration of prophylactic antibiotics solely to prevent endocarditis is no longer recommended for patients who undergo GU or GI tract procedures.

CHAPTER 25: PERIOPERATIVE MANAGEMENT OF COMPLICATIONS

KEY POINTS

- Postoperative febrile morbidity is related to infection in approximately 20% of cases and noninfectious causes in 80% of cases.
- Infection in older adults will not always present with classic findings. The amount of temperature elevation may not reflect the severity of the infection. Not uncommonly, the first signs of infection in older adults will be mental status changes. Also, the degree of leukocytosis may not reflect infection, being blunted or absent.
- Minimum urine output should be 0.5 mL/kg/hr. The use of a 20-mL/hr benchmark for all women is only an approximation and should be adjusted for the patient's weight.
- Because of the shifts in water balance, the postoperative hemoglobin at 72 hours is a more accurate measurement of operative and postoperative blood loss than a hemoglobin at 24 hours.
- After subtracting the effects of the operative blood loss from the preoperative hemoglobin, a further reduction in hemoglobin of 1 to 2 points reflects a postoperative hemorrhage of approximately 500 mL.
- Women should be transfused when their hemoglobin falls below 7, or sooner if they are symptomatic or have significant cardiac or pulmonary comorbidities.

KEY POINTS—cont'd

- Microatelectasis is a common occurrence developing during almost all pelvic surgeries and is persistent 24 hours postoperatively in approximately 50% of women. Current studies have demonstrated that there is no association between fever and the amount of atelectasis diagnosed radiologically.
- Radiographic diagnoses are approximately 60% accurate for bacterial or viral pneumonia in women with laboratory-proved pneumonia.
- Rapid loss of 20% of a woman's blood volume produces mild shock, whereas a loss of greater than 40% of blood volume results in severe shock.
- From 15% to 45% of surgical blood loss is absorbed onto drapes, pads, and other areas. Thus blood levels in the suction bottle are inaccurate markers of total operative blood loss.
- Massive blood loss has been defined as hemorrhage that results in replacement of 50% of circulating blood volume in less than 3 hours.
- Returning a patient to the operating room to control hemorrhage is often a difficult decision. However, when indicated this decision should not be postponed, and the patient should have an exploratory operation as soon as possible after volume replacement.
- The extent of wound or pelvic hematomas is determined by the potential size of the compartment into which the bleeding occurs. Retroperitoneal or broad ligament hematomas may contain several units of blood.
- Superficial phlebitis is the leading cause of an enigmatic postoperative fever during the third, fourth, or fifth postoperative day.
- The clinical management of mild superficial thrombophlebitis includes rest, elevation, and local heat. Moderate to severe superficial thrombophlebitis may be treated with nonsteroidal antiinflammatory agents.
- Venous thrombosis and PE are the direct causes of approximately 40% of deaths in gynecologic cases once the diagnosis is confirmed.
- Signs and symptoms of pulmonary emboli are nonspecific; however, the most common symptoms are chest pain, dyspnea, apprehension, tachypnea, rales, and an increase in the second heart sound over the pulmonic area.
- Intermittent in-and-out catheterization is preferable to continuous drainage with a Foley catheter for women with intermediate-term voiding dysfunction.
- Although symptoms of urinary incontinence may present within a few hours of the operative procedure, most fistulas usually present 8 to 12 days after operation, and occasionally as late as 25 to 30 days after the operation.
- If there is a suspicion that trauma to the bladder has occurred during an operative procedure, continuous catheter drainage for 3 to 5 days usually results in spontaneous healing.
- Approximately 25% of adult women experience postoperative nausea and vomiting.
- Normal return of bowel function after abdominal surgery can take 3 to 7 days. The left colon takes the longest to resume function, approximately 72 hours after surgery. If an ileus lasts for longer than 5 to 7 days, a diagnosis of mechanical bowel obstruction or another cause for the ileus should be considered.
- Postoperative oral feeding is safe and efficacious. This practice is preferred as it facilitates recovery and shortens hospital stay.
- The difference between small bowel obstruction and adynamic ileus is subtle, because adynamic ileus can be associated with partial obstruction of the small intestine. The use of Gastrografin contrast can be both diagnostic and therapeutic.
- Second- and third-generation cephalosporins are the antibiotics associated with the highest risk of developing *C. difficile* diarrhea.
- The incidence of postoperative wound infection is increased eightfold when the woman's preoperative weight exceeds 200 pounds. The thickness of subcutaneous tissue is the greatest risk factor for wound infection in women undergoing abdominal hysterectomy.
- Necrotizing fasciitis involves the subcutaneous tissue and superficial fascia. It rapidly expands in the subcutaneous spaces. This condition is a surgical emergency and patients should have operative débridement as soon as possible.
- The incidence of wound dehiscence is approximately 1 in 200 gynecologic operations. Wound infection is found in approximately 50% of women with wound disruption.
- The classic feature of an impending wound disruption is the spontaneous passage of copious serosanguineous fluid from the abdominal incision.
- Most postoperative pelvic infections are polymicrobial, usually from endogenous vaginal flora, and approximately 60% to 80% involve anaerobic organisms.
- Common causes of femoral neuropathy are continuous pressure from self-retaining retractors or exaggerated hip flexion or abduction in the dorsal lithotomy position in thin women.
- Discharge instructions should be given in verbal and written forms, and the gynecologist should anticipate the most common questions.

CHAPTER 26: ABNORMAL UTERINE BLEEDING

KEY POINTS

- The mean amount of menstrual blood loss in one cycle in normal women was previously reported to be approximately 35 mL but may be as much as 60 mL, with an average loss of 13 mg of iron.
- Heavy menstrual bleeding occurs in 9% to 14% of healthy women, and most have a normal duration of menses.
- A systematic and standardized nomenclature exists for the characterization of abnormal uterine bleeding.
- Pregnancy should always be ruled out in women presenting with AUB.
- Diagnostic tests in women with menorrhagia include measurement of hemoglobin, serum iron, serum ferritin, β -hCG, TSH, and PRL levels, endometrial biopsy and hysteroscopy, sonohysterography, and hysterosalpingography. MRI may be helpful in the diagnosis of adenomyosis or surgical planning for leiomyoma but is not part of the initial evaluation.
- High doses of oral or IV estrogen will usually stop acute bleeding episodes in most cases of abnormal bleeding. An alternative regimen is high-dose oral progestogen for a week, with tapering of the dosage thereafter.
- Patients who are being treated for abnormal uterine bleeding due to endometrial causes (and who are ovulatory) may be given oral contraceptives, NSAIDs (antiprostaglandins), antifibrinolytics or a prolonged course of progestogens, or levo-norgestrel released locally from an IUS. Those treated with the LNG-IUS have similar outcomes at 1 year to those treated by surgery.
- NSAIDs administered during menses reduce MBL by 20% to 50% in women with ovulatory DUB.
- LNG-IUS is the first-line therapy for heavy menstrual bleeding due to anticoagulation or inherited bleeding disorders.
- D&C should be used to stop the acute bleeding episode in patients with hypovolemia or those older than 45 years. D&C only treats the acute episode of excess uterine bleeding, not subsequent episodes.
- Various endometrial ablation techniques achieve a 22% to 55% amenorrhea success rate at 1 year but an 86% to 99% satisfaction rate with regard to normalizing menstruation.
- Within 4 years after endometrial ablation, approximately 25% of women treated will have a hysterectomy.
- Abnormal uterine bleeding has become the leading cause for hysterectomy in the United States.

CHAPTER 27: PRINCIPLES OF RADIATION THERAPY AND CHEMOTHERAPY IN GYNECOLOGIC CANCER

KEY POINTS

- Electromagnetic radiation is a form of energy that has no mass or charge and travels at the speed of light.
- The inverse square law states that the energy measured from a radiation source is inversely proportional to the square of the distance from the radiation source.
- Each delivered radiation dose kills a constant fraction of tumor cells irradiated. Oxygen can render radiation-induced DNA damage permanent.
- The effect of photon radiation (low LET) on tissues is altered by tissue oxygenation, whereas neutron radiation (high LET) is independent of oxygenation.
- The cell replication cycle consists of M (mitosis), G1 (Gap1 = RNA and protein synthesis), S (DNA synthesis), and G2 (Gap2 = RNA and protein synthesis). When the cell is not in the replication cycle, it is in the G0 phase.
- The dose of radiation delivered to a tumor depends on the energy of the source, the size of the treatment field, and the depth of the tumor beneath the surface. Increasing the dose increases the depth of maximum dose beneath the skin surface.
- Radiation acts on cells primarily in the M phase, making rapidly proliferating cells the most radiosensitive.
- Normal tissues repair the radiobiologic effects of radiation more effectively than tumor tissue.
- Radiation side effects usually involve erythema of the skin, without desquamation and mild fatigue.
- Uncommon side effects include lowering of the circulating blood cells, dysuria and urinary frequency, diarrhea, bowel injury, and fistula formation.
- Cytotoxic chemotherapeutic agents act on various phases of the cell cycle, primarily affecting rapidly proliferating cells, and at a given dose destroy a constant fraction of tumor cells.
- Growth factors or G-CSF are used to limit the hematologic toxicity of chemotherapy.
- After the completion of the staging and primary surgical treatment, the current standard of care is six cycles of a taxane-platinum-containing chemotherapy regimen.
- If recurrence is less than 6 months after completion of chemotherapy, the tumor is defined to be platinum or taxane resistant.
- The antitumor activity of second-line chemotherapy regimens is similar; the choice of treatment for recurrent disease depends on residual toxicities, physician preference, and patient convenience. Participation in a clinical trial is also a reasonable option for these patients.

CHAPTER 28: INTRAEPITHELIAL NEOPLASIA OF THE LOWER GENITAL TRACT (CERVIX, VAGINA, VULVA)

KEY POINTS

- HPV infection is the cause of virtually all cases of cervical cancer.
- Almost all HPV infections regress spontaneously, but if the infection persists, dysplasia and cancer may develop.
- Smoking increases the likelihood that an HPV infection will persist or progress.
- Vaccines are available that prevent HPV infection and the development of dysplasia and cancer.
- When Pap testing is used widely, it decreases the incidence of cervical cancer by approximately 70%.
- The Bethesda System (TBS) terminology is used for the reporting of cervical cytology specimens.
- The colposcope is used to evaluate women with abnormal Pap tests.
- In some cases, an HPV infection can lead to a precancer of the cervix, called *CIN*. *CIN* is graded as 1, 2, or 3, depending on the depth of the epithelial thickness involved.
- *CIN* 1 should be observed rather than treated because it usually regresses spontaneously.
- *CIN* 2/3 can be treated by ablation with cryotherapy or excision with LEEP or cold knife conization.

CHAPTER 29: MALIGNANT DISEASES OF THE CERVIX

KEY POINTS

- Carcinomas of the cervix are predominantly squamous cell carcinomas (85% to 90%), and approximately 10% to 15% are adenocarcinomas.
- Squamous cell carcinomas appear to have a viral and venereal association, particularly with HPV. In the United States, squamous cell carcinoma is more frequent in blacks than in whites.
- Cervical carcinoma is the third most frequent malignancy of the lower female genital tract, after endometrial and ovarian cancer, and the second most frequent cause of death, after ovarian cancer.
- Definitive diagnosis of microinvasive carcinoma is established only by means of cervical conization, not biopsy. The margins of the cone should be free of neoplastic epithelium before conservative therapy is undertaken.
- Microinvasive carcinoma of the cervix can be effectively treated by total hysterectomy, with a 5-year survival rate of almost 100%, but recurrent neoplasia can develop after 5 years. However, a precise and reliable definition of microinvasion is controversial.
- Prognosis in squamous cell cancer of the cervix is related to tumor stage and lesion volume (size), depth of invasion, and spread to lymph nodes.
- The prognosis of adenocarcinoma of the cervix is related to tumor stage, size, grade, and depth of invasion. Large adenocarcinomas tend to be poorly differentiated.
- Metastases to regional pelvic nodes in stage I squamous carcinomas correlate with lesion size, depth of invasion, and the presence of capillary lymphatic space involvement, and correlate inversely with patient age.
- Cervical carcinomas are locally invasive tumors that spread primarily to the pelvic tissues and then to the pelvic and paraaortic lymph nodes. Less frequently, hematogenous spread to the liver, lung, and bone occurs.
- The risk of the spread of cervical carcinoma to pelvic nodes is approximately 15% for stage I, 29% for stage II, and 47% for stage III. For the paraaortic nodes, the figures are 6% for stage I, 19% for stage II, and 33% for stage III.
- Stage IB carcinomas of the cervix may be treated equally effectively by radical hysterectomy and pelvic node dissection or radiation. The 5-year survival rate is approximately 80%. If lymph nodes are free of tumor, the 5-year survival rate is approximately 90%; if the nodes contain metastatic tumor, the rate is 50%. Improved overall survival rates have been reported for patients with tumors smaller than 4 cm in diameter treated by preliminary brachytherapy followed by radical hysterectomy.
- Surgery is often used for treating stage IB and early stage IIA carcinomas of the cervix, particularly for smaller tumors and for younger patients to preserve their ovarian function. Surgery produces less scarring and vaginal fibrosis than radiation and is preferred for women with a pelvic mass, pelvic infection, or history of conditions such as inflammatory bowel disease, which increase the risk for radiation complications.
- High-stage tumors are treated by chemoradiation. Current programs usually use cisplatin, 40 mg/m² weekly, during external treatment and with brachytherapy.
- Most cancers of the cervix are treated by radiation therapy (teletherapy and brachytherapy). Radiation doses vary with tumor size and stage but are approximately 50 to 65 Gy at point B and 80 to 85 Gy at point A. Current practice is to combine radiation with simultaneous chemotherapy to optimize the results.
- Improved cure rates of cervical cancers are obtained with increased doses, which also lead to an increased frequency of complications. Large increments in dose may increase complications without increasing cure rates.

Continued

KEY POINTS—cont'd

- Complications following radiation are related to dose and volume of tissue treated; these include radiation inflammation of the bladder or bowel, which may lead to pain, bleeding, or, infrequently, fistula formation. The normal cervix is resistant to radiation, and the dose can be as high as 200 to 250 Gy over 2 months. The rectum should be limited to doses of 70 Gy or less and the bladder to doses of 80 Gy or less. Overall, the rate of moderate to severe radiation complications for treatment of all stages is approximately 10%.
- Worldwide 5-year survival rates reported for patients with carcinomas of the cervix are as follows: stage IA, 95%; stage IB, 80%; stage II, 70%; stage III, 50%; and stage IV, 20% with radiation therapy alone.
- Pregnancy does not adversely affect the survival rate for women with carcinoma of the cervix, stage for stage.
- Approximately one third of patients treated for cervical carcinoma develop tumor recurrence, and approximately 50% of these recurrences are located in the pelvis; most occur within 2 years.
- Patients whose recurrences occur more than 3 years after primary therapy have a better prognosis than those with earlier recurrence.
- Pelvic exenteration in carefully selected patients with central pelvic recurrence can lead to a 5-year survival rate of 50% or better.
- Chemotherapy of recurrent squamous cell carcinoma of the cervix does not produce long-term cures, but recent results suggest that cisplatin-paclitaxel-bevacizumab should be considered the standard treatment for patients with stage IVB recurrent or metastatic cervix cancer.
- Leg pain following the distribution of the sciatic nerve or unilateral leg swelling is often an indication of pelvic recurrence of carcinoma of the cervix.

CHAPTER 30: NEOPLASTIC DISEASES OF THE VULVA

KEY POINTS

- Squamous cell carcinomas constitute 90% of primary vulvar malignancies. More than 80% of patients are older than 50 years at the time of diagnosis.
- Cancer of the vulva accounts for approximately 4% of malignancies of the lower female genital tract and occurs less frequently than uterine, ovarian, and cervical cancers.
- Paget disease generally occurs in postmenopausal women and is usually treated by wide excision. Invasive carcinomas at other sites should be ruled out.
- Prolonged use of fluorinated corticosteroids to treat itching accompanying vulvar dystrophy can lead to vulvar contraction.
- Topical testosterone is sometimes beneficial to treat lichen sclerosus but is absorbed systemically and occasionally can produce masculinizing symptoms.
- Studies have indicated that symptomatic lichen sclerosus is a premalignant condition preceding carcinoma by a mean of 4 years. The tumors that develop tend to be clitoral in location and identified in patients older than age 40 years.
- HPV vulvar infection is common. Intraepithelial neoplasia occurs much less frequently.
- HPV-positive tumors tend to occur in younger patients, and these tumors tend to have a better prognosis than HPV-negative tumors.
- A clear progression of dysplasia–carcinoma in situ (VIN I, II, and III) to invasive carcinoma in the vulva has not been clearly established. VIN may spontaneously regress. VIN III has an approximately 3.4% risk of progression to invasive carcinoma.
- Intraepithelial neoplasia of the vulva is usually treated by local excision. Laser therapy of the atypical area may be used for younger patients who do not have raised lesions.
- Vulvar carcinomas less than 2 cm in diameter and depth of invasion less than 1 mm (3-mm thickness) rarely metastasize to regional nodes.
- Unilateral vulvar tumors (>2 cm from midline) usually metastasize to ipsilateral inguinofemoral nodes only.
- Prognosis in vulvar cancer is primarily related to lesion size, lymph node status, and stage.
- The risk of lymph node groin metastases is related to tumor differentiation, lesion thickness, lymphovascular space involvement, patient age, and tumor size.
- The deep pelvic nodes do not become involved with metastatic vulvar cancer unless the inguinofemoral nodes are affected.
- The 5-year survival rate of vulvar carcinoma with negative nodes is more than 95%. With one positive node, the 5-year survival is approximately the same, 94%; with two nodes, it decreases to 80% and with three or more to 12%.
- Advanced vulvar tumors encroaching on the urethra or anus may be treated by radiation followed by wide radical excision rather than exenteration. Enhanced results have also been reported with the combined use of chemotherapy and radiation.
- Verrucous carcinomas are a variant of squamous cancer that do not metastasize to regional nodes. Radiation therapy is contraindicated, and local surgical excision is the treatment of choice.
- Melanomas constitute 5% of vulvar cancers and are the most frequent nonsquamous cell malignancies.
- The overall 5-year survival of patients with vulvar melanoma is approximately 50%.
- Superficial spreading melanomas tend to occur in younger patients and have a better prognosis than nodular melanomas.
- Prognosis of vulvar melanoma is related to tumor invasion (Clark's level) and to tumor thickness.
- Basal cell carcinoma of the vulva is treated by wide local excision.

CHAPTER 31: MALIGNANT DISEASES OF THE VAGINA

KEY POINTS

- Predisposing factors associated with the development of vaginal intraepithelial neoplasia include infection with HPV, previous radiation therapy to the vagina, immunosuppressive therapy, and HIV infection.
- The tendency of intraepithelial squamous neoplasia to develop anywhere in the lower female genital tract is termed a *field defect* and describes the increased risk of premalignant changes occurring in the cervix, vagina, or vulva.
- Most cases of VAIN occur in the upper third of the vagina.
- VAIN can be treated by excision, laser, 5-FU, or imiquimod. Excision is often used for VAIN-3. Laser treatment is generally used for discrete lesions once invasion has been ruled out, and 5-FU and imiquimod cream are used to treat diffuse, multicentric, low-grade disease.
- The most common primary vaginal malignancy is squamous cell carcinoma (90%).
- Most cancers occurring in the vagina are metastatic.
- Vaginal cancers constitute less than 2% of gynecologic malignancies.
- Tumors of the upper vagina have a lymphatic drainage to the pelvis similar to cervical tumors. Tumors of the lower third of the vagina drain to the pelvic nodes and also to the inguinal nodes, similar to vulvar tumors.
- Radical surgery may be used to treat low-stage tumors, primarily of the upper vagina, in younger patients.
- Radiation therapy is the most frequently used modality for the treatment of squamous cell carcinoma of the vagina. Ideally, at least 7000 to 7500 cGy is administered in less than 9 weeks. Concurrent chemoradiation should strongly be considered.
- The overall 5-year survival rate of patients treated for squamous cell carcinoma of the vagina is approximately 45%.
- Clear cell adenocarcinoma is often associated with prenatal DES exposure. Prognosis is improved if the patient is older than 19 years, the tumor has a predominant tubulocystic tumor pattern, and the disease is low stage. Those with a positive DES maternal history have a better prognosis.
- Local therapy for small, stage I clear cell adenocarcinoma of the vagina is best considered if the tumor is smaller than 2 cm in diameter, invades less than 3 mm, and is predominantly of the tubulocystic histologic type. Pelvic nodes should be sampled and be free of tumor.
- The overall 5-year survival rate of patients treated for clear cell adenocarcinoma is approximately 80%, partially because of the high proportion of low-stage cases.
- Vaginal melanomas are usually fatal. They occur primarily in patients older than 50 years.
- Endometrioid adenocarcinomas of the vagina may occur through the malignant transformation of endometriosis, often associated with the use of unopposed estrogen or tamoxifen.
- Endodermal sinus tumors occur in children younger than 2 years. They secrete α -fetoprotein and are usually treated by multiagent chemotherapy, followed by surgical excision.
- Sarcoma botryoides occurs primarily in children younger than 8 years. It is treated by a multimodality approach using multiagent chemotherapy with surgical removal and occasionally irradiation.

CHAPTER 32: NEOPLASTIC DISEASES OF THE UTERUS

KEY POINTS

- Endometrial carcinoma is the most common malignancy of the female genital tract. In the United States, the lifetime risk of endometrial cancer is 3%.
- Most women who develop endometrial cancer are between 50 and 65 years of age.
- Women with Lynch syndrome (hereditary nonpolyposis colorectal cancer syndrome) have a 40% to 60% lifetime risk of endometrial cancer, which is similar to their lifetime risk of colon cancer.
- Chronic unopposed estrogen stimulation of the endometrium leads to endometrial hyperplasia and in some cases adenocarcinoma. Other important predisposing factors include obesity, nulliparity, late menopause, and diabetes.
- The risk of a woman developing endometrial carcinoma increases three times if her body mass index is greater than 30 kg/m².
- Tamoxifen use increases the risk of endometrial neoplasia two- to threefold.
- The primary symptom of endometrial carcinoma is postmenopausal bleeding. Women with abnormal bleeding should undergo an endometrial sampling to rule out endometrial pathology.
- Cytologic atypia in endometrial hyperplasia is the most important factor in determining malignant potential.
- Simple hyperplasia will develop into endometrial cancer in 1% of patients, whereas complex hyperplasia will develop into cancer in 29% of patients.

Continued

KEY POINTS—cont'd

- Studies have found that there is a 40% concurrent rate of endometrial cancer in patients with a preoperative diagnosis of complex atypical hyperplasia.
- Prognosis in endometrial carcinoma is related to tumor grade, tumor stage, histologic type, and degree of myometrial invasion.
- Older patients with atypical hyperplasia are at increased risk of malignant progression compared with younger patients.
- A key determinant of the risk of nodal spread of endometrial carcinoma is depth of myometrial invasion, which is often related to tumor grade.
- Well-differentiated (grade 1) endometrial carcinomas usually express steroid hormone receptors, whereas poorly differentiated (grade 3) tumors usually do not express receptors.
- Uterine serous carcinoma is an aggressive histologic subtype associated with metastatic disease even in the absence of myometrial invasion.
- Ninety percent of recurrences of adenocarcinoma of the endometrium occur within 5 years.
- Overall survival rates for patients with adenocarcinoma of the endometrium by stage are as follows: stage I, 86%; stage II, 66%; stage III, 44%; stage IV, 16% (overall there is a 72.7% 5-year survival rate combining clinical and operative staging systems).
- Histologic variants of endometrial carcinoma with a poor prognosis include uterine serous carcinoma and clear-cell carcinoma.
- Patients with uterine serous or clear-cell carcinoma of the endometrium should have a full staging laparotomy similar to that for ovarian carcinoma.
- The most frequent sites of distant metastasis of adenocarcinoma of the endometrium are the lung, retroperitoneal nodes, and abdomen.
- Primary treatment of endometrial cancer includes hysterectomy, bilateral salpingo-oophorectomy, pelvic cytology, bilateral pelvic and paraaortic lymphadenectomy, and resection of all disease. The exceptions include young premenopausal women with stage I and grade 1 endometrial carcinoma associated with endometrial hyperplasia, and women with increased risk of mortality secondary to medical comorbidities.
- Postoperative adjuvant radiation has not been shown to improve overall survival.
- Patients with high-stage or recurrent disease should be treated in a multimodality approach including chemotherapy, radiation, or hormone therapy.
- Uterine sarcomas make up less than 5% of uterine malignancies.
- Uterine sarcomas are treated primarily by operation including removal of the uterus, tubes, and ovaries.
- Endometrial stromal sarcomas are low-grade sarcomas with an indolent course.
- Multiagent chemotherapeutic regimens are usually prescribed for metastatic sarcomas; complete responses are rare and usually temporary.

CHAPTER 33: NEOPLASTIC DISEASES OF THE OVARY**KEY POINTS**

- Ovarian cancer is the leading cause of death from gynecologic cancer, but it occurs less frequently than endometrial cancers.
- Ovarian cancers in women older than 50 years are diagnosed at a more advanced stage, leading to a worse prognosis than for younger women.
- The risk of ovarian cancer is decreased by oral contraceptive use. Tubal ligation and hysterectomy also appear to decrease the risk.
- Most ovarian carcinomas are diagnosed in stage III or IV.
- Ovarian cancer risk rises from approximately 1.4% in general to 5% to 7% if the woman has one or two first- or second-degree relatives with ovarian cancer.
- Patients with ovarian cancer are at increased risk of developing breast cancer and endometrial cancer.
- It is important that the follow-up of ovarian cancer patients includes monitoring for breast cancer.
- Epithelial tumors are the most frequent ovarian neoplasm. They account for two thirds of all ovarian neoplasms and 85% of ovarian cancers.
- The major ovarian epithelial tumor cell types recapitulate müllerian-type epithelium (serous, endosalpinx; mucinous, endocervix; endometrioid, endometrium).
- Serous ovarian neoplasms are the most common type of epithelial tumors. Serous adenocarcinomas tend to be high grade, are the most virulent, and have the worst prognosis of epithelial adenocarcinomas. They are bilateral in 33% to 66% of cases.
- A cystic adnexal mass smaller than 8 cm in diameter in a menstruating female is most frequently functional.
- The normal postmenopausal ovary is approximately 1.5 to 2 cm in diameter.
- The risk of an ovarian tumor being malignant is approximately 33% in a woman older than 45, whereas it is less than 1 in 15 for those 20 to 45 years of age. More than 50% of ovarian cancers occur in women older than 50.
- There are three types of ovarian tumors with a serous histology: traditional serous adenocarcinomas, surface papillary tumors (ovary <4 cm), and primary peritoneal

KEY POINTS—cont'd

- carcinomas (serous carcinomas metastatic to the ovary, with normal ovarian size).
- Most ovarian carcinomas start from small microscopic foci and spread throughout the peritoneum before becoming clinically evident (de novo origin), especially serous and poorly differentiated tumors.
 - Ovarian carcinomas having a cystic origin are primary mucinous or endometrioid and are more likely to be discovered at a low stage.
 - A vaginal ultrasound finding of a unilocular cyst of 5 cm or smaller in a perimenopausal woman can usually be followed without surgical intervention.
 - Vaginal ultrasonography may detect early ovarian carcinoma but has not been proved to be a cost-effective screening technique.
 - The primary distribution spread of epithelial carcinoma is transcoelomic to the visceral and parietal peritoneum, diaphragm, and retroperitoneal nodes.
 - The risk of retroperitoneal node spread of epithelial carcinoma in apparent stage I cases is greatest for poorly differentiated tumors, for which the risk can reach 10% to 20%. The risk of retroperitoneal node spread increases in higher-stage cases.
 - The prognosis of a patient with ovarian epithelial carcinoma is related primarily to tumor stage and tumor grade, and to the amount of residual tumor remaining after primary resection.
 - Laparoscopic or robotic staging of early ovarian cancers appears to be feasible and comprehensive, without compromising survival.
 - The 5-year survival rate for patients with borderline epithelial ovarian carcinoma (grade 0) is close to 100% for stage I cases and more than 90% for all stages.
 - The overall 5-year survival rate for patients with stage I ovarian carcinoma is 65%. For stage I, grade 1, the survival rate is reported to be more than 80%.
 - Optimal surgical debulking (R0-microscopic residual) appears to confer a survival advantage in cases of stages III and IV ovarian carcinoma.
 - Interval cytoreduction has little additional effect on overall survival if a maximal attempt is made at primary surgery.
 - Neoadjuvant chemotherapy can reduce surgical morbidity; a randomized trial has indicated that this strategy may be equivalent to standard treatment for advanced-stage patients with surgery followed by chemotherapy.
 - IP chemotherapy appears to benefit patients with optimal cytoreduction more than conventional IV chemotherapy, but with greater toxicity.
 - CT scanning for patients with ovarian cancer can be approximately 80% to 90% effective for detecting tumor in retroperitoneal nodes, but it is much less successful in detecting intra-abdominal disease.
 - Assessing the ovarian CA-125 level is useful to help monitor patients with ovarian carcinoma. Reaction to the antigen is positive in approximately 80% of cases.
 - A rapid decrease in CA-125 values after treatment indicates a more favorable prognosis.
 - The initial response rate of ovarian epithelial carcinomas multiagent chemotherapy is more than 90%, but the proportion of patients who survive decreases to approximately 30% in 5 years. Initial treatment is usually with platinum and taxane agents.
 - Recurrent ovarian cancer is difficult to cure.
 - Factors determining response to recurrent chemotherapy regimens include time to treatment progression, distribution and volume of disease, and performance status.
 - Combination chemotherapy for platinum-sensitive recurrent disease improves response rates, with a less clear effect on survival.
 - Secondary cytoreduction appears to benefit patients with limited recurrent disease who undergo complete tumor removal. The benefit may be most evident before chemotherapy for recurrence.
 - Germ cell tumors are the second most common type of ovarian neoplasms and account for approximately 20% to 25% of all ovarian tumors.
 - In women younger than 30 years, the most frequent ovarian neoplasm is a germ cell tumor; approximately one third of these germ cell tumors are malignant in those younger than 21. For women younger than 30 years, the most common ovarian neoplasm is the dermoid.
 - The most common germ cell tumor is the benign cystic teratoma (dermoid). It is bilateral in 10% to 15% of the cases. Approximately 30% are calcified.
 - Malignant germ cell tumors are usually unilateral except dysgerminomas, which are bilateral in approximately 10% to 15% of patients.
 - Dysgerminomas are the most common malignant germ cell tumors and account for 1% to 2% of ovarian cancers.
 - The prognosis for a patient with an immature teratoma is related to tumor grade and tumor stage. These tumors are the second most common type of malignant germ cell tumor.
 - The 5-year survival rate of stage IA pure dysgerminoma treated by unilateral salpingo-oophorectomy is more than 90%.
 - Pure dysgerminomas are radiocurable. However, multiagent chemotherapy, particularly with etoposide and platinum, with or without bleomycin, will frequently result in complete remission. Approximately two thirds of cases present as stage IA.
 - Most patients with malignant ovarian germ cell tumors can be treated successfully with fertility-sparing surgery followed by BEP chemotherapy. Patients who do not require postoperative chemotherapy include those with stage IA dysgerminoma and stage IA, grade 1, immature teratoma. However, there has been a trend toward surveillance rather than chemotherapy for patients with stage I tumors of any histologic subtype.
 - Multiagent chemotherapy has improved survival in patients with malignant germ cell tumors, preserving childbearing function in most cases. Standard chemotherapy consists of the BEP regimen.

Continued

KEY POINTS—cont'd

- Gonadoblastomas are sex cord–stromal germ cell tumors that usually arise in dysgenetic gonads in patients with a Y chromosome; these are cured by removal.
- Granulosa cell tumors and Sertoli-Leydig tumors usually behave as low-grade malignancies, but there may be late recurrences.
- For patients with primary metastatic or recurrent sex cord–stromal tumors of the ovary, platinum-based chemotherapy is the treatment of choice. Commonly used regimens include BEP and paclitaxel-carboplatin.
- Some metastatic granulosa cell tumors may respond to hormone therapy, such as leuprolide acetate, tamoxifen, or aromatase inhibitors.
- Fibroma is the most common benign solid ovarian tumor.
- The most frequent sites of origin of tumors metastatic to the ovary are the lower reproductive tract, gastrointestinal tract, and breast.

CHAPTER 34: FALLOPIAN TUBE AND PERITONEAL CANCER

KEY POINTS

- There is increasing evidence that many cases of ovarian and peritoneal carcinoma may actually arise from the fallopian tube, thereby underestimating the incidence of fallopian tube carcinoma.
- Fallopian tube and peritoneal cancers are similar entities to epithelial ovarian cancer.
- Fallopian tube and peritoneal cancers have similar clinical characteristics, patterns of spread, and response to treatment compared with ovarian cancer.
- The primary risk factor for fallopian tube and peritoneal cancer is an inherited mutation in the *BRCA1* or *BRCA2* tumor suppressor gene.
- The most common histologic subtype of fallopian tube and peritoneal carcinoma is high-grade serous carcinoma.
- The treatment of fallopian tube and peritoneal cancer is identical to that for ovarian cancer and typically includes a combination of surgery and chemotherapy.
- Prognosis for ovarian and peritoneal cancer is most strongly related to the stage of disease and amount of residual tumor following the initial tumor reduction surgery.
- Fallopian tube cancer has been shown to have a better prognosis compared with ovarian and peritoneal cancer, but this may be because of a higher rate of *BRCA* mutation carriers in women with fallopian tube cancer.

CHAPTER 35: GESTATIONAL TROPHOBLASTIC DISEASE

KEY POINTS

- Persistent abnormal bleeding following normal pregnancy, abortion, or ectopic pregnancy should lead to a consideration of the diagnosis of GTD. Pulmonary nodules present on chest x-ray after a normal pregnancy suggest GTD. β -hCG levels will be elevated in these situations.
- Investigation of a young woman with metastatic disease of unknown primary should include a β -hCG level measurement.
- The risk of GTN after CHM is 15% to 20%, and it is only 1% to 5% after PHM.
- Approximately 50% of cases of GTN follow molar pregnancy, 25% follow normal pregnancy, and 25% follow abortion or ectopic pregnancy.
- The major risk factors for molar pregnancy include maternal age (>45 and <16 years) and a history of prior HM.
- The risk of HM is approximately 0.75 to 1/1000 pregnancies in North America.
- The risk of a subsequent HM after a primary mole increases 5- to 40-fold.
- Complete moles are of paternal origin, are diploid, and carry a 20% risk of GTD sequelae.
- Partial moles are of maternal and paternal origin, are triploid, and are rarely (2% to 4%) followed by GTD. They nonetheless require follow-up for potential malignant sequelae, as done for a complete mole.
- The monitoring of trophoblastic disease and its follow-up is accomplished by measurement of the β -hCG level.
- The diagnosis of a molar pregnancy can be established with ultrasonography and may coexist with a normal pregnancy.
- Hydatidiform moles are effectively and safely evacuated from the uterus using suction D&C.
- Medical complications of HM are rare but may include anemia, gestational hypertension before 20 weeks, hyperthyroidism, hyperemesis gravidarum, cardiac failure, and, rarely, pulmonary insufficiency.

KEY POINTS—cont'd

- Patients are classified into low- or high-risk categories. Low-risk patients are treated with single-agent methotrexate or actinomycin D; high-risk patients receive combination chemotherapy, usually with EMA/CO.
- The cure rate for low-risk patients approaches 100%.
- Patients with high-risk metastatic GTN are successfully treated with chemotherapy in more than 70% of cases.
- Surgery plays an important role in the treatment of PSTT and ETT. They are both relatively chemoresistant.
- Patients treated for GTD should not become pregnant for approximately 6 months after treatment to allow accurate follow-up of β -hCG levels.
- Fertility rates and pregnancy outcomes are similar in patients treated for GTD compared with those in the general population.
- Patients treated with the EMA/CO regimen have an increased rate of secondary malignancies, particularly hematologic malignancies.

CHAPTER 36: MOLECULAR ONCOLOGY IN GYNECOLOGIC CANCER

KEY POINTS

- The immune system consists of the innate and adaptive immune systems. The innate system is present at birth and consists of natural barriers, NK cells, macrophages, and the complement system. The adaptive immune system adapts to infection and consists of T and B cells.
- The cellular immune response occurs as a result of T lymphocytes reacting via a surface TCR that processes antigens presented to it by an APC in conjunction with MHC molecules.
- T-cell activation can result in activation of helper or inducer (Th) cells, cytotoxic or suppressor T cells, or cytokine production.
- Th cells recruit macrophages and cytotoxic or suppressor cells.
- Cytotoxic T cells have the ability to lyse infected cells or signal B cells to produce antibody.
- Humoral immunity results from antigenic stimulation of a B lymphocyte, which differentiates into a plasma cell and secretes antibody (immunoglobulin).
- The complement cascade provides a basis for the inflammatory response and can also mediate cytotoxicity.
- Cytokines (lymphokines) are regulatory substances of the immune system produced as a result of T-cell activation, cell damage by a virus, or other cells, such as macrophages and monocytes, involved in the immune response.
- Passive therapy transfers components of the acquired immune system to the recipient with cancer (e.g., monoclonal antibodies directed toward tumor-specific antigens).
- Active immunotherapy uses a patient's own immune system for protection against infection (e.g., vaccines).
- There are three types of genes associated with malignant development: oncogenes, tumor suppressor genes, and DNA mismatch repair genes.
- Malignant change is seen with point mutations, chromosomal aberration, gene amplification (increase in number of copies), or chromosomal translocation.
- *Ras* oncogenes are part of a group of signal transducer oncogenes that relay messages from the membrane to the cell nucleus. They are activated generally by point mutations.
- Growth factor genes include *C-erb-B2 (Her-2/neu)*, which can be overexpressed and act as a tumor-specific target for monoclonal antibody therapy; these are especially useful in breast cancer therapy.
- Nuclear oncogenes include *myc* and *fos* and can activate other genes as well as stimulate DNA replication.
- Angiogenesis is the formation of new blood vessels in order for tumors to grow.
- Tumor suppressor genes such as *Rb* and *p53* restrain cell growth. They have two copies and, in general, alteration of both copies leads to a mutant expression, which allows tumorigenesis to occur.
- *BRCA1* and *BRCA2* mutations confer a high lifetime risk of breast or ovarian cancer. Mutation screening may be appropriate for women with family histories, suggesting a hereditary predisposition to breast or ovarian cancer.
- DNA mismatch repair genes act by recognizing and fixing errors in the DNA helix resulting from incorrect pairings of nucleotides. They prevent the accumulation of genetically damaged material in the cell.

CHAPTER 37: PRIMARY AND SECONDARY DYSMENORRHEA, PREMENSTRUAL SYNDROME, AND PREMENSTRUAL DYSPHORIC DISORDER

KEY POINTS

- Primary dysmenorrhea almost always occurs before the age of 20 years. Secondary dysmenorrhea may occur at any time during the menstrual years.
- Approximately 75% of all women complain of primary dysmenorrhea. Approximately 15% have severe symptoms.
- Education, supportive therapy, and NSAIDs are the treatments of choice for primary dysmenorrhea. Seventy-two percent of women suffering from dysmenorrhea report significant pain relief with this treatment strategy.
- COCs reduce the prevalence and severity of dysmenorrhea. They can be used in extended cycles for better relief. This is also a reasonable first-line treatment, especially if contraception is desired.
- If dysmenorrhea symptoms are not relieved with NSAIDs, Ocs, or their combination, additional evaluation for pelvic pathology should be considered.
- Approximately 3% to 8% of all women suffer from clinically relevant PMS, with 2% demonstrating PMDD.
- PMS patients often suffer depression during the luteal phase, but it is not as severe as the depression noted by patients with endogenous depression when measured by standard depression scales. It can be difficult to distinguish PMS from depression with luteal phase exacerbation.
- The most useful diagnostic tool in caring for PMS and PMDD patients is a prospective symptom diary.
- Educating patients about the diagnosis of PMS or PMDD is critical. Exercise along with consideration for judicious calcium or vitamin B₆ supplementation may relieve PMS symptoms.
- Therapy with psychoactive drugs, particularly the SSRIs, has been demonstrated in RCTs to relieve PMS and PMDD symptoms. These medications should be considered first-line therapy. Specific cautions for the use of these agents must be followed. For women who also desire contraception, COCs are a valid option with demonstrated improvement in PMS/PMDD symptoms.

CHAPTER 38: PRIMARY AND SECONDARY AMENORRHEA AND PRECOCIOUS PUBERTY

KEY POINTS

- Primary amenorrhea is diagnosed if no menstrual function has occurred by age 15, or 5 years after initial breast development.
- The incidence of secondary amenorrhea of more than 6 months' duration in the general population is approximately 0.7%.
- The incidence of amenorrhea lasting more than 6 months after discontinuation of oral contraceptives is 0.8%.
- The most important and probably most common cause of amenorrhea in adolescent girls is anorexia nervosa.
- An adolescent 13 years of age or older without any breast development has estrogen deficiency caused by an abnormality, which needs diagnostic evaluation.
- Menarche is delayed approximately 0.4 year for each year of premenarchal athletic training.
- Gonadal failure is the most common cause of primary amenorrhea, accounting for almost 50% of patients with this disorder.
- Individuals with gonadal failure and an X chromosome abnormality are shorter than 63 inches in height.
- The testes of individuals with androgen resistance have approximately a 20% chance of becoming malignant after the age of 20 years.
- Uterovaginal agenesis is the second most common cause of primary amenorrhea, with an incidence of approximately 15% of individuals with this symptom.
- Approximately one third of individuals with gonadal failure have major cardiovascular or renal abnormalities.
- Congenital renal abnormalities occur in approximately one third of women with congenital absence of the uterus.
- The differential diagnosis between estrogen deficiency caused by gonadal failure and hypogonadotropic hypogonadism is best established with measurement of serum FSH.
- The diagnosis of gonadal failure, or hypergonadotropic hypogonadism, can be established if the FSH level exceeds 30 mIU/mL.
- Individuals with gonadal failure should have a peripheral karyotype obtained to determine whether a Y chromosome is present. If it is present, or if there are signs of hyperandrogenism, the gonads should be excised to prevent the development of malignancy, mainly a gonadoblastoma.
- Individuals with primary amenorrhea and hypogonadotropic hypogonadism do not need karyotyping but need a cranial CT scan to rule out a CNS tumor.
- The most frequent cause of IUAs is curettage performed during pregnancy or shortly thereafter.
- When women experience weight loss to 15% or more below ideal body weight, amenorrhea can occur because of CNS-hypothalamic dysfunction. The normal cyclic pattern of LH pulsatility is not present in individuals with functional hypothalamic amenorrhea. Either there is no LH pulse activity or there are pulses of slow frequency, similar to those in the normal luteal phase.

KEY POINTS—cont'd

- The GnRH alterations, as reflected in LH pulsatility, in persons with severe weight loss and anorexia nervosa are similar to those seen in normal prepubertal girls. When they regain weight, GnRH changes similar to those occurring during puberty take place.
- When uterine bleeding fails to occur after progestin is administered, E₂ levels are usually lower than 30 pg/mL.
- In contrast to hypothalamic disorders, pituitary causes of amenorrhea can be associated with ACTH and TSH deficiency.
- Individuals with premature ovarian failure or insufficiency have two different histologic findings: generalized sclerosis or primordial follicles scattered through the stroma.
- Women with premature ovarian failure or insufficiency may have antibodies to gonadotropins and other endocrine organs, indicating an autoimmune origin.
- A karyotype should be obtained in women with premature ovarian failure or insufficiency who are younger than 25 years but is not necessary in those who are older.
- Amenorrhea with low estrogen levels is associated with decreased bone density.
- The most frequent cause of secondary amenorrhea is hypothalamic dysfunction.
- Physiologic development in females with precocious puberty usually follows the normal sequence of changes of secondary sexual characteristics.
- If signs of pubertal progression (precocious puberty) are present in a girl, a workup is warranted by the age of 8 years.
- The two primary concerns of parents of children with precocious puberty are the social stigma associated with the child being physically different from her peers and the diminished ultimate height caused by the premature closure of epiphyseal growth centers.
- The exact cause of the majority of cases of GnRH-dependent (true or complete) precocious puberty is unknown; however, approximately 30% of cases are secondary to CNS disease.
- A definitive diagnosis is established more often for GnRH-independent (pseudoprecocious or incomplete) puberty and is usually related to an ovarian or adrenal disorder.
- Breast hyperplasia is a normal phenomenon in neonates and may persist until up to 6 months of age.
- The most common cause of GnRH independent precocious puberty is a functioning ovarian tumor. Granulosa cell tumors are the most common type, accounting for approximately 60% of neoplasms.
- The primary emphasis of the diagnostic workup of a child with precocious puberty should be to rule out life-threatening neoplasms of the ovary, adrenal glands, or CNS. The secondary emphasis is to delineate the speed of the maturation process, because this is critical when making a decision about therapy.
- The goals of therapy for precocious puberty are to reduce gonadotropin secretion, reduce or counteract the peripheral actions of sex steroids, and decrease the growth rate to normal and thus slow skeletal maturation. This is best accomplished with the use of GnRH agonists.
- The effect on adult height depends on the chronologic age at which GnRH therapy is initiated, with greater success if initiated at a younger age. The child with precocious puberty and her family need intensive counseling.

CHAPTER 39: HYPERPROLACTINEMIA, GALACTORRHEA, AND PITUITARY ADENOMAS

KEY POINTS

- The main symptoms of hyperprolactinemia are galactorrhea and amenorrhea, the latter caused by alterations in normal GnRH release.
- Pathologic causes of hyperprolactinemia include pharmacologic agents (e.g., tranquilizers, narcotics, antihypertensive drugs), hypothyroidism, chronic renal disease, chronic neurostimulation of the breast, hypothalamic disease, and pituitary tumors (e.g., prolactinoma, acromegaly, Cushing disease).
- Autopsy studies reveal that prolactinomas are present in approximately 10% of the population.
- Approximately 70% of women with hyperprolactinemia, galactorrhea, and amenorrhea with low estrogen levels will have a prolactinoma.
- Most macroadenomas enlarge with time; almost all microadenomas do not.
- The initial operative cure rate for microadenomas is approximately 80% and 30% for macroadenomas, but the long-term recurrence rate is at least 20% for each.
- In women with hyperprolactinemia and no macroadenoma, bromocriptine or cabergoline treatment returns PRL levels to normal in 90%, induces ovulatory cycles in 80%, and eradicates galactorrhea in 60%.
- The dopamine agonist of choice is cabergoline, because of increased efficacy and fewer side effects.
- Without prior treatment, 2.7% of women with microadenomas develop symptoms, whereas 22.9% of women with a macroadenoma will develop symptoms. Estrogen therapy or oral contraceptives will not stimulate the growth of PRL-secreting microadenomas and can be used for treatment of hyperprolactinemia and hypogonadism.
- Surgical treatment of prolactinomas is recommended only for patients who fail to respond or do not comply with medical management.

CHAPTER 40: HYPERANDROGENISM/ANDROGEN EXCESS

KEY POINTS

- The major androgen produced by the ovaries is testosterone and that of the adrenal glands is DHEAS.
- There are three markers of androgen production, one for each compartment in which androgens are produced. In the ovary, it is testosterone; in the adrenal gland, DHEAS; and in the periphery, 3α -diol-G.
- Approximately 85% of testosterone is bound to SHBG and is biologically inactive, 10% to 15% is bound to albumin, and 1% to 2% is unbound. Both of the latter fractions are biologically active.
- Commercial assays for testosterone and unbound testosterone in women may be inaccurate; more detailed assays should be requested, and unbound testosterone is best assessed by the ratio of testosterone and SHBG.
- Women with idiopathic hirsutism have increased 5α -RA.
- There are three criteria to diagnose PCOS; the diagnosis is based on clinical criteria, not laboratory values.
- The most frequently used diagnostic criteria for PCOS (called the *Rotterdam criteria*) require finding any two of the following: menstrual irregularity, hyperandrogenism, or polycystic ovaries on ultrasound.
- Women with ovarian neoplasms have testosterone levels more than 2.5 times the upper limits of the normal range.
- The diagnosis of LOHD is established if the basal (early morning) serum 17-hydroxyprogesterone levels are greater than 2 to 3 ng/mL or if the level 1 hour after infusion of 0.25 μ g ACTH is more than 10 ng/mL.
- Women with LOHD have a block in cortisol biosynthesis of 11β -hydroxylase or 21 -hydroxylase, resulting in increased circulating levels of 17-hydroxyprogesterone.
- Because of the length of the hair growth cycle, response should not be expected until after 3 months of therapy.
- The best treatment for hirsutism is with an oral contraceptive, often together with an antiandrogen, with spironolactone being the preferred agent. Response rates are approximately 70%.
- Acne vulgaris is often a manifestation of androgen excess and may be effectively treated with oral contraceptives and sometimes with the addition of an antiandrogen. The response rate is approximately 90%.
- Female pattern hair loss (androgenic alopecia) may be due to enhanced scalp androgen action (5α -reductase activity). It is best treated with antiandrogen therapy, but the response rate is poor at ~30%.
- Excessive hair removal should be carried out once excessive androgen action (if present) has been suppressed. Laser treatment is more effective than electrolysis, although the latter is preferred for light-colored hair.

CHAPTER 41: POLYCYSTIC OVARY SYNDROME

KEY POINTS

- There are three criteria to diagnose PCOS; the diagnosis is based on clinical criteria, not laboratory values.
- The most frequently used diagnostic criteria for PCOS (called the *Rotterdam criteria*) require finding any two of the following: menstrual irregularity, hyperandrogenism, or polycystic ovaries on ultrasound.
- The disorder is heterogeneous and is not a single gene disorder, although several susceptibility genes have been identified; environmental influences are most likely involved as well.
- If untreated, women with PCOS have an increased risk of developing diabetes mellitus and hypertension after menopause; women with the disorder may have increased cardiovascular disease, although whether cardiovascular mortality is increased has not been confirmed.
- Treatment of women with PCOS should be directed at the specific complaint: menstrual function, skin disorders of androgen excess, or subfertility. Typically, more than one complaint exists and can be dealt with concomitantly unless the woman is trying to conceive.
- Weight gain and metabolic concerns (particularly insulin resistance, prediabetes, etc.) are extremely common and should be treated aggressively (usually with lifestyle management), particularly before pregnancy.
- Long-term consequences of PCOS include cardiovascular and metabolic concerns and the increased risks of endometrial and ovarian cancer, unless OCs have been used. With ovarian aging, cycles may become more regular, and some but not all the symptoms of PCOS may disappear as women approach menopause. The age of menopause may be later.
- Women with PCOS who desire fertility should be treated with agents that stimulate ovulation. Letrozole and clomiphene are first-line agents, with the former being more successful. Gonadotropins and ovarian "drilling" are second-line treatments, which are less commonly used today in the United States, with an approach of progressing women to IVF more quickly.

CHAPTER 42: INFERTILITY EPIDEMIOLOGY EVALUATION

KEY POINTS

- Approximately 10% of all U.S. couples with women of reproductive age are infertile, approximately more than 7 million women, and the incidence of infertility steadily increases in women after age 30.
- Among fertile couples who have coitus in the week before ovulation, approximately 20% (monthly fecundability, 0.2) have a chance of developing a clinical pregnancy.
- In the United States, approximately 20% of cases of infertility are caused by anovulation, 30% to 40% by an abnormality of semen production, 30% to 40% by pelvic disease, and approximately 10% to 20% of cases are unexplained.
- A systematic evaluation of factors involved in infertility should be carried out rapidly, along with markers of ovarian reserve (antral follicle count, AMH); this will help frame the discussion with couples as to how best to proceed with treatment.
- Of all the causes of infertility, treatment of anovulation results in the greatest success with ovulation induction, if no other causes of infertility are present; conception rates over time are close to those of a normal fertile population.
- Letrozole for ovulation induction in women with polycystic ovary syndrome may be superior to the use of clomiphene.
- When conception occurs after clomiphene treatment in anovulatory women, the incidence of multiple gestation is increased to approximately 8%; almost all of them being twin pregnancies. The incidences of clinical spontaneous abortion, ectopic gestation, intrauterine fetal death, and congenital malformation are not significantly increased, although ectopic pregnancies are more common following assisted reproductive technology.
- The prognosis for fertility after tubal reconstruction depends on the amount of damage to the tube as well as the location of the obstruction. Mild abnormalities of the proximal tube may be treated with selective catheterization/cannulation under fluoroscopy. Large hydrosalpinges (distal disease) are best treated by salpingectomy and IVF.
- If both proximal and distal obstructions of the tube exist, intrauterine pregnancy is uncommon, and operative reconstruction should not be performed; IVF is the best therapy.
- In women with unexplained infertility, the use of COS and IUI with clomiphene/IUI or gonadotropins/IUI yields monthly fecundity rates of approximately 8% to 10% (at least doubling the baseline rate) and should be the initial treatment for unexplained infertility. Use of gonadotropins does not offer a major advantage over clomiphene and carries more risks in terms of hyperstimulation and multiple pregnancies.
- After three to six cycles of COS/IUI, IVF should be offered as the next step, and IVF should be the primary therapy in women around age 40.

CHAPTER 43: IN VITRO FERTILIZATION

KEY POINTS

- For IVF with and without ICSI, the delivery rate per cycle in which ova are retrieved is as high as 50%, depending on the age of the woman. The rate of pregnancy following IVF is directly related to the number of embryos placed in the uterine cavity. The rate of pregnancy is inversely related to the age of the female patient.
- Strict guidelines set forth by ASRM, which limit the number of embryos transferred, has reduced the rate of high-order multiple pregnancies in the United States.
- Preimplantation genetic selection and diagnosis allow for screening of embryos for aneuploidy or genetic disease prior to embryo transfer. Because advancing reproductive age is associated with higher rates of aneuploid embryos, PGS may help improve pregnancy rates in older women.
- Donor in vitro fertilization offers women who cannot conceive with their own oocytes the opportunity to experience pregnancy.
- Oocyte and embryo cryopreservation gives women the possibility of maintaining their future fertility potential even when faced with the possibility of premature menopause due to gonadotoxic medical treatments. Though still experimental, ovarian tissue freezing is another possible method of fertility preservation. Oocyte cryopreservation is available for healthy females who are interested in elective fertility preservation, but they need to be carefully counseled about the low pregnancy rates associated with cryopreserved oocytes.
- IVF technology has helped to expand research into stem cell therapy, which may further improve treatments for infertility as well as other medical conditions in the near future.

Smarter search. Faster answers.

Smarter, Faster Search for Better Patient Care

**Unlike a conventional search engine, ClinicalKey
is specifically designed to serve doctors by providing
three core components:**

1 Comprehensive Content

The most current, evidence-based answers available for every medical and surgical specialty.

2 Trusted Answers

Content supplied by Elsevier, the world's leading provider of health and science information.

3 Unrivaled Speed to Answer

Faster, more relevant clinical answers, so you can spend less time searching and more time caring for patients.

Start searching with ClinicalKey today!
