Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Preface

Try to learn something about everything and everything about something.

Thomas Huxley

Comprehensive Gynecology is now in its seventh edition, and it is humbling to note that it has almost been 30 years since the first edition was published in 1987.

The current editors are indebted to our mentors who pioneered the original work. The contributions of Drs. William Droegemueller, Authur L Herbst, Daniel R. Mishell, Jr., and Morton A. Stenchever were monumental and provided the impetus for our following in their footsteps. We are also saddened by the fact that in 2015, we lost Mort, who is now in a better place. Also, as we close out this edition, we have just learned that we have also lost our esteemed mentor, Dan Mishell, who passed away in May 2016. Both men have contributed so much to the field, and to us personally, and have done so much to improve the lives of women.

In line with the quote above from Huxley, the British biologist and philosopher, we continue to attempt to be *comprehensive*. We want the reader to be comfortable with all aspects of gynecology; some readers will wish to be more expert in certain subspecialty areas such as urogynecology, oncology, or reproductive endocrinology.

In this edition we are privileged to welcome Fidel Valea as one of the editors, taking over the duties from Vern L. Katz, who elected to retire. We would like to thank Vern once again for his contributions.

Rather than adding new chapters, we have split some in two to provide better focus on the subject areas, and also organized the chapters to provide better flow. We have added several co-authors, continuing the trend we established with the previous edition. This is a major departure from the early editions, where the four editors wrote all of the chapters. We feel adding additional talent to the authorship provides a more comprehensive and validated approach to the dissemination of knowledge in gynecology.

In this edition, we have provided the most important references in the body of the chapter, allowing the reader to have immediate access to the source, rather than having to search for the reference. However, we have maintained a full bibliography for many chapters, available online.

In this edition we have also provided video content to make this a more visual experience for the reader. New and better illustrations have also been added to assist in visual learning. The cover is also a departure from our previous editions and speaks to our wish to impart a visual experience and emphasize contemporary techniques of minimally invasive procedures for gynecological surgery.

Nearly every chapter has maintained key points of importance, which have been bundled together in an online synopsis of the entire book. This will allow rapid assessment of the content of each chapter for more in-depth reading of areas of greater interest as well as provide key learning facts in all areas of gynecology.

We hope readers will enjoy this edition and learn as much as they can from this ever-evolving field in order to provide better health care for women.

We would like to give a big thanks to our editors, Kate Dimock, and particularly Rae Robertson, who have stewarded us through this process.

We would also like to give a big thank you, with great appreciation and love, to our families, without whose support and encouragement this project could not have been accomplished.

Fertilization and Embryogenesis

Meiosis, Fertilization, Implantation, Embryonic Development, Sexual Differentiation

Thomas M. Price

Several areas of medical investigation have brought increased attention to the processes of fertilization and embryonic development, including teratology, stem cell research, immunogenetics, and assisted reproductive technology. The preimplantation, implantation, and embryonic stages of development in the human can now be studied because of the development of newer techniques and areas of research. This chapter considers the processes of oocyte meiosis, fertilization and early cleavage, implantation, development of the genitourinary system, and sex differentiation.

OOCYTE AND MEIOSIS

The oocyte is a unique and extremely specialized cell. The primordial germ cells in both males and females are large eosinophilic cells derived from endoderm in the wall of the yolk sac. These 700 to 1300 cells migrate to the germinal ridge by way of the dorsal mesentery of the hindgut by ameboid action by 5 to 6 weeks. Oogenesis begins with the replication of the diploid oogonia through mitosis to produce primary oocytes, reaching a peak number of 600,000 (95% prediction interval: 70,000–5,000,000) at 18 to 22 weeks of gestation. Through apoptosis the numbers decline to about 360,000 (95% prediction interval: 42,000 to 3,000,000) at menarche (Wallace, 2010). As can be seen, there is a large variance among individuals and a direct correlation between the number of fetal oocytes and the age of menopause. Accelerated apoptosis is seen in Turner syndrome resulting in few oocytes at birth (Modi, 2003).

The meiotic process actually begins at 10 to 12 weeks' gestation and is the mechanism by which diploid organisms reduce their gametes to a haploid state so that they can recombine again during fertilization to become diploid organisms. In humans, this process reduces 46 chromosomes to 23 chromosome structures in the gamete. The haploid gamete contains only one chromosome for each homologous pair of chromosomes, so it has either the maternal or paternal chromosome for each pair, but not both. Meiosis is also the mechanism by which genetic exchange is completed through chiasma formation and crossing over (recombination) between homologous chromosome

pairs. Two meiotic cell divisions are required to produce haploid gametes. In the human female, oogonia enter meiosis in “waves” (Fig. 1.1)— that is, not all oogonia enter meiosis at the same time. Meiosis initiation is dependent on mesonephric-produced retinoic acid (Childs, 2011).

Oocytes in the first substage of prophase, leptotene, are found in the human fetal ovary as early as 10 weeks' gestation. With increasing gestational age, greater proportions of oocytes in later stages of meiosis may be observed, and by the end of the second trimester of pregnancy, the majority of oocytes in the fetal ovary have cytologic characteristics that are consistent with the diplotene/dictyotene substages of prophase I of meiosis I (the stage at which the oocytes are arrested until ovulation) (Fig. 1.2).

Meiosis is preceded by interphase I during which DNA replication occurs, thus transforming the diploid oogonia with a DNA content of $2N$ to an oocyte with a DNA content of $4N$. Meiosis is defined in two stages. The first, known as the reduction division (division I, or meiosis I) initiates in the fetal ovary but is then arrested and completed at the time of ovulation.

Meiosis I starts with prophase I (prophase includes leptotene, zygotene, pachytene, and diplotene), which occurs exclusively during fetal life and sets the stage for genetic exchange that ensures genetic variation in our species (Fig. 1.3). Leptotene is

Figure 1.1 Diagrammatic representation of the different meiotic cell types and their proportions in the ovary during fetal life. (Courtesy of Edith Cheng, MD.)

Figure 1.2 Diagram of oocyte meiosis. For simplicity, only one pair of chromosomes is depicted. Prophase stages of the first meiotic division occur in the female during fetal life. The meiotic process is arrested at the diplotene stage ("first meiotic arrest"), and the oocyte enters the dictyotene stages. Meiosis I resumes at puberty and is completed at the time of ovulation. The second meiotic division takes place over several hours in the oviduct only after sperm penetration. (Courtesy of Edith Cheng, MD.)

proportionately the most abundant of all the prophase I sub-stages in the early gestations. Cells in this meiotic phase are characterized by a large nucleus with fine, diffuse, string-like chromatin evenly distributed within the nucleus (Fig. 1.3, A). Chromatin of homologous pairs occupies "domains" and does not occur as distinct linear strands of chromosomes. The zygotene substage is defined by the initiation of pairing, which is characterized by the striking appearance of the synaptonemal complex formation in some of the chromosomes (Fig. 1.3, B). There is cytologic evidence of chromosome condensation and linearization, and the chromatin is seen as a fine, string-like structure. The pachytene substage is the most easily recognizable period of the prophase and is characterized by clearly defined chromosomes that appear as continuous ribbons of thick beadlike chromatin (Fig. 1.3, C). By definition, this is the substage in which all homologues have paired. In this substage, the paired homologues are structurally composed of four closely opposed chromatids and are known as a *tetrad*. The frequency of oocytes in pachytene increases with gestational age and peaks in the mid-second trimester of pregnancy (at about 20 to 25 weeks' gestation). The diplotene substage is a stage of desynapsis that occurs as the synaptonemal complex dissolves and the two homologous chromosomes pull away from each other. However, these bivalents, which are composed of a maternally and a paternally derived chromosome, are held together at the centromere and at sites of chiasma formation

Figure 1.3 Fetal ovary with fluorescent in situ hybridization. The first three images are meiotic cells from a 21-week fetal ovary. **A**, Fluorescent in situ hybridization (FISH) with a whole chromosome probe for chromosome X was completed to visualize the pairing characteristics of the X chromosome during leptotene. **B**, Zygotene. **C**, Pachytene. **D**, Image of a meiotic cell from a 34-week fetal ovary that underwent dual FISH with probes for chromosomes 13 (green signal) and 21 (red signal) to illustrate the pairing characteristics of this substage of prophase in meiosis I. (Courtesy of Edith Cheng, MD.)

that represent sites where crossing over has occurred (Fig. 1.3, D). In general, chiasma formation occurs only between chromatids of homologous pairs and not between sister chromatids. Usually, one to three chiasmata occur for each chromosome arm. Oocytes at this stage of prophase I constitute the majority of third-trimester fetal and newborn ovaries. Diplotene merges with diakinesis, the last substage of meiosis I, and is a stage of transition to metaphase, lasting many years in humans (Speed, 1985).

With puberty, folliculogenesis occurs with progression of the follicle, consisting of the oocyte and granulosa cells from primordial to antral characterized by granulosa cell proliferation, development of gonadotropin receptors, and expression of enzymes for sex steroid production (Baerwald, 2012). It takes approximately 85 days for a follicle to mature to the point of ovulation. There is no change in the chromosome stage during folliculogenesis.

Meiosis I resumes with the surge of luteinizing hormone prior to ovulation completing metaphase, anaphase, and telophase. The result is two daughter cells, which are diploid ($2N$) in DNA content but contain 23 chromosome structures, each containing two closely held sister chromatids. One daughter cell,

the oocyte, receives the majority of the cytoplasm, and the other becomes the first polar body. The polar body is located in the perivitelline space between the surface of the oocyte (oolemma) and the zona pellucida (ZP).

Meiosis II is rapid with the oocyte advancing immediately to metaphase II where the sister chromatids for each chromosome are aligned at the equatorial plate, held together by spindle fibers at the centromere. With sperm penetration, meiosis II is completed with extrusion of the second polar body yielding a haploid oocyte ($1N$), entered by a haploid ($1N$) sperm (Fig. 1.4).

FERTILIZATION AND EARLY CLEAVAGE

In most mammals, including humans, the egg is released from the ovary in the metaphase II stage (Fig. 1.5). When the egg enters the fallopian tube, it is surrounded by a cumulus of granulosa cells (cumulus oophorus) and intimately surrounded by a clear zona pellucida (ZP). Within the zona pellucida are both the egg and the first polar body. Meanwhile, spermatozoa are transported through the cervical mucus and the uterus and into the fallopian tubes.

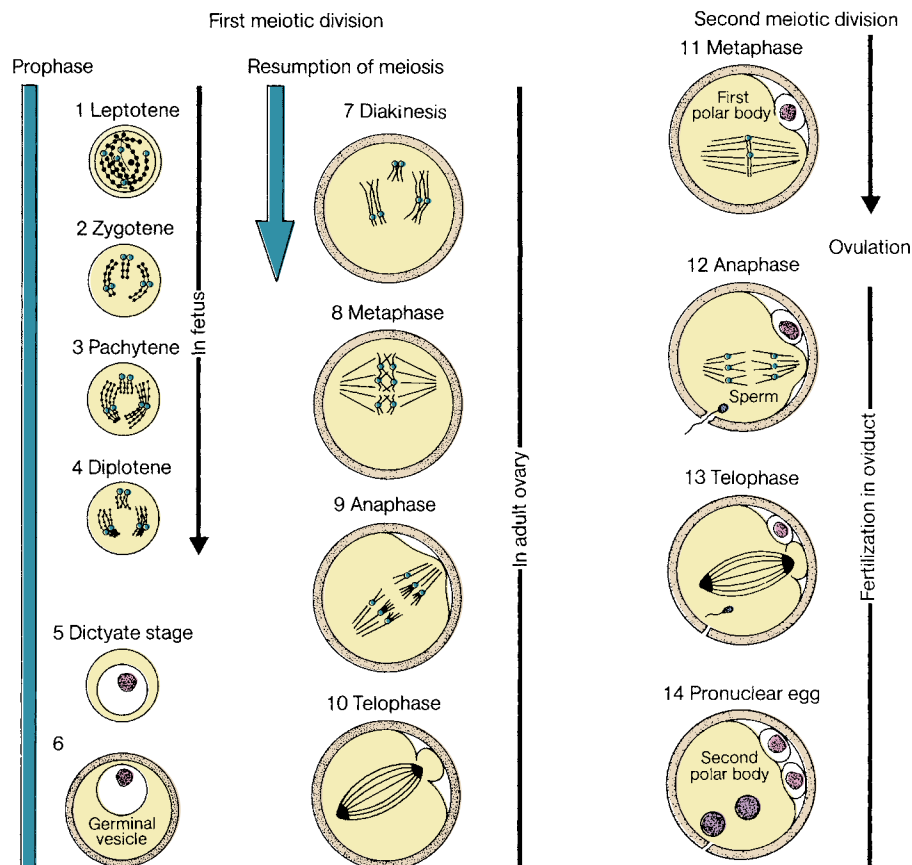

Figure 1.4 Diagram of oocyte meiosis. For simplicity, only three pairs of chromosomes are depicted (1 to 4). Prophase stages of the first meiotic division, which occur in most mammals during fetal life. The meiotic process is arrested at the diplotene stage ("first meiotic arrest"), and the oocyte enters the dictyate stages (5 to 6). When meiosis is resumed, the first maturation division is completed (7 to 11). Ovulation occurs usually at the metaphase II stage (11), and the second meiotic division (12 to 14) takes place in the oviduct only after sperm penetration. (From Tsafiri A. Oocyte maturation in mammals. In: Jones RE, ed. *The Vertebrate Ovary*. New York: Plenum; 1978.)

Figure 1.5 Summary of the ovarian cycle, fertilization, and human development during the first week. Stage 1 of development begins with fertilization in the uterine tube and ends when the zygote forms. Stage 2 (days 2 to 3) comprises the early stages of cleavage (from 2 to about 32 cells, the morula). Stage 3 (days 4 to 5) consists of the free (unattached) blastocyst. Stage 4 (days 5 to 6) is represented by the blastocyst attaching to the posterior wall of the uterus, the usual site of implantation. The blastocysts have been sectioned to show their internal structure. (From Moore KL, Persaud TVN. *The Developing Human: Clinically Oriented Embryology*. 7th ed. Philadelphia: WB Saunders; 2003.)

Although 20 million to 200 million sperm may enter the vagina during intercourse, only 1 in 25,000 will make it to the fallopian tubes (Williams, 1993). This journey involves processes of capacitation, chemotaxis, hyperactivated motility, and acrosome reaction (Fig. 1.6). Capacitation precedes all other changes and involves initial removal of cholesterol from the plasma membrane altering the permeability and fluidity. This allows the influx of calcium and bicarbonate with many downstream effects such as increased cyclic adenosine monophosphate (cAMP), protein tyrosine phosphorylation, and activation of protein kinases (Aitken, 2013). A function of capacitation is to allow localization of protein complexes

in the head of the sperm, which will subsequently bind the ZP. Chemotaxis is shown by a greater number of sperm in the ampullary portion of the fallopian tube containing a cumulus-oocyte-complex (COC) compared with the side lacking a COC. In vitro, follicular fluid acts as a chemoattractant, possibly due to progesterone, but the exact responsible constituent(s) of the fluid continues to be debated (Eisenbach, 1999). Hyperactivated motility involves increased vigorous movement of the sperm in order to penetrate the cumulus (granulosa) cells surrounding the oocyte and is most likely due to progesterone. A major action of progesterone is to increase calcium influx into the sperm with multiple downstream effects. Likely, the

Figure 1.6 Acrosome reaction and a sperm penetrating an oocyte. The detail of the area outlined in **A** is given in **B**. 1, Sperm during capacitation, a period of conditioning that occurs in the female reproductive tract. 2, Sperm undergoing the acrosome reaction, during which perforations form in the acrosome. 3, Sperm digesting a path through the zona pellucida by the action of enzymes released from the acrosome. 4, Sperm after entering the cytoplasm of the oocyte. Note that the plasma membranes of the sperm and oocyte have fused and that the head and tail of the sperm enter the oocyte, leaving the sperm's plasma membrane attached to the oocyte's plasma membrane. (From Moore KL, Persaud TVN. *The Developing Human: Clinically Oriented Embryology*. 7th ed. Philadelphia: WB Saunders; 2003.)

progesterone concentration increases as the sperm approaches the egg, resulting in more aggressive motility. When the egg is reached, receptor complexes on the outer most plasma membrane bind to specific ZP glycoprotein receptors (primarily ZP 3). These interactions are very species specific. Human sperm can only bind to the ZP of human, baboon, and gibbon oocytes.

Binding results in fenestrations forming between the plasma membrane and the underlying acrosome membrane releasing enzymes including acrosin (a serine protease) to locally degrade the ZP (Chiu, 2014).

As many sperm may initially bind the ZP, a mechanism must be in place to prevent fertilization by more than one sperm

(polyspermia). With initial binding of the sperm membrane to the oolemma, a calcium-dependent release of cortical granules occurs. Cortical granules are vesicles containing protein made during oogenesis and located in the periphery of the cell. Contents are released into the perivitelline space and function to modify ZP proteins and enlarge the perivitelline space to prevent sperm entry (Talbot, 2003). With sperm entry, the oocyte completes its second meiotic division, casting off the second polar body into the perivitelline space.

The majority of a single sperm enters the oocyte, and this is indeed the case during intracytoplasmic sperm injection (ICSI) for infertility. Only the centrioles and the nucleus survive, whereas mitochondria in the midpiece and tail are destroyed. The sperm centrioles interact with α -tubulin from the oocyte to form a microtubule network for migration of pronuclei and subsequent separation of chromosomes during the first mitosis (Schatten, 2009). Thus mitochondria are of maternal origin, whereas centrioles are paternal.

Early cell division (cleavage) is not synchronous and varies in time (Fig. 1.7). Time intervals from two pronuclei to two-cell, two-cell to three-cell, three-cell to four-cell, and four-cell to five-cell are 26 hours, 12 hours, 0.8 hours, and 14 hours, respectively, as determined with time-lapse photography during in vitro fertilization (IVF) (Meseguer, 2011). A significant number of fertilized oocytes do not complete cleavage for a number of reasons, including failure of appropriate chromosome arrangement on the spindle, specific gene defects that prevent the formation of the spindle, and environmental factors. Importantly, teratogens acting at this point are usually either completely destructive or cause little or no effect. Twinning may occur by the separation of the two cells produced by cleavage, each of which has the potential to develop into a separate embryo (Hall, 2003). Twinning may occur at any stage until the formation of the blastocyst (blast), because each cell is totipotent. Both genetic and environmental factors are probably involved in the causation of twinning.

MORULA AND BLASTULA STAGE: EARLY DIFFERENTIATION

After fertilization, the *zygote* (the term for a fertilized egg) has a diameter of 83 to 105 μm and undergoes rapid mitotic division to reach the next stage of approximately 16 cells called a *morula*. After 4 to 5 days traversing the fallopian tube, the embryo arrives into the uterine cavity at the blast stage. The blast is characterized by a cavity (blastocoele) and differentiation of cells into the trophoblast (TE), which will ultimately produce the fetal membranes and placenta and the inner cell mass (ICM), which will produce the fetus. During IVF, the blast forms 5 days after fertilization with a diameter of 155 to 265 μm consisting of about 40 TE cells and 20 ICM cells. In the human, implantation generally takes place 3 days after the embryo enters the uterus. The development of the blast with the separation of the ICM from the developing TE together make up the first stage of differentiation in the embryo. Differentiation within the ICM proceeds fairly rapidly, and if separation of cells and twinning occur at this point, the twins may be conjoined in some fashion.

Advances in assisted reproductive technology and genetics now provide practitioners assess to the early embryo for preimplantation genetic diagnosis (PGD) of single-gene disorders

or preimplantation genetic screening (PGS) for chromosome abnormalities (Fig. 1.8). This technique involves removal of up to 20 TE cells from the day 5 blast for analysis. For PGD of single-gene disorders, DNA is extracted from the cells and the mutation analyzed by polymerase chain reaction (PCR) amplification or single nucleotide polymorphism (SNP) microarray. For PGS of chromosomal defects such as aneuploidy or structural rearrangements, analysis of DNA is performed with comparative genomic hybridization (CGH)-array (Fiorentino, 2014) or partial genomic sequencing (next-generation sequencing).

IMPLANTATION

Implantation consists of apposition, attachment, and invasion. This complex process has much redundancy and involves multiple factors including ovarian hormones, cytokines, transcription factors, growth factors, and extracellular matrix proteins (ECMs) (Table 1.1). Both the endometrium and the embryo produce these factors. Communication between the embryo and the endometrium is key. Implantation occurs 7 to 10 days after ovulation corresponding to cycle days 21 to 24 of an idyllic 28-day cycle with ovulation on day 14. During apposition the human embryo is oriented with the ICM and polar TE (TE next to the ICM) adjacent to the endometrium.

For attachment to the endometrium, the embryonic cells must first be expelled from the surrounding ZP in the process of “hatching.” Hatching involves rupture of the ZP in one small area as opposed to a general dissolution of the entire ZP. This may involve hydrostatic pressure from inside the ZP and from zonal proteases produced by the TE and endometrium. These cysteine proteases, named *cathepsins*, are essential for hatching. Attachment of the embryonic cells to the endometrial cells involves cell adhesion proteins, integrins, and ECM proteins such as fibronectin, laminin, and collagen. Integrins are cell surface proteins, which bind extracellular matrix proteins and are expressed on both the luminal epithelium and TE.

Invasion of the TE cells next occurs by penetrating between the luminal epithelial cells, through the basement membrane and into the stroma of the endometrium. These initial TE cells form the extravillous trophoblasts (EVTs), which invade down to the inner third of the myometrium for anchoring and into the spiral arteries for remodeling. During spiral artery remodeling, endovascular EVT disorganize and partially replace the smooth muscle wall and the vascular endothelial cells. Proliferation of endovascular EVT leads to plugging and obstruction of the decidual spiral arteries resulting in a decrease in blood flow and oxygen tension. Low oxygen promotes the proliferation and transformation of cytotrophoblast to syncytiotrophoblast. Prior to 8 weeks' gestation, nutrition to the embryo is derived from endometrial gland secretion and plasma seeping through the obstructed spiral arteries into the intervillous space. With continued remodeling of the spiral arteries, patency is reestablished and maternal blood cells enter the intervillous space at around 9 weeks' gestation with a rise in oxygen tension. Lack of adequate EVT invasion and spiral artery remodeling is a key feature in preeclampsia, intrauterine growth restriction, and stillbirth (Brosens, 2002).

The idea of low oxygen tension during early embryo development has been explored with IVF. With a limited number of

Figure 1.7 Six photomicrographs of fresh, unmounted human eggs and embryos. **A**, Recently retrieved human oocyte surrounded by cumulus cells. **B**, Fertilized oocyte demonstrating male and female pronuclei and both polar bodies at approximately 11 and 12 o'clock position. **C**, Two-cell zygote with scattered cumulus cells remaining attached to the zona pellucida. **D**, Eight-cell zygotes. **E**, Blastocyst with the inner cell mass seen at 12 o'clock. **F**, A hatching blastocyst in which a portion of the trophoblast has extruded from the zona pellucida at the 4 o'clock position. (Courtesy of Douglas Raburn, PhD.)

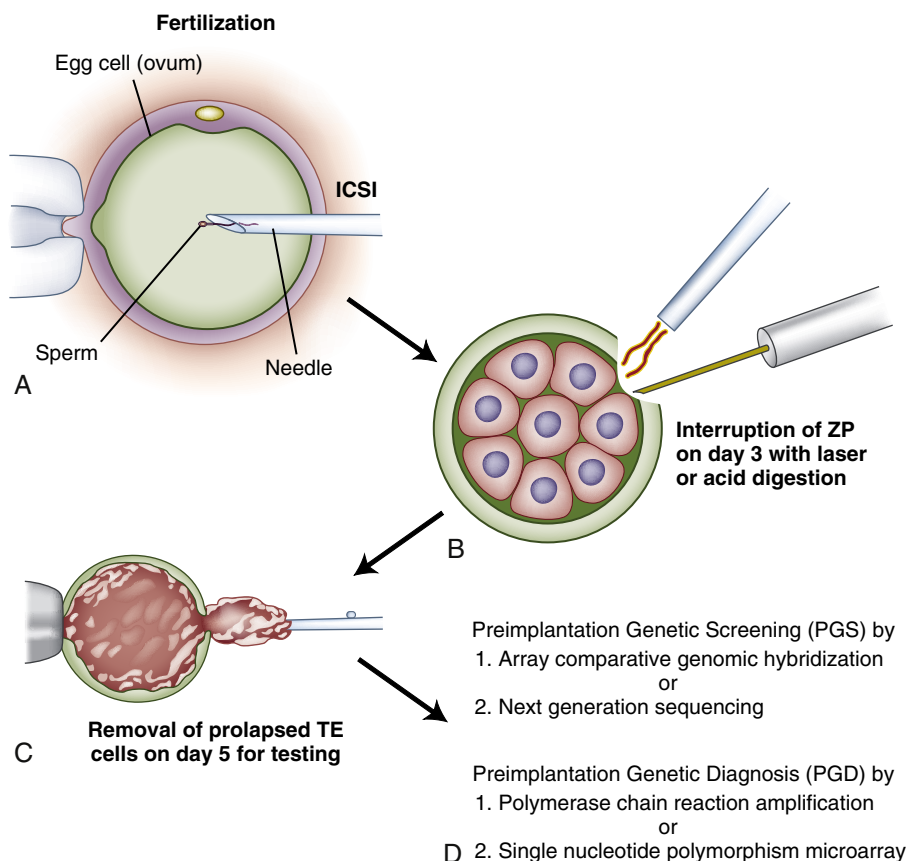

Figure 1.8 Schematic of preimplantation testing. **A**, Commonly the oocyte is fertilized with a single sperm using the technique of intracytoplasmic sperm injection (ICSI). This precludes the possibility of contamination from sperm remaining attached to the outside of the embryo during embryo biopsy. **B**, On day 3 of culture, when the embryo has cleaved to about eight cells, a small opening is made in the zona pellucida (ZP) with either a laser or brief exposure to an acid solution. **C**, By day 5 of culture, the embryo has progressed to the blastocyst stage and a portion of the trophoblast (TE) cells have prolapsed out the opening in the zona pellucida. These cells are removed for subsequent DNA isolation. **D**, DNA from trophoblast cells is used to determine chromosome number, insertions, and deletions for preimplantation genetic screening (PGS) using techniques of array comparative genomic hybridization (aCGH) or next-generation sequencing (NGS). DNA may also be used to detect single-gene abnormalities for different diseases using single nucleotide polymorphism (SNP) microarray or polymerase chain reaction (PCR) amplification in the process of preimplantation genetic diagnosis (PGD).

Table 1.1 Events of Implantation

Event	Days after Ovulation
Zona pellucida disappears	4-5
Blastocyst attaches to epithelial surface of endometrium	6
Trophoblast erodes into endometrial stroma	7
Trophoblast differentiates into cytotrophoblastic and syncytial trophoblastic layers	7-8
Lacunae appear around trophoblast	8-9
Blastocyst burrows beneath endometrial surface	9-10
Lacunar network forms	10-11
Trophoblast invades endometrial sinusoids, establishing a uteroplacental circulation	11-12
Endometrial epithelium completely covers blastocyst	12-13
Strong decidual reaction occurs in stroma	13-14

trials, culturing embryos in 5% oxygen as opposed to 20% oxygen results in a modest increase in the implantation rate (Bonteke, 2012).

Villous trophoblast form finger-like projections extending into the intervillous space and thus surrounded by maternal blood. Syncytiotrophoblast form the outer layer with an underlying layer of precursor cytotrophoblast surrounding matrix containing capillaries, fibroblasts, and macrophages. Cytotrophoblasts become less numerous as pregnancy progresses.

Blood levels of the pregnancy hormone human chorionic gonadotropin (hCG) can be detected within 48 hours of implantation. Regular hCG is produced by the syncytiotrophoblast of placental villi. Blood levels peak at 56 to 68 days, reach a nadir at 18 weeks, and then remain fairly constant until delivery. Gonadotropin-releasing hormone (GnRH) produced in the cytotrophoblast and syncytiotrophoblast induces expression of hCG. In spontaneous pregnancies hCG can be detected 9 days following follicle rupture observed by ultrasound. In IVF pregnancies, the

hormone can be found 8 days after embryo transfer. hCG levels rise, exponentially up to 8 weeks from the last menstrual period, but the doubling time increases as the level increases. For example, in a conception cycle with ovulation on cycle day 14, the doubling time from cycle days 25 to 37 for hCG is 1.6 days and from days 38 to 44 it is 2.3 days (Zegers-Hochschild, 1994). The doubling time is independent of the number of gestations, although the absolute hCG level is higher for multiple pregnancies.

The classic action of regular hCG is maintenance of the corpus luteum (CL) by binding the luteinizing hormone (LH) receptor for continued estrogen and progesterone production. Yet other identified actions include promotion of angiogenesis in the uterus, myometrial relaxation, inhibition of immune interaction at the utero-placental interface, stimulation of fetal testosterone production, and mediation of hyperemesis through receptors in the brain.

Hyperglycosylated hCG (H-hCG) is produced by the EVT. H-hCG is key in promoting angiogenesis and cell invasion and correspondingly is found in the early first trimester. The protein does not activate the LH receptor and does not preserve CL function. Instead it appears to function via the transforming growth factor beta (TGF- β) receptor (Berndt, 2013). Low levels of H-hCG indicate poor EVT development and are associated with spontaneous abortion and early preeclampsia (Fournier, 2015).

DECIDUALIZATION

Progesterone is responsible for “decidualization” of the endometrium. This refers to morphologic and functional changes in stromal cells. In humans, stromal cells close to the spiral arteries undergo progesterone-induced decidual changes in the late secretory phase, and this process progresses throughout the stroma with implantation and hCG production. A pregnancy within the uterus is not required and decidualization is a common finding with ectopic pregnancies. Decidual cells show morphologic changes of increased size with increased glycogen and lipid accumulation (Maruyama, 2008). With pregnancy the endometrium is now referred to as the *decidua*, separated into areas of the decidua basalis or placentalis, which interacts with the TE (area of mature placenta), the decidua vera or parietalis (decidua distant from the implantation site), and the decidua capsularis (surrounding the embryo on the side opposite the placenta).

Another classic histologic change seen in early pregnancy is the Arias-Stella reaction (Fig. 1.9). This occurs in the glandular cells with a hallmark of nuclear enlargement. These cells may be misinterpreted as atypical or malignant. In the presence of hCG, the Arias-Stella reaction may be seen in extrauterine tissues such as endometriosis, vaginal adenosis, paraovarian cysts, and mucinous cystadenomas (Arias-Stella, 2002).

Morphologically luminal epithelial cells develop extensions of the plasma membrane called *pinopods* (also called *uterodomes*) during the window of receptivity. Pinopods function to release key proteins including leukemia inhibitory factor (LIF) through exocytosis and apocrine secretion (Kabir-Salmani, 2005).

Downstream effects of progesterone-dependent decidualization have not been completely elucidated, but loss-of-function studies show the necessity of transcription factors including CCAAT/enhancer binding protein Beta (C/EBP β), Homeobox A10 (Hoxa10), Forkhead/winged helix protein (FoxO1), and chicken ovalbumin upstream promoter (COUP-TFII).

Figure 1.9 Photomicrograph of the Arias-Stella reaction. hCG action results in nuclear enlargement in endometrial glandular cells (arrows) resulting in visual characteristics of malignant cells. Magnification, $\times 200$. (Courtesy of Rex Bentley, MD.)

A functional progesterone receptor requires interaction with “chaperone” proteins. In mice, one of these proteins, named *FK506 binding protein 52* (FKBP52), is expressed in the endometrium during the window of receptivity, and a loss of function mutation disrupts decidualization.

LIF is a cytokine produced by endometrial glandular cells around the time of implantation. LIF acts on EVT to increase the fibronectin production necessary for embryo attachment and invasion. Mice lacking expression of LIF (knockout) have both failure of decidualization and implantation (Chen, 2000).

Indian hedgehog (Ihh) protein is a morphogen produced by luminal epithelial cells under the control of progesterone. Morphogens are signaling proteins that diffuse throughout the decidua yielding a concentration gradient. Signaling is dependent on the concentration in a given area. *Ihh* knockout mice fail to decidualize or implant (Ramathal, 2010).

EMBRYO-ENDOMETRIAL COMMUNICATION

Implantation involves molecular interactions between the embryo and the adjacent endometrium. For example, the embryo produces heparin-binding epidermal growth factor-like growth factor (HB-EGF), which is both found on the cell membrane and is released from the cell (soluble). HB-EGF induces expression of itself in the adjacent endometrial cells (auto-induction loop). HB-EGF on the endometrial cells then acts to attach the embryo via EGF receptors expressed on the embryo (Lim, 2009). Additionally, the soluble HB-EGF from the embryo induces expression of cyclooxygenase to increase prostacyclin (PGI₂) in the endometrium resulting in enhanced endometrial vascular permeability to help with embryo invasion (Kim, 1999).

IMMUNOLOGY OF IMPLANTATION

The paternal contribution to the embryo results in the mother being exposed to allogenic cells. Although villous trophoblasts do not express major human leukocyte antigens (HLA), the EVTs express HLA-C, E, and G, which may be recognized by

the maternal immune system. Thus the maternal immune system must be locally suppressed to prevent rejection.

The majority of immune cells in the decidua are uterine natural killer (uNK) cells. These cells are present in the secretory endometrium, under the control of progesterone, and increase in number with pregnancy to form an infiltrate around the invading EVT. These cells start to dissipate in the second trimester. uNK cells are not cytotoxic to trophoblast cells and in fact appear to be supportive. A low number of uNK cells in the decidua of early pregnancy is associated with poor invasion of the EVT. Cytokines such as interferon gamma and angiogenic factors secreted by uNK cells are key to proper EVT development and function.

T-helper (Th) cells are also found in the decidua and are functionally classified as Th1 (cellular immunity), Th2 (humoral immunity), Th3 (production of transforming growth factor-beta for immunosuppression), and Tr1 (production of interleukin 10 for immunosuppression) (Saito, 2007). In early pregnancy, there is an increase in the percentage of decidual Th2 and Th3 cells.

T-regulatory cells (Tregs) function in antigen recognition for future immune tolerance. Mice lacking Treg cells experience abortion when mated with an allogenic male but not when mated with a syngenic male (Darasse-Jeze, 2006). These cells are key in developing tolerance to male antigens. Development of immunity to specific paternal antigens may explain observations including lower preeclampsia rates in women exposed to their partner's semen prior to pregnancy compared with women conceiving with donor insemination (Salha, 1999), and the lower preeclampsia rate in the second pregnancy with the same partner as opposed to a new partner.

EARLY ORGANOGENESIS IN THE EMBRYONIC PERIOD

During the third week after fertilization, the primitive streak forms in the caudal portion of the embryonic disk, and the embryonic disk begins to grow and change from a circular to a pear-shaped configuration. At that point the epithelium superiorly is considered ectoderm and will eventually give rise to the developing central nervous system, and the epithelium facing downward toward the yolk sac is endoderm. During this week the neuroplate develops with its associated notochordal process. By the sixteenth day after conception the third primitive germ layer, the intraembryonic mesoderm, begins to form between the ectoderm and endoderm. Early mesoderm migrates cranially, passing on either side of the notochordal process to meet in front in the formation of the cardiogenic area. The heart soon develops from this area. Later in the third week, extraembryonic mesoderm joins with the yolk sac and the developing amnion to contribute to the developing membranes.

An intraembryonic mesoderm develops on each side of the notochord and neural tube to form longitudinal columns, the paraxial mesoderm. Each paraxial column thins laterally into the lateral plate mesoderm, which is continuous with the extraembryonic mesoderm of the yolk sac and the amnion. The lateral plate mesoderm is separated from the paraxial mesoderm by a continuous tract of mesoderm called the *intermediate mesoderm*. By the twentieth day, paraxial mesoderm begins to divide into paired linear bodies known as *somites*. About 38 pairs of somites form during the next 10 days. Eventually a total of 42 to 44 pairs will develop, and these will give rise to body musculature (O'Rahilly, 1979).

Angiogenesis, or blood vessel formation, can be seen in the extraembryonic mesoderm of the yolk sac by day 15 or 16. Embryonic

vessels can be seen about 2 days later and develop when mesenchymal cells known as *angioblasts* aggregate to form masses and cords called *blood islands*. Spaces then appear within these islands, and the angioblasts arrange themselves around these spaces to form primitive endothelium. Isolated vessels form channels and then grow into adjacent areas by endothelial budding. Primitive blood cells develop from endothelial cells as the vessels develop on the yolk sac and allantois. However, blood formation does not begin within the embryo until the second month of gestation, occurring first in the developing liver and later in the spleen, bone marrow, and lymph nodes. Separate mesenchymal cells surrounding the primitive endothelial vessels differentiate into muscular and connective tissue elements. The primitive heart forms in a similar manner from mesenchymal cells in the cardiogenic area. Paired endothelial channels, called *heart tubes*, develop by the end of the third week and fuse to form the primitive heart. By the twenty-first day, this primitive heart has linked up with blood vessels of the embryo, forming a primitive cardiovascular system. Blood circulation starts about this time, and the cardiovascular system becomes the first functioning organ system within the embryo (Clark, 1987). All the organ systems form between the fourth week and seventh week of gestation.

A teratogenic event that takes place during the embryonic period gives rise to a constellation of malformations related to the organ systems that are actively developing at that particular time. Thus cardiovascular malformations tend to occur because of teratogenic events early in the embryonic period, whereas genitourinary abnormalities tend to result from later events. Teratogenic effects before implantation often cause loss of the embryo but not malformations. The effects of a particular teratogen depend on the individual's genetic makeup, other environmental factors in play at the time, the embryonic developmental stage during which the teratogenic exposure occurred, and in some cases the dose of the teratogen and the duration of exposure. Some teratogens in and of themselves are actually harmless, but their metabolites cause the damage. Teratogens may be chemical substances and their by-products, or they may be physical phenomena, such as temperature elevation and irradiation. The embryo is most sensitive to teratogens during organogenesis of the embryonic period from 18 to 56 days postconception. Prior to day 18, exposure is most likely to result in either embryo death with miscarriage or no effect, as the majority of cells are pluripotent (Polifka, 2002). Teratogen exposure after the embryonic period of development may injure or kill the embryo or cause developmental and growth retardation but usually will not be responsible for specific malformations. The period of embryonic development is said to be complete at 56 days (8 weeks) from fertilization or 70 days (10 weeks) from the last menstrual period followed by the fetal stage.

DEVELOPMENT OF THE GENITOURINARY SYSTEM

The development of the genital organs is intimately involved with the development of the renal system.

RENAL DEVELOPMENT

Nephrogenic cords develop from the intermediate mesoderm as early as the 2-mm embryo stage, beginning in the more cephalad portions of the embryo. Three sets of excretory ducts and tubules

develop bilaterally (Little, 2010). The first, the pronephros, with its pronephric ducts, forms in the most cranial portion of the embryo at about the beginning of the fourth week after conception. The tubules associated with the duct probably have no excretory function in the human, but the caudal end will form the adrenal gland. Late in the fourth week, a second set of tubules, the mesonephric tubules, and their accompanying mesonephric ducts begin to develop. These are associated with tufts of capillaries, or glomeruli, and tubules for excretory purposes. Thus the mesonephros functions as a fetal kidney, producing urine for about 2 or 3 weeks. As new tubules develop, those derived from the more cephalad tubules degenerate. Usually about 40 mesonephric tubules function on either side of the embryo at any given time. The gonads arise from the central region of the mesonephros. The metanephros, or permanent kidney, begins its development early in the fifth week of gestation and starts to function late in the seventh or early in the eighth week. The metanephros develops both from the metanephrogenic mass of mesoderm, which is the most caudal portion of the nephrogenic cord, and from its duct system, which is derived from the metanephric diverticulum (ureteric bud). It is a cranially growing outpouching of the mesonephric duct close to where it enters the cloaca. The metanephric duct system gives rise to the ureter, the renal pelvis, the calyces, and the collecting tubules of the adult kidney. A critical process in the development of the kidney requires that the cranially growing metanephric diverticulum meets and fuses with the metanephrogenic mass of mesoderm so that formation of the kidney can take place. Originally the metanephric kidney is a pelvic organ, but by differential growth it becomes located in the lumbar region (Moritz, 1999).

The fetus produces urine starting at 8 weeks' gestation (Underwood, 2005). Starting in the second trimester, fetal urine is a major contributor to amniotic fluid volume. The fetus may swallow the amniotic fluid and recirculate it through the digestive system. Congenital abnormalities that impair normal development or function of the fetal kidneys generally result in little or no amniotic fluid (oligohydramnios or anhydramnios), whereas structural abnormalities of the gastrointestinal tract or neuromuscular conditions that prevent the fetus from swallowing can lead to excess amniotic fluid (polyhydramnios).

BLADDER AND URETHRA

The embryonic cloaca is divided by the urorectal septum into a dorsal rectum and a ventral urogenital sinus. The urogenital sinus, in turn, is divided into three parts: the cranial portion (the vesicourethral canal), which is continuous with the allantois; a middle pelvic portion; and a caudal urogenital sinus portion, which is covered externally by the urogenital membrane. The epithelium of the developing bladder is derived from the endoderm of the vesicourethral canal. The muscular layers and serosa of the bladder develop from adjacent splanchnic mesenchyme. As the bladder develops, the caudal portion of the mesonephric ducts is incorporated into its dorsal wall. The portion of the mesonephric duct distal to the points where the metanephric duct is taken up into the bladder becomes the trigone of the bladder. Although this portion is mesoderm in origin, it is probably epithelialized eventually by endodermal epithelium from the urogenital sinus. In this way the ureters, derived from the metanephric duct, come to open directly into the bladder.

In the male the mesonephric ducts open into the urethra as the ejaculatory ducts. Also in the male, mesenchymal tissue surrounding the developing urethra where it exits the bladder develops into the prostate gland, through which the ejaculatory ducts traverse. Figure 1.10 demonstrates graphically the development of the male and female urinary systems.

The epithelium of the female urethra is derived from endoderm of the vesicourethral canal. The urethral sphincter develops from a mesenchymal condensation around the urethra after the division of the cloaca in the 12- to 15-mm embryo. Following the opening of the anal membrane at the 20- to 30-mm stage, the puborectalis muscle appears. At 15 weeks' gestation, striated muscle can be seen, and a smooth muscle layer thickens at the level of the developing bladder neck, forming the inner part of the urethral musculature. Thus the urethral sphincter is composed of both central smooth muscle and peripheral striated muscle. The sphincter develops primarily in the anterior wall of the urethra in a horseshoe or omega shape (Matsuno, 1984).

MOLECULAR BASIS OF SEX DIFFERENTIATION

Genetic sex is determined at the time of conception. A Y chromosome is necessary for the development of the testes, and the testes are responsible for the organization of the sexual duct system into a male configuration and for the suppression of the paramesonephric (müllerian) system of the female. In the absence of a Y chromosome or in the absence of a gonad, development will be female in nature. Male differentiation is determined by expression of the *SRY* gene found on the short arm of the Y chromosome. *SRY* protein is a transcription factor and expression is unique to the Sertoli cell of the developing testis. *SRY* induces expression of another transcription factor, *SOX9*, which is also obligatory for male sex differentiation. A loss of function mutation of either *SRY* or *SOX9* results in XY sex reversal, in which genetic males are phenotypic females. Several genes regulate *SRY/SOX9* expression including Wilms' tumor suppressor 1 (*Wt1*) and steroidogenic factor 1 (*Sf1*). *WT1* is a transcription factor expressed in both urinary tract and gonadal tissue. A loss of function mutation results in glomerulosclerosis and gonadal dysgenesis. *Sf1* encodes a nuclear receptor necessary for steroidogenesis, gonadal differentiation, and adrenal formation. A loss of function mutation is associated with adrenal failure and XY sex reversal (Ozisik, 2003).

Although ovarian formation can only occur in the absence of *SRY/SOX9*, there are unique genes necessary for development. *FoxL2* encodes a transcription factor necessary for granulosa cell expansion. A loss of function mutation causes ovarian failure with other associated abnormalities found in blepharophimosis-ptosis-epicanthus inversus syndrome (BPES) (De Baere, 2001). *BMP15*, located on the X chromosome, and *GDF9* on chromosome 5 encode growth factors expressed in oocytes required for granulosa cell proliferation. A heterozygous loss of function mutation results in ovarian failure (Di Pasquale, 2004).

The understanding of the molecular basis of sex determination continues to expand with more than 25 genes so far identified in the process (Wilhelm, 2007).

Figure 1.10 Diagrams showing division of the cloaca into the urogenital sinus and rectum; absorption of the mesonephric ducts; development of the urinary bladder, urethra, and urachus; and changes in the location of the ureters. **A**, Lateral view of the caudal half of a 5-week embryo. **B**, **D**, and **F**, Dorsal views. **C**, **E**, **G**, and **H**, Lateral views. The stages shown in **G** and **H** are reached by the twelfth week. (From Moore KL, Persaud TVN. *The Developing Human: Clinically Oriented Embryology*. 7th ed. Philadelphia: WB Saunders; 2003.)

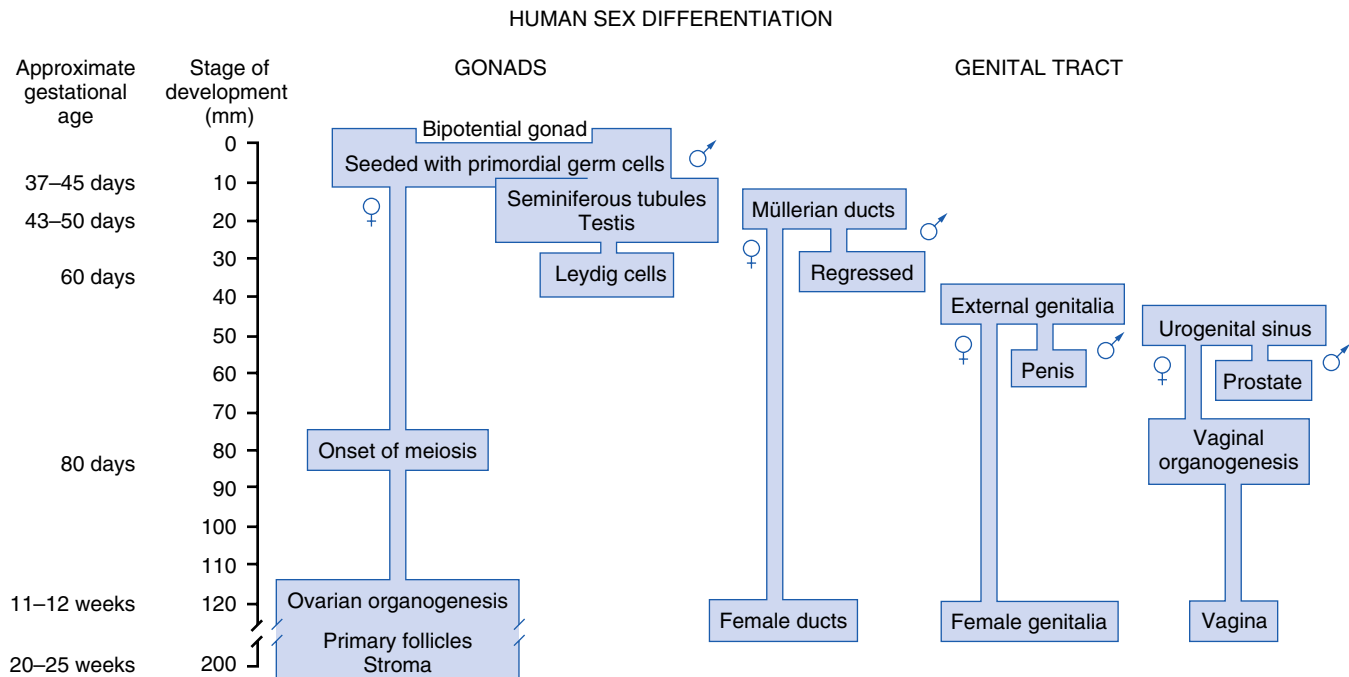

Figure 1.11 Development of sexual differentiation in the human. Note the lag from male to female development. (Modified from Grumbach MM, Hughes IA, Conte FA. Disorders of sex differentiation. In: Larsen PR, Kronenberg HM, Melmed S, et al, eds. *Williams Textbook of Endocrinology*. 10th ed. Philadelphia: WB Saunders; 2003:870.)

GENITAL DEVELOPMENT

Male gonadal development precedes female development (Fig. 1.11). During the fifth week after conception, coelomic epithelium, later known as *germinal epithelium*, thickens in the area of the medial aspect of the mesonephros. As germinal epithelial cells proliferate, they invade the underlying mesenchyme, producing a prominence known as the *gonadal ridge*. In the sixth week the primordial germ cells, which have formed at about week 4 in the wall of the yolk sac, migrate up the dorsal mesentery of the hindgut and enter the undifferentiated gonad. The somatic cells of the primitive gonadal ridge then differentiate into interstitial cells (Leydig cells) and Sertoli cells. As they do so, the primordial germ cells and Sertoli cells become enclosed within seminiferous tubules, and the interstitial cells remain outside these tubules. Sertoli cells are encased in the seminiferous tubules in the seventh and eighth weeks. In the eighth week, Leydig cells differentiate and begin to produce testosterone. At this point the mesonephric (wolffian) duct differentiates into the vas deferens, epididymis, and seminal vesicles, whereas the paramesonephric duct (müllerian duct) is suppressed because of the secretion and action of anti-müllerian hormone (AMH), also known as *müllerian inhibitory substance* (MIS), by Sertoli cells.

Primary sex cords, meanwhile, have condensed and extended to the medullary portion of the developing testes. They branch and join to form the rete testis. The testis therefore is primarily a medullary organ, and eventually the rete testis connects with the tubules of the mesonephric system and joins the developing epididymal duct.

Development of the ovary occurs at about the eleventh or twelfth week, although the primordial germ cells have migrated

several weeks earlier to the germinal ridge (Fig. 1.12). Two functional X chromosomes are necessary for optimal development of the ovary. Deletion of either the short arm or the long arm of a single X chromosome precludes normal ovarian function, with the former being associated with Turner syndrome (Simpson, 1999). The processes of gonadal development are schematically summarized in Figure 1.13.

GENITAL DUCT SYSTEM

Early in embryonic life, two sets of paired genital ducts develop in each sex: the mesonephric (wolffian) ducts and the paramesonephric (müllerian) ducts. The mesonephric duct development precedes the paramesonephric duct development. The paramesonephric ducts develop on each side of the mesonephric ducts from the evaginations of the coelomic epithelium. The more cephalad ends of the ducts open directly into the peritoneal cavity, and the distal ends grow caudally, fusing in the lower midline to form the uterovaginal primordium. This tubular structure joins the dorsal wall of the urogenital sinus and produces an elevation, the müllerian tubercle. The mesonephric ducts enter the urogenital sinus on either side of the tubercle.

MALE GENITAL DUCTS

Seminiferous tubules are produced in the fetal testes during the seventh and eighth weeks after conception. During the eighth week, interstitial (Leydig) cells differentiate and begin to produce testosterone. Male internal genital development is mainly dependent on testosterone, whereas external genitalia are dependent on 5 α -dihydrotestosterone (DHT). Testosterone produced

Figure 1.12 Ovary in embryo. **A**, The developing ovary (O) in a 9-week-old fetus is shown close to the developing kidney (K). **B**, At this stage of development, the columns of primordial germ cells (G) are embedded in a mesenchymal stroma (S) covered by a layer of cuboidal surface cells (E). (From Stevens A, Lowe J. *Human Histology*. 3rd ed. Philadelphia: Elsevier Mosby; 2005:357.)

by the Leydig cells stimulates growth and development of the wolffian duct structures of vas deferens, epididymis, and seminal vesicles. DHT formed in target tissues by the enzyme type 2 5 α -reductase is responsible for formation of the prostate, scrotum, and penis (Thigpen, 1993).

Maternal hCG production may be key to male genital development. The maximum serum level of hCG at approximately 8 weeks postconception or 10 menstrual weeks correlates with the timing of male genital formation, and the highest fetal testosterone levels are seen at 11 to 17 weeks with a subsequent decline (Reyes, 1974). hCG acting via the LH receptor is responsible for stimulating Leydig cell testosterone production.

The bulbourethral glands, which are small structures that develop from outgrowths of endodermal tissue from the membranous portion of the urethra, incorporate stroma from the adjacent mesenchyme. The most distal portion of the paramesonephric duct remains, in the male, as the appendix of the testes. The most proximal end of the paramesonephric duct remains as a small outpouching within the body of the prostate gland, known as the prostatic utricle. Rarely, the prostatic utricle is developed to the point where it will excrete a small amount of blood and cause hematuria in adult life (Schuhrke, 1978).

FEMALE GENITAL DUCTS

In the absence of AMH, the mesonephric ducts regress, and the paramesonephric ducts develop into the female genital tract. This process begins at about 6 weeks and proceeds in a cephalad to caudal fashion. The more cephalad portions of the paramesonephric ducts, which open directly into the peritoneal cavity, form the fallopian tubes. The fused portion, or uterovaginal primordium, gives rise to the epithelium and glands of the uterus and cervix. Endometrial stroma and myometrium are derived from adjacent mesenchyme. Failure of development of the paramesonephric ducts leads to agenesis of the cervix and the uterus referred to as *müllerian agenesis* or

Mayer-Rokitansky-Kuster-Hauser syndrome (Langman, 1982). Failure of fusion of the caudal portion of these ducts may lead to a variety of uterine anomalies, including complete duplication of the uterus and cervix or partial duplication of a variety of types, which are outlined in Chapter 11. Peritoneal reflections in the area adjacent to the fusion of the two paramesonephric ducts give rise to the formation of the broad ligaments. Mesenchymal tissue here develops into the parametrium.

Pietryga and Wózniać studied the development of uterine ligaments, documenting the development of the round ligament at the eighth week, the cardinal ligaments at the tenth week, and the broad ligament at week 19. From weeks 8 to 17, the round ligament is connected to the uterine tube (Pietryga, 1992). Beginning at week 18 it comes to arise from the edge of the uterus.

The vagina develops from paired solid outgrowths of endoderm of the urogenital sinus—the sinovaginal bulbs. These grow caudally as a solid core toward the end of the uterovaginal primordium. This core constitutes the fibromuscular portion of the vagina. The sinovaginal bulbs then canalize to form the vagina. Abnormalities in this process may lead to either transverse or horizontal vaginal septa. The junction of the sinovaginal bulbs with the urogenital sinus remains as the vaginal plate, which forms the hymen. This remains imperforate until late in embryonic life, although occasionally, perforation does not take place completely (imperforate hymen). Failure of the sinovaginal bulbs to form leads to agenesis of the vagina (Griffin, 1976).

Auxiliary genital glands in the female form from buds that grow out of the urethra. The buds derive contributions from the surrounding mesenchyme and form the urethral glands and the paraurethral glands (Skene glands). These glands correspond to the prostate gland in males. Similar outgrowths of the urogenital sinus form the vestibular glands (Bartholin glands), which are homologous to the bulbourethral glands in the male. The remnants of the mesonephric duct in the female include a small structure called the *appendix vesiculosa*, a few

Figure 1.13 Schematic illustration showing differentiation of the indifferent gonads of a 5-week embryo (top) into ovaries or testes. Left side shows the development of testes resulting from the effects of the testis-determining factor (TDF), also called the *SRY gene*, located on the Y chromosome. Note that the gonadal cords become seminiferous cords, the primordium of the seminiferous tubules. The parts of the gonadal cords that enter the medulla of the testis form the rete testis. In the section of the testis at the bottom left, observe that there are two kinds of cells: spermatogonia derived from the primordial germ cells and sustentacular (Sertoli) cells derived from mesenchyme. The right side shows the development of ovaries in the absence of TDF. Cortical cords have extended from the surface epithelium of the gonad, and primordial cells have entered them. They are the primordia of the oogonia. Follicular cells are derived from the surface epithelium of the ovary. (From Moore KL, Persaud TVN. *The Developing Human: Clinically Oriented Embryology*. 7th ed. Philadelphia: WB Saunders; 2003.)

blind tubules in the broad ligaments (the epoophoron), and a few blind tubules adjacent to the uterus (collectively called the *paroöphoron*). Remnants of the mesonephric duct system are often present in the broad ligaments or may be present adjacent to the uterus or the vagina as Gartner duct cysts (Deppisch, 1975). The epoophoron or paroöphoron may develop into cysts. Cysts of the epoophoron are known as *paraovarian cysts* (Chapter 18). Remnants of the paramesonephric duct in the female may be seen as a small, blind cystic structure attached by a pedicle to the distal end of the fallopian tube—the hydatid of Morgagni. Table 1.2 categorizes the adult derivatives and residual remnants of the urogenital structures in both the male and the female. Figure 1.14 outlines schematically the development of the internal sexual organs in both sexes.

EXTERNAL GENITALIA

In the fourth week after fertilization, the genital tubercle develops at the ventral tip of the cloacal membrane. Two sets of lateral bodies—the labioscrotal swellings and urogenital folds—develop soon after on either side of the cloacal membrane. The genital tubercle then elongates to form a phallus in both males and females. By the end of the sixth week, the cloacal membrane is joined by the urorectal septum. The septum separates the cloaca into the urogenital sinus ventrally and the anal canal and rectum dorsally (Hynes, 2004). The point on the cloacal membrane where the urorectal septum fuses becomes the location of the perineal body in later development. The cloacal membrane is then divided into the ventral urogenital membrane and the dorsal anal membrane. These membranes then open, yielding the

vulva and the anal canal. Failure of the anal membrane to open gives rise to an imperforate anus. With the opening of the urogenital membrane, a urethral groove forms on the undersurface of the phallus, completing the undifferentiated portion of external genital development. Differences between male and female embryos can be noted as early as the ninth week, but the distinct final forms are not noted until 12 weeks' gestation (Fig. 1.15).

The phallus grows in length to form a penis, and the urogenital folds are pulled forward to form the lateral walls of the urethral groove on the undersurface of the penis. These folds then fuse to form the penile urethra. Defects in fusion of various amounts give rise to various degrees of hypospadias. The skin at the distal margin of the penis grows over the glans to form the prepuce (foreskin). The vascular portion of the penis (corpora cavernosa penis and corpus cavernosum urethrae) arises from the mesenchymal tissue of the phallus. Finally, the labioscrotal swellings grow toward each other and fuse in the midline to form the scrotum. Later in embryonic life, usually at about the twenty-eighth week, the testes descend through the inguinal canal guided by the gubernaculum (Frey, 1984).

Feminization of the undifferentiated external genitalia occurs in the absence of androgen stimulation. The embryonic phallus does not demonstrate rapid growth and becomes the clitoris. Urogenital folds do not fuse except in front of the anus. The unfused urogenital folds form the labia minora. The labioscrotal folds fuse posteriorly in the area of the perineal body but laterally remain as the labia majora. Beyond 12 weeks' gestation, the labioscrotal folds will not fuse if the fetus is exposed to androgens, though masculinization may occur in other organs of the external genitalia such as growth of the clitoris. The labioscrotal

Table 1.2 Male and Female Derivatives of Embryonic Urogenital Structures

Embryonic Structure	DERIVATIVES	
	Male	Female
Labioscrotal swellings	Scrotum	Labia majora
Urogenital folds	Ventral portion of penis	Labia minora
Phallus	Penis	Clitoris
	Glans, corpora cavernosa penis, and corpus spongiosum	Glans, corpora cavernosa, bulb of the vestibule
Urogenital sinus	Urinary bladder	Urinary bladder
	Prostate gland	Urethral and paraurethral glands
	Prostatic utricle	Vagina
	Bulbourethral glands	Greater vestibular glands
	Seminal colliculus	Hymen
Paramesonephric duct	Appendix of testes	Hydatid of Morgagni
		Uterus and cervix
		Fallopian tubes
Mesonephric duct	Appendix of epididymis	Appendix vesiculosus
	Ductus of epididymis	Duct of epoophoron
	Ductus deferens	Gartner duct
	Ejaculatory duct and seminal vesicle	—
Metanephric duct	Ureters, renal pelvis, calyces, and collecting system	Ureter, renal pelvis, calyces, and collecting system
Mesonephric tubules	Ductuli efferentes	Epoophoron
	Paradidymis	Paroöphoron
Undifferentiated gonad	Testis	Ovary
Cortex	Seminiferous tubules	Ovarian follicles
Medulla	—	Medulla
	Rete testis	Rete ovarii
Gubernaculum	Gubernaculum testis	Round ligament of uterus

Figure 1.14 Schematic drawings illustrating development of the male and female reproductive systems from the genital ducts and urogenital sinus. Vestigial structures are also shown. **A**, Reproductive system in a newborn male. **B**, Female reproductive system in a 12-week fetus. **C**, Reproductive system in a newborn female. (From Moore KL, Persaud TVN. *The Developing Human: Clinically Oriented Embryology*. 7th ed. Philadelphia: WB Saunders; 2003.)

Figure 1.15 Scanning electron micrographs (SEMs) of the developing male external genitalia. **A**, SEM of the perineum during the indifferent state of a 17-mm, 7-week embryo ($\times 100$). 1, Developing glans of penis with the ectodermal cord. 2, Urethral groove continuous with the urogenital sinus. 3, Urogenital folds. 4, Labioscrotal swellings. 5, Anus. **B**, External genitalia of a 7.2-cm, 10-week female fetus ($\times 45$). 1, Glans of clitoris. 2, External urethral orifice. 3, Opening into urogenital sinus. 4, Urogenital folds (labia minora). 5, Labioscrotal swelling (labia majora). 6, Anus. **C**, SEM of the external genitalia of a 5.5-cm, 10-week male fetus ($\times 40$). 1, Glans of penis with ectodermal cord. 2, Remains of urethral groove. 3, Urogenital folds in the process of closing. 4, Labioscrotal swelling fusing to form the raphe of the scrotum. 5, Anus. (From Moore KL, Persaud TVN. *The Developing Human: Clinically Oriented Embryology*. 7th ed. Philadelphia: WB Saunders; 2003.)

folds fuse anteriorly to form the mons pubis. A portion of the urogenital sinus between the level of the hymen and the labia develops into the vestibule of the vagina, into which the urethra, the vagina, and the ducts of Bartholin glands enter. Female external genitalia are intensely estrogen receptor-positive compared with the genitalia of the male. These receptors may be seen primarily in the stroma of the labia minora and in the periphery of the glans and interprepuce (Kalloo, 1993). The presence of such receptors suggests that there may be a direct role of maternal estrogens in the development of female external genitalia.

Virilization, masculinization, of a female (karyotype XX) fetus may occur from exposure to androgens, either from the mother or through fetal androgens as a result of genetic deficiencies in the steroid biosynthetic pathway such as occurs in congenital adrenal hyperplasia.

The ovaries do not descend into the labioscrotal folds. A structure similar to the gubernaculum develops in the inguinal canal, giving rise to the round ligaments, which suspend the uterus in the adult. Figure 1.16 summarizes the development of the external genitalia in each sex.

KEY POINTS

- Oocyte meiosis is arrested at the prophase I from the fetal period until the time of ovulation.
- Fertilization occurs in the ampulla of the fallopian tube before the second polar body is cast off.
- After fertilization, first cell division leading to the two-cell embryo takes about 26 hours.
- The human embryo enters the uterus somewhere between 4 and 5 days after conception at the blastocyst stages of development.
- Implantation occurs when trophoblastic cells contact endometrium and burrow beneath the surface. This generally takes place 3 days after the embryo enters the uterus.
- Twinning due to embryo splitting may occur at any time until the formation of the blastocyst, after which time each cell is no longer pluripotent.
- The earliest fetal epithelium to develop is the ectoderm, the second is the endoderm, and the third is the mesoderm.
- hCG is secreted by the syncytiotrophoblast at about the time of implantation. It doubles in quantity every 1.2 to 2 days until 7 to 9 weeks' gestation.
- Angiogenesis is seen by day 15 or 16. Embryonic heart function begins in the third week of gestation.
- Organogenesis is complete by postconception day 56.
- The mesonephric duct system gives rise in the male to the epididymis, vas deferens, and seminal vesicles. Remnants of the mesonephric duct system in the female remain as parovarian cysts and the Gartner duct.
- The paramesonephric duct system develops in the female to give rise to the fallopian tube, uterus, and cervix. Remnants give rise to the hydatid of Morgagni at the end of the fallopian tubes. Remnants in the male remain as the appendix of the testes and prostatic utricle. This duct system is suppressed in the male by the action of AMH.
- The vagina develops from the sinovaginal bulbs, which are outgrowths of the urogenital sinus. Failure of these bulbs to form leads to agenesis of the vagina.
- The adult kidney develops from the metanephros, and its collecting system (ureter and calyceal system) develops from the metanephric (ureteric) bud from the mesonephric duct.
- The urinary bladder develops from the urogenital sinus.
- The *SRY* gene on the Y chromosome is responsible for the development of testes. Without the presence of this gene, the gonadal development is ovarian. With the absence of Sertoli cells, AMH is not produced, the paramesonephric duct system develops into a phenotypic female configuration, and the mesonephric duct system is suppressed.
- The genital tubercle elongates to form the penis in the male and the clitoris in the female.
- Two functional X chromosomes are necessary for optimal development of the ovary.

GENETIC BASIS OF DISEASE

Medical research and medical care have been profoundly influenced by the advancement of science that succeeded in sequencing the human genome, allowing scientists to concentrate on translating this genomic text to meaningful prose. As the code is deciphered with increasing resolution, it is apparent that virtually all human diseases have an underlying genetic component, although the conversion from *genotype* to ultimate clinical *phenotype* is not always easily understood.

The overarching goals of medical care have not changed: diagnose, treat, and focus on disease prevention. The new promise of medicine in the postgenomic era is to individualize these goals, such that lifestyle interventions, screening modalities, and pharmaceuticals can be tailored to each person based on his or her unique genomic sequence. These goals have begun to materialize, through examples such as detailed breast cancer screening for women in families with known *BRCA1* or *BRCA2* mutations, or tailored chemotherapeutic regimens based on molecular testing of an individual tumor. Furthermore, there is unprecedented public accessibility of the technology for genomic screening or application of genetic information to medical treatment. Since completion of the Human Genome Project in April 2003, technology has advanced at an extraordinary pace to allow *high-throughput* data generation at increasingly reasonable cost. High-throughput methods involve automation of experiments or assays to allow for simultaneous large-scale repetition. Over the first post-genomic decade, the time to prepare and sequence a complete human genome plummeted from 13 years to a matter of 3 to 4 days, and the cost dropped from just under \$30 million to around \$1000 (Topol, 2014).

As a result, genetics is a field that all health care professionals need a basic level of familiarity with, not just the subspecialists. Genetics, genomics, and the technology to interpret the information are now an integral part of mainstream medicine (Table 2.1). The obstetrician/gynecologist is often the first-line provider in helping patients navigate this complicated landscape. This chapter focuses on developing a basic understanding of genetic makeup, heritability, and the most commonly used tools for detecting genetic disorders in patients or their offspring.

BUILDING BLOCKS OF GENETICS

MOLECULAR BUILDING BLOCKS

Genetic information is encoded in *deoxyribonucleic acid* (DNA) in the nucleus of each cell of the body. DNA molecules are made up of two complementary linear sequences of nucleotides intertwined together as a double helix. The backbone of the linear DNA molecule is composed of a phosphate and a pentose sugar (deoxyribose) to which is attached a nitrogen base. Four such bases are found in a DNA molecule: two purines (adenine [A] and guanine [G]) and two pyrimidines (thymine [T] and cytosine [C]). Purine and pyrimidine occur in equal amounts; A is always paired with T in the two strands of the double helix, and G is always paired with C. The order of bases along the molecule is the genetic *sequence*, and the complete sequence of all 6 billion bases in an individual cell nucleus (3 billion paired bases, arranged in linear antisense strands) makes up the *human genome*.

The Central Dogma published by Francis Crick in 1970 remains at the heart of molecular biology (Crick, 1970). The DNA is transcribed to a complementary *ribonucleic acid* (RNA) molecule (messenger RNA), which may be modified by regulatory sequences or three-dimensional (3D) structure. Three-base *codons* are read and translated to amino acids that are linked to form a protein with some function within the cell or organism (Fig. 2.1). The traditional concept of a *gene* refers to a unit of DNA sequence that codes for production of a protein. Surprisingly, with completion of the Human Genome Project, this gene-centric view of biology turned out to be only the tip of the iceberg in understanding the complex manner in which the genetic sequence translates to human life. Of the 3 billion base pairs that make up the genome, only about 1.5% of the assembled sequence codes for proteins. This coding portion, or *exome* contains about 20,000 to 25,000 genes, which is only a fraction of previous estimates that were predicated on gene number correlating with complexity of the species (Gerstein, 2007). There is now significant interest in the remaining 98.5% of the genome, in how it carries out the blueprint of life. There is a growing field of discovery in the regulatory function of specialized noncoding RNA molecules, called *microRNA* (*miRNA*), which appear to be the gatekeepers of many biologic processes (Pritchard, 2012).

MITOSIS/MEIOSIS

The full genome consists of two copies of the total DNA sequence, packaged into two homologous sets of 23 separate *chromosomes* (22 autosome pairs and 1 allosome, or sex chromosome pair). During cell division, an exact replica of this biologic blueprint is passed to each daughter cell through the process of mitosis. The formation of gametes requires even distribution of the chromosomes to the progeny through the process of meiosis, as described in [Chapter 1](#). Upon fertilization, the zygote regains a full diploid complement of genetic material, equally derived from each parent. This process of replicating, packaging, and passing on genetic material from generation to generation forms the basis of heredity. Furthermore, errors in these processes can cause sequence changes or rearrangement of larger portions of DNA, introducing genetic variation or pathology, depending on the location of the change.

GENOMIC VARIATION

Genetic Variation

On April 14, 2003, the Human Genome Project was declared complete, with successful sequencing of the full human genome. Initial interpretation of the sequence result claimed 99.9% similarity between healthy individuals at the DNA sequence level, leaving only 0.1% of the genome sequence to account for individual differences in phenotype ([Lee, 2007](#)). Each alternative form of genetic code at any given *locus* is referred to as an *allele*. An individual inherits two alleles of every genetic locus, one from each parent. If both inherited alleles are made up of the same sequence, the individual is *homozygous* for the given locus. If the alleles are different, the individual is *heterozygous*. The allelic options at any given genetic locus derive from single nucleotide substitutions within the DNA sequence. Population sampling has demonstrated that among healthy individuals, the genetic sequence differs at around 10 million points (out of 3.2 billion DNA base pairs). These naturally occurring differences are called *single nucleotide polymorphisms*, or SNPs. To be classified as an SNP, two or more versions of nucleotide sequence must be present in at least 1% of the general population. The term *SNP* is used to describe genetic variation of healthy individuals, as no disease-causing nucleotide change is this common. An example of an SNP known to mediate susceptibility to disease is the delta 32 allele of the beta-chemokine receptor 5, or CCR5. Individuals carrying one copy of the delta 32 allele are somewhat resistant to infection by HIV, the virus that causes AIDS, and individuals with two copies (delta 32 homozygotes, ~1% of whites) are almost completely immune to infection by HIV ([Huang, 1996](#)). Thus the genetic variant is not the cause of disease (HIV) but is importantly associated with the manifestation of disease in humans.

In addition to individual sequence variation, comparative genome studies between individual sequences have revealed a far more pervasive form of genetic variation, termed *copy number variants* (CNV) ([Iafrate, 2004](#); [Sebat, 2004](#)). These are structural variants, made up of relatively large DNA segments (ranging in size from 1000 bp to 500,000 bp or more) that appear in a variable number at a given genetic locus, and cumulatively affect 360 million nucleotides, or about 12% of the human genome ([Redon, 2006](#)). A CNV can be either benign or pathogenic, and a large proportion of identified CNV have as yet unknown significance.

Thus, although SNPs introduce genetic variation at the level of individual base substitutions, CNVs represent variation in the “dose” of a relatively large DNA segment. The collection of genetic sequence variants (SNPs) or CNVs within an individual forms a sort of biologic landscape that will influence how that person experiences or responds to external influences such as challenge from an invading pathogen or ultraviolet ray exposure from the sun. Thus understanding genetic variation in the form of SNPs and CNVs and their biologic influence can reveal a predisposition toward disease, variable susceptibility to infections, or diverse responses to pharmaceuticals as well as side effects from the same compounds. In other words, genetic variation is at the core of our collective goal of “individualized medicine,” in which preventive strategies or “designer drugs” can be tailored to an individual based on one’s genomic information.

Epigenetic Variation

There are forms of genetic variation that do not involve a change in nucleotide sequence. Instead, persistent alterations in three-dimensional DNA structure can change the expression pattern of a gene. Covalent modification of histones to alter *chromatin* structure and the covalent addition of methyl groups to cytosine residues in the DNA are the most commonly seen three-dimensional DNA alterations. These patterns of *epigenetic* modification of genes are replicated through successive cell divisions despite unchanged DNA sequence and have the potential to be heritable ([Portela, 2010](#)).

Two well-studied mechanisms of epigenetic modification influencing disease phenotype include genomic imprinting and CpG island methylation patterns. Genomic imprinting is a process by which hypermethylation of a specific parental allele causes that allele of the gene to be silenced, and disease may arise if the remaining allele is abnormal. Variable methylation of CpG islands in cancer cells can promote tumorigenesis through loss of proliferative supervision of the cell. Epigenetics is a growing field for understanding complex genotype-phenotype interactions. Epigenetic mechanisms such as methylation have been shown to play a role in multiple other human disease types beyond cancer, including neurodevelopmental disorders, neurodegenerative and neurologic diseases, and autoimmune diseases ([Portela, 2010](#)).

GENETIC PATHOLOGY

The term *mutation* is generally reserved for new changes in the genetic code that lead to altered function and clinical consequences. A gene mutation occurs when there has been a change in the genetic code. The mutation may involve changing a single base, known as a *point mutation*, or a larger segment, in which bases are removed, duplicated, or inserted. Mutations occur as a result of environmental damage to DNA, through errors during DNA replication or repair, and through uneven crossing over and genetic exchange during meiosis. The loss or gain of bases in a protein-coding region may disrupt the reading frame of the triplet codons. Alternatively, a change in base sequence in a noncoding region of DNA may alter the ability of regulatory proteins or RNA molecules to bind to the DNA. Point mutations within the gene could result in an amino acid substitution, leading to different products with

altered functions. Figure 2.2 demonstrates such an occurrence for sickle cell anemia caused by the substitution of a single base at a single point. In contrast to sickle cell anemia where there is only one mutation, the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene is an example of a gene for which more than 1000 mutations or alleles have been described to date. Some genes also have regions that are more prone to mutational events (hot spots).

SINGLE GENE DISORDERS

Disease-causing genetic alterations are categorized by patterns of familial segregation. Any evaluation of the segregation pattern of a trait or disease in a family requires the development of a three-generation *pedigree* (Fig. 2.3). This graphic representation of family history data assists in determining the transmission

Hemoglobin-Binding Protein	DNA Triplet Codons		Amino Acid
HgbA (normal)	CTT	CTC	Glutamic acid
HgbS	CAT	CAC	Valine
HgbC	TTT	TTC	Lysine

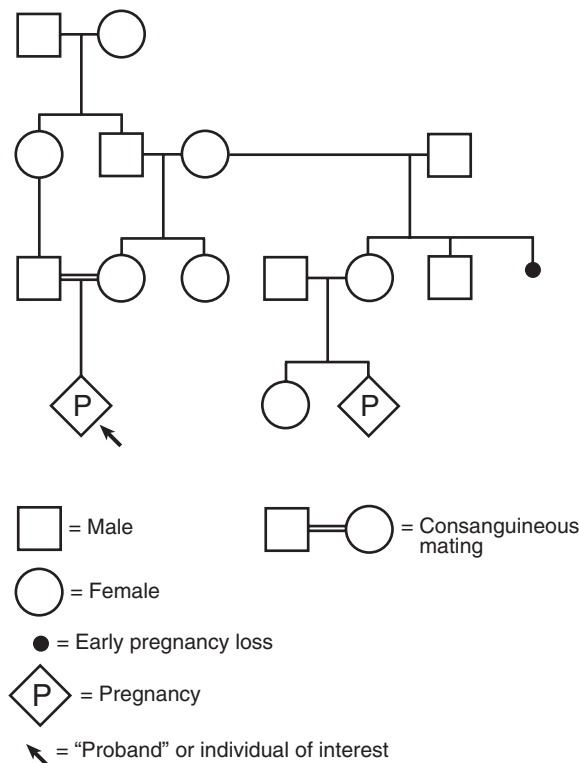

Figure 2.3 Standard figures and nomenclature for a pedigree. (Courtesy of Edith Cheng, MD.)

pattern of the gene, as well as predicting the risk of recurrence. In some conditions, the pattern of transmission and the constellation of clinical characteristics of affected individuals in the pedigree provide the diagnosis, which otherwise would not be evident if only one individual were evaluated.

Mendelian Inheritance Patterns

Autosomal Dominant

In an autosomal dominant mode of inheritance, only one copy of the mutated gene is required for expression of the trait, and the individual is said to be heterozygous for the trait. There are more than 4000 known autosomal dominant conditions, and most occur in the heterozygous form in affected individuals. With a few exceptions, autosomal dominant conditions occurring in the homozygous form (two copies of the affected gene) are rare, the phenotype is more severe, and they are often lethal. An example is achondroplasia, in which two copies of the mutated gene result in a lethal condition.

The general characteristics of autosomal dominant inheritance are illustrated in Figure 2.4 and summarized as follows:

1. Every affected individual has an affected parent (unless this is a new mutation—to be discussed later). The inheritance pattern is vertical.
2. If reproductively fit, the affected person has a 50% risk of transmitting the gene with each pregnancy.
3. The sexes are affected equally.
4. There is father-to-son transmission.
5. An individual who does not carry the mutation will have no risk of transmission to his or her offspring.

Three additional properties associated with, but not exclusive to, autosomal dominant traits are variable *expressivity*, *penetrance*, and new mutations. Variable expressivity describes the severity of the phenotype in individuals who have the mutation. Some autosomal dominant conditions have a clear clinical demarcation between affected and unaffected individuals. However, some conditions express the clinical consequences of the mutation in varying degrees among members of the same family and between different families. These differences in expression are modified by age, sex of the affected individual, the individual's genetic background, and the environment. Variable expression of a condition can lead to difficulties in diagnosis and interpretation of inheritance pattern. Penetrance refers to the probability that a gene will have any clinical manifestation at all in a person

Figure 2.4 Example of autosomal dominant inheritance. (Courtesy of Edith Cheng, MD.)

known to have the mutation. A condition is 100% penetrant if all individuals with the mutation have any clinical feature of the disease (no matter how minor). A number of autosomal dominant conditions are the result of new mutations. For example, about 70% of achondroplasia cases occur as new mutations. Because this condition has 100% penetrance, the recurrence risk in subsequent pregnancies in the normal parents of an affected child is extremely low, but the risk to the offspring of the affected is 50%. If an autosomal dominant condition is associated with poor reproductive fitness, then the likelihood that the cases occurred because of new mutation is greater.

Autosomal Recessive

Autosomal recessive conditions are rare and require the affected individual to have two copies of the mutant allele (homozygous) in order to manifest the condition. In the heterozygote carrier, the product of the normal allele is generally able to compensate for the mutant allele and prevent occurrence of the disease. Figure 2.5 is a typical pedigree illustrating autosomal recessive inheritance. The following general statements can be made about an autosomal recessive trait:

- 1. The characteristic will occur equally in both sexes.
- 2. For an offspring to be at risk, both parents must have at least one copy of the mutation.
- 3. If both parents are heterozygous (carriers) for the condition, on average 25% of the offspring will be homozygous for the mutation and manifest the condition, and 50% will be carriers and unaffected. The remaining 25% will not have inherited the mutation at all, will be unaffected, and will not be at risk of transmitting the mutation to any offspring.
- 4. Consanguinity is often present in families demonstrating rare autosomal recessive conditions.

Figure 2.5 Pedigree illustrating autosomal recessive inheritance. Here the parents of the affected children are first cousins, as denoted by the double line connecting them. (Courtesy of Edith Cheng, MD.)

- 5. If the disease is relatively rare, it will be clustered among the siblings and will not be seen among other family members such as ancestors, cousins, aunts, and uncles.

Because autosomal recessive conditions require two copies of the mutant allele, and because most matings are not consanguineous, counseling couples about the risk for an autosomal recessive condition requires knowledge of the carrier frequency of the condition in the general population. Cystic fibrosis exemplifies the importance of knowing the population in which screening/counseling is being provided (Table 2.2). Depending on the ethnic group of the mother and father, the risk for a child having cystic fibrosis could be as high as 1 in 1936 ($1/22 \times 1/22 \times 1/4$) if they are Northern European white or considerably less so if they are of Asian descent.

X-linked Trait

The human X chromosome is quite large, containing about 160 million base pairs, or about 5% of the nuclear DNA. Of the 500 genes that have been mapped to the X chromosome, 70% are known to be associated with disease phenotypes. Diseases caused by genes on the X chromosome are said to be X linked, and most are recessive. In contrast, the Y chromosome is quite small, about 70 million base pairs, and contains only a few genes.

The expression of genes located on the X chromosome demonstrate a unique characteristic known as dosage compensation, a concept which was described by Mary Lyon in the 1960s to explain the equalization of X-linked gene products in males and females (Lyon, 1961). Achievement of dosage compensation is through the principles of X inactivation, also known as the *Lyon hypothesis*. The tenets of the Lyon hypothesis are as follows:

- 1. One X chromosome in each cell is randomly inactivated in the early female embryo (soon after fertilization).
- 2. The inactivation process is random: either the paternally or maternally derived X chromosome is chosen. The female is thus a mosaic for genes located on the X chromosome.
- 3. All descendants of the cell will have the same inactive X chromosome.

The Lyon hypothesis is supported by clinical evidence derived from animal and human observations of traits located on the X chromosome, such as the calico cat pattern of red and black patches of fur on female cats but not on male cats. In humans, males and females have equal quantities of the enzyme glucose-6-phosphate dehydrogenase (G6PD), which is encoded by a gene on the X chromosome. The mechanism for X inactivation

Table 2.2 Carrier Frequencies for Cystic Fibrosis in Different Populations

Ethnicity	Chance of Being Carrier	Chance Both Carriers*
European descent	1 in 29	1 in 841
Hispanic American	1 in 46	1 in 2116
African American	1 in 65	1 in 4225
Asian American	1 in 90	1 in 8100

*The chance for an affected child being born to these couples is the chance that both are carriers times $\frac{1}{4}$.

is unknown at this time but clearly requires the presence of the X inactivation center, which has been mapped to the proximal end of the long arm of the X chromosome (Xq). This center contains an unusual gene called the *X-inactive specific transcript* (*XIST*), which seems to control X inactivation, a process that cannot occur in its absence.

The principles of the Lyon hypothesis remain true for the majority of genes located on the X chromosome. The silencing of these genes appears to occur as a function of DNA methylation at the promoter regions of these genes. However, several regions remain genetically active on both chromosomes. They include the pseudoautosomal regions located at the tips of the long and short arms, which are the regions that contain the genes for steroid sulfatase, the Xg blood group, and Kallman syndrome (hypogonadism and anosmia). The pseudoautosomal region on the short arm shares extensive homology with the Y chromosome and is the region involved in the pairing of the X and Y chromosome at meiosis.

Another exception to the Lyon hypothesis is that one X chromosome is nonrandomly, preferentially inactivated. This is observed for most cases of *translocations* between an X chromosome and an autosome. If the translocation is balanced, the structurally normal X chromosome is preferentially inactivated. If the translocation is unbalanced, then the structurally normal X chromosome is always active. These nonrandom patterns of inactivation are an attempt to minimize the clinical consequences of the chromosomal rearrangement. Studies can be done to look at patterns of inactivation, as in the case of prenatal diagnosis, to predict the clinical consequences of a de novo X/autosome translocation in the fetus.

Random inactivation confers a mosaic state for the carrier female. The normal allele is able to compensate for the abnormal allele (as in autosomal recessive traits), and carrier females of X-linked recessive conditions usually do not have clinical manifestations of the disease. Occasionally, however, there is skewed or less than 50-50 chance of inactivation such that the X chromosome carrying the normal allele is inactivated more frequently. In such cases, carrier females display some features of the condition and are referred to as *manifesting heterozygotes*. Manifesting heterozygotes have been described for hemophilia A, Duchenne muscular dystrophy, ornithine transcarbamylase deficiency, and X-linked color blindness. Genetic counseling of recurrence risks for an X-linked recessive condition depends on the sex of the affected parent and of the offspring. Figure 2.6 is a pedigree illustrating X-linked recessive inheritance, the characteristics of which are the following:

1. Affected individuals are usually males unless X-chromosome activation is skewed in the carrier female or the female is homozygous for the trait.
2. The affected males in a kindred are related through females.
3. The gene is not transmitted from father to son.
4. All daughters of affected males will be carriers.
5. Daughters of carrier females have a 50% chance of being carriers; sons of carrier females have a 50% chance of being affected.

X-linked Dominant Inheritance

The major feature of X-linked dominant inheritance is that all heterozygotes, both male and female, manifest the condition.

Although the pedigree may resemble autosomal dominant inheritance, the distinguishing feature is that affected males never have affected sons, and all daughters of affected males are affected. There are usually more affected females than males, and the majority of the females are heterozygotes. Examples of diseases with this mode of inheritance are hypophosphatemic rickets and Rett syndrome.

Non-Mendelian Inheritance Patterns (Complex Traits)

Trinucleotide-Repeat Disorders: Unstable Mutations

In the early 1990s a new class of genetic conditions was recognized as being due to unstable dynamic mutations in a gene. In classic genetic inheritance, the diseases and their inheritance patterns are due to mutations that are passed on from generation to generation in a stable form. That is, all affected members in a family have the identical inherited mutation. In 1991, however, a number of reports began to describe a new class of genetic condition in which the gene mutation was dynamic and would change with different affected individuals within a family. The most common group of disorders is known as *triplet*, or *trinucleotide repeat*, disorders. More than a dozen diseases are now known to be associated with unstable trinucleotide repeats (Table 2.3) (Cummings, 2000).

These conditions are characterized by an expansion of variable size, within the affected gene, of a segment of DNA that contains a repeat of three nucleotides such as CAGCAGCAG (CAG) $_n$, or CCGCCG (CCG) $_n$. These triplet repeats are unstable in that they tend to expand as the gene is passed on from generation to generation. The molecular mechanism is most likely misalignment at the time of meiosis. The result of increasing triplet expansion is progressively earlier onset or more severe manifestation of disease with each successive generation. This phenomenon is known as *anticipation*.

The commonality of this group of genetic conditions stops at the shared molecular mechanism. Each disease, otherwise, has its own features. Some, such as myotonic dystrophy, are inherited in an autosomal dominant pattern, but others, such as Friedrich ataxia, are autosomal recessive conditions. The susceptibility of the triplet repeat to expand also may depend on the parent of origin: paternal in Huntington disease and exclusively maternal in fragile X syndrome.

Figure 2.6 Pedigree illustrating X-linked recessive condition. (Courtesy of Edith Cheng, MD.)

Table 2.3 Some Commonly Known Disorders Associated with Unstable Triplet Repeats

Disease	Inheritance Pattern	Triplet Repeat	Location of Expansion	REPEAT NUMBER		
				Normal	Unstable	Affected
Huntington disease	Autosomal dominant	CAG	Exon coding region	<36	29-35	>35
Fragile X	X-linked	CGG	5' untranslated region	<55	56-200	>200
Myotonic dystrophy	Autosomal dominant	GTG	3' untranslated region	<35	50-100	>100
Spinal cerebellar ataxias*	Autosomal dominant	CAG	Exon	<40	Different for each subtype	>40
Friedrich ataxia	Autosomal recessive	GAA	Intron of gene	<33	34-65	>65

*Spinal cerebellar ataxias are a heterogeneous group of conditions, all of which appear to be associated with a CAG repeat. Each subtype has its own specific range of normal, unstable, and affected repeat sizes.

Fragile X Syndrome

Fragile X syndrome, a disease within the unstable triplet group, is the most common heritable form of moderate mental retardation and is second to Down syndrome among the causes of mental retardation in males. In women, a mild carrier state may present as premature menopause. The gene is located on the X chromosome at Xq27.3 and causes a pattern of abnormalities, including mental retardation and characteristic facial features. Disease frequency is approximately 1 in 4000 male births. The condition is due to an expansion of the triplet repeat CGG located in the untranslated region of the first exon of the gene called *FMRI* (fragile X mental retardation 1). The triplet expansion blocks normal function of the *FMRI* gene, thus causing the syndrome.

Normal individuals have about 8 to 50 copies of the CGG triplet, whereas affected individuals have from 200 to more than 1000 copies. Individuals with an intermediate number of copies (52 to 200) are known as *premutation carriers*; this level of “expansion” renders the triplet-repeat segment unstable. These carriers are generally unaffected but are at risk for having affected children or descendants if the premutation expands in successive generations. The premutation, however, can be passed on without expanding.

Long-term follow-up of premutation carriers has revealed that these individuals are not necessarily “unaffected.” Premature ovarian failure has been associated with female premutation carriers, and in men, a syndrome of atypical adult-onset ataxia (FXTAS) has now been described (Hagerman, 2004).

Although the unstable triplet is transmitted in an X-linked pattern, the probabilities of the different phenotypes are far from traditional X-linked inheritance. Understanding of this feature of the fragile X syndrome is crucial to genetic counseling and assessing recurrence risks. The possible outcomes of the offspring of a premutation carrier female are the following:

1. Male offspring—three possibilities:
 - a. Unaffected by not having inherited the X chromosome with the premutation.
 - b. Unaffected by inheriting the X chromosome with the premutation, which did *not* expand (about 20% of the time); this male, however, is at risk for passing the premutation to his daughters, who in turn will be at risk for having affected children. Therefore, for this male, his grandchildren will be at risk for the fragile X syndrome.
 - c. Affected by having inherited the abnormal X chromosome, in which the premutation also expanded to a full mutation.

2. Female offspring—four possibilities:

- a. Unaffected by not having inherited the X chromosome with the premutation.
- b. Unaffected by inheriting the X chromosome with the premutation that did *not* expand.
- c. Unaffected, but inherited the X chromosome with an expansion—about 50% of females with the expansion appear to be clinically unaffected.
- d. Affected by inheriting the X chromosome with an expansion.

Genomic Imprinting and Uniparental Disomy

Genomic imprinting and uniparental disomy refers to the differential activation or expression of genes depending on the parent of origin. In contrast to Mendel's hypothesis that the phenotype of a gene is no different if inherited from the mother or the father, we now understand that there is a group of diseases in which the parent of origin of a gene or chromosome plays a role in the phenotype of the affected individual. The best-studied example of this mechanism is Prader-Willi syndrome (PWS) and Angelman syndrome (AS). Both diseases arise from loss of function of the same gene on chromosome 15, but two different disease phenotypes arise depending on which parental allele is affected. PWS is characterized by obesity, hyperphagia, small hands and feet, hypogonadism, and mental retardation (Jones, 2006). In about 70% of cases, cytogenetic deletion of the proximal arm of the paternally inherited chromosome 15 is observable (15q11-q13). In contrast, the same deletion of the maternally inherited chromosome 15 results in the Angelman phenotype of severe mental retardation, short stature, spasticity, and seizures (Jones, 2006). Interestingly, 30% of subjects with PWS do not have a cytogenetic deletion but rather inherit two intact chromosomes 15 from the mother. No genetic information on chromosome 15 is inherited from the father. This is referred to as *maternal uniparental disomy*. Individuals with Angelman syndrome without a cytogenetic deletion have two copies of the paternally derived chromosome 15 and no chromosome 15 from the mother, a condition termed *paternal uniparental disomy*. These findings indicate that for the region of 15q11-q13, the expression of the PWS phenotype is brought on by the absence of a paternal contribution of the genes in this region. Likewise, the expression of Angelman syndrome is due to the absence of the maternal contribution of genes located at 15q11-q13. The genes in this region are said to be “imprinted” because their parent of origin has been “marked.”

Many regions of the human genome have now demonstrated evidence of imprinting. Knowledge of diseases that occur as a

result of imprinting has implications in prenatal diagnosis, especially when *mosaicism* is encountered.

Germline Mosaicism

Mosaicism is defined as the presence of two or more genetically different cell lines in the same individual or tissue derived from a single zygote. All females, because of X inactivation, are mosaics for genes on the X chromosome. Mosaicism, however, is not necessarily evenly or randomly distributed throughout the body. In other words, using the entire body as the whole organism, an individual is mosaic either because different organs or tissues have genetically different cells, but each organ or tissue has the same cell line, or because the genetically different cell lines are dispersed throughout many tissues in the body. The distinction between these two types of mosaicism is particularly important in making a prenatal diagnosis in cases in which mosaicism is identified in amniotic fluid cells. For instance, one cannot be confident that a fetus identified as being mosaic trisomy 21 would necessarily have a less severe mental retardation phenotype because of mosaicism. The brain cells could be all full trisomy 21, but the cells of the skin could all be normal diploid. In germline mosaicism, the implication is that the mutation is present in only one parent and arose during embryogenesis in all or some of the germ line cells but few or none of the somatic cells of the embryo. This concept was developed to explain recurrence of a genetic condition in a sibship (usually autosomal dominant) in which incorrect diagnosis, autosomal recessive inheritance, reduced penetrance, or variable expression could not be the reason for the recurrence. The best example of germline mosaicism is osteogenesis imperfecta type II (lethal form). At the molecular level, the mutation causing the condition is dominant—that is, only one copy of the abnormal gene is necessary to cause this perinatal lethal condition. Yet there are families in which multiple affected pregnancies are seen in the same couple or one parent has recurrences with different partners. If the spontaneous mutation rate for an autosomal dominant mutation is 1 chance in 10^5 , then the probability of two independent spontaneous mutations for the same lethal autosomal dominant condition is $(1/10^5)^2$, a highly unlikely event. Germline mosaicism is now well documented for about 6% of cases of osteogenesis imperfecta type II (Zlotogora, 1998). Unfortunately, the exact recurrence risk is difficult to assess because the proportion of gametes containing the mutation is unknowable.

Mitochondrial Inheritance: Maternal Inheritance

Most inherited conditions occur as a result of mutations in the DNA of the nucleus (nuclear genome). However, mitochondria have their own DNA molecules, which contain a small fraction of genes whose product are vital to the function of the cell. Mitochondrial DNA (mtDNA), which was completely sequenced in 1981, is small, about 16.5 kilobase pairs (kbp), and is packaged as a circular chromosome located in the mitochondria. A growing number of conditions resulting from abnormalities of the mitochondria have now been identified. Because the mitochondrial apparatus and its function are under the control of both nuclear and mitochondrial genes, many diseases affecting the mitochondria do not follow the typical Mendelian pattern of inheritance. Each human cell contains a population of several hundred or more mitochondria in its cytoplasm. Most of the

subunits that make up the mitochondrial apparatus are encoded by the nuclear genome.

Because the primary function of the mitochondria is to provide energy in the form of adenosine triphosphate (ATP) for the cell, mutations that affect the genes that code for oxidative phosphorylation will likely result in cell dysfunction and death. The organs most affected would be those that depend heavily on mitochondria. The diseases that result are generally neuromuscular in nature, such as encephalopathies, myopathies, ataxias, and retinal degeneration, but the mutations have *pleiotropic* effects, meaning multiple different clinical traits are caused by a single gene defect (Johns, 1995).

The most significant characteristic of mitochondrial diseases caused by mutations in mtDNA is that they are all maternally inherited. This is because the cytoplasm of the ovum is abundant with mitochondria, but the sperm contain very few mitochondria. Therefore an individual's mitochondria (and mtDNA) are essentially all inherited from the mother. If the mother has an mtDNA mutation, then all of her children will inherit that mutation. When a mutation arises in the DNA of a mitochondrion in the cytoplasm of the ovum, it is at first one mutation in one mitochondrion. However, as replication and division of this mutated mitochondrion occur, they become randomly distributed among the normal mitochondria and between the daughter cells. One daughter cell by chance may contain a large population of mitochondria with the mutation, but the other has none or very little. Fertilization of the egg with a large proportion of mitochondria containing the mutation would result in an offspring that is at risk for manifesting a mitochondrial disease. Leber hereditary optic neuropathy (LHON) is a well-known mitochondrial disease in which rapid, bilateral loss of central vision occurs as a result of a mutation in mitochondrial DNA. Males and females are affected equally, and all affected individuals are related through maternal lineage.

A second feature of mitochondrial diseases is that of variable expression. Within each cell and tissue, there is a threshold for energy production below which the cells will degenerate and die. Organ systems with large energy requirements will be most susceptible to mitochondrial abnormalities. Thus, if there is an mtDNA mutation, the severity of the mitochondrial disease will depend on the proportion of mitochondria with the mutation that the individual inherited from his or her mother and the susceptibility of different tissues to altered ATP metabolism.

In contrast, abnormalities of mitochondrial function caused by mutations of genes encoded in the nuclear genome will exhibit traditional Mendelian inheritance patterns; autosomal dominant, autosomal recessive and X-linked patterns of mitochondrial disorders have been observed. A few mitochondrial diseases occur as sporadic somatic mutations and have little or no recurrence risk. Table 2.4 lists some of the currently known diseases of mitochondrial function and their inheritance patterns.

Multifactorial Inheritance

Multifactorial inheritance is defined as traits or characteristics produced by the action of several genes, with or without the interplay of environmental factors. A number of structural abnormalities occurring as isolated defects and not part of a syndrome, such as cleft lip with or without cleft palate, open neural tube defect (including anencephaly and spina bifida), and

Table 2.4 Features of Some Disorders of Mitochondrial Function

Disease	Features	Genetics	Inheritance Pattern
Barth syndrome	Dilated cardiomyopathy, cyclic neutropenia, skeletal myopathy, growth deficiency, abnormal mitochondria	Nuclear DNA encoding mitochondrial protein tafazzin (<i>TAZ</i> gene)	X linked
Friedreich ataxia	Limb movement abnormalities, dysarthria, absent tendon reflexes	Nuclear DNA encoding mitochondrial protein frataxin (<i>FXN</i> gene, triplet repeat)	Autosomal recessive
Leber hereditary optic neuropathy (LHON)	Blindness, rapid optic nerve death in young adulthood	Mitochondrial DNA	Maternal
Leigh disease (subacute necrotizing encephalomyelopathy)	Infant onset progressive psychomotor regression following viral illness, hypotonia, peripheral neuropathy, lactic acidosis	Many genes: 20%-25% mitochondrial DNA (includes neuropathy, ataxia, and retinitis pigmentosa [NARP]) 75%-80% nuclear DNA	Mitochondrial DNA: maternal Nuclear DNA: autosomal recessive or X linked
MERRF	Myotonic epilepsy, ragged red fibers in muscle, ataxia, sensorineural deafness	Mitochondrial DNA	Maternal
MELAS	Mitochondrial encephalopathy, lactic acidosis, stroke-like episodes, sensorineural deafness	Mitochondrial DNA	Maternal
MIDD	Maternally inherited diabetes and deafness	Mitochondrial DNA	Maternal
MNGIE	Mitochondrial neurogastrointestinal encephalopathy, childhood-onset gastrointestinal dysmotility, peripheral neuropathy	Nuclear DNA (<i>TYMP</i> gene) causes destabilization of mitochondrial DNA	Autosomal recessive

cardiac defects, are examples of such conditions. When both parents are normal and an affected child is produced, the chance of recurrence is generally between 2% and 5% for any given pregnancy. Because the underlying mechanisms by which the genes and the environment interact to cause these conditions are largely unknown, genetic counseling of recurrence risks must measure the observed recurrence risks in collections of families to generate a population-based empiric risk. These risk rates, however, are modified by many factors including ethnicity, the sex of the carrier parent, the sex of the affected parent and at-risk offspring, the presence of the defect in one or both parents, the number of affected family members, and consanguineous parentage (Kuller, 1996).

CHROMOSOMAL ABNORMALITIES

In general, genetic replication machinery of the cell is astonishingly accurate, and there are many repair mechanisms the cell uses to maintain fidelity of DNA copies. Thus the incidence of any given single gene disorder, even in high prevalence populations, is relatively low. In contrast, the distribution of genetic material during cell division by mitosis or meiosis is far more prone to mistakes, so that on a population level the risk of chromosome level genetic rearrangements occurs at least 100 times more frequently than single gene disorders. Consider the rate of 1 in 2500 for white babies affected by cystic fibrosis (the most common inherited disease in this population), compared with the estimation that an abnormal chromosome complement occurs in up to 4% of clinically recognized pregnancies (Creasy, 2014).

A variety of chromosome abnormalities may occur during meiosis or mitosis (see Chapter 1) leading to an abnormal *karyotype*, or chromosome complement visible under light microscopy. Chromosome abnormalities fall into several general categories, and many clinical conditions are associated with each type.

Numerical Chromosomal Abnormalities

Two terms are used in the description of numerical chromosomal abnormalities: *aneuploidy* refers to an extra or missing chromosome, such as in trisomy 21 (Down syndrome) or monosomy X (Turner syndrome), respectively; *polyploidy* refers to numerical chromosome abnormalities in which there is an addition of an entire complement of haploid chromosomes, such as in triploidy, in which three haploid sets occur (69, XXX or XXY or XYY). Numerical or aneuploid chromosome abnormalities involve either autosomes or sex chromosomes. Most occur as the result of *nondisjunction* during meiosis or mitosis in which homologous chromosome pairs fail to disjoin. The result in meiosis is that one daughter cell receives two copies of the homologues and the other receives none. Fertilization with a gamete containing a normal chromosome complement will result in a zygote that is either trisomic or monosomic (Fig. 2.7).

The majority of trisomic conceptions are nonviable, and autosomal trisomies have been seen in abortus material in all but chromosomes 1 and 17. However, trisomies 21, 18, 13, and 22 can result in live births and are associated with advanced maternal age (Fig. 2.8). Trisomy 13 (Patau syndrome) occurs in approximately 1/10,000 live births. The syndrome is characterized by prenatal growth restriction and multiple severe structural defects involving the midline (holoprosencephaly, cleft lip/palate,

Figure 2.7 Graphic representation of meiotic nondisjunction. (Courtesy of Edith Cheng, MD.)

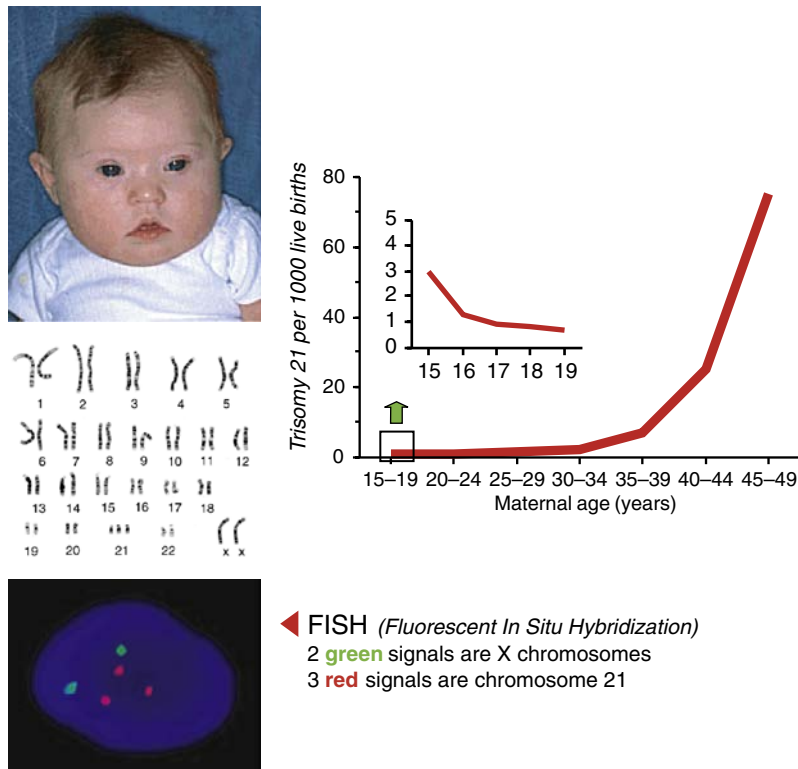

Figure 2.8 Trisomy 21 infant with karyotype demonstrating three separate chromosomes 21. Interphase fluorescent in situ hybridization (FISH) illustration of screening for trisomy 21. Graph illustrating the maternal age association and increasing risk for aneuploidy. Note that there is an increased risk at the peripubertal ages as well. (Courtesy of Edith Cheng, MD.)

cardiac defects), and postaxial polydactyly. Trisomy 18 (Edwards syndrome) is found in 1/6000 live births and is associated with prenatal growth restriction, rocker bottom feet, and cardiac and renal defects. Trisomy 21 is the most common viable autosomal trisomy and has an incidence of 1/800 live births. The majority (95%) of individuals with Down syndrome have complete

trisomy 21—that is, three separate copies of chromosome 21 because of maternal nondisjunction. However, about 2% to 3% of individuals with clinical Down syndrome have a structural rearrangement (Robertsonian translocation—to be discussed in the next section), and another 1% to 3% are mosaic for trisomy 21 (Jones, 2006). Trisomy 22 has been seen in a few live-born

individuals and is associated with severe neurologic impairment. Monosomic states involving autosomes are extremely rare and generally lethal.

Sex chromosome aneuploidy usually occurs in the trisomic state. Monosomy Y is lethal and has never been seen in a clinical situation or even in an abortus. In contrast, monosomy of the X chromosome (known as *Turner syndrome*) is the most common chromosomal abnormality found in first trimester abortuses. Because most 45,X conceptions are lethal, the actual incidence of live female births is about 1/5000. At birth, Turner syndrome is characterized by lymphedema, hypotonia, and webbed neck. Girls with Turner syndrome have short stature, a broad chest with widely spaced nipples, cubitus valgus (widened carrying angle of the arms), and gonadal dysgenesis resulting in a lack of secondary sex characteristics, amenorrhea, and infertility (Fig. 2.9). Other features include congenital heart disease (coarctation of the aorta is the most common), kidney disease, and hypertension in later life. Intelligence is generally normal although spatial perception abnormalities are common (Jones, 2006). Hormonal supplementation during puberty allows girls with Turner syndrome to develop secondary sex characteristics.

Unlike autosomal trisomies in which the majority are maternally derived, the 45,X karyotype occurs through

paternal nondisjunction and is not associated with advanced maternal or paternal age. There is no increased recurrence for 45,X, which accounts for 50% of women with Turner syndrome. Another 30% to 40% of individuals are mosaic for the 45,X cell line and another cell line (usually 46,XX) because of postzygotic nondisjunction during mitosis. The clinical features of these women will vary depending on the proportion of normal 46,XX cell lines present. However, females who are mosaic with a 45,X/46,XY karyotype are at an increased risk for gonadoblastoma. Therefore women suspected of having Turner syndrome should have a chromosomal analysis, not only for diagnosis but for exclusion of mosaicism for a 46,XY cell line. The remaining 10% to 20% of individuals with Turner syndrome have a structural abnormality of the X chromosome (Table 2.5).

Other trisomies involving the sex chromosomes are seen in 47,XXX, 47,XXY (Klinefelter syndrome), and 47,XYY karyotypes. The incidence of 47,XXX is approximately 1/1000 live female births and is due to maternal nondisjunction associated with increasing maternal age. Most women are phenotypically normal with the exception of possible mild developmental delay; fertility is normal and there may be a slightly increased risk for offspring with aneuploidy involving the sex chromosomes and

Figure 2.9 **A**, Photo of a 20-week fetus with Turner syndrome, 45,X. This fetus was diagnosed during a routine 20-week ultrasound for anatomy and growth and was found to have a large cystic hygroma and hydrocephalus. The autopsy revealed a complex cardiac defect, abnormal kidneys, streaked ovaries, and malrotation of the gut with the appendix in the left lower quadrant. **B**, A 17-year-old woman with Turner syndrome. Note the short stature, poor sexual development, and increased carrying angles at elbows. Subject also has webbing of the neck. (**A**, Courtesy of Drs. W. Tony Parks and Corrine Fligner, Department of Pathology, University of Washington.)

autosomes. Klinefelter syndrome, 47,XXY, is a common sex chromosome abnormality associated with maternal age and occurs in 1/1000 live male births. Clinical features include tall gynecoid stature, gynecomastia (with an increased risk for breast cancer), and testicular atrophy. Mental retardation is not a typical feature, but affected individuals may have IQ scores that are lower than those of their siblings. Nondisjunction during spermatogenesis involving the Y chromosome leads to 47,XXY. These males may be taller than average, but they are otherwise phenotypically normal. Contrary to previous and outdated observational studies, this sex chromosome aneuploidy is not associated with an increased disposition to violent crime. However, behavioral problems such as attention deficit disorder may be observed.

Nondisjunctional events during mitosis in the early embryo (after fertilization) will produce individuals with cell populations containing different chromosome numbers. This condition, known as *mosaicism*, may involve the autosomes or the sex

chromosomes. The actual phenotype depends on the proportion of aneuploid and euploid cells in the embryo and in the specific organs or tissues involved.

Structural Chromosome Abnormalities

Chromosome breaks and rearrangements may lead to no obvious phenotypic consequences (genetically balanced), loss or gain of chromosomal material (genetically imbalanced) that produces abnormalities, or abnormalities resulting from the interruption of a critical gene at the breakpoint site on the chromosome. Types of structural rearrangements include *translocations* (reciprocal and Robertsonian), insertions, *inversions*, *isochromosomes*, duplications, and deletions. The rate of formation of balanced rearrangements is generally very low, 1.6×10^{-4} , although some chromosomal segments (hot spots) are more prone to breakage than others.

Balanced Reciprocal Translocations

Translocations occur as a result of a mutual and physical exchange of chromosome (genetic) material between nonhomologous chromosomes, or chromosomes that are not part of an identical matched pair. There are two main types of translocations, reciprocal and Robertsonian. Balanced reciprocal translocations are found in about 1/11,000 newborns. Figure 2.10 is an example of a hypothetical balanced translocation between the short arms (p arm) of two chromosomes. The carrier of a reciprocal balanced translocation is usually phenotypically normal. However, the carrier is at an increased risk for producing offspring who are chromosomally abnormal. The viability of the genetically unbalanced gametes is highly dependent on the location and amount of involved DNA. In general, however, the recurrence for an unbalanced conception is 3% to 5% for male carriers and 10%

Table 2.5 Karyotypes Discovered in Subjects with Phenotypic Characteristics of Turner Syndrome

Karyotype	Error
45,X	Deletion X
45,Xi(Xq)	Deletion Xp, Isochromosome Xq
45,X,Xq	Deletion Xp
45,X/46,XX	Mosaicism
45,X/46,XX/47,XXX	Mosaicism
45,X/46,XY	Mosaicism
45,X/46,XY/47,XXY	Mosaicism
45,XringX	Ring chromosome
46,XX	Phenotype with normal karyotype

Figure 2.10 Schematic representation of segregation patterns of a diploid gamete with a reciprocal balanced translocation. Here, exchanges have occurred between the short arms of chromosomes 1 and 3. The two pairs of chromosomes pair in a quadriradial fashion. There are three potential axes in which the cell can divide. Only two of the six potential gametes will be genetically balanced. (Courtesy of Edith Cheng, MD.)

to 15% for female carriers of reciprocal balanced translocations. Recurrence risks depend on the chromosomes involved and the size of the translocated segments.

A second and important type of translocation is the Robertsonian translocation. This is a structural rearrangement between the acrocentric chromosomes: chromosome pairs 13, 14, 15, 21, and 22. These chromosomes have a centromere that is severely offset from the center such that the short arm (p arm) contains minimal genetic material, which can be lost with little or no functional consequence. In this structural rearrangement, the short arms (p arms) of two nonhomologous chromosomes are lost, and the long arms fuse at the *centromere*, forming a single chromosome structure. Figure 2.11 is an example of a Robertsonian translocation involving chromosomes 14 and 21. The phenotypically normal carrier of a Robertsonian translocation has 45 chromosomes in each cell because the two acrocentric chromosomes involved in the translocation have formed into one chromosome structure. This Robertsonian translocation carrier is genetically balanced—that is, he or she has two copies of each chromosome. However, the gametes are at risk to be unbalanced.

One important exception in translocation Down syndrome is that associated with a 21q21q translocation. Here, the chromosome structure is composed of two chromosomes 21. Although this chromosome rearrangement is extremely rare, this translocation confers a 100% risk that the carrier will have abnormal gametes and 100% of viable gametes will result in a conception with Down syndrome. The only other possible outcome is monosomy 21, a complement that is miscarried early.

Chromosome inversions occur when two breaks occur on a chromosome followed by a 180-degree turn of the segment and reinsertion at its original breakpoints. If the centromere is included in the inverted segment, it is called a *pericentric inversion*. If the centromere is not involved, then the inversion is called a *paracentric inversion*. Chromosome inversions are generally considered balanced and usually do not confer an abnormal phenotype unless one of the breakpoints disrupts a critical gene. Inversions, however, do interfere with pairing at meiosis and can result in gametes with chromosome abnormalities.

Isochromosomes occur as a result of the chromosome dividing along the horizontal axis rather than the longitudinal axis at the centromere. The result is a chromosome that has two copies of one arm (p or q) and no copies of the other. Isochromosomes involving autosomes are generally lethal because the resultant conception will be both trisomic and monosomic for genetic information. However, an isochromosome involving the long arm of the X chromosome (iso Xq) is compatible with life.

Finally, deletions and duplications of chromosome segments arise from unequal crossing over at meiosis or from crossing over during pairing of inversions or reciprocal translocations. Breaks resulting in loss of chromosome material at the tip are called *terminal deletions*, and loss of chromosome material between two breaks within a chromosome is called an *interstitial deletion*. There are several well-documented terminal deletion syndromes, including cri du chat (5p-) syndrome, characterized by microcephaly, profound mental retardation, growth retardation, a unique facial appearance, and a distinctive catlike cry.

Figure 2.11 Karyotype demonstrating a Robertsonian translocation between chromosomes 13 and 14. Notice that there are only 45 chromosome structures, but this male is genetically diploid. (Courtesy of Edith Cheng, MD.)

For each of the previously described structural chromosome rearrangements, counseling and prognosis in the prenatal diagnostic setting are critically dependent on comparison to parental karyotypes. Phenotype correlations, particularly with balanced translocations and inversions, may be highly variable and dependent on whether the chromosomal break points disrupt critical genes. If the rearrangement found in a fetal sample is inherited from one of the parents, there is a higher likelihood of a normal phenotype, whereas *de novo* structural rearrangements have an increased risk of microscopic missing genetic material with phenotypic consequences.

Microdeletion/Duplication or Contiguous Gene Syndromes
The discussion in the previous section described only phenotypes that were associated with chromosome abnormalities visible with traditional cytogenetic techniques and light microscopy that imply involvement of large segments of chromosomes containing a large number (hundreds) of genes. High-resolution chromosome banding and advances in molecular cytogenetic technology have revealed a new class of chromosome syndromes known as *microdeletions*. These are contiguous gene syndromes in which the involved chromosome region(s) are submicroscopic and so small that a molecular cytogenetic technique such as targeted fluorescent *in situ* hybridization (FISH), or some form of sequence analysis, is necessary to localize the affected region. Table 2.6 lists some of the more commonly recognized syndromes, most of which are due to deletions; however, some duplication syndromes have now been identified. The phenotypes of these conditions are due to the absence (or duplication) of multiple contiguous genes within the involved region. Fine mapping of the breakpoints in some of these conditions has implicated unequal or abnormal recombination between low-copy repetitive DNA sequences in the area of the deleted or duplicated regions. The discovery of microdeletion/duplication or contiguous gene syndromes has been important in clinical genetics and genetic counseling in that it finally provides a diagnosis, recurrence risk, and prenatal diagnosis for a large group of syndromes that previously had no cytogenetic confirmation. Moreover, these “naturally occurring” sequestered small regions of contiguous genes have provided a powerful tool for developmental geneticists to decipher the critical genes for normal human development. For example, the 22q11 region appears to be rich in genes responsible for specific congenital heart defects and craniofacial anomalies. Importantly, microdeletions/duplications have no age-associated risk of occurrence (Wapner, 2012).

CHROMOSOME ABNORMALITIES AND PREGNANCY OUTCOME

The incidence and types of chromosome abnormalities differ among spontaneous abortions, stillbirths, and live births. Experience from pregnancies achieved by assisted reproductive technology indicates that 15% of fertilized ova fail to divide. Another 15% fail to implant, and 25% to 30% are aborted spontaneously prior to formation of villi. Of the roughly 40% of fertilized ova that survive the first missed menstrual period, as many as one fourth are aborted spontaneously, so only about 30% to 35% of fertilized ova actually result in live-born infants. Chromosome and lethal genetic abnormalities play a major role in early losses (Zinaman, 1996). This topic is discussed further in Chapter 16. In continuing pregnancies, chromosome abnormalities occur in 1 out of every 154 live births (0.6% overall incidence). The breakdown by type of abnormality is as follows: 22% autosomal trisomy (most commonly trisomy 21, followed by a much lower incidence of trisomy 18 and trisomy 13), 37% sex chromosome aneuploidy, and 41% structural abnormalities (including translocations, insertions, inversions, isochromosomes, duplications, and deletions). Trisomy 21 is the most commonly occurring singular genetic abnormality in live births, occurring at a rate of 1 in 830 live births (0.1%) (Creasy, 2014).

PERINATAL GENETICS

There is currently available technology to detect a wide range of the previously described genetic and biochemical abnormalities in a developing fetus. As a result, the indications to pursue screening or diagnostic testing for a patient who is pregnant or considering pregnancy include each of the following: known family history of a specific disease, family history suggestive of hereditary neurodevelopmental or cognitive disorders, ethnic background with increased carrier frequency of certain diseases, personal history of miscarriage or infertility, increased risk of aneuploidy related to maternal age, or simply population-based screening risk.

GENETIC TESTING

Although genetic assessment in some form has become commonplace, it is critically important that providers and patients carefully consider the objectives and potential results of the individual testing options when selecting a test. In the case of aneuploidy screening, the assayed markers only pertain to a *subset*

Table 2.6 Common Microdeletion/Contiguous Gene Syndromes

Syndrome	Incidence	CHROMOSOME		Size (Mb)
		Location	Abnormality	
Sotos	Rare	5q35	Deletion	2.2
Smith-Magenis	1/25,000	17p11.2	Deletion and duplication	4
Williams-Beuren	1/20,000-1/50,000	7q11.23	Deletion	1.5-1.8
Charcot-Marie-Tooth Type Ia / HNPP	1/10,000	17p12	Duplication and deletion	1.5
DiGeorge/velocardiofacial	1/4,000	22q11.21-q11.23	Deletion	1.5
Cat's eye	Rare	22q11	Duplication	3
der(22) Emanuel	Rare		Duplication	3
Neurofibromatosis	1/40,000-1/80,000	17q11	Deletion	1.5

of genetic material (usually the most common trisomies, affecting chromosomes 21, 13, 18, and possibly sex chromosomes), and abnormal results require follow up before any diagnosis can be made. Measuring the value of screening tests is traditionally based on sensitivity (detection rate), false-positive rate, and positive predictive value within a population. The predictive value of these tests, or the chance that a positive or negative result is a true positive or true negative, is highly dependent on the prevalence of the disease in the population.

Testing for a specific disease may be warranted by family history or ethnic background, and prenatal diagnosis may potentially allow interventions before the disease would have been detected in the child clinically (Table 2.7). In some rare cases, diagnosis in utero may allow the opportunity to preclude irreversible changes in early development. However, the provider must relay the *scope* and *accuracy* of available testing modalities. For instance, a test that detects a phenotypic manifestation of disease (such as biochemical screening of hexosaminidase activity to assess for Tay-Sachs) is more sensitive for detecting an affected fetus than a genetic sequence panel that may include only a subset of the disease-causing mutations. Alternatively, combination testing “panels” may be available that allow assessment for multiple diseases at once, but all tests are based on the same molecular methods, such as DNA sequence or SNP analysis, so sensitivity of detection for specific diseases may be sacrificed. The increasing availability of these “expanded carrier screening panels” has prompted the American College of Obstetricians and Gynecologists to issue guidelines for patient consent prior to offering expanded screening (Edwards, 2015):

1. Carrier screening of any nature is voluntary, and it is reasonable to accept or decline.
2. Results of genetic testing are confidential and protected in health insurance and employment by the Genetic Information Non-Discrimination Act of 2008.
3. Conditions included on expanded carrier screening panels vary in severity. Many are associated with significant adverse outcomes such as cognitive impairment, decreased life expectancy, and need for medical or surgical intervention.

4. Pregnancy risk assessment depends on accurate knowledge of paternity. If the biologic father is not available for carrier screening, accurate risk assessment for recessive conditions is not possible.
5. A negative screen does not eliminate risk to offspring.
6. Because expanded carrier screening includes a large number of disorders, it is common to identify carriers for one or more conditions. In most cases, being a carrier of an autosomal recessive condition has no clinical consequences for the individual carrier. If each partner is identified as a carrier of a different autosomal recessive condition, offspring are not likely to be affected.
7. In some instances, individuals may learn that they have two pathogenic variants for a condition (homozygous or compound heterozygous) and thus learn through carrier screening that they have an autosomal recessive condition that could affect their personal health. Some expanded screening panels screen for selected autosomal dominant and X-linked conditions, and likewise individuals may learn that they have one of these conditions that might affect their health. Referral to an appropriate specialist for medical management and genetic counseling is indicated in such circumstances to review the inheritance patterns, recurrence risks, and clinical features.

Genetic Counseling and Risk Assessment

Ordering and sending a genetic test is simple, but the counseling time to ensure appropriate interpretation of the results (positive or negative) is crucial and often time consuming. The role of the care providers (genetic counselors and physicians) is to conduct nondirectional counseling of screening and diagnostic options to provide prospective parents with information to optimize pregnancy outcomes based on their personal values and preferences.

All patients considering genetic screening or testing should have the opportunity to meet with providers who can perform formal pedigrees, conduct patient education and counseling on advantages and disadvantages of testing, and discuss the availability of screening and invasive diagnostic testing when needed.

Table 2.7 Common Autosomal Recessive Disorders in Ethnic Groups: Carrier Screening Recommended

Ethnic Group	Genetic Disorder	Carrier Frequency in Ethnic Group	Frequency of Carrier Couples	Screening Test Available?	Detection Rate (%)
African ancestry	Sickle cell disease (HbS and C)	HbS, 1:10 HbC, 1:20	1:130	Hb electrophoresis	100
	Sickle cell S- β -thalassemia			MCV, Hb electrophoresis	
	α -Thalassemia			MCV, DNA	
Ashkenazi Jews (and Jews of unknown descent)	Tay-Sachs disease	1:30	1:150	Hexosaminidase A level	98
	Canavan disease	1:40	1:1600	DNA mutation	
	Familial dysautonomia	1/32	1:32	DNA mutation	99
Chinese	α -Thalassemia		1:625	MCV	
French Canadian, Cajun	Tay-Sachs disease			Hexosaminidase A level	
Mediterranean (Italian/Greek/Turks/Spaniards)	β -Thalassemia		1:900	MCV	
All patients seeking preconception counseling (especially whites of European origin)	Cystic fibrosis	1:25-29	1:625	DNA mutation	80*

Hb, Hemoglobin; MCV, mean corpuscular volume.

*Depends on ethnic group: 70% for southern European descent, 90% for northern European descent.

Before screening or testing, the patient needs to understand the options that may ensue from a positive test result.

Biochemical and Sonographic Screening

Multiple screening options are available for detecting fetuses at risk for the most common aneuploidy syndromes, namely trisomies 21, 18, and 13. The choice of test will depend on the gestational age at presentation, number of fetuses, previous obstetric history, family history, availability of sonologists or sonographers certified to detect or measure test parameters, and options or preferences for pregnancy termination.

First trimester screening typically consists of serum measurement of pregnancy-associated plasma protein A (PAPP-A) and either free or total beta human chorionic gonadotropin (β hCG) combined with sonographic measurement of a fluid collection at the back of the fetal neck called the *nuchal translucency* (the three measurements together are called “combined first trimester screening”). Nuchal translucency measurements are validated for the specific gestational age window from 10^{4/7} weeks to 13^{6/7} weeks as determined by crown-rump length, and guidelines for measurement are standardized, which must be followed for the test to maintain published detection rates. A nuchal translucency measurement less than 3 mm is considered normal (Malone, 2005). The primary advantage of first trimester screening is earlier results, which allow for greater privacy and broader options of diagnostic testing and reproductive choices.

Second trimester biochemical screening for aneuploidy (available between about 15 and 20 weeks’ gestation) combines measurement of maternal serum alpha-fetoprotein (msAFP), human chorionic gonadotropin (hCG), and unconjugated estriol (to make up the “triple screen”), and it may include inhibin A (called a “quad screen”). There are various iterations of screening, which combine elements of both first and second trimester screening measurements, and performance statistics of these methods depend on the specific analytes included, whether the measurements are independent of one another, and the timing of risk calculation. The most favorable performance statistics are achieved with the “integrated screening” approach, which combines first trimester PAPP-A and nuchal translucency with quad markers in the second trimester, and results are not reported until all measurements are obtained. This method has a Down syndrome detection rate of 94% to 96% with a false-positive rate of 5%, but the advantage of an early result is lost if first trimester screening results are withheld until second trimester screening results have been obtained (Malone, 2005).

Abnormal results of some of the individual elements assayed in aneuploidy screening are also predictive of adverse pregnancy outcomes. For example, abnormal biochemical markers on both first and second trimester screens have been associated with fetal

growth restriction, intrauterine fetal demise, preterm delivery, Smith-Lemli-Opitz syndrome (low estriol), and oligohydramnios—albeit with low predictive value (Smith, 2006). Maternal serum AFP (msAFP) is very useful for detection of neural tube defects when measured between 16 and 18 weeks’ gestation; the American College of Obstetricians and Gynecologists (ACOG) recommendations include msAFP alone (not in conjunction with the quad screen) as an adjunct test for women who choose first trimester screening for aneuploidy (ACOG, 2007).

Cell-Free DNA Analysis Noninvasive Prenatal Testing

Early attempts at noninvasive genetically based prenatal screening were focused on isolation of intact fetal cells within the maternal circulation. To date, this technology has been unsuitable for clinical application due to multiple technologic obstacles such as limited numbers of fetal cells, unreliable recovery of fetal cells, and evidence that the cells persist long after pregnancy, thus complicating specificity in the setting of subsequent pregnancies (Bianchi, 2002).

In contrast, the development of methods to identify fetally derived cell-free DNA in maternal plasma has been more successful (Lo, 1997). The initial application of technology to assess cell-free fetal DNA was focused on single-gene disorders for which the abnormal DNA sequence was known in the family, or for determination of fetal gender in cases of families carrying traits for X-linked recessive diseases.

The advent of next-generation sequencing, a high-throughput method of sequencing millions of DNA fragments simultaneously in parallel, rapidly expanded the amount of data that can be gathered from fetal DNA in maternal plasma in a time frame amenable to prenatal screening applications. As a result, cell-free DNA tests to screen for fetal aneuploidy moved quickly through development and into clinical use by 2011 in the United States and Asia, followed by Canada and Europe in 2012. The performance statistics for Down syndrome detection in a high-risk population are far better than any other available methods (Table 2.8); however, the supplementary predictive value of nuchal translucency measurement or biochemical testing is lost (Gil, 2015). There are several available platforms for cell-free fetal DNA analysis; providers should be familiar with whether a chosen assay is designed to detect all chromosomes or only selected chromosomal regions. Furthermore, there is active debate over how to interpret results that are insufficient or results that are discrepant from confirmatory invasive testing. Causes of discrepant results include low fetal fraction of DNA, confined placental mosaicism, true fetal mosaicism, maternal sex chromosome abnormality, organ transplant, co-twin demise, maternal chromosome deletion, maternal tumor, and lab error. Inadequate fetal fraction

Table 2.8 Screening Test Performance: Prenatal Screening for Down Syndrome

Test	Detection Rate	False-Positive Rate	PPV (High-Risk) Tri21 Prevalence 1:100	PPV (Low-Risk) Tri21 Prevalence 1:500
Combined First Tri (NT, PAPP-A, hCG)	80%	3%	21%	5%
Quad (AFP, hCG, inhibin A, estriol)	60%	3%	17%	4%
Sequential screen (Combined First Tri plus Quad)	97%	3%	24%	6%
Cell-free DNA (all methods combined, [Gil, 2015])	99.2%	0.09%	91.3%	67.8%

has been repeatedly demonstrated in a higher proportion of women with elevated body mass index (BMI), and average fetal fraction varies between ethnic groups. Interestingly, the aneuploidy rate is much higher in samples with inadequate fetal fraction than in the general population, suggesting that “no readout” results should be considered a form of positive screen (Norton, 2015).

Current guidelines from multiple U.S. and international professional societies recommend the use of cell-free DNA screening be limited to women with increased risk of fetal aneuploidy. This includes women of advanced maternal age (>35 years at delivery); women with ultrasound findings indicating increased risk of trisomy 13, 18, or 21; prior pregnancy history of a fetus with trisomy 13, 18, or 21; biochemical screening result positive for increased risk of aneuploidy; or known parental balanced Robertsonian translocation with increased risk of trisomy 13 or 21. The relatively lower contribution of Down syndrome to all congenital anomalies in a low-risk cohort argues for the use of a screening tool with a broader scope. Nonetheless, cell-free fetal DNA screening is an area of active research and development, and detection capabilities for a wider range of microdeletion/duplication syndromes may be routine in the near future (Wapner, 2014).

There are promising data on testing applications for accurate detection of fetal microdeletion syndromes such as 22q11.2 (DiGeorge), deletion 5p (cri du chat), and 1p36 (Noonan) using an SNP-based noninvasive prenatal testing (NIPT) approach (Wapner, 2015). Microdeletions are a significant cause of neurocognitive abnormalities, and, importantly, they have no age associated risk, so younger patients have a much higher likelihood of having a child with a clinically significant microdeletion than of having a child with trisomy 21. Thus validation of microdeletion testing from cfDNA samples will significantly expand the utility of NIPT in the general population.

DIAGNOSTIC TECHNIQUES FOR GENETIC ABNORMALITIES

Invasive Prenatal Diagnostic Tests

For the goal of prenatal *diagnosis*, the most commonly employed forms of genetic testing are chorionic villus sampling and amniocentesis to obtain cellular samples from pregnancy tissue for cytogenetic analysis.

In the early days of prenatal diagnosis, invasive testing options were offered to women with a high age-related risk of aneuploidy. However, current ACOG recommendations are that all women, regardless of age or risk, be offered biochemical or ultrasound screening and invasive testing (ACOG, 2007). The decision to pursue invasive testing must incorporate considerations of level of risk that the fetus is affected, level of risk associated with the procedure, and the patient's personal impression of the impact of having an affected child. Of note, the risks involved with invasive testing may be much lower than estimates that have been previously quoted since the advent of invasive testing in the 1970s. Results of a meta-analysis that included only contemporary large studies (published after the year 2000, reporting greater than 1000 procedures) demonstrated no significant difference in the risk of miscarriage prior to 24 weeks' gestation for women undergoing amniocentesis or chorionic villus sampling (CVS) compared with those who do

not have invasive testing (Akolekar, 2015). Procedure-related risk of miscarriage for amniocentesis was 0.1%, and for CVS it was 0.2%.

Nevertheless, rates of performance of these invasive procedures are significantly declining as screening tests with higher detection rates and lower false-positive rates have become available (i.e., cell-free DNA screening). It is important to note that the range of abnormalities that can be detected is far greater with invasive testing than with any available noninvasive screening tests.

CVS can be performed early in pregnancy (9 to 12 weeks' gestation), in which a biopsy of cytotrophoblast tissue is obtained via ultrasound-guided transabdominal or transcervical route. The patient should be aware of a small rate (1.1%) of indicated follow-up testing to resolve issues from maternal cell contamination or placental mosaicism, but overall cytogenetic diagnosis is successful in 99.7% of those tested (Ledbetter, 1990).

Amniocentesis, generally performed after 15 completed weeks of pregnancy, involves ultrasound-guided transabdominal collection of amniotic fluid containing sloughed fetal cells from skin, gastrointestinal tract, amnion and genitourinary tract.

The predominant use for CVS or amniocentesis samples is cytogenetic analysis. Cells can be analyzed directly or after cell culture for about a week to synchronize cells in metaphase for chromosomal Giemsa staining, or G-banding. With this type of staining, each chromosome has a unique pattern. The stained chromosomes are visualized under light microscopy, and large deletions or rearrangements can be detected (resolution on the order of 5 million to 10 million base pairs, or Mb). Higher resolution or more specific testing for known disease-causing chromosome regions such as 22q11 requires molecular cytogenetic technology. The most widely used procedure is fluorescent in situ hybridization (FISH). FISH takes advantage of the complimentary nature of DNA. In this approach, denatured DNA sequences labeled with a fluorescent dye are hybridized onto denatured chromosomes that have been immobilized onto a slide. The chromosomes are then viewed with a wavelength of light that excites the fluorescent dye (Fig. 2.12). FISH is a powerful tool to confirm or diagnose syndromes that are due to microdeletions of segments of chromosome material (Fig. 2.13).

At the individual gene level, disease-specific testing for families that carry known genetic mutations may be performed on cells from either of these invasive methods using polymerase chain reaction (PCR)-based methods (discussed later). An updated list of relatively common genetic conditions for which DNA-based prenatal diagnosis is available is kept on the Genetic Testing Registry website (www.ncbi.nlm.nih.gov/gtr).

Another powerful diagnostic and investigational tool for human chromosome analysis directly expanded from FISH technology is comparative genome hybridization (CGH). CGH is used to measure differences in copy number or dosage of a particular chromosome segment. Its initial application was in the study of gene dosage in normal and cancer cell lines (Fig. 2.14). This technology has since come into widespread use due to automated platforms allowing for assessment of thousands or even millions of DNA molecules at once and rapidly decreasing cost (see *Chromosomal Microarray*, presented later).

WCP: Chromosomes 1 and 4

Figure 2.12 Example of fluorescent in situ hybridization (FISH) with whole-chromosome DNA (whole-chromosome paint [WCP]) from chromosomes 1 (red signal) and 4 (green signal) hybridized onto a metaphase nucleus containing all 46 chromosomes. This FISH study revealed a translocation of a piece of material from chromosome 4 onto chromosome 1. (Courtesy of Lisa Shaffer, PhD, Washington State University.)

Deletion of 11p

Figure 2.13 Example of FISH technology in the diagnosis of microdeletion syndromes. Here, standard karyotyping appears to be normal. However, using FISH microdeletion probes, this child was discovered to have a submicroscopic deletion (arrow) of the terminal section of the long arm of chromosome 1. The other chromosome containing the red signal is the normal chromosome. (Courtesy of Lisa Shaffer, PhD, Washington State University.)

Molecular Genetic Analysis Techniques

Polymerase Chain Reaction, Southern Blot, Restriction Fragment Length Polymorphism, Linkage

The use of polymerase chain reaction (PCR) permits rapid amplification of a sequence of DNA or multiple different sequences simultaneously for analysis. This is essentially a form of cloning, because PCR can selectively amplify a single sequence of DNA or RNA several billion-fold in only a few hours. By taking advantage of the double-stranded complementary pairing characteristics of DNA, the PCR reaction separates (denatures) the

Figure 2.14 Schematic example of how microarray technology can be used to study or compare gene expression patterns from different sources. Here it is used to compare the gene expression profiles of two different tumors. However, one can easily substitute DNA from two individuals with diabetes. (Courtesy of Edith Cheng, MD.)

two strands and uses each strand as a template to synthesize two more copies (Fig. 2.15). Target sequences of DNA flanked by primers undergo repeated cycles of heat penetration, hybridization with primers, and DNA synthesis, resulting in an exponential amplification of the target DNA sequence. The amplified DNA sequences can then be “cut” by bacterial enzymes, called *restriction endonucleases*, which recognize and cut specific nucleotide sequences (restriction sites) in the double-stranded DNA molecule. Each enzyme recognizes a unique sequence of nucleotides, usually a palindrome of four to eight base pairs (bp) in length. Because of this sequence specificity, the pattern of DNA fragments resulting from restriction endonuclease digestion will

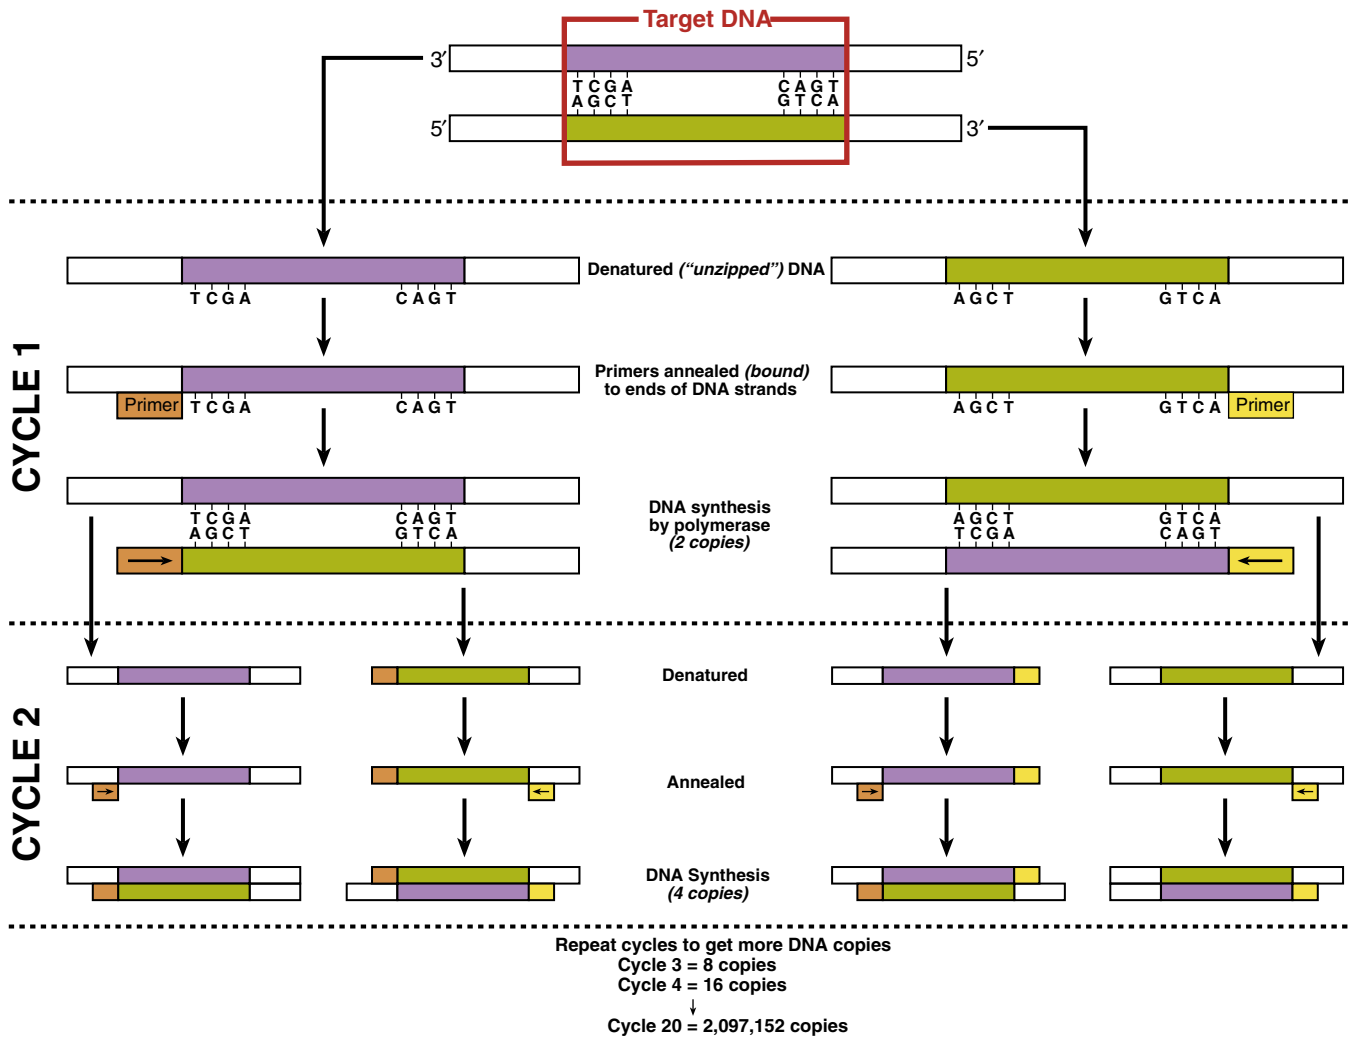

Figure 2.15 Schematic representation of the polymerase chain reaction (PCR). (Courtesy of Edith Cheng, MD.)

be unique to each gene sequence. The resulting fragments are separated by gel electrophoresis, transferred (blotted) onto a membrane, and hybridized with a radioactively labeled probe with known sequence. This method, known as *Southern blotting*, permits identification of specific DNA fragments of interest and, in some cases, the number of copies of the fragment. Figure 2.16 is an example of how Southern blotting is used to detect the sickle cell gene. Mutations within a gene or near a gene can also alter the recognition sites of restriction endonucleases, which will generate an altered length of DNA fragment containing the gene of interest. These restriction fragment length polymorphisms (RFLPs) can be used to follow the transmission of a gene in a family.

When "direct testing" is not possible, as is the case when the disease-causing gene has not been isolated, when the gene is too large to sequence, or when a mutation cannot be directly found, indirect testing using linkage analysis is the alternative strategy. The simplest explanation for this concept is that DNA markers located (or tightly linked) to the presumptive disease-causing gene/mutation are used as road maps to identify the travel or passage of the gene from an

affected parent to an at-risk offspring. This strategy requires that the affected individual has markers that are informative—in other words, unique or distinctive from markers of the nonaffected individual. Multiple family members, both affected and unaffected, must have DNA available for linkage analysis in order for this approach to be informative. The "markers" are often RFLPs. Figure 2.17 uses autosomal dominant breast cancer as an example of how linkage studies are used to predict the inheritance of a gene for which direct mutational analysis is not possible.

Chromosomal Microarray

Chromosomal microarray is a high-throughput technique to detect relative "dose" of genetic material by comparison to a reference standard. A microarray generally consists of a thin slice of glass or silicon about the size of a postage stamp on which threads of synthetic nucleic acids are arrayed. Sample probes are added to the chip, and matches are read by an electronic scanner. The resolution of chromosomal microarray is on the order of 10 to 400 kb, or more than 100-fold greater resolution than traditional G-banding karyotyping.

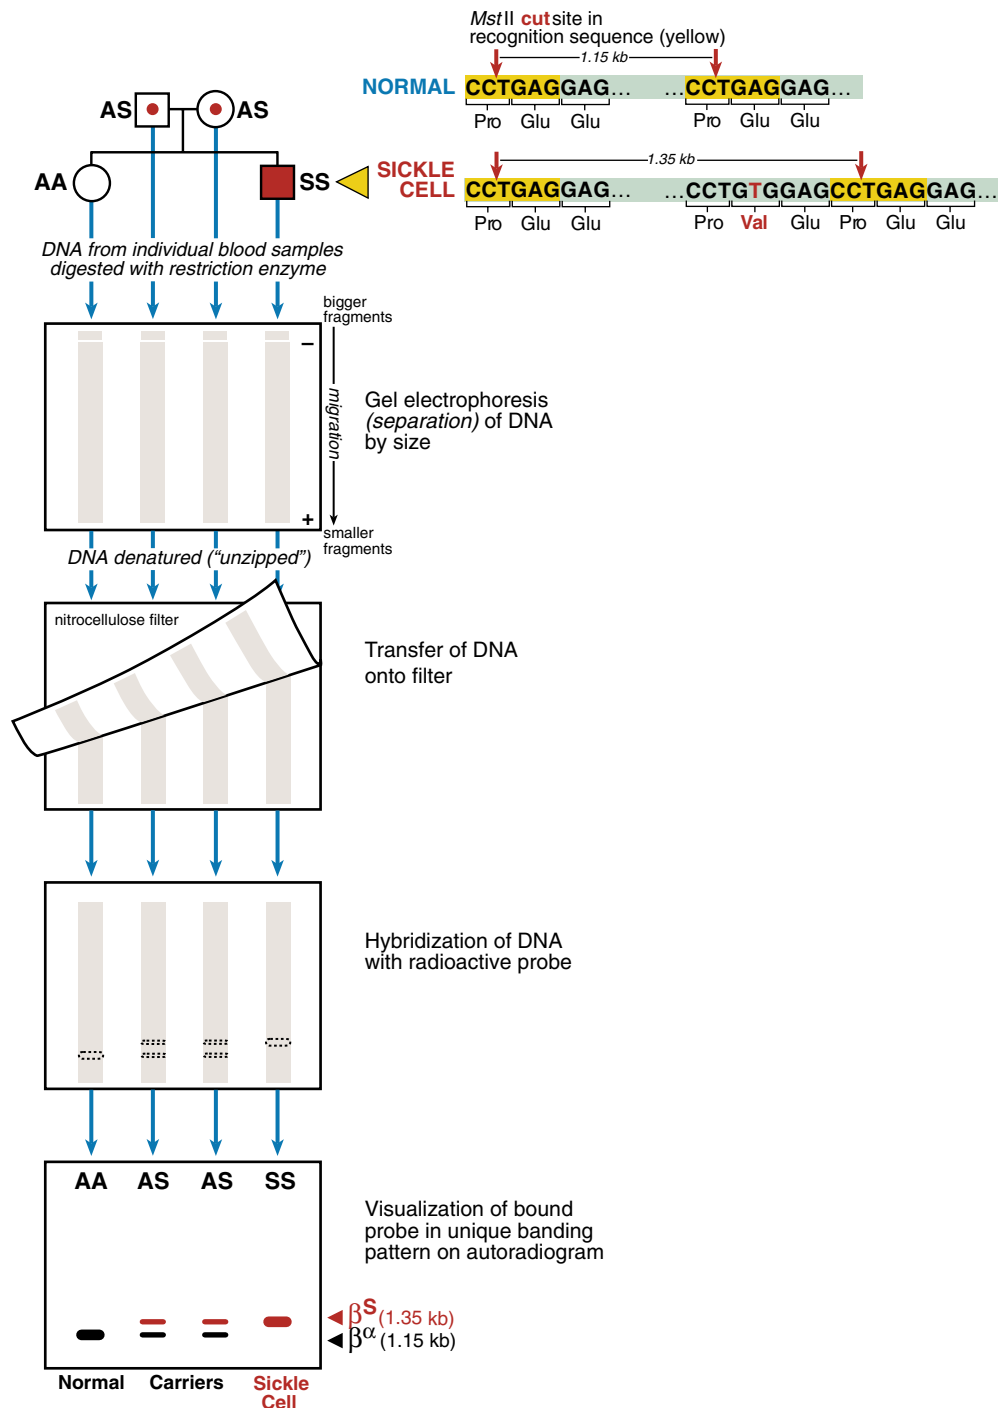

Figure 2.16 Schematic representation of the Southern blot procedure—in this case, for diagnosis of sickle cell disease. Genomic DNA from the carrier parents, an unaffected daughter, and the affected son is extracted from a sample of peripheral blood. The DNA samples are digested with restriction enzymes and fragmented into smaller pieces. In this case, the restriction enzyme *Mst*II is used specifically because it recognizes the normal sequences that encompass the codons for glutamic acid at position 6 of the hemoglobin A polypeptide. The DNA fragments are separated based on size by gel electrophoresis, then they are transferred (blotted) onto a nitrocellulose filter. The DNA of the filter paper is then hybridized with a specifically labeled DNA probe containing the sequences of interest. The fluorescent or radioactive probe is visualized as bands at sites where the genomic DNA has hybridized with the labeled DNA. (Courtesy of Edith Cheng, MD.)

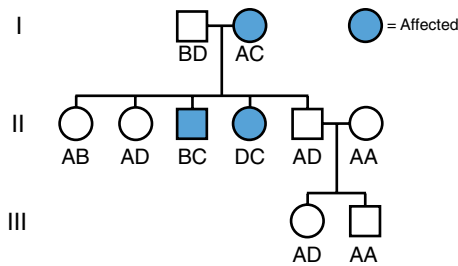

Figure 2.17 Hypothetical autosomal dominant condition illustrating the principle of indirect mutational analysis. Genetic markers A, B, C, and D are used. In this pedigree, it appears that the condition segregates (travels) with marker C. Therefore the male and female in generation III, who did not inherit marker C, are not expected to manifest the condition. (Courtesy of Edith Cheng, MD.)

There are two general platforms in common use for genome assessment. The first is a form of comparative genomic hybridization, or “array CGH.” In brief, two genomic libraries are mixed and hybridized to a panel of reference sequences such that relative “doses” of hybridized sequence can be quantitated. Using this platform, a patient’s genome is compared with a normal control, and readout is expressed by comparative intensity between the patient and the control (Snijders, 2001).

The second popular platform is an SNP array. In an SNP array, probes are chosen from DNA locations known to vary by a single base pair. A patient’s DNA is hybridized to the array (note this platform does not require a normal standard), and readout is by absolute intensity of signal from bound DNA fragments. This method can detect more abnormalities than just copy number, such as uniparental disomy, determine zygosity, parent of origin for a given mutation, and maternal cell contamination (Beaudet, 2008).

In neonatal and pediatric studies, microarray results have revealed underlying genetic etiologies for 15% to 20% of cases with previously unexplained developmental delay, intellectual disability, or congenital anomalies. Only about 3% of these cases would have been diagnosed by traditional karyotype (Miller, 2010).

In contrast to neonatal studies, which have the advantage of correlating genomic findings with complete physical exam and behavioral phenotype, prenatal applications are limited to phenotypic findings that can be detected by ultrasound. Several studies have demonstrated the incremental diagnostic utility of chromosomal microarray analysis in the setting of a fetus with one or more anomalies on ultrasound but normal karyotype. A prospective National Institute of Child Health and Human Development (NICHD) study identified clinically relevant copy number variants by microarray in 6% of anomalous fetuses with a normal karyotype (Wapner, 2012). Furthermore, the likelihood of identifying either pathogenic CNV or CNV of uncertain significance was more likely in fetuses with multiple anomalies, whereas for isolated findings, the greatest yield was in cardiac and renal anomalies (Donnelly, 2014). Chromosomal microarray is considered the first-line test of an individual with unexplained birth defects or mental retardation, or in unexplained stillbirth (Hillman, 2015).

Clinicians and genetic counselors must continue to exercise reasonable caution when interpreting results of microarray findings. Accurate genotype-phenotype correlations will require

ongoing expansion of CNV databases. Many CNV may have dose-dependent phenotypic effects or may be modified by the presence of other genotypic variants.

Traditionally, screening modalities focused on diseases that significantly affect quality of life and have a fetal, neonatal, or early childhood onset and well-defined phenotype. In the post-genome era with high-throughput microarray technology, the identification of molecular alterations in DNA may reveal previously unrecognized genetic variants associated with disease. Yet variant recognition currently outstrips our ability to interpret these alterations. Previously unreported and relatively rare variants with unknown phenotypes will be identified, which requires skilled counseling and interpretation to help patients decide what to do with this information. Informing patients of variants of uncertain significance may generate significant anxiety and negative anticipation. Learning that one’s fetus has an abnormality with unquantifiable risks of consequences naturally fosters apprehension, may lead to ambiguity about continuing the pregnancy, and has the potential to cast a shadow of worry in the parents’ minds throughout the life of the child.

Preimplantation Genetic Diagnosis and Preimplantation Genetic Screening

Preimplantation genetic diagnosis (PGD) refers to single cell extraction and genetic analysis from either an embryo or the polar body from an oocyte during the process of in vitro fertilization (see also Chapter 1). Initial impetus was to decrease the chances of propagating known genetic disorders in a family. The earliest application was in the setting of a patient known to carry an X-linked recessive gene, so only female embryos (by definition unaffected by the disease of interest) were transferred to the uterus. Since that time, PGD also has become readily available for diagnosis of translocations, single-gene disorders, and inherited mutations that are known to cause cancer susceptibility syndromes.

In contrast to disease-causing genetic abnormalities, there have been numerous studies attempting to use chromosomal aneuploidy screening of a single preimplantation cell (preimplantation genetic screening [PGS]) to improve assisted reproductive technology outcomes. All of the initial studies were based on FISH analysis of the single preimplantation cell, and none of these were able to demonstrate improved live birth rates following selection of embryos designated euploid by this method, thus ACOG did not recommend PGS for management of recurrent miscarriage or recurrent implantation failures (ACOG, 2009). More recently, however, SNP and PCR-based screening methods have been developed and are shown to be more comprehensive and accurate than FISH-based methods for aneuploidy diagnosis in embryo biopsy. A randomized trial using PGS to transfer a single euploid embryo demonstrated improved pregnancy rates compared with untested blastocyst transfer while decreasing the incidence of multiple pregnancies (Forman, 2013).

Sequencing

Sequencing determines the complete nucleotide sequence, or specific order of nucleotides in a gene. By listing the full code, variations from an accepted “normal” (reference or consensus sequence) may be discovered. This has the potential to uncover pathogenic variants as well as benign variants and, given our

limited understanding of how the genome is translated, will certainly identify variants of uncertain significance to clinical phenotype.

Clinical use of sequence data from the whole exome (protein-coding region of DNA), or ultimately the whole genome, is considered the next frontier in genetic diagnostic techniques. Whole-exome sequencing continues to raise the bar of expectation for molecular diagnosis with genetic analysis methods. The first large series of clinically applied whole exome analysis touted a 25% molecular diagnosis rate among all patients referred for phenotypes suggesting potential genetic component, and among patients in the study with a neurologic phenotype, molecular diagnosis was as high as 33% (Yang, 2013).

Goals of this magnitude have come within reach through development of *next-generation sequencing*. The original technique of sequencing, called *Sanger sequencing*, involves synthesizing multiple copies of DNA that is complementary to a single-stranded template of interest using nucleotide-specific chain terminators. This generates synthesized fragments of varying length that can be arranged by size, and the reactions containing each terminating base (A, T, G, or C) are kept separated. Then, by “reading” the terminating base of the synthesized copies from smallest to largest, the sequence of the original single-stranded template is revealed. This molecular method was revolutionary, but very time consuming, labor intensive, and limited to relatively short DNA sequences. The quest to uncover the sequence of all 3 billion bases in the human genome propelled extraordinary improvements in scale, speed, and data management. Next-generation sequencing involves preparation of a full DNA library (no longer one small segment at a time) by amplifying (making many copies) and fragmenting the DNA source of interest (genomic DNA, coding DNA). The DNA library now consists of thousands or even millions of small overlapping DNA copy fragments, which are physically bound to a solid surface (platform specific, often beads or glass slides). The fragments are loaded into specialized multiplex machines for parallel sequencing; in other words, the sequence of every fragment on the surface can be assayed simultaneously. Individual sequence reads are subsequently aligned (recall the expected overlap due to random fragmentation of many identical copies of DNA) using various bioinformatics platforms for comparison to a reference sequence. The full set of aligned reads reveals the entire sequence of the starting DNA product. Thus next-generation sequencing can apply the concept of Sanger sequencing to an entire genome with results produced in matter of hours.

At present, the practical clinical application of sequencing is to search one or many genes (or the whole genome) for a causative mutation in the setting of a recognized abnormal phenotype. Particularly in pediatric literature, sequencing has been reported to identify the genetic cause in cases of rare malformation syndromes and previously unexplained neurodevelopmental morbidity. Sequencing can be useful in prenatal counseling or diagnosis if the specific mutation can be identified for a previous child affected by a genetic disorder. Consider, for example, a family with a child diagnosed with cystic fibrosis, but only one parent has one of the known CF mutations. Sequencing of the CF gene in the *proband*, or first affected child, may reveal the previously unrecognized causative mutation in that family.

Data generated from sequencing methods are vast. The primary limitation of both whole-exome sequencing (WES) and

whole-genome sequencing (WGS) is that accurate interpretation lags behind the ability to generate sequence data because sequencing is high throughput, but there are currently no similar high-throughput assays of function to assess putative pathologic sequence findings. There is enough natural variation in the human genome that any putative finding requires rigorous validation at the level of sequence, molecular function, and interaction within the full biologic system.

There are many interrogation tools to assess protein-coding portions of the genome. However, the comprehension of the remaining 98.5% of DNA sequence is relatively nascent, with no current way to assay functional loss or gain from these regions (Goldstein, 2013).

GENETICS OF REPRODUCTIVE MALIGNANCIES

All cancer is genetic. However, most cancer is not inherited. For a normal cell line to be transformed into a malignant cell line, several genetic mutations in that somatic cell line must occur that alter cell growth and differentiation. All cells have mechanisms to either repair a mutation or inhibit growth and replication if errors in DNA occur. Thus before malignancy can arise, most cancer cells have to “escape” those repair functions. The first mutations must occur in either DNA repair genes or genes that suppress growth of abnormal cells (the genes that maintain the integrity of the genome). Subsequent mutations are then passed on to daughter cells. Increasing cell replications occur, and as mutations build up, some will allow the cell line to grow abnormally and often confer biologic advantages over surrounding normal cells. When “enough” DNA change occurs, the resulting abnormal cells are capable of metastasizing, thereby usurping resources of vital organs and, without treatment, eventually may lead to death. This process of multiple sequential mutations is called the “multistep process of cancer.” In 5% to 10% of families with cancer, there is a germline (inherited) mutation that predisposes certain tissues to begin to move through the multistep series of mutations more easily. More than 50 inherited cancer syndromes have been described, although the majority of these are inherited through highly penetrant mutations in a dominant fashion. These inherited cancer genes do not cause cancer; rather they allow cancer to “happen more easily.” Inherited cancer syndromes that affect female organs are listed in (Table 2.9).

Carefully regulated cellular processes, such as differentiation, proliferation, and programmed cell death, are altered in cancer cells. The stages of carcinogenesis are termed *initiation* (single initial proliferative cell), *promotion* (acquired selective growth advantage), *progression* (tumor characteristics become irreversible), and *metastasis* (process by which cells are displaced). Types of genes and genetic mechanisms involved in malignancy may be grouped into four categories: oncogenes, tumor suppressor genes, DNA repair genes, and epigenetic mechanisms.

Oncogenes (gain of function) behave as growth-promoting genes, and they act in a genetically dominant manner. In other words, only one abnormal copy of the gene will produce a clinically relevant phenotype due to increased gene function. They originate from normal cellular genes called proto-oncogenes. The proto-oncogenes have normal functions within a cell to

Table 2.9 Inherited Cancer Syndromes Affecting Gynecologic Organ Systems

Body Part	Cancer Syndrome	Gene Name/ Location
Breast	Inherited breast-ovarian cancer (autosomal dominant; tumor suppressor gene, involved in the maintenance of genomic stability)	<i>BRCA1</i> , 17q21
	Inherited breast-ovarian cancer (autosomal dominant; tumor suppressor gene, involved in the maintenance of genomic stability)	<i>BRCA2</i> , 13q12.3
	Li-Fraumeni (autosomal dominant; regulates the cell-cycle arrest that is required to permit repair of DNA damage)	<i>p53</i> , 17p13.1
	Cowden	<i>PTEN</i> , 10q23.31

HNPCC, Hereditary nonpolyposis colorectal cancer.

control and enhance cell growth. Oncogene activation (through mutation) can lead to either increased expression of proteins or changes in structure and function of a proto-oncogene's product. For example, the HER 2/neu receptor may be overexpressed by an oncogene. Only a few inherited cancer syndromes involve oncogenes. Examples include the *RET*, *CDK4*, and *KIT* oncogenes. The *RET* oncogene is the underlying cause of multiple endocrine neoplasia (MEN type 2). These individuals have an increased risk to develop endocrine tumors.

Tumor suppressor genes restrain cell growth in damaged cells; therefore loss of the tumor suppressor gene through mutation leads to increased cell proliferation of abnormal cells and cancer development. They account for the majority of autosomal dominant cancer syndromes. Some examples include *BRCA1* and *BRCA2* genes, and the *p53* gene (Li-Fraumeni syndrome). Tumor suppressor genes are dominantly inherited. However, on the cellular level, they are recessive. In other words, a cell must have two genetic hits (one hit to each copy of the gene in question) before the cell can head down the multistep process to cancer. The first hit is inherited, and the second hit is acquired.

DNA repair genes identify and mend DNA replication errors made during replication. When they are nonfunctional, replication errors can lead to cancer development. Lynch syndrome

(hereditary nonpolyposis colorectal cancer [HNPCC]) has at least four mismatch repair genes (*MLH1*, *MSH2*, *MSH6*, and *PMS2*) that predispose an individual to colon cancer and uterine cancer. One could imagine these genes as editors that find and correct spelling errors. Loss of their function allows mutations to accumulate and leads the daughter cells down the path of the multistep process of cancer. There are other genes that concentrate on repairing DNA sequences that were damaged by an external source such as radiation. Some examples include Fanconi anemia, Bloom syndrome, ataxia-telangiectasia, and xeroderma pigmentosum. These are the few cancer syndromes that follow an autosomal recessive pattern of inheritance.

Epigenetic mechanisms, as discussed previously, involve alterations in patterns of DNA methylation or DNA packaging (3D structure determined by histone interaction and nucleosome positioning). Cancer cells are frequently characterized by global loss of DNA methylation with paradoxical hypermethylation at CpG islands of certain promoters. Coupled with aberrant packaging that may expose inappropriate genetic areas to allow transcription, the overall consequence is abnormal gene expression, either increased or decreased. One can use this clinically to try and identify the 3% to 5% of patients with endometrial cancer that have Lynch syndrome. Lynch syndrome differs from other hereditary cancer syndromes in that the actual tumor tissue can be screened for Lynch syndrome using immunohistochemistry (IHC) for the four mismatch repair proteins (*MLH1*, *MSH2*, *MSH6*, *PMS2*), microsatellite instability (MSI) analysis, and *MLH1* hypermethylation testing. Positive tests will require confirmatory diagnostic testing, but they help guide germline genetic testing. In an attempt to identify Lynch syndrome in women with endometrial cancer, the Society of Gynecologic Oncology Clinical Practice Statement on Screening for Lynch Syndrome in Endometrial Cancer recommends that all women who are diagnosed with endometrial cancer should undergo systematic clinical screening for Lynch syndrome (review of personal and family history) or molecular screening. Molecular screening of endometrial cancers for Lynch syndrome is the preferred strategy when resources are available (SGO, 2014).

When considering a family history of cancer, one should first obtain a complete history, including who has and who has not had cancer in the family. This information will help determine to which group the family likely belongs: *average risk* (sporadic—somatic cell changes), *moderate risk* (common exposures—somatic cell changes or low penetrance genes), or *high risk* (inherited cancer genes—germline mutations). For certain cancer syndromes, computer models are available to help determine the chance a family has an inherited cancer syndrome. It is important to note that taking a detailed family history involves more than asking who has had cancer. One important factor to be cognizant of is the difference between primary cancers, recurrences, and metastatic disease. Patients rarely understand the subtleties of these important distinctions and inadvertently report inaccurate information. It is common for a woman to tell her physician about a family member who was treated for uterine cancer. Upon detailed history taking the physician finds that the woman had a procedure for cervical dysplasia. This type of information is critical to sort this out in order to provide a risk estimate. Once it is determined to which group the person belongs, then an estimation of that person's risk to develop cancer can be determined, and, finally,

an individualized cancer screening recommendations can be agreed upon. Generally, at-risk patients should be referred to genetic counselors or medical geneticists with particular expertise in cancer genetics.

CANCER GENOME SEQUENCING

With the advent of next-generation sequencing there are several commercial entities providing fast and relatively inexpensive tumor DNA sequencing that has not only revolutionized the genetic research on cancer but also created potentially new therapeutic opportunities as well. Tumor specimens can be tested for a “panel” of genes with a known association to cancer and specifically looking for genetic mutations that are “actionable” mutations, in that pharmacologic agents exist, that target these mutations. Different tumor types can have genetic features in common, making them treatable with the same drugs aimed at the genetic defect. Consider Herceptin, the first cancer drug approved for use with a DNA test to determine who should receive it (now there is also a protein-based test). The U.S. Food and Drug Administration (FDA) cleared it in 1998 to target breast cancers that overexpress the *HER2* gene, a change that drives the cancer cells to multiply. The same mutation has been found in gastric, ovarian, and other cancers. As a result of testing, the drug was approved in 2010 to treat patients with gastric cancers that overexpress the *HER2* gene. The potential application of the next-generation sequencing technology is vast but still needs to be subject to scientific scrutiny before it replaces more standard treatment options.

ETHICAL CONSIDERATIONS OF GENETIC DIAGNOSIS

Commonly identified “pitfalls” of identifying genetic anomalies that lead to formidable counseling challenges include variants of unknown significance (VOUS), identification of adult-onset disease or parental presymptomatic disorders, revelation

of nonpaternity, unsuspected consanguinity, findings linked to diseases with variable expressivity, or microdeletions involving a gene linked to cancer development or progression. There are also growing concerns that complete sequence data may lead to overstated associations of disease with findings of genetic variation.

Prenatal genetic discovery, whether through cell-free DNA screening or direct analysis techniques such as chromosomal microarray or whole-exome sequencing, may have especially precarious consequences. There is a relative paucity of information when basing disease prediction on genetic information alone. Due to variations in strength of association with a given phenotype, differences in penetrance, and potential influence of other genetic or environmental factors on disease phenotype, the weight of the evidence for the reported finding must be carefully considered before irrevocable action such as pregnancy termination or fetal treatment is undertaken. The potential impact even goes beyond the possibility of pregnancy termination. Consider the effect of incidental findings such as Mendelian diseases with adult-onset symptoms, or inherited mutations of cancer-associated genes. This raises the risk of labeling the unborn child as well as the parents or extended family with a predestined illness. Furthermore, these findings may cause considerable unfounded anxiety throughout pregnancy and into childhood, depending on the strength of disease association.

At the outset of the Human Genome Project in 1990, the National Human Genome Research Institute established the Ethical, Legal, and Social Implications (ELSI) Program, a component of the extramural genomics research program of the National Institutes of Health (NIH) (McEwen, 2014). This program has focused on four high-priority areas: the use and interpretation of genetic information, clinical integration of genetic technology, issues surrounding genetics research, and public and professional education about these issues. Research such as the programs funded under ELSI are essential to establish basic guidelines; however, the uses and influence of genetic/genomic diagnosis are vast, and ultimately the individual provider must assume responsibility for pursuing and interpreting the information conscientiously.

KEY POINTS

- Virtually all human diseases have an underlying genetic component. All health care professionals need a basic level of familiarity with genetics and genomics, as this is an integral part of mainstream medicine.
- Genetic variation between healthy individuals exists in the form of SNPs and CNVs providing different “doses” of a large repeated DNA sequence at a given genetic locus, or alterations in three-dimensional DNA structures called *epigenetic modification*.
- Naturally occurring variations in genetic sequence, such as SNPs, may mediate an individual’s susceptibility to disease or responsiveness to a particular medication.
- The human genome contains about 3 billion base pairs, of which only about 1.5% makes up the exome, or protein-coding portion. The remaining 98.5% of the human genetic sequence encodes biologically active nucleic acid molecules, which are an active area of molecular biology research.
- Genetic pathology can arise from alteration in the sequence of a gene, changes in the normal amount of a gene product, or sequence changes in regulatory regions, which prevent the cell from expressing the intended gene product.
- When a heterozygous individual who has an autosomal dominant trait mates with a normal individual, 50% of their offspring will have the trait.
- When two individuals who carry an autosomal recessive trait mate, 25% of their offspring will demonstrate the trait and 50% will be carriers.
- X-linked recessive characteristics are transmitted from maternal carriers to male offspring and will affect 50% of the male offspring.

Continued

KEY POINTS—cont'd

- The mechanism of trinucleotide repeat disorders is DNA misalignment during meiosis, which leads to unstable dynamic expansion of the number of three-nucleotide repeats within the gene as it is passed from generation to generation, causing progressively more severe manifestations of disease.
- Prader-Willi and Angelman syndromes demonstrate the concept that certain regions of genetic material are imprinted and depend on dose and inheritance from two separate gametes for normal function.
- The phenotype and severity of disorders that affect the mitochondria are determined by the source of the genetic material (nuclear or mitochondrial DNA), the proportion of affected mitochondria inherited by the cell, as well as the threshold for energy production needed in the affected cell.
- In general, if a couple produces an offspring with a multifactorial defect and the problem has never occurred in the family, it can be expected to be repeated in 2% to 5% of subsequent pregnancies.
- Individuals who carry balanced rearrangements of genetic material are phenotypically normal, but their gametes are at risk for unbalanced genetic content, which may lead to infertility or recurrent pregnancy loss.
- Nondisjunctional events have been described in every autosome except chromosomes 1 and 17. Live births can result from nondisjunctional events involving chromosomes 21, 18, 13, or 22, and these occur more commonly with advancing maternal age.
- There are screening and diagnostic tests available for prenatal diagnosis of a large number of genetic diseases and syndromes. Indications for testing may include family history of a specific disease or recurrent clinical phenotype, ethnic background with increased carrier frequency of a certain disease, poor obstetric outcome history, increased maternal age, or population-based prevalence risk.
- In genetic counseling, the role of the care providers (genetic counselors and physicians) is to conduct nondirectional counseling of screening and diagnostic options in order to provide prospective parents with information to optimize pregnancy outcomes based on their personal values and preferences. Before screening or testing, the patient needs to understand the options that may ensue from a positive test result.
- Genetic screening based on cell-free fetal DNA is currently recommended only for women with increased risk of fetal aneuploidy.
- Definitive diagnosis of a genetic disease in the prenatal period requires tissue diagnosis obtained through invasive testing methods such as preimplantation genetic diagnosis, chorionic villus sampling, or amniocentesis.
- With next-generation sequencing, it is possible to determine the complete sequence data for an individual exome (protein-coding region) or genome (complete genetic material). However, accurate interpretation of these data is limited by unknown function of natural genetic variation and noncoding DNA regions, which make up the majority of the sequence.
- All cancer is genetic. However, most cancer is not inherited. For a normal cell line to be transformed into a malignant cell line, several genetic mutations in that somatic cell line must occur that alter cell growth and differentiation.
- In 5% to 10% of families with cancer, there is a germline (inherited) mutation that predisposes certain tissues to become malignant.
- Types of genes and genetic mechanisms involved in malignancy may be grouped into four categories: oncogenes, tumor suppressor genes, DNA repair genes, and epigenetic mechanisms of aberrant DNA packaging.
- Oncogenes (gain of function) behave as growth-promoting genes, and they act in a genetically dominant manner. In other words, only one abnormal copy of the gene will produce a clinically relevant phenotype due to increased gene function.
- Tumor suppressor genes restrain cell growth in damaged cells; therefore loss of the tumor suppressor gene through mutation leads to increased cell proliferation of abnormal cells and cancer development. They account for the majority of autosomal dominant cancer syndromes.
- DNA repair genes identify and mend DNA replication errors made during replication. When they are nonfunctional, replication errors can lead to cancer development.
- Epigenetic mechanisms involve alterations in patterns of DNA methylation or DNA packaging (3D structure determined by histone interaction and nucleosome positioning).
- Lynch syndrome has a prevalence of 3% to 5% in all patients with newly diagnosed endometrial cancer.
- In patients with endometrial cancer, the actual tumor tissue can be screened for Lynch syndrome using IHC for the four mismatch repair proteins (MLH1, MSH2, MSH6, and PMS2), MSI analysis, and MLH1 hypermethylation testing.

Reproductive Anatomy Gross and Microscopic, Clinical Correlations

Fidel A. Valea

The organs of the female reproductive tract are classically divided into the external and the internal genitalia. The external genital organs are present in the perineal area and include the mons pubis, clitoris, urinary meatus, labia majora, labia minora, vestibule, Bartholin glands, and periurethral glands. The internal genital organs are located in the true pelvis and include the vagina, uterus, cervix, oviducts, ovaries, and surrounding supporting structures. This chapter integrates the basic anatomy of the female pelvis with clinical situations.

Embryologically, the urinary, reproductive, and gastrointestinal tracts develop in close proximity. This relationship continues throughout a woman's life span. In the adult, the reproductive organs are in intimate contact with the lower urinary tract and large intestines. Because of the anatomic proximity of the genital and urinary systems, altered pathophysiology in one organ often produces symptoms in an adjacent organ. The gynecologic surgeon should master the intricacy of these anatomic relationships to avoid surgical complications. The clinician must also appreciate that wide individual differences in anatomic detail exist among patients. Understanding these variations is one of the greatest challenges of clinical medicine.

This chapter focuses on the norms of human anatomy; it does not duplicate the completeness of an anatomic text or surgical atlas.

EXTERNAL GENITALIA

Vulva

The *vulva*, or *pudendum*, is a collective term for the external genital organs that are visible in the perineal area. The vulva consists of the following: the mons pubis, labia majora, labia minora, hymen, clitoris, vestibule, urethra, Skene glands, Bartholin glands, and vestibular bulbs (Fig. 3.1).

The boundaries of the vulva extend from the mons pubis anteriorly to the rectum posteriorly and from one lateral genitocrural fold to the other. The entire vulvar area is covered by keratinized, stratified squamous epithelium. The skin becomes thicker, more pigmented, and more keratinized as the distance from the vagina increases.

MONS PUBIS

The mons pubis is a fatty, rounded eminence that develops hair after puberty. It is directly anterior and superior to the symphysis pubis. The hair pattern, or escutcheon, of most women is triangular. Genetic and racial differences produce a variety of normal hair patterns, with approximately one in four women having a modified escutcheon that has a diamond (male-like) pattern.

LABIA MAJORA

The labia majora are two large, longitudinal, cutaneous folds of adipose and fibrous tissue. Each labium majus is approximately 7 to 8 cm in length and 2 to 3 cm in width. The labia extend from the mons pubis anteriorly to become lost in the skin between the vagina and the anus in the area of the posterior fourchette. The skin of the outer convex surface of the labia majora is pigmented and covered with hair follicles. The thin skin of the inner surface does not have hair follicles but has many sebaceous glands. Histologically the labia majora have both sweat and sebaceous glands (Fig. 3.2). The apocrine glands are similar to those of the breast and axillary areas. The size of the labia is related to fat content. Usually the labia atrophy after menopause. The labia majora are homologous to the scrotum in the male. The clinical significance of the hair-bearing areas of the vulva is that conditions that involve the skin, such as vulvar intraepithelial neoplasia (VIN), may be found as deep as 3 mm below the surface as it can involve the skin down the hair shafts. That is not the case in the non-hair-bearing areas, such as the labia minora, where the full thickness of the epidermis is usually no more than 1 mm. Hence, treatment of the non-hair-bearing areas would not have to be any deeper than 1 mm to be effective, whereas treatment of the hair-bearing areas would have to be at least 3 mm in depth to cover the potentially deeper skin down the hair shafts.

LABIA MINORA

The labia minora, or nymphae, are two small, red cutaneous folds that are situated between the labia majora and the vaginal orifice. They are more delicate, shorter, and thinner than the labia majora. Anteriorly, they divide at the clitoris to form superiorly the prepuce and inferiorly the frenulum of the clitoris. Histologically they are composed of dense connective tissue with

Figure 3.1 The structures of the external genitalia that are collectively called the *vulva*. (Modified from Pritchard JA, MacDonald PC, Gant NF. *Williams' Obstetrics*. 17th ed. New York: Appleton-Century-Crofts; 1985:8.)

Figure 3.2 Histologic section from the labia majora. Note the eccrine glands and ducts. HF, Hair follicles; SG, sebaceous glands. (From Stevens A, Lowe J. *Human Histology*. 3rd ed. Philadelphia: Elsevier; 2002:346.)

erectile tissue and elastic fibers, rather than adipose tissue. The skin of the labia minora is less cornified and has many sebaceous glands but no hair follicles or sweat glands. The labia minora and the breasts are the only areas of the body rich in sebaceous glands but without hair follicles. Among women of reproductive age, there is considerable variation in the size of the labia minora. They are relatively more prominent in children and postmenopausal women. The labia minora are homologous to the penile urethra and part of the skin of the penis in males.

HYMEN

The hymen is a thin, usually perforated membrane at the entrance of the vagina. There are many variations in the structure and shape of the hymen. The hymen histologically is covered by stratified squamous epithelium on both sides and consists of

fibrous tissue with a few small blood vessels. Small tags, or nodules, of firm fibrous material, termed *carunculae myrtiformes*, are the remnants of the hymen identified in adult females.

CLITORIS

The clitoris is a short, cylindric, erectile organ at the superior portion of the vestibule. The normal adult glans clitoris has a width less than 1 cm, with an average length of 1.5 to 2 cm. Previous childbearing may influence the size of the clitoris, but age, weight, and oral contraceptive use do not change the anatomic dimensions. Usually, only the glans is visible, with the body of the clitoris positioned beneath the skin surface. The clitoris consists of a base of two crura, which attach to the periosteum of the symphysis pubis. The body has two cylindric corpora cavernosa composed of thin-walled, vascular channels that function as erectile tissue (Fig. 3.3). The distal one third of the clitoris is the glans, which has many nerve endings. The clitoris is the female homologue of the penis in the male.

VESTIBULE

The vestibule is the lowest portion of the embryonic urogenital sinus. It is the cleft distal to the vagina between the labia minora that is visualized when the labia are held apart. The vestibule extends from the clitoris to the posterior fourchette. The orifices of the urethra and vagina and the ducts from Bartholin glands open into the vestibule. Within the area of the vestibule are the remnants of the hymen and numerous small mucinous glands.

URETHRA

The urethra is a membranous conduit for urine from the urinary bladder to the vestibule. The female urethra measures 3.5 to 5 cm in length. The mucosa of the proximal two thirds of the urethra is composed of stratified transitional epithelium, whereas the distal one third is stratified squamous epithelium. The distal orifice is 4 to 6 mm in diameter, and the mucosal edges grossly appear everted.

Figure 3.3 A histologic section of the clitoris. Note the two corpus cavernosa (CC), the septum (S), and the fibrous-collagenous sheath (F). Multiple nerve endings may be seen surrounding the clitoris. PC, Pacinian touch corpuscles. (From Stevens A, Lowe J. *Human Histology*. 3rd ed. Philadelphia: Elsevier; 2002:346.)

SKENE GLANDS

Skene glands, or paraurethral glands, are branched, tubular glands that are adjacent to the distal urethra. Usually Skene ducts run parallel to the long axis of the urethra for approximately 1 cm before opening into the distal urethra. Sometimes the ducts open into the area just outside the urethral orifice. Skene glands are the largest of the paraurethral glands; however, many smaller glands empty into the urethra. Skene glands are homologous to the prostate in the male.

BARTHOLIN GLANDS

Bartholin glands are vulvovaginal glands that are located immediately beneath the fascia at about 4 and 8 o'clock, respectively, on the posterolateral aspect of the vaginal orifice. Each lobulated, racemose gland is about the size of a pea. Histologically the gland is composed of cuboidal epithelium (Fig. 3.4). The duct from each gland is lined by transitional epithelium and is approximately 2 cm in length. Bartholin ducts open into a groove between the hymen and the labia minora. Bartholin glands are homologous to Cowper glands in the male.

VESTIBULAR BULBS

The vestibular bulbs are two elongated masses of erectile tissue situated on either side of the vaginal orifice. Each bulb is immediately below the bulbocavernosus muscle. The distal ends of the vestibular bulbs are adjacent to Bartholin glands. They are homologous to the bulb of the penis in the male.

CLINICAL CORRELATIONS

The skin of the vulvar region is subject to both local and general dermatologic conditions. The intertriginous areas of the vulva

Figure 3.4 A histologic section of a Bartholin gland. Note the multiple alveoli draining into a central duct. (From Shea CR, Stevens A, Dalziel KL, Robboy SJ. Vulva. In: Robboy SJ, Anderson MC, Russell P, eds. *Pathology of the Female Reproductive Tract*. Edinburgh: Churchill Livingstone; 2002:36.)

Figure 3.5 Photograph of left Bartholin duct cyst. (From Di Donato V, Bellati F, Casorelli A, et al. CO₂ laser treatment for Bartholin gland abscess: ultrasound evaluation of risk recurrence. *J Minim Invasive Gynecol*. 2013;20[3]:346-352.)

remain moist, and obese women are particularly susceptible to chronic infection. The vulvar skin of a postmenopausal woman is sensitive to topical cortisone and testosterone but insensitive to topical estrogen. The most common large cystic structure of the vulva is a Bartholin duct cyst (Fig. 3.5). This condition may become painful if the cyst develops into an acute abscess. Chronic infections of the periurethral glands may result in one or more urethral diverticula. The most common symptoms of a urethral diverticulum are similar to the symptoms of a lower urinary tract infection: urinary frequency, urgency, and dysuria.

Figure 3.6 A schematic drawing of a cross section of the female pelvis, demonstrating the H shape of the vagina. Note the surrounding levator ani muscle. (Modified from Pritchard JA, MacDonald PC, Gant NF. *Williams' Obstetrics*. 17th ed. New York: Appleton-Century-Crofts; 1985:12.)

Vulvar trauma such as straddle injuries frequently results in large hematomas or profuse external hemorrhage. The richness of the vascular supply and the absence of valves in vulvar veins contribute to this complication. The abundant vascularity of the region promotes rapid healing, with an associated low incidence of wound infection in episiotomies or obstetric tears of the vulva. The subcutaneous fatty tissue of the labia majora and mons pubis are in continuity with the fatty tissue of the anterior abdominal wall. Infections in this space such as cellulites and necrotizing fasciitis are poorly contained and may extend cephalad in rapid fashion.

INTERNAL GENITALIA

VAGINA

The vagina is a thin-walled, distensible, fibromuscular tube that extends from the vestibule of the vulva to the uterus. The potential space of the vagina is larger in the middle and upper thirds. The walls of the vagina are normally in apposition and flattened in the anteroposterior diameter. Thus the vagina has the appearance of the letter H in cross section (Fig. 3.6).

The axis of the upper portion of the vagina lies fairly close to the horizontal plane when a woman is standing, with the upper portion of the vagina curving toward the hollow of the sacrum. In most women an angle of at least 90 degrees is formed between the axis of the vagina and the axis of the uterus (Fig. 3.7). The vagina is held in position by the surrounding endopelvic fascia and ligaments.

The lower third of the vagina is in close relationship with the urogenital and pelvic diaphragms. The middle third of the vagina is suspended by the lower portion of the cardinal ligaments and supported by the levator ani muscles. The upper third is suspended by the upper portions of the cardinal ligaments and the parametria. The vagina of

reproductive-age women has numerous transverse folds, vaginal rugae. They help provide accordion-like distensibility and are more prominent in the lower third of the vagina. The cervix extends into the upper part of the vagina. The spaces between the cervix and attachment of the vagina are called *fornices*. The posterior fornix is considerably larger than the anterior fornix; thus the anterior vaginal length is approximately 6 to 9 cm in comparison with a posterior vaginal length of 8 to 12 cm. Vaginal length is increased slightly by a woman's weight and height. Age, conversely, leads to a shortening of vaginal length. A study by Tan and colleagues noted a decrease of 0.08 cm per 10 years. Menopause leads to further shortening.

Histologically the vagina is composed of four distinct layers. The mucosa consists of a stratified, nonkeratinized squamous epithelium (Fig. 3.8). If the environment of the vaginal mucosa is modified, as in uterine prolapse, then the epithelium may become keratinized. The squamous epithelium is similar microscopically to the exocervix, although the vagina has larger and more frequent papillae that extend into the connective tissue. The normal vagina does not have glands. The next layer is the lamina propria, or tunica. It is composed of fibrous connective tissue. Throughout this layer of collagen and elastic tissue is a rich supply of vascular and lymphatic channels. The density of the connective tissue in the endopelvic fascia varies throughout the longitudinal axis of the vagina. The muscular layer has many interlacing fibers. However, an inner circular layer and an outer longitudinal layer can be identified. The fourth layer consists of cellular areolar connective tissue containing a large plexus of blood vessels.

The vascular system of the vagina is generously supplied with an extensive anastomotic network throughout its length. The vaginal artery originates either directly from the uterine artery or as a branch of the internal iliac artery arising posterior to the origin of the uterine and inferior vesical arteries.

Figure 3.7 A median sagittal section through the pelvis. The peritoneum is shaded blue. Note the proximal vagina at a diagonal axis and in a near 90-degree juxtaposition to the uterus. In this woman, the uterus is anteverted. (From Standing S, ed. *Gray's Anatomy*. 39th ed. Edinburgh: Churchill Livingstone; 2005:1321.)

The vaginal arteries may be multiple arteries on each side of the pelvis. There is an anastomosis with the cervical branch of the uterine artery to form the azygos arteries. Branches of the internal pudendal, inferior vesical, and middle hemorrhoidal arteries also contribute to the interconnecting network and the longitudinal azygos arteries.

The venous drainage is complex and accompanies the arterial system. Below the pelvic floor, the principal venous drainage occurs via the pudendal veins. The vaginal, uterine, and vesical veins, as well as those around the rectosigmoid, all provide venous drainage of the venous plexuses surrounding the middle and upper vagina.

The nerve supply of the vagina comes from the autonomic nervous system's vaginal plexus, and sensory fibers come from the pudendal nerve. Pain fibers enter the spinal cord in sacral segments two to four. There is a paucity of free nerve endings in the upper two thirds of the vagina.

The lymphatic drainage is characterized by its wide distribution and frequent crossovers between the right and left sides of the pelvis. In general the primary lymphatic drainage of the upper third of the vagina is to the external iliac nodes, the middle third of the vagina drains to the common and internal iliac nodes, and the lower third has a complex and variable distribution, including the common iliac, superficial inguinal, and perirectal nodes.

CLINICAL CORRELATIONS

In clinical practice, anatomic descriptions of pelvic organs are derived from Latin roots, such as the word *vagina*, which is derived from the Latin word for sheath. In contrast, the names for surgical procedures of pelvic organs are derived from Greek roots. *Colpectomy*, *colporrhaphy*, and *colposcopy* are derived from *kolpos* (fold), the Greek word for the *vagina*, or *hysterectomy* (Greek) versus *uterus* (Latin).

Clinicians should consider the H shape of the vagina when they insert a speculum and inspect the walls of the vagina. The posterior fornix is an important surgical landmark, because it provides direct access to the cul-de-sac of Douglas. The distal course of the ureter is an essential consideration in vaginal surgery. Ureteral injury can result from vaginally placed sutures to obtain hemostasis with vaginal lacerations. The anatomic proximity and interrelationships of the vascular and lymphatic networks of the bladder and vagina are such that inflammation of one organ can produce symptoms in the other. For example, vaginitis sometimes produces urinary tract symptoms such as frequency and dysuria.

The Gartner duct cyst, a cystic dilation of the embryonic mesonephros (Fig. 3.9), is usually present on the lateral wall of the vagina. However, in the lower third of the vagina these cysts are present anteriorly and may be difficult to distinguish from a large urethral diverticulum.

Figure 3.8 Histologic section of the vaginal squamous epithelium (M). Submucosa (S) is well vascularized (lamina propria). SM, Smooth muscle. (From Stevens A, Lowe J. *Human Histology*. 3rd ed. Philadelphia: Elsevier; 2002:347.)

An interesting phenomenon is the source of vaginal lubrication during intercourse. For years there was speculation on how an organ without glands is able to “secrete” fluid. Vaginal lubrication occurs from a transudate produced by engorgement of the vascular plexuses that encircle the vagina. This richness of vascularization allows many drugs to readily enter the systemic circulation when placed in the vagina. Medications that are absorbed vaginally go directly into the systemic circulation, bypassing the liver and its metabolism on the first round through the circulation.

The anatomic relationship between the long axis of the vagina and other pelvic organs may be altered by pelvic relaxation resulting primarily from the trauma of childbirth. Atrophy or weakness of the endopelvic fascia and muscles surrounding the vagina may result in the development of a cystocele, rectocele, or enterocele, all possibly contributing to a vaginal vault prolapse. One of many popular operations for vaginal vault prolapse is fixation of the vaginal apex to the sacrospinous ligament. A rare complication of this operation is massive hemorrhage, usually from the arterial or venous branches of the inferior gluteal or pudendal vasculature.

CERVIX

The lower, narrow portion of the uterus is the cervix. The word *cervix* originates from the Latin word for *neck*. The Greek word

Figure 3.9 Mesonephric duct remnant in the vaginal wall. (From Robboy SJ, Anderson MC, Russell P, eds. *Pathology of the Female Reproductive Tract*. Edinburgh: Churchill Livingstone; 2002:77.)

for *neck* is *trachelos*, and when the cervix is removed, the surgical procedure is termed *trachelectomy*. The cervix may vary in shape from cylindric to conical. It consists of predominantly fibrous tissue in contrast to the primarily muscular corpus of the uterus.

The vagina is attached obliquely around the middle of the cervix; this attachment divides the cervix into an upper, supravaginal portion and a lower segment in the vagina called the *portio vaginalis* (Fig. 3.10). The supravaginal segment is covered by peritoneum posteriorly and is surrounded by loose, fatty connective tissue—the parametrium—anteriorly and laterally.

The canal of the cervix is fusiform, with the widest diameter in the middle. The length and width of the endocervical canal varies; it is usually 2.5 to 3 cm in length and 7 to 8 mm at its widest point. The width of the canal varies with the parity of the woman and changing hormonal levels. The cervical length increases in pregnancy, with maximal length in the second trimester. The cervical canal opens into the vagina at the external os of the cervix. In the majority of women, the external os is in contact with the posterior vaginal wall. The external os is small and round in nulliparous women. The os is wider and gaping following vaginal delivery. Often lateral or stellate scars are residual marks of previous cervical lacerations.

The mucous lining of the endocervical canal of nulliparous women is arranged in longitudinal folds, called plicae palmariae, with secondary branching folds, the arbor vitae (Fig. 3.11). These folds, which form a herringbone pattern, disappear following vaginal delivery.

A single layer of columnar epithelium lines the endocervical canal and the underlying glandular structures. This specialized epithelium secretes mucus, which facilitates sperm transport.

Figure 3.10 A schematic drawing of a posterior view of the cervix, uterus, fallopian tube, and ovary. Note that the cervix is divided by the vaginal attachment into an external portio segment and a supravaginal segment. Note that the uterus is composed of the dome-shaped fundus, the muscular body, and the narrow isthmus. Note the fimbria ovarica, or ovarian fimbria, attaching the oviduct to the ovary. (Modified from Clemente CD. *Anatomy: A Regional Atlas of the Human Body*. 3rd ed. Baltimore-Munich: Urban & Schwarzenberg; 1987.)

Figure 3.11 An electron micrograph of the endocervical canal, demonstrating the arbor vitae. These folds and crypts provide a reservoir for sperm. (From Singer A, Jordan JA. *The anatomy of the cervix*. In Jordan JA, Singer A, eds. *The Cervix*. Philadelphia: WB Saunders; 1976:18.)

An abrupt transformation usually is seen at the junction of the columnar epithelium of the endocervix and the nonkeratinized stratified squamous epithelium of the portio vaginalis (Fig. 3.12). The stratified squamous epithelium of the exocervix is identical to the lining of the vagina.

The dense, fibromuscular cervical stroma is composed primarily of collagenous connective tissue and mucopolysaccharide ground substance. The collagen framework and ground substance are sensitive to hormonal effects. The connective tissue contains approximately 15% smooth muscle cells and a small

Figure 3.12 A histologic section through the squamocolumnar junction of the cervix. Note the abrupt transformation from squamous to columnar epithelium. (From Standing S, ed. *Gray's Anatomy*. 39th ed. Edinburgh: Churchill Livingstone; 2005:1335.)

Figure 3.13 A low-power histologic section of the cervix. The stroma (S) has a small amount of smooth muscle. The ectocervix (ECx) is covered in stratified squamous epithelium. The endocervix (ECC) is lined by tall columnar cells. NF, Nabothian follicles, a normal finding; TZ, transformation zone. (From Stevens A, Lowe J. *Human Histology*. 3rd ed. Philadelphia: Elsevier; 2002:349.)

amount of elastic tissue (Fig. 3.13). However, there are few muscle fibers in the distal portions of the cervix.

It is not surprising that the cervical and uterine vascular supplies are interrelated. The arterial supply of the cervix arises from the descending branch of the uterine artery. The cervical arteries run on the lateral side of the cervix and form the coronary artery, which encircles the cervix. The azygos arteries run longitudinally in the middle of the anterior and posterior aspects of the cervix and the vagina. There are numerous anastomoses between these vessels and the vaginal and middle hemorrhoidal arteries. The venous drainage accompanies these arteries. The lymphatic drainage of the cervix is complex, involving multiple chains of nodes. The principal regional lymph nodes are the obturator, common iliac, internal iliac, external iliac, and visceral nodes of the parametria. Other possible lymphatic drainage includes the following chains of nodes: superior and inferior gluteal, sacral, rectal, lumbar, aortic, and visceral nodes over the posterior surface of the urinary bladder. The stroma of the endocervix is rich in free nerve endings. Pain fibers accompany the parasympathetic fibers to the second, third, and fourth sacral segments.

CLINICAL CORRELATIONS

The major arterial supply to the cervix is located on the lateral cervical walls at the 3 and 9 o'clock positions, respectively. Therefore a deep figure-of-eight suture through the vaginal mucosa and cervical stroma at 3 and 9 o'clock helps to reduce blood loss during procedures such as cone biopsy. If the gynecologist is overzealous in placing such a hemostatic suture high in the vaginal fornix, it is possible to compromise the course of the distal ureter just before it enters the bladder.

The transformation zone of the cervix is an important anatomic landmark for clinicians. This area encompasses the transition from stratified squamous epithelium to columnar epithelium. Most cervical dysplasia develops within this transformation zone. The position of a woman's transformation zone, in relation to the long axis of the cervix, depends on her age and hormonal status. When the female is young the transformation zone is located further out on the cervical portio; this is called an *ectropion*. This is a normal finding, especially during pregnancy. As a woman ages, the transformation zone migrates higher up the endocervical canal.

The endocervix is rich in free nerve endings. Occasionally, women experience a vasovagal response during transcervical instrumentation of the uterine cavity. Serial cardiac monitoring during insertion of intrauterine devices demonstrates a reflex bradycardia in some women. The sensory innervation of the exocervix is not as concentrated or sophisticated as that of the endocervix or external skin. Therefore usually the exocervix may be cauterized by either cold or heat without major discomfort to the patient.

The lymphatic drainage of the cervix is fairly organized as described earlier. Similar to other disease sites, sentinel lymph node (SLN) mapping and biopsy for cervical cancer is replacing the more traditional full lymphadenectomies in favor of fewer complications, specifically lymphedema. Sentinel lymph node mapping in cervical cancer was first described in 1999 by Echt and coworkers when they injected 13 patients who had early stage cervical cancer with a blue dye, lymphazurin, and identified SLNs in 15% (Echt, 1999). This technique has been refined over the years and is now performed using near-infrared fluorescence imaging and indocyanine green (ICG) with detection of SLNs in 85% to 90% of cases.

UTERUS

The uterus is a thick-walled, hollow, muscular organ located centrally in the female pelvis. Adjacent to the uterus are the urinary bladder anteriorly, the rectum posteriorly, and the broad ligaments laterally (Figs. 3.7 and 3.14). The uterus is globular and slightly flattened anteriorly; it has the general configuration of an inverted pear. The short area of constriction in the lower uterine segment is termed the *isthmus* (Fig. 3.15). The dome-shaped top of the uterus is termed the *fundus*. The lower edge of the fundus is described by an imaginary line drawn between the site of entrance of each oviduct. The size and weight of the normal uterus depend on previous pregnancies and the hormonal status of the individual. The uterus of a nulliparous woman is approximately 8 cm long, 5 cm wide, and 2.5 cm thick and weighs 40 to 50 g. In contrast, in a multiparous woman, each measurement is approximately 1.2 cm larger, and normal

Figure 3.14 The organs of the female pelvis. The uterus is surrounded by the bladder anteriorly, the rectum posteriorly, and the folds of the broad ligaments laterally. (Modified from Clemente CD. *Anatomy: A Regional Atlas of the Human Body*. 3rd ed. Baltimore-Munich: Urban & Schwarzenberg; 1987.)

Figure 3.15 A surgical specimen of a uterus that has been opened. (From Robboy SJ, Anderson MC, Russell P, eds. *Pathology of the Female Reproductive Tract*. Edinburgh: Churchill Livingstone; 2002:241.)

uterine weight is 20 to 30 g heavier. The upper limit for weight of a normal uterus is 110 g. The capacity of the uterus to enlarge during pregnancy results in a 10- to 20-fold increase in weight at term. After menopause the uterus atrophies in both size and weight.

The cavity of the uterus is flattened and triangular. The oviducts enter the uterine cavity at the superolateral aspects of the cavity in the areas designated the cornua. In the majority of women, the long axis of the uterus is both anteverted in respect to the long axis of the vagina and anteflexed in relation to the long axis of the cervix. However, a retroflexed uterus is a normal variant found in approximately 25% of women.

The uterus has three layers, similar to other hollow abdominal and pelvic organs. The thin, external serosal layer makes up the visceral peritoneum. The peritoneum is firmly attached to the uterus in all areas except anteriorly at the level of the

internal os of the cervix, where it is only loosely attached. The wide middle muscular layer is composed of three indistinct layers of smooth muscle. The outer longitudinal layer is contiguous with the muscle layers of the oviduct and vagina. The middle layer has interlacing oblique, spiral bundles of smooth muscle and large venous plexuses. The inner muscular layer is also longitudinal. The endometrium is a reddish mucous membrane that varies from 1 to 6 mm in thickness, depending on hormonal stimulation (Fig. 3.16). The uterine glands are tubular and composed of tall columnar epithelium. The cells of the endometrial stroma resemble embryonic connective tissue with scant cytoplasm and large nuclei (Fig. 3.17). The endometrium may be divided into an inner stratum basale and an outer stratum functionale. The stratum functionale may be further subdivided into an inner compact stratum and a more superficial spongy stratum. Only the stratum functionale responds to fluctuating hormonal levels.

The uterine and ovarian arteries provide the arterial blood supply of the uterus. The uterine arteries are large branches of the hypogastric arteries, whereas the ovarian arteries originate directly from the aorta. The veins of the pelvic organs accompany the arteries. Therefore venous drainage from the fundus goes to the ovarian veins and blood from the corpus exits via the uterine veins into the iliac veins. The lymphatic drainage of the uterus is complex. The lymphatics from the fundus and the body of the uterus go to the aortic, lumbar, or pelvic nodes surrounding the iliac vessels, especially the internal iliac nodes. However, it is possible for metastatic disease from the uterus to be found in the superior inguinal nodes transported via lymphatics in the round ligament, or directly spread to the paraaortic nodes. Surprisingly, the lymphatic drainage of the uterus is not that different from the lymphatic drainage of the cervix.

In contrast to other pelvic organs, the afferent sensory nerve fibers from the uterus are in close proximity to the sympathetic nerves. Afferent nerve fibers from the uterus enter the spinal

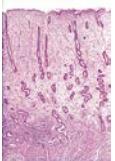

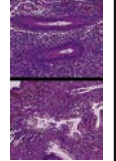

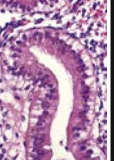

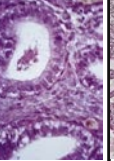

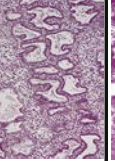

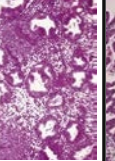

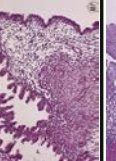

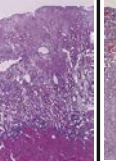

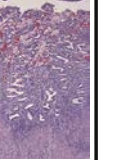

Day of Cycle		Before 14	15-16	17	18	19-22	23	24-25	26-27	28+

cord at the eleventh and twelfth thoracic segments. The sympathetic nerve supply to the uterus comes from the hypogastric and ovarian plexus. The parasympathetic fibers are largely derived from the pelvic nerve and from the second, third, and fourth sacral segments.

CLINICAL CORRELATIONS

Removal of the uterus is termed *hysterectomy*, which is derived from the Greek word *hystera*, meaning *womb*. The symptoms of primary dysmenorrhea are treated successfully in most women by prostaglandin synthetase inhibition. Usually a woman's pain is controlled by oral medication. However, it is possible to alleviate uterine pain by cutting the sensory nerves that accompany the sympathetic nerves. This operation is termed a *presacral neurectomy*. During the operation, the gynecologist must be careful to avoid injuring the ureters and also careful to control hemorrhage from vessels in the retroperitoneal space.

The position of the fundus of the uterus in relation to the long axis of the vagina is quite variable. Not only are there differences among individual women, but also in the same woman differences occur secondary to normal activity. In some women the uterus is anteflexed or anteverted, whereas in others the normal position is retroflexed or retroverted. In the 1930s and 1940s, a retroflexed uterus was believed to be one of the primary causes of pelvic pain. To alleviate this condition, many women underwent an anterior uterine suspension. Modern gynecologists have abandoned the suspension operation as a treatment for pelvic pain.

The arterial blood supply enters the uterus on its lateral margins. This relationship allows morcellation of an enlarged uterus to facilitate removal of multiple myomas without appreciably increasing blood loss during vaginal hysterectomy.

Methods of transcervical female sterilization, designed to occlude the tubal ostia at the uterine cornua, are effective and commonly used (Essure). Prior to the application of this method, procedures that blindly injected caustic solutions into the uterine cornua had a high failure rate. Individual differences

Figure 3.18 Intraoperative view of sentinel lymph node mapping with isosulfan blue dye on the left and indocyanine green on the right. (From Sinno AK, Fader AN, Roche KL, et al. A comparison of colorimetric versus fluorometric sentinel lymph node mapping during robotic surgery for endometrial cancer. *Gynecol Oncol.* 2014;134[2]:281-286.)

in the size and shape of the uterine cavity and muscular spasm of this region are the primary reasons that sufficient amounts of the caustic chemicals did not reach the fallopian tubes in up to 20% of patients.

Similar to the lymphatic drainage of the cervix, the lymphatic drainage of the uterus has also been studied. Sentinel lymph nodes can also be found on either side of the pelvis/paraortic areas in 85% to 90% of cases using near-infrared fluorescence imaging and indocyanine green (ICG) (Abu-Rustum, 2014) (Fig. 3.18).

OVIDUCTS

The paired uterine tubes, more commonly referred to as the *fallopian tubes* or *oviducts*, extend outward from the superolateral portion of the uterus and end by curling around the ovary. The oviducts are also referred to using the prefix *salpingo-*, from the Greek *salpinx*, meaning a tube. The tubes are contained in a free edge of the superior portion of the broad ligament. The mesentery of the tubes, the mesosalpinx, contains the blood supply and nerves. The uterine tubes connect the cornua of the uterine cavity and the peritoneal cavity. The ostia into the endometrial cavity are 1.5 mm in diameter, whereas the ostia into the abdominal cavity are approximately 3 mm in diameter.

The oviducts are between 10 and 14 cm in length and slightly less than 1 cm in external diameter. Each tube is divided into four anatomic sections. The uterine intramural, or interstitial, segment is 1 to 2 cm in length and is surrounded by myometrium. The isthmic segment begins as the tube exits the uterus and is approximately 4 cm in length. This segment is narrow, 1 to 2 mm in inside diameter, and straight. The isthmic segment has the most highly developed musculature. The ampullary segment is 4 to 6 cm in length and approximately 6 mm in inside diameter. It is wider and more tortuous in its course than other segments. Fertilization normally occurs in the ampullary portion of the tube. The infundibulum is the distal trumpet-shaped portion of the oviduct. From 20 to 25 irregular finger-like projections, termed *fimbriae*, surround the abdominal ostia of the tube. One of the largest fimbriae is attached to the ovary, the fimbria ovarica.

The tube contains numerous longitudinal folds, called *plicae*, of mucosa and underlying stroma. Plicae are most prominent in the ampullary segment (Fig. 3.19). The mucosa of the oviduct has three different cell types. Columnar ciliated epithelial cells are most prominent near the ovarian end of the tube and overall compose 25% of the mucosal cells (Fig. 3.20). Secretory cells, also columnar in shape, compose 60% of the epithelial lining and are more prominent in the isthmic segment. Narrow peg cells are

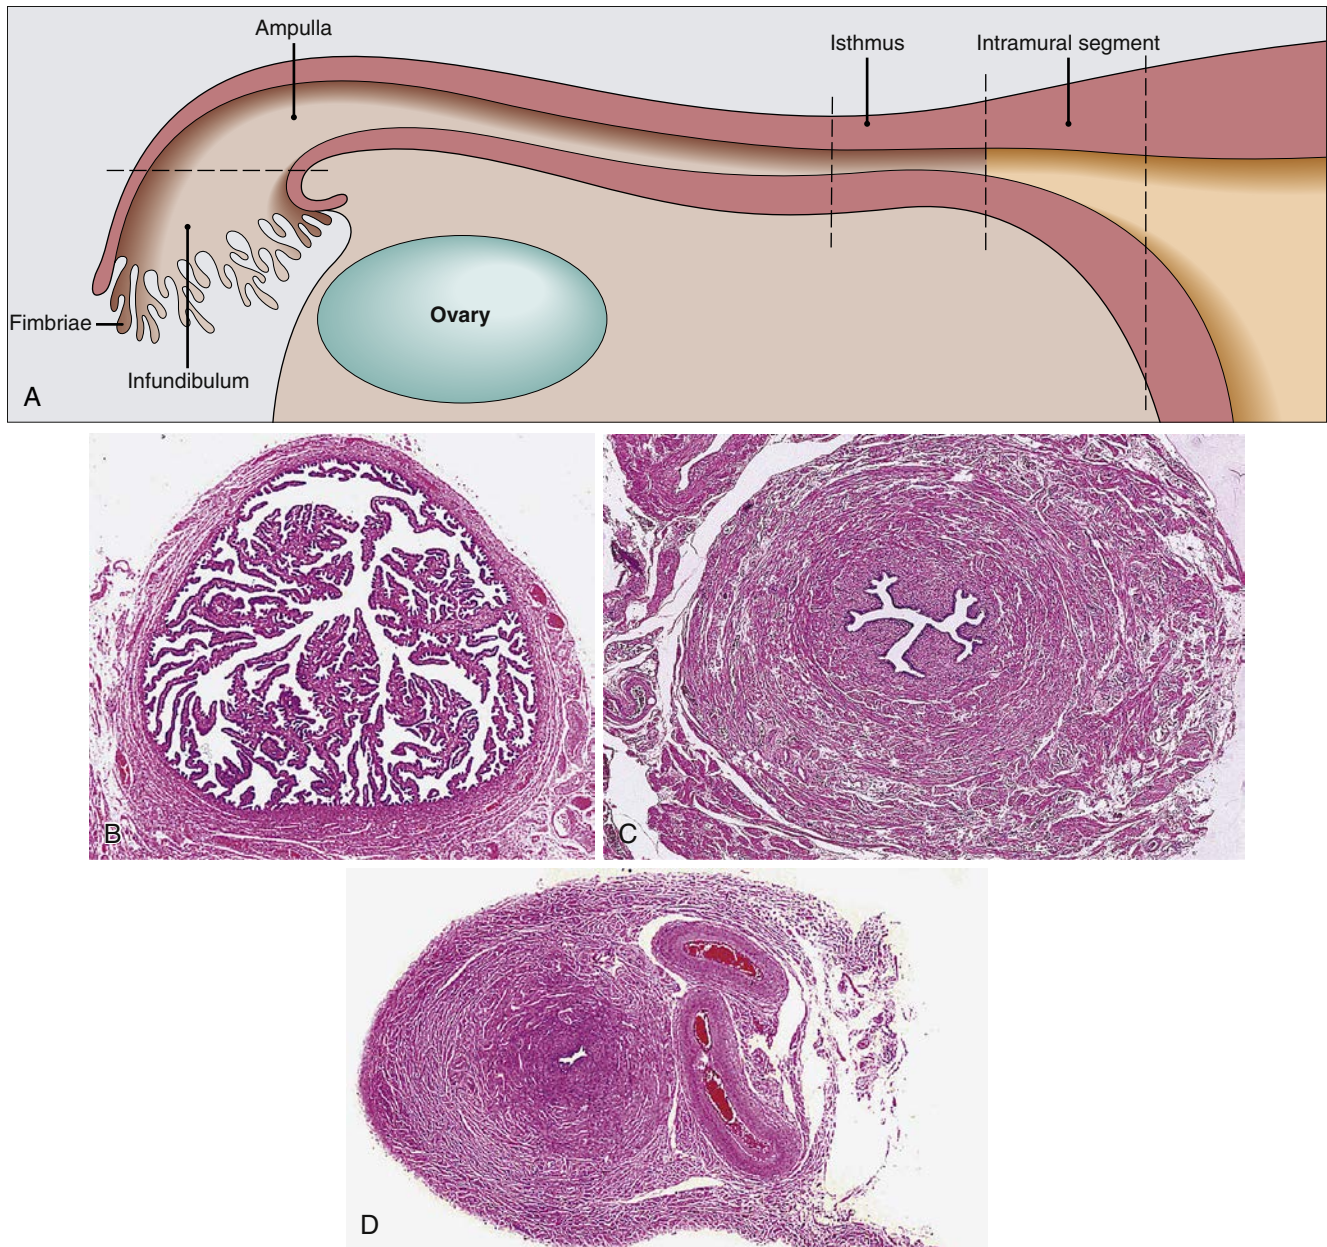

Figure 3.19 The fallopian tube. **A**, Schematic representation. Note that the intramural segment is within the uterine body. **B**, Low-power histologic section from the ampulla. **C**, Section from the isthmus of the tube. **D**, Section from the isthmus. Note the thick muscular wall. (**A**, **B**, and **D**, From Stevens A, Lowe J. *Human Histology*. 3rd ed. Philadelphia: Elsevier; 2002:354; **C**, From Robboy SJ, Anderson MC, Russell P, eds. *Pathology of the Female Reproductive Tract*. Edinburgh: Churchill Livingstone; 2002:416.)

found between secretory and ciliated cells and are believed to be a morphologic variant of secretory cells. The stroma of the mucosa is sparse. However, there is a thick lamina propria with vascular channels between the epithelium and muscular layers. The smooth muscle of the tube is arranged into inner circular and outer longitudinal layers. Between the peritoneal surface of the tube and the muscular layer is an adventitial layer that contains blood vessels and nerves.

The arterial blood supply to the oviducts is derived from terminal branches of the uterine and ovarian arteries. The arteries

anastomose in the mesosalpinx. Blood from the uterine artery supplies the medial two thirds of each tube. The venous drainage runs parallel to the arterial supply. The lymphatic system is separate and distinct from the lymphatic drainage of the uterus. Lymphatic drainage includes the internal iliac nodes and the aortic nodes surrounding the aorta and the inferior vena cava at the level of the renal vessels. The tubes are innervated by both sympathetic and parasympathetic nerves from the uterine and ovarian plexuses. Sensory nerves are related to spinal cord segments T11, T12, and L1.

CLINICAL CORRELATIONS

The majority of ectopic pregnancies occur in the oviduct. The acute abdominal and pelvic pain that women with an ectopic pregnancy experience is believed to be caused by hemorrhage. The most catastrophic bleeding associated with ectopic pregnancy occurs when the implantation site is in the intramural segment of the tube.

The isthmic segment of the oviduct is the preferred site to apply an occlusive device, such as a clip, for female sterilization. The right oviduct and appendix are often adjacent. Clinically it may be difficult to differentiate inflammation of the tube from acute appendicitis. Accessory tubal ostia are discovered frequently and always connect with the lumen of the tube. These accessory ostia are usually found in the ampullary portion of the tube.

The wide mesosalpinx of the ampullary segment of the tube allows torsion of the tube, which occasionally results in ischemic atrophy of the ampullary segment. Paratubal or paraovarian cysts

Figure 3.20 Electron micrograph of the tubal mucosa from the ampulla. CC, Ciliated cells; SC, secretory cells. (From Stevens A, Lowe J. *Human Histology*. 3rd ed. Philadelphia: Elsevier; 2002:354.)

can reach 5 to 10 cm in diameter and occasionally are confused with ovarian cysts before surgery.

Although a definitive anatomic sphincter has not been identified at the uterotubal junction, a temporary physiologic obstruction has been identified during hysterosalpingography. Sometimes clinicians may alleviate this temporary obstruction by giving the patient intravenous sedation, a paracervical block, or intravenous glucagon.

OVARIES

The paired ovaries are light gray, and each one is approximately the size and configuration of a large almond. The surface of the ovary of adult women is pitted and indented from previous ovulations. The ovaries contain approximately 1 to 2 million oocytes at birth. During a woman's reproductive lifetime, about 8000 follicles begin development. The growth of many follicles is blunted in various stages of development; however, approximately 300 ova eventually are released. The size and position of the ovary depend on the woman's age and parity. During the reproductive years, ovaries weigh 3 to 6 g and measure approximately 1.5 cm × 2.5 cm × 4 cm. As a woman ages, the ovaries become smaller and firmer in consistency. The long axis of the ovary is vertical in a nulliparous woman who is standing, and the ovary rests in a depression of peritoneum named the ovarian fossa. Immediately adjacent to the ovarian fossa are the external iliac vessels, the ureter, and the obturator vessels and nerves.

Three prominent ligaments determine the anatomic mobility of the ovary (Fig. 3.21). The posterior portion of the broad ligament forms the mesovarium, which attaches to the anterior border of the ovary. The mesovarium contains the arterial anastomotic branches of the ovarian and uterine arteries, a plexus of veins, and the lateral end of the ovarian ligament. The ovarian ligament is a narrow, short, fibrous band that extends from the

Figure 3.21 The posterior aspect of the broad ligament—spread out to demonstrate the ovary. (From Standring S, ed. *Gray's Anatomy*. 39th ed. Edinburgh: Churchill Livingstone; 2005:1322.)

lower pole of the ovary to the uterus. The infundibulopelvic ligament, or suspensory ligament of the ovary, forms the superior and lateral aspect of the broad ligament. This ligament contains the ovarian artery, ovarian veins, and accompanying nerves. It attaches the upper pole of the ovary to the lateral pelvic wall.

The ovary is subdivided histologically into an outer cortex and an inner medulla (Fig. 3.22). The ovarian surface is covered by a single layer of cuboidal epithelium, termed the *germinal epithelium*. This term is a misnomer because the cells are similar to those of the coelomic mesothelium, which forms the peritoneum, and because the germinal epithelium is not related to the histogenesis of graafian follicles. If the ovary is transected, numerous transparent, fluid-filled cysts are noted throughout the cortex. Microscopically these are graafian follicles in various stages of development, active or regressing corpus luteum, and atretic follicles. The stroma of the cortex is composed primarily of closely packed cells around the follicles. These specialized connective tissue cells form the theca. The medulla contains the ovarian vascular supply and a loose stroma. The specialized polyhedral hilar cells are similar to the interstitial cells of the testis.

Each of the ovarian arteries arises directly from the aorta just below the renal arteries. They descend in the retroperitoneal space, cross anterior to the psoas muscles and internal iliac vessels, and enter the infundibulopelvic ligaments, reaching the mesovarium in the broad ligament. The ovarian blood supply enters through the hilum of the ovary. The venous drainage of the ovary collects in the pampiniform plexus and consolidates

into several large veins as it leaves the hilum of the ovary. The ovarian veins accompany the ovarian arteries, with the left ovarian vein draining into the left renal vein, whereas the right ovarian vein connects directly with the inferior vena cava.

The lymphatic drainage of the ovaries is primarily to the aortic nodes adjacent to the great vessels at the level of the renal veins. Metastatic disease from the ovary occasionally takes a shorter course to the iliac nodes. The autonomic and sensory nerve fibers accompany the ovarian vasculature in the infundibulopelvic ligament. They connect with the ovarian, hypogastric, and aortic plexuses.

CLINICAL CORRELATIONS

The size of the “normal” ovary during the reproductive years and the postmenopausal period is important in clinical practice. Before menopause a normal ovary may be up to 5 cm in length. Thus a small physiologic cyst may cause an ovary to be 6 to 7 cm in diameter. In contrast, the normal atrophic postmenopausal ovary usually cannot be palpated during pelvic examination.

It is important to emphasize that the ovaries and surrounding peritoneum are not devoid of pain and pressure receptors. Therefore it is not unusual for a woman during a routine pelvic examination to experience discomfort when normal ovaries are palpated bimanually.

Figure 3.22 A schematic drawing of the ovary. Note the single layer of cuboidal epithelium called the *germinal epithelium*. Note the graafian follicles in different stages of development. (From Standing S, ed. *Gray's Anatomy*. 39th ed. Edinburgh: Churchill Livingstone; 2005:1324.)

Attempts have been made to alleviate chronic pelvic pain by performing an ovarian denervation operation by cutting and ligating the infundibulopelvic ligaments. This operation has been abandoned because of the high incidence of cystic degeneration of the ovaries, which resulted from the interruption of their primary blood supply that was associated with the neurectomy procedure.

The close anatomic proximity of the ovary, ovarian fossa, and ureter is emphasized in surgery to treat severe endometriosis or pelvic inflammatory disease. It is important to identify the course of the ureter to facilitate removal of all of the ovarian capsule that is adherent to the peritoneum and surrounding structures so as to avoid immediate ureteral injury and residual retroperitoneal ovarian remnants in the future. Prophylactic oophorectomy is performed at the time of pelvic operations in many peri- and postmenopausal women. Sometimes bilateral oophorectomy is technically more difficult when associated with a vaginal procedure in contrast to an abdominal or laparoscopic hysterectomy. Vaginal removal of the ovaries may be facilitated by identifying the anatomic landmarks, similar to the abdominal approach, and separately clamping the round ligaments and infundibulopelvic ligaments.

VASCULAR SYSTEM OF THE PELVIS

Several generalizations should be made in describing the network of arteries that bring blood to the female reproductive organs. The arteries are paired, bilateral, and have multiple collaterals (Fig. 3.23). The arteries enter their respective organs laterally and then unite with anastomotic vessels from the other side of the pelvis near the midline. There is a long-standing teaching generalization that the pelvic reproductive viscera lie within a loosely woven basket of large veins with numerous interconnecting venous plexuses. The arteries thread their way through this interwoven mesh of veins

to reach the pelvic reproductive organs, giving off numerous branching arcades to provide a rich blood supply.

ARTERIES

Inferior Mesenteric Artery

The inferior mesenteric artery, a single artery, arises from the aorta approximately 3 cm above the aortic bifurcation. It supplies part of the transverse, descending and sigmoid colon, as well as the rectum, and terminates as the superior hemorrhoidal artery. The inferior mesenteric artery is occasionally torn during node dissections performed in staging operations for gynecologic cancer. Because of the rich collateral circulation from the middle and inferior hemorrhoidal arteries, as well as the marginal artery of Drummond, the inferior mesenteric artery can be ligated without compromise of the distal portion of the colon.

Ovarian Artery

The ovarian arteries originate from the aorta just below the renal vessels. Each one courses in the retroperitoneal space, crosses anterior to the ureter, and enters the infundibulopelvic ligament. As the artery travels medially in the mesovarium, numerous small branches supply the ovary and oviduct. The ovarian artery unites with the ascending branch of the uterine artery in the mesovarium just under the suspensory ligament of the ovary.

Common Iliac Artery

The bifurcation of the aorta occurs at the level of the fourth lumbar vertebra, forming the two common iliac arteries. Each common iliac artery is approximately 5 cm in length before the vessel divides into the external iliac and hypogastric arteries.

Hypogastric Artery (Internal Iliac Artery)

The hypogastric arteries are short vessels, approximately 3 to 4 cm in length. Throughout their course they are in close proximity to the ureters, which are anterior, and to the hypogastric veins, which are posterior. Most commonly (variations are frequent),

Figure 3.23 The arteries of the reproductive organs. Note the paired arteries entering laterally and freely anastomosing with each other. (Modified from Clemente CD. *Anatomy: A Regional Atlas of the Human Body*. 3rd ed. Baltimore-Munich: Urban & Schwarzenberg; 1987.)

each hypogastric artery branches into an anterior and a posterior division (or trunk). The branching is usually 2 cm from the common iliac. The posterior trunk gives off three parietal branches: the iliolumbar, lateral sacral, and superior gluteal arteries. The anterior trunk has nine branches. The three parietal branches are the obturator, internal pudendal, and inferior gluteal arteries. The six visceral branches include the umbilical, middle vesical, inferior vesical, middle hemorrhoidal, uterine, and vaginal arteries. The superior vesical artery usually arises from the umbilical artery. The individual branches of the hypogastric artery may vary from one woman to another.

Uterine Artery

The uterine artery arises from the anterior division of the hypogastric artery and courses medially toward the isthmus of the uterus. Approximately 2 cm lateral to the endocervix, it crosses over the ureter and reaches the lateral side of the uterus. The ascending branch of the uterine artery courses in the broad ligament, running a tortuous route to finally anastomose with the ovarian artery in the mesovarium (Fig. 3.24). Through its circuitous route in the parametrium, the uterine artery gives off numerous branches that unite with arcuate arteries from the other side. This series of arcuate arteries develops radial branches that supply the myometrium and the basalis layer of the endometrium. The arcuate arteries also form the spiral arteries of the functional layer of the endometrium. The descending branch of the uterine artery produces branches that supply both the cervix and the vagina. In each case the vessels enter the organ laterally and anastomose freely with vessels from the other side.

VAGINAL ARTERY

The vaginal artery may arise either from the anterior trunk of the hypogastric artery or from the uterine artery. It supplies blood to the vagina, bladder, and rectum. There are extensive anastomoses with the vaginal branches of the uterine artery to form the azygos arteries of the cervix and vagina.

Internal Pudendal Artery

This artery is the terminal branch of the hypogastric artery and supplies branches to the rectum, labia, clitoris, and perineum.

VEINS

The venous drainage of the pelvis begins in small sinusoids that drain to numerous venous plexuses contained within or immediately adjacent to the pelvic organs. Invariably there are numerous anastomoses between the parietal and visceral branches of the venous system. In general the veins of the female pelvis and perineum are thin walled and have few valves.

The veins that drain the pelvic plexuses follow the course of the arterial supply. Their names are similar to those of the accompanying arteries. Often multiple veins run alongside a single artery. One special exception is the venous drainage of the ovaries. The left ovarian vein empties into the left renal vein, whereas the right ovarian vein connects directly with the inferior vena cava.

CLINICAL CORRELATIONS

Although the external iliac artery and its branches do not supply blood directly to the pelvic viscera, they are important landmarks in surgical anatomy. The fact that the external iliac artery gives rise to the obturator artery in 15% to 20% of women must be considered in radical cancer operations with associated node dissections of the obturator fossa. The external iliac artery also gives rise to the inferior epigastric artery. The inferior epigastric artery should be avoided when performing laparoscopic operative procedures.

In certain clinical situations associated with profuse hemorrhage from the female pelvis, hypogastric artery ligation is performed. Because of the extensive collateral circulation, this operation does not produce hypoxia of the pelvic viscera but reduces hemorrhage by decreasing the arterial pulse pressure.

Figure 3.24 A photograph of an injected specimen demonstrating the rich anastomoses of the uterine and ovarian arteries. (From Warwick R, Williams PL. *Gray's Anatomy*. 35th ed. Edinburgh: Churchill Livingstone; 1973:1361.)

Middle sacral artery—anastomoses with lateral sacral artery of hypogastric

Branches from External Iliac Artery

Deep iliac circumflex artery—anastomoses with iliolumbar and superior gluteal of hypogastric

Inferior epigastric artery—gives origin to obturator artery in 25% of cases, providing additional anastomoses of external iliac with medial femoral circumflex and communicating pelvic branches

Branches from Femoral Artery

Medial femoral circumflex artery—anastomoses with obturator and inferior gluteal arteries from hypogastric

Lateral femoral circumflex artery—anastomoses with superior gluteal and iliolumbar arteries from hypogastric

From Mattingly RF, Thompson JD. *Te Linde's Operative Gynecology*. 6th ed. Philadelphia: JB Lippincott; 1985.

The extent of collateral circulation after hypogastric artery ligation depends on the site of ligation and may be divided into three groups (Box 3.1).

In cases of intractable pelvic hemorrhage, it may be necessary to supplement the effects of bilateral hypogastric artery ligation with ligation of the anastomotic sites between the ovarian and uterine vessels. Ligation of the terminal end of the ovarian artery (utero-ovarian ligament) preserves the direct blood supply to the ovaries and minimizes the fear of subsequent cystic degeneration of the ovaries that may occur after ligation of the vessels in the infundibulopelvic ligaments. Arterial embolization provides an alternative approach to ligation. A catheter is advanced under fluoroscopic visualization, and small particulate material is injected to produce hemostasis in the bleeding vessels. This less invasive technique, when appropriate, may preserve fertility. A rare condition that presents an interesting challenge to the clinician is a congenital arteriovenous (A-V) malformation in the female pelvis. Most of these A-V fistulas are treated with preoperative embolism and subsequent operative ligation.

One of the treatments for repetitive embolization arising from thrombosis is the placement of a vascular umbrella into the inferior vena cava. Collateral circulation exists between the portal venous system of the gastrointestinal tract and the systemic venous circulation through anastomosis in the pelvis, especially in the hemorrhoidal plexus. The pelvic veins also anastomose with the presacral and lumbar veins. Thus though rare, patients may develop trophoblastic emboli to the brain without the trophoblast being filtered by the capillary system in the lungs.

LYMPHATIC SYSTEM**EXTERNAL ILIAC NODES**

The external iliac nodes are immediately adjacent to the external iliac artery and vein (Figs. 3.25 and 3.26). There are two distinct

Figure 3.25 Schematic view of the pelvic lymph nodes. (From Plentl AA, Friedman EA. *Lymphatic System of the Female Genitalia*. Philadelphia: WB Saunders; 1971:13.)

groups, one situated lateral to the vessels and the other posterior to the psoas muscle. The distal portion of the posterior group is enclosed in the femoral sheath. Most of the lymphatic channels to this group of nodes originate from the vulva, but there are also channels from the cervix and lower portion of the uterus. The external iliac nodes receive secondary drainage from the femoral and internal iliac nodes.

INTERNAL ILIAC NODES

The internal iliac nodes are found in an anatomic triangle whose sides are composed of the external iliac artery, the hypogastric artery, and the pelvic sidewall. Included in this clinically important area are nodes with special designation, including the nodes of the femoral ring, the obturator nodes, and the nodes adjacent to the external iliac vessels. This rich collection of nodes receives channels from every internal pelvic organ and the vulva, including the clitoris and urethra. The sentinel lymph nodes from the cervix and uterus are frequently found within the internal iliac chain of nodes, most commonly, inferior and medial to the bifurcation of iliac vein.

COMMON ILIAC NODES

The common iliac nodes are a group of nodes located adjacent to the vessels that bear their name and are between the external iliac and aortic chains. Most of these nodes are found lateral to the vessels. To remove this chain, it is necessary to dissect the common iliac vessels away from their attachments to the psoas muscle, as well as the genitofemoral nerve, which is commonly encased

Figure 3.26 A lateral view of the female pelvis demonstrating the extensive lymphatic network. Note that most of the lymphatic channels follow the courses of the major vessels. (Modified from Clemente CD. *Anatomy: A Regional Atlas of the Human Body*. 3rd ed. Baltimore-Munich: Urban & Schwarzenberg; 1987.)

in lymph nodes. This group receives lymphatics from the cervix, uterus, ovary, and the upper portion of the vagina. Secondary lymphatic drainage from the internal iliac, external iliac, superior gluteal, and inferior gluteal nodes flows to the common iliac nodes.

INFERIOR GLUTEAL NODES

A small group of lymph nodes, the inferior gluteal nodes, are located in anatomic proximity to the ischial spines and are adjacent to the sacral plexus of nodes. It is difficult to remove these nodes surgically. The nodes receive lymphatics from the cervix, the lower portion of the vagina, and Bartholin glands. This group of nodes secondarily drains to the internal iliac, common iliac, superior gluteal, and subaortic nodes.

SUPERIOR GLUTEAL NODES

The superior gluteal nodes are a group of nodes found near the origin of the superior gluteal artery and adjacent to the medial and posterior aspects of the hypogastric vessels. The superior gluteal nodes receive primary lymphatic drainage from the cervix and the vagina. Efferent lymphatics from this chain drain to the common iliac, sacral, or subaortic nodes.

SACRAL NODES

The sacral nodes are found over the middle of the sacrum in a space bounded laterally by the sacral foramina. These nodes receive lymphatic drainage from both the cervix and the vagina. Secondary drainage from these nodes runs in a cephalad direction to the subaortic nodes.

SUBAORTIC NODES

The subaortic nodes are arranged in a chain and are located below the bifurcation of the aorta, immediately anterior to the most caudal

portion of the inferior vena cava and over the fifth lumbar vertebra. The primary drainage to this chain of nodes is from the cervix, with a few lymphatics from the vagina. This group is the first secondary chain to receive the efferent lymphatics as lymph flow progresses in a cephalad direction from the majority of other pelvic nodes.

AORTIC NODES

The many aortic nodes are immediately adjacent to the aorta on both its anterior and lateral aspects, predominantly in the furrow between the aorta and inferior vena cava. Primary lymphatics drain from all the major pelvic organs, including the cervix, uterus, oviducts, and especially the ovaries. The aortic chain receives secondary drainage from the pelvic nodes. In general, primary afferent lymphatics drain into the nodes over the anterior aspects of the aorta, whereas secondary efferent drainage from other pelvic nodes is found in those nodes situated lateral and posterior to the aorta.

RECTAL NODES

The rectal nodes are found subfascially and in the loose connective tissue surrounding the rectum. Primary drainage from the cervix flows to the superior rectal nodes, and drainage from the vagina appears in the rectal nodes in the anorectal region. Secondary drainage from the rectal nodes goes to the subaortic and aortic groups.

PARAUTERINE NODES

The number of lymph nodes in the group of parauterine nodes is small; most frequently there is a single node immediately lateral to each side of the cervix and adjacent to the pelvic course of the ureter. Though anatomists frequently do not comment about the parauterine nodes, the group receives special attention in radical surgical operations to treat uterine or cervical malignancy.

Figure 3.27 A lymphangiogram of the pelvis and lumbar areas. This radiograph shows the course of the lymphatics from the deep femoral nodes into the iliac nodes. Note the extensive network of nodes in the inguinal region. (From Clemente CD. *A Regional Atlas of the Human Body*. 3rd ed. Baltimore-Munich: Urban & Schwarzenberg; 1987.)

Primary drainage to this node originates in the vagina, cervix, and uterus. Secondary drainage from this node is to the internal iliac nodes on the same side of the pelvis.

SUPERFICIAL FEMORAL NODES

The superficial femoral nodes are a group of nodes found in the loose, fatty connective tissue of the femoral triangle between the superficial and deep fascial layers. These lymph nodes receive lymphatic drainage from the external genitalia of the vulvar region, the gluteal region, and the entire leg, including the foot. Efferent lymphatics from this group of nodes penetrate the fascia lata to enter the deep femoral nodes (Fig. 3.27).

DEEP FEMORAL NODES

The deep femoral nodes are located in the femoral sheath, adjacent to both the femoral artery and the vein within the femoral triangle. The femoral triangle is the anatomic space lying immediately distal to the fold of the groin. The boundaries of the femoral triangle are the sartorius and adductor longus muscles and the inguinal ligament. Each space contains, from medial to lateral, the femoral vein, artery, and nerve. This chain receives the primary lymphatics for the lower extremity and receives secondary efferent lymphatics from the superficial lymph nodes and thus the vulva. This group of lymph nodes is in direct continuity with the iliac and internal iliac chains.

CLINICAL CORRELATIONS

A precise knowledge of pelvic lymphatics is important for the gynecologic oncologist who is surgically determining the extent of spread of a pelvic malignancy. Aortic and pelvic lymphadenectomy

operations require precise knowledge of normal anatomy and possible anomalies in both the urinary and vascular systems. The fact that most lymphatic metastatic spread from ovarian carcinoma occurs in a cephalad direction should be emphasized. This explains the importance of sampling paraaortic nodes in staging operations for some ovarian and uterine malignancy. In carcinoma of the vulva, lymphatic drainage is usually unilateral for cancers that are clearly lateral to the midline but may drain to either side with midline or near midline lesions of the pelvis (Coleman, 2013). Thus bilateral node sampling is important for midline lesions, although most vulvar cancers less than 4 cm in size can be managed with SLN mapping and biopsy; limiting the extent of nodal dissection and hopefully limiting morbidity as well. Frequently, the SLN from vulvar cancer surgery can be found just inferior and lateral to the pubic tubercle (Fig. 3.28).

Pelvic hemorrhage, usually from venous bleeding, is the most common acute complication of a lymph node dissection because most pelvic lymph nodes are in anatomic proximity to major pelvic vessels. Lymphocysts in the retroperitoneal space are the most common chronic complication associated with radical node dissections.

For many years it was believed that all the superficial femoral nodes drained to a sentinel node called the *Cloquet node*. The Cloquet node, by the present classification system, would be one of the most distal and medial of the nodes in the external iliac chain. The Cloquet node is only of historical interest, because the assumption is neither anatomically nor clinically correct.

INNERVATION OF THE PELVIS

INTERNAL GENITALIA

The innervation of the internal genital organs is supplied primarily by the autonomic nervous system. The sympathetic

Figure 3.28 Photo of blue vulvar sentinel lymph node with blue lymphatic channel leading to the node. (Courtesy of Fidel A. Valea, MD.)

portion of the autonomic nervous system originates in the thoracic and lumbar portions of the spinal cord, and sympathetic ganglia are located adjacent to the central nervous system. In contrast, the parasympathetic portion originates in cranial nerves and the middle three sacral segments of the cord, and the ganglia are located near the visceral organs. Although the fibers of both subdivisions of the autonomic nervous system frequently are intermingled in the same peripheral nerves, their physiologic actions are usually directly antagonistic. As a broad generalization, sympathetic fibers in the female pelvis produce muscular contractions and vasoconstriction, whereas parasympathetic fibers cause the opposite effect on muscles and vasodilation.

The semantics of pelvic innervation are confusing and imprecise. A *plexus* is a mixture of preganglionic and postganglionic fibers; small, inconsistently placed ganglia; and afferent (sensory) fibers. Throughout both the anatomic and surgical literature, a plexus may also be termed a *nerve*. For example, the superior hypogastric plexus is also called the *pre-sacral nerve*.

Although autonomic nerve fibers enter the pelvis by several routes, most are contained in the superior hypogastric plexus, which is a caudal extension of the aortic and inferior mesenteric plexuses. The superior hypogastric plexus is found in the retroperitoneal connective tissue. It extends from the fourth lumbar vertebra to the hollow over the sacrum. In its lower portion the plexus divides to form the two hypogastric nerves, which run laterally and inferiorly. These nerves fan out to form the inferior hypogastric plexus

in the area just below the bifurcation of the common iliac arteries. The nerve trunks descend farther into the base of the broad ligament, where they join with parasympathetic fibers to form the pelvic plexus. Both motor fibers and accompanying sensory fibers reach the pelvic plexus from S2, S3, and S4 via the pelvic nerves, or *nervi erigentes*. The pelvic plexus is found adjacent to the coccygeus muscle and sacrospinous ligaments. This “complex” is richly vascularized. The motor fibers to the levator ani (levator ani nerve) arise from the S2 to S4 nerve roots (primarily S3 and S4), traversing perpendicular to the muscle bundles and branching out to innervate the muscle fibers. The levator ani nerve does not innervate the anal sphincter, but the nerve is responsible for pelvic floor support. The pudendal nerve fibers also originate from the sacral plexus, with nerve fibers from S2 to S4. From the pelvic plexus, secondary plexuses are adjacent to all pelvic viscera, namely, the rectum, anus, urinary bladder, vagina, and Frankenhäuser plexus in the uterosacral ligaments. The Frankenhäuser plexus is extensive and contains both myelinated and nonmyelinated fibers passing primarily to the uterus and cervix, with a few fibers passing to the urinary bladder and vagina. The ovarian plexus, like the blood supply to the ovaries, is not part of the hypogastric system. The ovarian plexus is a downward extension of the aortic and renal plexuses.

It is impossible to separate afferent, sensory fibers from pelvic organs into morphologically independent tracts. Most fibers accompany the vascular system from the organ and then enter plexuses of the autonomic nervous system before eventually entering white rami communicates to the cell bodies in dorsal root ganglia of the spinal column. The major sensory fibers from the uterus accompany the sympathetic nerves, which enter the nerve roots of the spinal cord in segments T11 and T12. Thus referred uterine pain is often located in the lower abdomen. In contrast, afferents from the cervix enter the spinal cord in nerve roots of S2, S3, and S4. Referred pain from cervical inflammation and uterine irritation is characterized as low back pain in the lumbosacral region.

EXTERNAL GENITALIA

The pudendal nerve and its branches supply the majority of both motor and sensory fibers to the muscles and skin of the vulvar region. The pudendal nerve arises from the second, third, and fourth sacral roots. It has an interesting course in which it initially leaves the pelvis via the greater sciatic foramen. Next, it crosses beneath the ischial spine, running on the medial side of the internal pudendal artery. The pudendal nerve then reenters the pelvic cavity and travels in Alcock canal, which runs along the lateral aspects of the ischial rectal fossa. As the nerve reaches the urogenital diaphragm, it divides into three branches: the inferior hemorrhoidal, the deep perineal, and the superficial perineal (Fig. 3.29). The dorsal nerve of the clitoris is a terminal branch of the deep perineal nerve.

The skin of the anus, clitoris, and medial and inferior aspects of the vulva is supplied primarily by distal branches of the pudendal nerve. The vulvar region receives additional sensory fibers from three nerves. The anterior branch of the ilioinguinal nerve sends fibers to the mons pubis and the upper part of the labia majora. The genital femoral nerve supplies fibers to the

Figure 3.29 A posterior view of the female perineum demonstrating the pudendal nerve emerging externally. The nerve divides into three segments as it passes out of the pelvis: the inferior hemorrhoidal nerve and the deep and superficial perineal nerves. The clitoral nerve is the terminal branch of the deep perineal nerve. (Modified from Mattingly RF, Thompson JD. *Te Linde's Operative Gynecology*. 6th ed. Philadelphia: JB Lippincott; 1985:49.)

labia majora, and the posterior femoral cutaneous nerve supplies fibers to the inferoposterior aspects of the vulva.

ligament fixation for pelvic support may interfere with neural roots S2 to S4 and the muscle pudendal and levator ani nerves.

CLINICAL CORRELATIONS

An unusual but troublesome postoperative complication of gynecologic surgery is injury to the femoral nerve. During abdominal hysterectomy, the femoral nerve may be compromised by pressure from the lateral blade of a self-retaining retractor in the area adjacent to where the femoral nerve penetrates the psoas muscle. During vaginal surgery, the femoral nerve may be injured from exaggerated hyperflexion of the legs in the lithotomy position, because hyperflexion produces stretching and compression of the femoral nerve as it courses under the inguinal ligament.

Because of the low density of nerve endings in the upper two thirds of the vagina, women are sometimes unable to determine the presence of a foreign body in this area. This explains how a “forgotten tampon” may remain unnoticed for several days in the upper part of the vagina until its presence results in a symptomatic discharge, abnormal bleeding, or odor. Infrequent but serious complications of pudendal nerve block are hematomas from trauma to the pudendal vessels and intravascular injection of anesthetic agents. The vessels or nerves are in close anatomic proximity to the ischial spine.

The fallopian tube is one of the most sensitive of the pelvic organs when crushed, cut, or distended, a fact that is appreciated in performing tubal ligations with the patient under local anesthesia. Damage to the obturator nerve during radical pelvic operations does not affect the pelvis directly. Although the nerve has an extensive pelvic course, its motor fibers supply the adductors of the thigh, and its sensory fibers innervate skin over the medial aspects of the thigh. Stitches placed during sacrospinous

DIAPHRAGMS AND LIGAMENTS

PELVIC DIAPHRAGM

The pelvic diaphragm is a wide but thin muscular layer of tissue that forms the inferior border of the abdominopelvic cavity. Composed of a broad, funnel-shaped sling of fascia and muscle, it extends from the symphysis pubis to the coccyx and from one lateral sidewall to the other. The primary muscles of the pelvic diaphragm are the levator ani and the coccygeus (Fig. 3.30). This structure is the evolutionary remnant of the tail-wagging muscles in lower animals. The *endopelvic fascia* is another term often used interchangeably with the *pelvic diaphragm*. The *pelvic diaphragm* and *endopelvic fascia* are terms used to characterize the connective tissue, the support for the pelvis, and the pelvic floor. The pelvic diaphragm is composed of collagen, elastic tissue, and muscle.

The muscles of the pelvic diaphragm are interwoven for strength, and a continuous muscle layer encircles the terminal portions of the urethra, vagina, and rectum. The levator ani muscles constitute the greatest bulk of the pelvic diaphragm and are divided into three components, which are named after their origin and insertion: pubococcygeus, puborectalis, and iliococcygeus. Studies using magnetic resonance imaging (MRI) and three-dimensional ultrasound validate the change in terminology from pubococcygeus muscle to a more accurate name—the *pubovisceral muscle*. This grouping of the intermediate component of the levator ani muscle lies posterior to the pubic bone and may be visualized as pubovaginalis, puboanalis, and puboperinealis muscle bundles. These three bundles constitute the pubovisceralis. Cadaveric dissection has also validated the imaging studies. The puborectalis component of the levator ani

Figure 3.30 A superior view of the pelvic diaphragm and the pelvic floor. The primary muscles that compose this funnel-shaped sling are the coccygeus and the levator ani. (Modified from Mattingly RF, Thompson JD. *Te Linde's Operative Gynecology*. 6th ed. Philadelphia: Lippincott; 1985:41.)

muscle is dorsal to the rectum and helps form the sling supporting the rectum. The coccygeus is a triangular muscle that occupies the area between the ischial spine and the coccyx.

The paired levator ani muscles act as a single muscle and functionally are important in the control of urination, in parturition, and in maintaining fecal continence. The pelvic diaphragm is important in supporting both abdominal and pelvic viscera and facilitates equal distribution of intraabdominal pressure during activities such as coughing.

UROGENITAL DIAPHRAGM

The urogenital diaphragm, also called the *triangular ligament*, is a strong, muscular membrane that occupies the area between the symphysis pubis and ischial tuberosities (Fig. 3.31) and stretches across the triangular anterior portion of the pelvic outlet. The urogenital diaphragm is external and inferior to the pelvic diaphragm. Anteriorly, the urethra is suspended from the pubic bone by continuations of the fascial layers of the urogenital diaphragm. The free edge of the diaphragm is strengthened by the superficial transverse perineal muscle. Posteriorly, the urogenital diaphragm inserts into the central point of the perineum. Situated farther posteriorly is the ischiorectal fossa. Located more superficially are the bulbocavernosus and ischiocavernosus muscles.

The urogenital diaphragm has two layers that enfold and cover the striated, deep transverse perineal muscle. This muscle surrounds both the vagina and the urethra, which pierce the diaphragm. The pudendal vessels and nerves, the external sphincter of the membranous urethra, and the dorsal nerve to the clitoris are also found within the urogenital diaphragm. The deep transverse perineal muscle is innervated by branches of the pudendal nerve. The major function of the urogenital diaphragm is to support the urethra and maintain the urethrovesical junction.

LIGAMENTS

The pelvic ligaments are not classic ligaments but are thickenings of retroperitoneal fascia and consist primarily of blood and

lymphatic vessels, nerves, and fatty connective tissue. Anatomists call the retroperitoneal fascia *subserous fascia*, whereas surgeons refer to this fascial layer as *endopelvic fascia*. The connective tissue is denser immediately adjacent to the lateral walls of the cervix and the vagina.

Broad Ligaments

The broad ligaments are a thin, mesenteric-like double reflection of peritoneum stretching from the lateral pelvic sidewalls to the uterus (Fig. 3.32). They become contiguous with the uterine serosa, and thus the uterus is contained within two folds of peritoneum. These peritoneal folds enclose the loose, fatty connective tissue termed the *parametrium*. The broad ligaments afford minor support to the uterus but are conduits for important anatomic structures. Within the broad ligaments are found the following structures: oviducts; ovarian and round ligaments; ureters; ovarian and uterine arteries and veins; parametrial tissue; embryonic remnants of the mesonephric duct, Wolffian body, and secondary two ligaments; the mesovarium; and the mesosalpinx. The round ligament is composed of fibrous tissue and muscle fibers. It attaches to the superoanterior aspect of the uterus, anterior and caudal to the oviduct, and runs via the broad ligament to the lateral pelvic wall. It, too, offers little support to the uterus. The round ligament crosses the external iliac vessels and enters the inguinal canal, ending by inserting into the labia majora in a fanlike fashion. In the fetus a small, finger-like projection of the peritoneum, known as *Nuck canal*, accompanies the round ligament into the inguinal canal. Generally, the canal is obliterated in the adult woman.

Cardinal Ligaments

The cardinal, or Mackenrodt, ligaments extend from the lateral aspects of the upper part of the cervix and the vagina to the pelvic wall. They are a thickened condensation of the subserosal fascia and parametria between the interior portion of the two folds of peritoneum. The cardinal ligaments form the base of the broad ligaments, laterally attaching to the fascia

Figure 3.31 **A**, Schematic views of the perineum demonstrating superficial structures. Note the two layers of the urogenital diaphragm enfolding the deep transverse perineal muscle. **B**, Schematic views of the perineum demonstrating superficial structures and deeper structures. (Modified from Pritchard JA, MacDonald PC, Gant NF. *Williams' Obstetrics*. 17th ed. New York: Appleton-Century-Crofts; 1985:14.)

over the pelvic diaphragm and medially merging with fibers of the endopelvic fascia. Within these ligaments are found blood vessels and smooth muscle. The cardinal ligaments help to maintain the anatomic position of the cervix and the upper part of the vagina and provide the major support of the uterus and cervix.

Uterosacral Ligaments

The uterosacral ligaments extend from the upper portion of the cervix posteriorly to the third sacral vertebra. They are thickened near the cervix and then run a curved course around each side of the rectum and subsequently thin out posteriorly. The external surface of the uterosacral ligaments is formed by an inferoposterior fold of peritoneum at the base of the broad ligaments. The middle of the uterosacral ligaments is composed primarily

of nerve bundles. The uterosacral ligaments serve a role in the anatomic support of the cervix.

CLINICAL CORRELATIONS

The posterior fibers of the levator ani muscles encircle the rectum at its junction with the anal canal, thereby producing an abrupt angle that reinforces fecal continence. Surgical repair of a displacement or tear of the rectovaginal fascia and levator ani muscles resulting from childbirth is important during posterior colporrhaphy. Normal position of the female pelvic organs in the pelvis depends on mechanical support from both fascia and muscles. Vaginal delivery sometimes results in dysfunction of the anal sphincter. The etiology of this problem may be direct

Figure 3.32 A schematic drawing of the broad ligament, posterior view. Note the many structures contained within the broad ligament. Note the posterior aspect of the rectouterine fold, called the cul-de-sac, or pouch, of Douglas. (Modified from Clemente CD. *Anatomy: A Regional Atlas of the Human Body*. 3rd ed. Baltimore-Munich: Urban & Schwarzenberg; 1987.)

injury to the striated muscles of the pelvic floor or damage to the pudendal and presacral nerves (levator ani nerves) during labor and delivery.

The round ligament is an important surgical landmark in making the initial incision into the parietal peritoneum to gain access to the retroperitoneal space. Direct visualization of the retroperitoneal course of the ureter is an important step in many pelvic operations, including dissections in women with endometriosis, pelvic inflammatory disease, large adnexal masses, broad ligament masses, and pelvic malignancies. A cyst of the Nuck canal may be confused with an indirect inguinal hernia. When a large amount of fluid is placed in the abdominal cavity, post-operative bilateral labial edema may develop in some women because of patency of the canal of Nuck.

During pelvic surgery, traction on the uterus makes the uterosacral and cardinal ligaments more prominent. There is a free space approximately 2 to 4 cm below the superior edge of the broad ligament. In this free space there are no blood vessels, and the two sides of the broad ligament are in close proximity. Often gynecologic surgeons utilize this area to facilitate clamping of the anastomosis between the uterine and ovarian arteries.

NONGENITAL PELVIC ORGANS

URETERS

The ureters are whitish, muscular tubes, 28 to 34 cm in length, extending from the renal pelvis to the urinary bladder. The ureter is divided into abdominal and pelvic segments. The diameters vary. The abdominal segment is approximately 8 to 10 mm in diameter. The pelvic segment is approximately 4 to 6 mm. A congenital anomaly of a double, or bifid, ureter occurs in 1%

to 4% of females. Ectopic ureteral orifices may occur in either the urethra or the vagina. The abdominal portion of the right ureter is lateral to the inferior vena cava. The course of the left ureter is similar to its counterpart on the right side in that it runs downward and medially along the anterior surface of the psoas major muscle.

The iliopectineal line serves as the marker for the pelvic portion of the ureter. The ureters run along the common iliac artery and then cross over the iliac vessels as they enter the pelvis (Fig. 3.33). There is a slight variation between the two sides of the female pelvis. The right ureter tends to cross at the bifurcation of the common iliac artery, whereas usually the left ureter crosses 1 to 2 cm above the bifurcation.

The ureters follow the descending, convex curvature of the posterolateral pelvic wall toward the perineum. Throughout its course, the ureter is retroperitoneal in location. The ureter can be found on the medial leaf of the parietal peritoneum and in close proximity to the ovarian, uterine, obturator, and superior vesical arteries (Fig. 3.34). The uterine artery lies on the anterolateral surface of the ureter for 2.5 to 3 cm. At approximately the level of the ischial spine, the ureter changes its course and runs forward and medially from the uterosacral ligaments to the base of the broad ligament. There the ureter enters into the cardinal ligaments. In this location the ureter is approximately 1 to 2 cm lateral to the uterine cervix and is surrounded by a plexus of veins. A cross-sectional study by Hurd and colleagues, using computed tomography of women with normal anatomy, evaluated the distance from the ureter to the lateral aspect of the cervix. The measurement of the closest distance in any individual woman was (median of all subjects) 2.3 cm \pm 0.8 cm (Hurd, 2001). However, the authors noted that in 12% of women, the ureter was less than 0.5 cm from the cervix (Fig. 3.35). This finding emphasizes the caution needed in surgery

Figure 3.33 Photograph taken during a dissection of the lateral pelvic wall at the time of a radical hysterectomy. Note the ureter coursing over the common iliac artery in close proximity to the bifurcation. The ureter then drops under and very close to the uterine artery. The retractor is lifting the internal iliac vein. (Courtesy of Deborah Jean Dotters, MD, Eugene, OR.)

Figure 3.34 A schematic drawing of the female pelvis, lateral view, demonstrating the ureter's relation to the major arteries. Note the uterine artery crossing over the ureter. (From Buchsbaum HJ, Schmidt JD. *Gynecologic and Obstetric Urology*. Philadelphia: WB Saunders; 1978:24.)

Figure 3.35 Average location of the ureters in relation to the cervix. **A**, Sagittal view representing the plane from the computed tomography cut noted in **B**. The most proximal point from the ureter to the cervix. Bars represent standard deviation. (From Hurd WW, Chee SS, Gallagher KL, et al. Location of the ureters in relation to the uterine cervix by computed tomography. *Am J Obstet Gynecol*. 2001;184:338.)

to prevent ureteral injury. This close proximity also underscores the fact that ureteral injury may be unavoidable in some women. The ureter then runs upward (ventral) and medially in the vesical uterine ligaments to obliquely pierce the bladder wall. Just before entering the base of the bladder, the ureter is in immediate contact with the anterior vaginal wall and the inferolateral aspect of the space of Retzius.

The ureter has a rich arterial supply with numerous anastomoses from many small vessels that form a longitudinal plexus in the adventitia of the ureter, commonly referred to as the *Walden sheath*. The parent vessels that send branches to this arterial plexus surrounding the ureter include the renal, ovarian, common iliac,

hypogastric, uterine, vaginal, vesical, middle hemorrhoidal, and superior gluteal arteries. The ureter is resistant to injury resulting from devascularization unless the surgeon strips the adventitia from the muscular conduit. In general, the blood supply of the abdominal ureter comes from medial sources and the blood supply of the pelvic ureter originates from lateral sources.

URINARY BLADDER

The urinary bladder is a hollow muscular organ that lies between the symphysis pubis and the uterus. The size and shape of the bladder vary with the volume of urine it contains. Similarly, the anatomic proximity to other pelvic organs depends on whether the bladder is full or empty. The superior surface of the bladder is the only surface covered by peritoneum. The inferior portion is immediately adjacent to the uterus. The urachus is a fibrous cord extending from the apex of the bladder to the umbilicus. The urachus, which is the adult remnant of the embryonic allantois, is occasionally patent for part of its length. The base of the bladder lies directly adjacent to the endopelvic fascia over the anterior vaginal wall. The bladder neck and connecting urethra are attached to the symphysis pubis by fibrous ligaments. The prevesical or retropubic space of Retzius is the area lying between the bladder and symphysis pubis and is bounded laterally by the obliterated hypogastric arteries. This space extends from the fascia covering the pelvic diaphragm to the umbilicus between the peritoneum and transversalis fascia.

The mucosa of the anterior surface of the bladder is light red and has numerous folds. The inferoposterior surface delineated by the two ureteral orifices and the urethral orifice is the trigone. The trigone is a darker red than the rest of the bladder mucosa and is free of folds. When the bladder is empty, the ureteral orifices are approximately 2.5 cm apart. This distance increases to 5 cm when the bladder is distended. The muscular wall of the bladder, the detrusor muscles, is arranged in three layers. The arterial supply of the bladder originates from branches of the hypogastric artery: the superior vesical, inferior vesical, and middle hemorrhoidal arteries. The nerve supply to the bladder includes sympathetic and parasympathetic fibers, with the external sphincter supplied by the pudendal nerve.

RECTUM

The rectum is the terminal 12 to 14 cm of the large intestine. The rectum begins over the second or third sacral vertebra, where the sigmoid colon no longer has a mesentery. After the large intestine loses its mesentery, its anatomic posterior wall is in close proximity to the curvature of the sacrum. Anteriorly, peritoneum covers the upper and middle thirds of the rectum. The lowest one third is below the peritoneal reflection and is in close proximity to the posterior wall of the vagina. The rectum empties into the anal canal, which is 2 to 4 cm in length. The anal canal is fixed by the surrounding levator ani musculature of the pelvic diaphragm (see Fig. 3.5). The external sphincter of the anal canal is a circular band of striated muscle. Studies of the cross-sectional anatomy of the external anal sphincter by both ultrasound and magnetic resonance imaging have identified two distinct layers of the external anal sphincter. With MRI with three-dimensional reconstruction, Hsu and colleagues noted three separate components to the external

sphincter: a main muscle body, a separate encircling subcutaneous band of muscles, and bilateral wing-shaped muscle bands that attach near the ischiopubis (Hsu, 2005). They are a subcutaneous and a deep layer. The rectum, unlike other areas of the large intestine, does not have teniae coli or appendices epiploicae. The arterial supply of the rectum is rich, originating from five arteries: the superior hemorrhoidal artery, which is a continuation of the inferior mesenteric, the two middle hemorrhoidal arteries, and the two inferior hemorrhoidal arteries. Approximately 10% of carcinomas of the large bowel occur within the rectum. Therefore during rectal examination special emphasis to palpate the entire circumference of the rectum, not just the area of the rectovaginal septum, is an important part of screening for colon cancer.

CLINICAL CORRELATIONS

The anatomic proximity of the ureters, urinary bladder, and rectum to the female reproductive organs is a major consideration in most gynecologic operations. Surgical compromise of the ureter may occur during clamping or ligating of the infundibulopelvic vessels, clamping or ligating of the cardinal ligaments, or wide suturing in the endopelvic fascia during an anterior repair, even with apparent normal anatomy and utmost surgical care. Particular attention to the proximity of the distal ureter to the anterior vagina is very important. Operative injuries to the bladder or ureter occur in approximately 1 out of 100 major gynecologic operations. Bladder injuries are approximately five times more common than ureteral injuries. Two of the classic ways to differentiate a ureter from a pelvic vessel are (1) visualization of peristalsis after stimulation by a surgical instrument and (2) visualization of Auerbach plexuses, which are numerous, wavy, small vessels that anastomose over the surface of the ureter. Injury to the ureter or bladder during urethropexy operations for genuine stress incontinence is common. Therefore many surgeons routinely inject indigo carmine and either open the bladder or perform cystoscopy near the end of the operative procedure.

For years, gynecologic teachers have referred to the area in the base of the broad ligament near the cervix where the uterine artery crosses the ureter as the area where “water flows under the bridge.”

The urinary bladder, if properly drained, will heal rapidly after a surgical insult if the blood supply to the bladder wall is not compromised. This capacity allows the gynecologist to use suprapubic cystostomy tube without fear of fistula formation.

There are many different surgical techniques for the repair of urinary stress incontinence. They usually involve either suspension of the periurethral tissues or bladder neck itself. Occasionally, these surgical procedures are complicated by a significant amount of postoperative venous bleeding. A subfascial hematoma may extend as high as the umbilicus in the space of Retzius. One of the most common causes of female urinary incontinence is defective connective tissue, especially in the periurethral connective tissue, the pubourethral ligaments, and pubococcygeus muscles.

Rectal injury may occur during vaginal hysterectomy with associated posterior colporrhaphy. In the middle third of the vagina, the distance between vaginal and rectal mucosa is only a few millimeters, and usually the connective tissue is densely

Figure 3.36 Laparoscopic visualization of a normal pelvis. The probe is elevating the uterus to expose the cul-de-sac of Douglas. (Courtesy of Burke Beller.)

adherent and should be separated by sharp dissection. The rectum bulges anteriorly into the vagina in this area, producing a further challenge during the operative procedure.

OTHER STRUCTURES

CUL-DE-SAC OF DOUGLAS

The cul-de-sac of Douglas is a deep pouch formed by the most caudal extent of the parietal peritoneum. The cul-de-sac is a potential space and is also called the *rectouterine pouch* or *fold* (Figs. 3.32 and 3.36). It is anterior to the rectum, separating the uterus from the large intestine. The parietal peritoneum of the cul-de-sac covers the cervix and upper part of the posterior vaginal wall then reflects to cover the anterior wall of the rectum. The pouch is bounded on the lateral sides by the peritoneal folds covering the uterosacral ligaments.

PARAMETRIA

The parametria are the coats of extraperitoneal fatty and fibrous connective tissues adjacent to the uterus. The parametria lie between the leaves of the broad ligament and in the contiguous area anteriorly between the cervix and bladder. This connective tissue is thicker and denser adjacent to the cervix and vagina, where it becomes part of the connective tissue of the pelvic floor. The parametria may also thicken in response to radiation, pelvic cancer, infection, or endometriosis.

PARAVESICAL AND PARARECTAL SPACES

The paravesical and pararectal spaces are actually potential spaces that become true spaces when developed by the surgeon. Development of these spaces is useful in pelvic lymph node dissection and in radical pelvic surgery because it makes the anatomic landmarks so clear. The paravesical space is bordered medially by the bladder and upper vagina and is contiguous with, but lateral to, the space of Retzius. Laterally, it is bordered by the obturator fossa and the external iliac vessels. Inferiorly it is bordered by

the pubic ramus, and superiorly it is bordered by the cardinal ligament.

The pararectal space is developed by dissecting the adventitial tissue within the broad ligament, between the ureter (medially), and the internal iliac vessels (laterally). More deeply, the medial border is the rectum. Superiorly, the pararectal space is limited by the sacral hollow. Inferiorly, it is limited by the cardinal ligament, containing the uterine artery. The paravesical and pararectal spaces are actually potential spaces that become true spaces when developed by the surgeon. Development of these spaces is useful in pelvic lymph node dissection and in radical pelvic surgery because the anatomic landmarks become so clear.

CLINICAL CORRELATIONS

The parametria and cul-de-sac of Douglas are important anatomic landmarks in advanced pelvic infection and neoplasia. Intrauterine infection, cervical carcinoma, and endometrial carcinoma may penetrate the endocervical stroma or the

myometrium and secondarily may invade the loose connective tissue of the parametria.

The pouch of Douglas is easily accessible in performing transvaginal surgical procedures. Posterior colpotomy is frequently chosen for drainage of a pelvic abscess occurring in the cul-de-sac of Douglas.

When the paravesical and pararectal spaces have been developed and the uterus is held on traction medially, the pelvic anatomy, including the ureter, internal and external iliac vessels, obturator fossa, and the cardinal ligament, with the uterine artery crossing the ureter, can be clearly and readily identified.

Many women with uterine prolapse have an associated enterocele, which is a hernia that protrudes between the uterosacral ligaments. Occasionally the cul-de-sac of Douglas is obliterated by the inflammatory process associated with either endometriosis or advanced malignancy.

ACKNOWLEDGEMENT

I would like to thank Dr. Vern Katz for his contributions to this chapter in the previous edition.

KEY POINTS

- The labia majora are homologous to the scrotum in the male. The labia minora are homologous to the penile urethra and a portion of the skin of the penis in males.
- The clitoris is the female homologue of the penis in the male. Skene glands are homologous to the prostate gland in the male.
- The average length of the clitoris is 1.5 to 2 cm. Clinically, in determining clitoromegaly width is more important and should be less than 1 cm, for it is difficult to actually measure the length of the clitoris.
- The female urethra measures 3.5 to 5 cm in length. The mucosa of the proximal two thirds of the urethra is composed of stratified transitional epithelium, and the distal one third is stratified squamous epithelium.
- When a woman is standing, the axis of the upper portion of the vagina lies close to the horizontal plane, with the upper portion of the vagina curving toward the hollow of the sacrum.
- The vaginal length increases with weight and height, and it decreases with age.
- The lower third of the vagina is in close anatomic relationship to the urogenital and pelvic diaphragms.
- The middle third of the vagina is supported by the levator ani muscles and the lower portion of the cardinal ligaments.
- The primary lymphatic drainage of the upper third of the vagina is to the external iliac nodes, the middle third of the vagina drains to the common and internal iliac nodes, and the lower third has a wide lymphatic distribution, including the common iliac, superficial inguinal, and perirectal nodes.
- Descriptive terms for pelvic organs are derived from the Latin root, whereas terms relating to surgical procedures are derived from the Greek root.
- The length and width of the endocervical canal vary. The width of the canal varies with the parity of the woman and changing hormonal levels. It is usually 2.5 to 3 cm in length and 7 to 8 mm at its widest point.
- The fibromuscular cervical stroma is composed primarily of collagenous connective tissue and ground substance. The connective tissue contains approximately 15% smooth muscle cells and a small amount of elastic tissue.
- The major arterial supply to the cervix is located in the lateral cervical walls at the 3 and 9 o'clock positions.
- The pain fibers from the cervix accompany the parasympathetic fibers to the second, third, and fourth sacral segments.
- The transformation zone of the cervix encompasses the border of the squamous epithelium and columnar epithelium. The location of the transformation zone changes on the cervix depending on a woman's hormonal status.
- The uterus of a nulliparous woman is approximately 8 cm long, 5 cm wide, and 2.5 cm thick and weighs 40 to 50 g. In contrast, in a multiparous woman each measurement is approximately 1.2 cm larger and normal uterine weight is 20 to 30 g heavier. The maximal weight of a normal uterus is 110 g.
- In the majority of women, the long axis of the uterus is both anteverted in respect to the long axis of the vagina and anteflexed in relation to the long axis of the cervix. However, a retroflexed uterus is a normal variant found in approximately 25% of women.
- The uterine and ovarian arteries provide the arterial blood supply of the uterus. The uterine arteries are large branches of the anterior division of the hypogastric arteries, whereas the ovarian arteries originate directly from the aorta.

Continued

KEY POINTS—cont'd

- Afferent nerve fibers from the uterus enter the spinal cord at the eleventh and twelfth thoracic segments.
- The oviducts are 10 to 14 cm in length and are composed of four anatomic sections. Closest to the uterine cavity is the interstitial segment, followed by the narrow isthmic segment, then the wider ampullary segment, and distally the trumpet-shaped infundibular segment.
- The right oviduct and appendix are often anatomically adjacent. Clinically it may be difficult to differentiate inflammation of the upper portion of the genital tract and acute appendicitis.
- During the reproductive years, the ovaries measure approximately 1.5 cm × 2.5 cm × 4 cm.
- The ovary in nulliparous women rests in a depression of peritoneum named the *fossa ovarica*. Immediately adjacent to the ovarian fossa are the external iliac vessels, the ureter, and the obturator vessels and nerves.
- Three prominent ligaments determine the anatomic mobility of the ovary: the mesovarian, the ovarian ligament, and the infundibulopelvic ligament.
- The arterial supply of the pelvis is paired, bilateral, and has multiple collaterals and numerous anastomoses.
- The extent of collateral circulation after hypogastric artery ligation depends on the site of ligation and may be divided into three groups: branches from the aorta, branches from the external iliac arteries, and branches from the femoral arteries.
- The internal iliac nodes are found in an anatomic triangle whose sides are composed of the external iliac artery, the hypogastric artery, and the pelvic sidewall. This rich collection of nodes receives channels from every internal pelvic organ and the vulva, including the clitoris and urethra.
- The femoral triangle is the anatomic space lying immediately distal to the fold of the groin. The boundaries of the femoral triangle are the sartorius and adductor longus muscles and the inguinal ligament.
- The pudendal nerve and its branches supply the majority of both motor and sensory fibers to the muscles and skin of the vulvar region.
- The femoral nerve may be compromised by pressure on the psoas muscle during abdominal surgery and by hyperflexion of the leg during vaginal surgery.
- The pelvic diaphragm is important in supporting both abdominal and pelvic viscera and facilitates equal distribution of intraabdominal pressure during activities such as coughing. The levator ani muscles constitute the greatest bulk of the pelvic diaphragm.
- The major function of the urogenital diaphragm is to support the urethra and maintain the urethrovesical junction.
- Contained within the broad ligaments are the following structures: oviducts, ovarian and round ligaments, ureters, ovarian and uterine arteries and veins, parametrial tissue, embryonic remnants of the mesonephric duct and Wolffian body, and two secondary ligaments.
- The cardinal ligaments provide the major support to the uterus.
- A congenital anomaly of a double, or bifid, ureter occurs in 1% to 4% of females.
- When the urinary bladder is empty, the ureteral orifices are approximately 2.5 cm apart. This distance increases to 5 cm when the bladder is distended.
- The distal ureter enters into the cardinal ligament. In this location the ureter is approximately 1 to 2 cm lateral to the uterine cervix and is surrounded by a plexus of veins. In approximately 12% of women, the cervix will be less than 0.5 cm from the cervix.
- Two ways of distinguishing the ureter from pelvic vessels are (1) identification of peristalsis after stimulation with a surgical instrument and (2) identification of Auerbach plexuses.
- Surgical compromise of the ureters may occur during clamping or ligating of the infundibulopelvic vessels, clamping or ligating of the cardinal ligaments, or wide suturing in the endopelvic fascia during an anterior repair.
- The following three important axioms should be in the forefront of decision making during difficult gynecologic surgery: (1) do not assume that the anatomy of the left and right side of the pelvis are invariably identical mirror images; (2) during difficult operations with multiple adhesions, operate from known anatomic areas into the unknown; and (3) from the sage advice of a distinguished Canadian gynecologist, Dr. Henry McDuff: "If the disease be rampant and the anatomy obscure, and the plans of dissection not pristine and pure, do not be afraid, nor faint of heart, try the retroperitoneum, it's a great place to start."

Reproductive Endocrinology Neuroendocrinology, Gonadotropins, Sex Steroids, Prostaglandins, Ovulation, Menstruation, Hormone Assay

Nataki C. Douglas, Roger A. Lobo

The endocrine regulation of the reproductive system is very complex. Much information has been obtained since the 1980s, and new information is constantly becoming available. It would be impossible to include all of the findings in a single chapter. Thus this chapter presents only the basic information required to understand this complex topic. More detailed and in-depth information is found in the several books that have been dedicated to this subject.

Successful function of the reproductive system requires the involvement of several organs, none of which acts independently. This chapter discusses the physiology of the hypothalamic-pituitary-ovarian (HPO) axis. For ease of understanding, each organ will be discussed first as an individual unit; information will include the central nervous system control of gonadotropin-releasing hormone (GnRH), the primary neurohormone controlling the whole reproductive endocrine axis, the GnRH action on the anterior pituitary and the resultant secretion of the gonadotropins, the gonadotropins action on the ovaries and the release of gonadal steroids, and finally the action of these sex steroids on the uterus and cervix. Although it is fair to state that the HPO axis is driven by the hypothalamus and its release of GnRH, it is important to point out that normal function of the hypothalamic-pituitary-ovarian endocrine axis requires a remarkable information flow and coordination between each of these organs, as exemplified by the existing inhibitory and stimulatory feedback loops. Their relevance will become obvious in the discussion of the menstrual cycle, which will close the chapter.

HYPOTHALAMUS AND GnRH

The reproductive process begins in the brain, through the activation of the initial hormonal signal that will release gonadotropins from the pituitary gland. This hormone released by the hypothalamus is **gonadotropin-releasing hormone (GnRH)**, a decapeptide (10 amino acids) (Fig. 4.1). The *GnRH* gene (situated on the short arm of chromosome 8) encodes for a 92 amino acids precursor molecule, composed of a signal peptide sequence, the GnRH sequence itself, a posttranscriptional processing signal (3 amino acids long), and a 56-amino acid peptide

known as GnRH-associated peptide (GAP). (Several forms of the GnRH decapeptide have been identified, the principal of which is GnRH-2, which differs from GnRH by 3 amino acids. It is found in several areas of the body, where it may subserve functions unrelated to those of GnRH. Its role in fertility, if any, remains to be determined.)

ANATOMY

Relationship of the Olfactory and GnRH Systems in Early Fetal Life

Surprisingly, GnRH-synthesizing neurons do not originate within the brain, like the majority of all neurons. Rather, GnRH neurons derive from progenitor cells in the embryonic olfactory placode where they develop. In a particular journey unique for a neuron, GnRH neurons migrate toward the brain during early fetal life to reach the locations that they will occupy during adult life. This migration of GnRH neurons over long distances and through changing molecular environments suggests that numerous factors, local and possibly external, influence this process at its different stages. Such factors play critical roles, such as mediating the adhesion of GnRH neurons to changing surfaces along their voyage, promoting cytoskeleton remodeling, or modulating axonal guidance.

Functional connections between GnRH neurons and the hypophyseal portal system that will transport GnRH to the anterior pituitary gland are established by about 16 weeks of fetal life. Migration failure of GnRH neurons and the resultant lack of the establishment of functional connections are characteristic of patients with **Kallmann syndrome**, who show hypogonadotropic hypogonadism accompanied by anosmia (Tsai, 2006). In the 19-week old fetus with X-linked Kallmann syndrome, the GnRH neurons accompanying the olfactory nerves have been shown to be arrested in their voyage within the meninges, and therefore contact with the brain and the hypophyseal portal system is not established.

GnRH Neuronal System

In the adult, neurons producing GnRH are present in several hypothalamic nuclei as well as other parts of the brain. However, the majority of GnRH neurons controlling the HPO axis are

Figure 4.1 The 10-amino acid sequence of gonadotropin-releasing hormone (GnRH). (From Klerzky OA, Lobo RA. Reproductive neuroendocrinology. In: Mishell DR, Davajan V, Lobo RA, eds. *Infertility, Contraception and Reproductive Endocrinology*. 3rd ed. Cambridge, MA: Blackwell Scientific; 1991.)

located within the anterior hypothalamus and primarily within the medial basal hypothalamus, with the greatest number in the primate within the **arcuate nucleus**. The 92 amino acid GnRH precursor is released into the axons of these neurons and cleaved during transport to yield GnRH and GAP. (The biologic function of GAP or fragments thereof remains to be clarified.)

A substantial number of GnRH axons terminate within the external zone of the **median eminence** (infundibulum) where GnRH is released. This area is the site of an important capillary plexus, with a fenestrated epithelium similar to that of peripheral capillaries, which allows passage of large molecules. (These capillaries differ from brain capillaries, which are not fenestrated. Thus the median eminence is viewed as an area outside the blood-brain barrier.) This pathway is the most relevant one in regard to the control of the pituitary-ovarian axis (Fig. 4.2, A). Another substantial projection of GnRH axons is through circumventricular organs, the major of which is the organum vasculosum of the lamina terminalis (OVLT). These areas are also outside the blood-brain barrier. (The function of GnRH release into these areas remains somewhat unknown. One role may be to enable the release of GnRH into cerebrospinal fluid [CSF], perhaps to facilitate actions of GnRH in other areas of the brain. GnRH levels have been found to be elevated in CSF as opposed to being minimal in peripheral blood.) Another possible route of GnRH release may involve specialized ependymal cells, referred to as **tanycytes**. These have been found to extend from the lumen of the third ventricle to the external zone of the median eminence.

Transport of GnRH to the Anterior Pituitary

The capillary plexus of the external median eminence, into which GnRH is released, collects into several **hypophyseal portal vessels**, which descend along the pituitary stalk to terminate

within another capillary plexus (hence the term *portal*) within the anterior lobe of the pituitary (see Fig. 4.2, B). (Unlike the posterior lobe of the pituitary, also referred to as the neurohypophysis, the anterior lobe has no direct blood supply and receives all of its vascularization from this portal system.) The vascular arrangement whereby GnRH as well as other neurohormones reach the anterior pituitary is very important to the proper function of the endocrine system: it allows for the rapid (within minutes) and undiluted transport of relatively small amounts of neurohormones to the pituitary. This is especially crucial to GnRH, because this neurohormone has a short half-life of about 2 to 4 minutes (it is rapidly degraded by peptidases in blood; as a consequence, GnRH is not measurable in peripheral blood) and because of its pulsatile mode of release (discussed later).

PHYSIOLOGY

GnRH Pulse Generator

Studies have shown that GnRH is characteristically released intermittently, in a pulsatile fashion. Hence comes the concept of the **GnRH pulse generator** responsible for the pulsatile release of the hormone. GnRH pulses occur at about hourly intervals (Fig. 4.3). The rising edge of each GnRH pulse is abrupt, such that GnRH can increase by a factor of 50 within 1 minute. Each GnRH pulse is preceded by an increase in multiunit activity within the area of the arcuate nucleus.

Mechanisms Responsible for GnRH Pulsatility

The cellular basis and the mechanisms that determine the timing of the increase in multiunit activity resulting in pulsatile GnRH activity are still under study. First, there is a growing consensus that pulsatile activity originates from an inherent pace-making activity of the GnRH neuron itself: in vitro data have shown that

Figure 4.2 **A**, Nuclear organization of the hypothalamus, shown diagrammatically in a sagittal plane as viewed from the third ventricle. Rostral area is to the left and caudal area is to the right. Fast transport of GnRH pulses released into the median eminence from axons originating from GnRH neurons in the arcuate nucleus occurs through the portal vessels derived from the capillary plexus in the median eminence. **B**, The pituitary stalk and several individual hypophyseal portal veins transporting hypothalamic neurohormones to the anterior pituitary in a nonhuman primate. (**A**, Modified from Moore RY. Neuroendocrine mechanisms: cells and systems. In: Yen SSC, Jaffe R, eds. *Reproductive Endocrinology: Physiology, Pathophysiology and Clinical Management*. Philadelphia: WB Saunders; 1986. **B**, Courtesy of Drs. Peter Carmel and Michel Ferin.)

individual neurons have the capacity of spontaneous oscillations in activity. In this case, such activity would also require a synchronized action from enough neurons to provide a discrete GnRH pulse. Intercommunication between GnRH neurons may occur through gap junctions between such neurons, which have been demonstrated, and through synaptic forms of interaction between cells. Second, evidence has identified a key role of **kisspeptin**

(KISS1), a product of the *KISS1* gene, and its receptor (GPR54 or KISS1R) in the regulation of GnRH release ([Skorupskaite, 2014](#)). Kiss1 neurons have been found to directly innervate and stimulate GnRH neurons. In humans, mutations or targeted deletions of *KISS1* or of its receptor cause hypogonadotropic hypogonadism. Patients with these mutations, however, do not have anosmia, unlike those with Kallmann syndrome, suggesting that

Figure 4.3 GnRH release by the hypothalamus is pulsatile. Shown in the upper panel are hourly GnRH pulses over an 8-hour period in an ovariectomized monkey in the absence of ovarian steroid modulation. Note the concordance of LH pulses (*lower panel*). (From Xia L, Van Vugt D, Alston EJ, et al. A surge of gonadotropin-releasing hormone accompanies the estradiol-induced gonadotropin surge in the rhesus monkey. *Endocrinology*. 1992;131:2812.)

there are no major deficits in the embryonic migration of olfactory or GnRH neurons. KISS1 neurons within the arcuate nucleus (rodents) and infundibular nucleus (humans) express the estrogen, progesterone, and androgen receptors, and KISS1 signaling in the brain is implicated in mediating sex steroid feedback loops, especially during the preovulatory GnRH/luteinizing hormone (LH) surge. Kisspeptin has been used to induce egg maturation in women undergoing in vitro fertilization therapy, with subsequent fertilization of the mature eggs, embryo transfer into the uterus, and successful human pregnancy (Jayasena, 2014). There is the potential for routine use of kisspeptin to induce ovulation during fertility treatment cycles. KISS1 has also been shown to play a role in the initiation of puberty. A subpopulation of kisspeptin neurons in the human infundibular nucleus co-express neuropeptides neurokinin B and dynorphin (opioid inhibitor) (Skorupskaite, 2014). These kisspeptin-neurokinin-dynorphin (KNDy) neurons express neurokinin B and dynorphin receptors as well as estrogen and progesterone receptors. KNDy neurons coordinate inputs, including sex steroid feedback, to regulate pulsatile kisspeptin secretion. The interaction of KISS1 neurons with other neurotransmitter systems is currently being studied.

Modulatory Influences on GnRH Pulsatility

The foremost modulatory influence on the frequency and amplitude of GnRH pulses is exerted by the ovarian steroid hormones through their feedback loop actions. In general, estradiol is known to decrease GnRH pulse amplitude, whereas progesterone decreases GnRH pulse frequency (see the discussion presented later for details).

Numerous other studies suggest that the spontaneous activity of the GnRH pulse generator may also be modulated by a variety of additional stimulatory and inhibitory afferent neural signals. Stimulatory inputs to GnRH release may originate from

neurons using the biogenic amine neuroepinephrine (NE), the amino acid glutamate, and the peptide neuropeptide Y (NPY). Inhibitory inputs may come from amino acid gamma amino-butyric acid (GABA), the biogenic amine dopamine (DA), the endogenous opioid β -endorphin, and the neurosecretory peptide corticotropin-releasing hormone (CRH) neurons. These systems may affect the GnRH pulse generator either *tonally* or *conditionally*.

In the first category, we find, for example, NE as a potential tonal stimulator and GABA as a tonal inhibitor of GnRH release. Administration of α -adrenergic blockers has been shown to reduce pulse frequency in animals, in accord with the postulated tonal stimulatory role for NE. The role of GABA as a tonal inhibitor may be more prominent during the prepubertal period, at which time a diminishing inhibitory GABA tone may activate puberty and the resumption of GnRH pulsatile release. Glutamate's role is more uncertain, although it also is suspected in the initiation of pulses at puberty. Dopamine infusions in women are associated with a decrease in circulating LH and prolactin (dopamine is also known as the prolactin-inhibitory neurohormone). The effect on LH is thought to be mediated through GnRH because, in patients with hypothalamic amenorrhea in whom there appears to be an excess of dopaminergic tone, administration of a dopamine blocker may return the LH pulse frequency to normal. It should also be remembered that specific effects of neurotransmitters on GnRH neurons may be altered by the administration of certain drugs, which may interfere with the proper synthesis, binding, storage, or receptor function of these neurotransmitters. Thus upon treatment with such drugs (for example, methyl dopa, reserpine, tricyclic antidepressants such as propranolol, phentolamine, haloperidol, and cyproheptadine, selective serotonin reuptake inhibitors [SSRIs], or serotonin-norepinephrine reuptake inhibitors

[SNRIs]), patients may develop disorders such as oligomenorrhea or galactorrhea, the result of alterations in GnRH secretion or hyperprolactinemia. Other studies also suggest that hypothalamic prostaglandins may also modulate the release of GnRH; for instance, the midcycle surge of LH (see [Menstrual Cycle](#), presented later in the chapter) can be abolished in animals by the administration of aspirin or indomethacin, which block the synthesis of prostaglandins. Clinical studies have also shown that inhibition of prostaglandin at midcycle may disrupt ovulation.

In the second category, other systems may affect the GnRH system only *conditionally*—that is, under specific hormonal or physiologic conditions. One example is the endogenous opioid β -endorphin, which exerts an inhibitory action on GnRH pulsatile activity that depends largely on the endogenous endocrine milieu. This is related to the fact that ovarian hormones control the release of brain β -endorphin within the brain, which is lowest in the absence of estradiol, such as in the ovariectomized nonhuman primate, and highest in the presence of both estradiol and progesterone, such as during the luteal phase of the menstrual cycle. Experimental administration of the opiate antagonist, naloxone, during the luteal phase increases GnRH/LH pulse frequency, significantly suggesting the reversal of an inhibitory action under the endocrine milieu that characterizes the luteal phase. No effect on LH pulsatility follows naloxone injection in postmenopausal or ovariectomized women, unless they are replaced with an estrogen-progesterone therapy. Another example is corticotropin-releasing hormone (CRH), the main neuropeptide controlling the adrenal endocrine axis, which is released in greater amounts during stress. In this condition, increased CRH release negatively affects the GnRH pulse generator, which results in a decrease in GnRH pulse frequency. This action is indirect through the release of β -endorphin and is prevented by the administration of the opiate antagonist naloxone, as demonstrated in studies in nonhuman primates and in patients with hypothalamic amenorrhea, many of whom have elevated levels of cortisol.

Metabolic Influences and GnRH Release

There is good clinical evidence linking energy homeostasis and reproductive function in the human. A functional reproductive system requires an accurate integration of energy balance, and a significant imbalance may lead to reproductive dysfunction and amenorrhea. Nutritional deprivation and abnormal eating habits are known to interfere with the normal reproductive process. Anorexia nervosa is a well-known and extreme example of how alteration in food intake can result in the suppression of the menstrual cycle. Obesity also may contribute to menstrual disorders.

Growing evidence indicates that complex and extensively integrated physiologic mechanisms connect an active reproductive axis to the metabolic state. The brain, and in particular the hypothalamus and the GnRH pulse generator, function as the center for the integrative metabolic response process. The nature of the afferent signals that provide information about energy metabolism to the reproductive axis is presently under intense study, and data have shown possible roles for several energy-related proteins.

One such example is leptin, an anorexigenic protein that is the product of the *ob* gene and that is primarily produced by adipocytes ([Ahima, 2000](#)). Leptin levels are reduced when body

fat stores are decreased by fasting. Besides conveying metabolic information to several parts of the brain through its own receptors, leptin also appears to function as one of the metabolic cues regulating the GnRH pulse generator. High leptin levels are interpreted as conducive to reproduction, and the administration of leptin stimulates the secretion of GnRH and of the gonadotropins, with the effects most pronounced in individuals showing signs of reproductive impairment. Peripheral injections of leptin can prevent the reduction in GnRH/gonadotropins and the disturbances in cyclicity that accompany caloric reduction. *Ob/ob* mice, which are leptin deficient because of a mutated leptin gene, besides exhibiting a pronounced obesity, show a complete failure to display normal estrous cycles because of absent GnRH secretion. The latter can be reversed by leptin administration. Evidence suggests a role for kisspeptin in modulating metabolic leptin signals on the hypothalamus and pituitary ([Skorupskaite, 2014](#)). Forty percent of kisspeptin neurons in the mouse arcuate nucleus express leptin. Leptin-deficient mice show decreased expression of *Kiss1* mRNA. However, leptin administration only partially restores *Kiss1* mRNA levels, indicating that other mediators are involved in inhibiting kisspeptin signaling in leptin deficiency ([Smith, 2006](#)). Another example is the orexigenic peptide, neuropeptide Y (NPY), which is synthesized in the arcuate nucleus. During fasting, expression of *NPY* mRNA increases in this nucleus and intracerebroventricular injection of NPY stimulates food intake. NPY has been shown to affect pulsatile GnRH/LH activity in the nonhuman primate, but this occurs in two apparently contradictory modes, one excitatory and one inhibitory. It was shown in the ovariectomized monkey and rodent that a pulsatile intracerebroventricular infusion of NPY stimulates GnRH release, whereas a continuous infusion clearly decreases the pulsatile electric activity of GnRH neurons as well as pulsatile LH release. In accord with this observation of an inhibitory effect of NPY is that whereas fasting decreases LH secretion in normal mice, fasting mice lacking NPY Y1R have a higher pituitary LH content than wild-type ones. What these data suggest is that although a supportive effect of NPY on the GnRH pulse generator may occur within a limited window of normalcy (i.e., within a normal background of basic and pulsatile NPY release), in physiopathologic situations (i.e., in circumstances mimicking increased endogenous NPY activity such as in undernutrition) an inhibitory effect of NPY on the GnRH pulse generator can be observed. Evidence suggests that kisspeptin neurons can sense and convey information about energy status to GnRH neurons. In rodents, hypothalamic levels of *Kiss1* mRNA are reduced in metabolic conditions, such as undernutrition, uncontrolled diabetes, and immune/inflammatory challenge, which are associated with suppressed gonadotropins. Administration of kisspeptin in rodent models with disrupted metabolism and energy reserves restores gonadotropin secretion, suggesting a potentially important central role of *Kiss1* neurons in the regulation of reproduction by metabolic factors ([Skorupskaite, 2014](#)).

Overall, in regard to the reproductive system, the GnRH pulse generator actually acts as the link that connects the environment, the internal milieu, and the reproductive axis. Its overall activity most probably reflects the summation of simultaneous stimulatory and inhibitory inputs. It is evident that events, disorders, or drug administration may tip the physiologic balance, cause disruption or cessation of GnRH pulse activity, and lead to disruptions of the menstrual cycle and to reproductive disorders such as oligomenorrhea and hypothalamic amenorrhea.

ANTERIOR PITUITARY GLAND AND THE GONADOTROPINS

ANATOMY

The anterior pituitary (also referred to as the **adenohypophysis**) derives from the *Rathke pouch*, a depression in the roof of the developing mouth in front of the buccopharyngeal membrane. It originates at about the third week of life. Origin of the adenohypophysis contrasts with that of the posterior pituitary, the neurohypophysis, which develops as a direct extension of the brain. It should also be noted that whereas the neurohypophysis receives a direct arterial blood supply from the hypophyseal arteries, the only vascularization to the adenohypophysis is through the hypothalamic-hypophyseal portal system (into which GnRH and several other neuropeptides are secreted) (discussed earlier).

The gonadotropes are the specialized cells within the adenohypophysis that produce the **gonadotropins**. Upon stimulation of the gonadotropes by GnRH, two gonadotropins are released into the general circulation and regulate endocrine function in the ovaries and testes.

Prolactin is not a gonadotropin, but it is also secreted by the anterior pituitary gland and has important effects on reproduction function. For example, elevations in prolactin can inhibit GnRH release and result in anovulation and hypoerogenic amenorrhea. This inhibition is thought to be the result of inhibition of kisspeptin-1, which stimulates GnRH release (Bernard, 2015). Prolactin is covered in depth in Chapter 39.

PHYSIOLOGY

GnRH Receptor

Pulses of GnRH released by the GnRH neurons in the arcuate nucleus reach the gonadotropes in the anterior pituitary via the hypophyseal portal circulation. These GnRH pulses then act on GnRH receptors (**GnRH-R**) on the gonadotropes to stimulate both the synthesis and release of both gonadotropins, LH and follicle-stimulating hormone (FSH). Females with GnRH-R mutations typically present with incomplete or absent pubertal development and primary amenorrhea. Although reproductive function is compromised, conception may be successfully obtained following gonadotropin treatment.

On the cell membranes of the gonadotrope, GnRH interacts with high-affinity GnRH receptors. The gene encoding the GnRH-R is located on chromosome 4q13.2-13.3, spanning 18.9 kb. This receptor belongs to a large family of G protein-coupled receptors. These contain seven transmembrane helices connected by six alternating intracellular and extracellular loops, with the amino-terminus located on the extracellular side. In contrast to other protein receptors (see Fig. 4.9, presented later in the chapter), the GnRH-R lacks a carboxy-terminus located on the intracellular site.

Activation of the GnRH Receptor

GnRH activation of the receptor requires the release of constraining intramolecular bonds, which maintain the receptor in an inactive configuration. Once activated, the GnRH receptor stimulates cellular production of specific membrane-associated lipid-like diacylglycerols, which, acting as a second messenger,

activate several cellular proteins. Among these are the enzyme **protein kinase C (PKC)** and **extracellular signal-regulated kinase (ERK)**, a member of the **mitogen-activated protein kinase (MAPK)** cascade. Phosphorylated ERK activates transcription factors, the result being gene transcription of gonadotropin subunits and the synthesis of both gonadotropins.

Binding of GnRH to its receptor also rapidly mobilizes transient intracellular calcium, which triggers a burst of exocytosis to rapidly release LH and FSH. It also provokes a rapid influx of Ca^{++} into the cell from the extracellular pool, which in turn activates calmodulin, a calcium-binding protein, maintaining gonadotropin release. Diacylglycerols amplify the action of Ca^{++} -calmodulin, thereby synergistically enhancing the release of gonadotropins. Administration of a calmodulin antagonist has been shown to decrease GnRH-stimulated gonadotropin release.

Estrogens and the GnRH Receptor

Pulsatile GnRH increases *GnRH-R* gene expression and the number of GnRH-R on the gonadotrope's cell surface. The number of GnRH-R also varies with the hormonal environment, with highest number of receptors expressed when high concentrations of estrogens are present. This leads to an increase in the overall Ca^{2++} response and a significantly amplified gonadotropin response to a GnRH pulse. This action explains the variations in the gonadotropin response to GnRH at various times of the menstrual cycle: GnRH pulses of similar amplitude elicit greater gonadotropin responses during the late follicular phase and luteal phase when estradiol levels are highest, but the responses are lower during the early follicular phase when estradiol levels are lowest (Fig. 4.4).

GnRH Pulse Frequency and Gonadotropin Release

It is also important to note that varying frequencies of the GnRH pulse signal regulate gonadotropin subunit gene transcription differentially. Overall, a low GnRH pulse frequency favors FSH synthesis, whereas a high GnRH pulse frequency favors LH synthesis. This is well demonstrated experimentally where changing a pulsatile infusion from a high- to a low-pulse frequency results in a matter of days in an increase in the FSH:LH ratio (Fig. 4.5). This phenomenon may play a role during the luteal phase of the menstrual cycle and in the changing FSH:LH ratio that occurs during the passage from one menstrual cycle to another (see Luteal Phase, discussed later). It is also reflected in patients known to have a high GnRH pulse frequency, such as in women with polycystic ovary syndrome, in which a high proportion of patients have a characteristically elevated LH:FSH ratio.

GnRH Receptor Desensitization

Gonadotropin release following a GnRH pulse is rapid: within minutes, both FSH and LH are released. It is important to recognize that the pulsatile release mode of GnRH is essential for the maintenance and control of normal gonadotropin secretion.

In contrast to the response to the normal pulsatile mode of GnRH release, sustained exposure of the GnRH-R to constant GnRH concentrations drastically reduces the response of the gonadotrope to subsequent stimulation with GnRH. This phenomenon is referred to as *homologous desensitization* or **downregulation** of the receptor, which denotes a reduction

Figure 4.4 GnRH pulses of similar amplitude elicit greater overall gonadotropin responses during the late follicular phase and luteal phase when estradiol levels are highest, but they elicit lower responses during the early follicular phase when estradiol levels are lowest. Note also a greater early response in the late follicular phase, denoting greater LH reserves under the effect of estradiol. (From Hoff JD, Lasley BL, Wang CF, Yen SSC. The two pools of pituitary gonadotropins: regulation during the menstrual cycle. *J Clin Endocrinol Metab.* 1977;44:302.)

Figure 4.5 Increase in the FSH:LH ratio following a decrease in the GnRH pulse frequency (from 1 pulse/hour; *left and right panels*) to 1 pulse/3 hour (*center panel*). Experiment was performed in a monkey lacking endogenous GnRH and infused with GnRH. (From Wildt L, Hausler A, Marshall G, et al. Frequency and amplitude of gonadotropin-releasing hormone stimulation and gonadotropin secretion in the rhesus monkey. *Endocrinology.* 1981;109:376.)

in the ability of GnRH to elicit gonadotropin release after prior continuous exposure to GnRH. This phenomenon is well illustrated in a classic experiment performed by Knobil and collaborators in ovariectomized monkeys lacking endogenous GnRH secretion following lesion of the arcuate nucleus (Fig. 4.6). As illustrated, 6-minute duration pulses administered once an hour restored normal LH levels in these animals. In contrast, when a continuous mode of GnRH infusion was

Figure 4.6 GnRH release in a pulsatile mode is required for a normal pituitary gonadotropin response. An experiment was performed in a monkey lacking endogenous GnRH and infused with hourly pulses of GnRH (*left and right portions*) or with a continuous GnRH infusion (*center portion*). (From Belchetz PE, Plant TM, Nakai Y, et al. Hypophyseal responses to continuous and intermittent delivery of hypothalamic gonadotropin-releasing hormone. *Science.* 1978;202:631-633.)

substituted to the pulsatile mode, there occurs a profound inhibition of LH concentrations. This reflects desensitization of the GnRH receptor. This phenomenon, which takes a few days to be established, may reflect a loss of active cell surface receptors and be maintained by a loss of functional Ca^{++} channels. However, the mechanism of desensitization is still under investigation, and additional intermediary changes remain to be characterized.

GnRH Analogues and the GnRH Receptor

The GnRH half-life in the peripheral circulation is very short as peptidases rapidly degrade naturally occurring GnRH by cleaving the decapeptide molecule at the Gly⁶ to Leu⁷ and at the Pro⁹ to Gly¹⁰ bonds. However, by substituting amino acid 6 in the natural GnRH molecule with a d-amino or replacing amino acid 10 with a N-ethylamide (Na-CH₂-CH₃) or Aza-Gly (NHNHCO) moiety, gonadotropin-releasing hormone analogues (GnRH analogues) were synthesized and shown to have acquired a greater resistance to enzymatic proteolysis and hence a longer half-life (hours versus 2 to 4 minutes). Following administration of these **GnRH agonists**, there is an initial stimulation of gonadotropin release (flare), followed by the process of desensitization blocking the releasing effect on the gonadotropins. This observation has led to the clinical application of the functional desensitization property of **GnRH analogues (agonists)** having been used to induce a “medical castration” state by shutting down the pituitary-gonadal axis in a variety of clinical conditions. In contrast to GnRH agonists, **GnRH antagonists** act by competing with GnRH for receptor sites and thereby never activating a stimulatory signal. Many of these result from the substitution of amino acids at the 2 or 3 position. Thus GnRH antagonists have the advantage over the GnRH agonists of a rapidly decreasing LH and FSH release, without the flare. Clinical applications for both GnRH agonists and antagonists are listed in [Box 4.1](#).

Box 4.1 Clinical Applications of GnRH and Its Agonists

Activation of pituitary-gonadal function (GnRH)
 Delayed puberty
 Cryptorchidism
 Functional hypothalamic amenorrhea
 Hypogonadotropic hypogonadism (Kallmann syndrome)
 Pituitary-gonadal inhibition (agonists)
 Precocious puberty
 Hormone-dependent tumors
 Endometriosis
 Uterine leiomyoma
 Breast cancer
 Prostatic cancer
 Suppression of ovarian function in polycystic ovary syndrome
 and in vitro fertilization
 Premenstrual syndrome
 Abnormal uterine bleeding including clotting disorders
 Contraception
 Suppression of spermatogenesis
 Ovulation inhibition

Gonadotropins

There are two distinct gonadotropins: **luteinizing hormone (LH)** and **follicle-stimulating hormone (FSH)**. (A third gonadotropin, chorionic gonadotropin [hCG], is produced in the primate by the placenta.)

Structure

LH and FSH are glycoproteins of high molecular weight. They are heterodimers, containing two monomeric units (**subunits**). Both LH and FSH have a similar α -subunit, the structure (92 amino acids) of which is highly conserved. (The same α -subunit is also shared with hCG and thyroid-stimulating hormone [TSH].) However, β -subunits have different structures consisting of different amino acids and carbohydrates. These LH and FSH subunits are each encoded by a separate gene. (The hCG subunits are also different and encoded by six genes.)

The α - and β -subunits are joined by disulfide bonds, which are essential to maintain biologic activity. Reducing agents break the disulfides bounds and reduce or remove the biologic activity of the gonadotropin. Highly purified free subunits have little if any biologic activity relative to that of the intact hormone. However, it is the β -subunit that confers the specific biologic activity of each hormone. For instance, LH has a β -subunit of 121 amino acids, a structure that is responsible for the specificity of the interaction with the LH receptor. LH and FSH also differ in the composition of their sugar moieties. The different composition of several different oligosaccharides affects bioactivity and speed of degradation of each gonadotropin. For example, the biologic half-life of LH is 20 minutes, much shorter than that of FSH (3 to 4 hours). (The half-life of hCG is 24 hours.)

Although both gonadotropins act synergistically in the female, FSH acts primarily on the granulosa cells of the ovarian follicles to stimulate follicular growth, whereas LH acts primarily on the theca cells of these follicles as well as on the luteal cells to stimulate ovarian steroid hormone production (see the following discussion).

OVARIES**ANATOMY****Ovarian Gametogenesis (Oogenesis)**

Oogenesis begins in fetal life when the *primordial* germ cells, or **oogonia**, migrate to the genital ridge. The number of oogonia increases dramatically from about 600,000 by the second month of fetal life to a maximum of about 7 million by the sixth to seventh month. The oogonia then begin meiotic division (they are now referred to as **primary oocytes**) until they reach the diplotene stage of the prophase (the germinal vesicular stage), in which they will remain until stimulation by gonadotropins in adulthood during the menstrual cycle (discussed later). However, by a process of apoptosis and atresia of the enveloping follicle, which starts prenatally and persists throughout childhood, the number of primary oocytes declines drastically from about 2 to 4 million at birth to become 90% depleted by puberty. Further depletion of the pool occurs throughout adulthood, so by age 37, only about 25,000 and by age 50 only about 1000 oocytes remain.

The traditional dogma that mammals have fixed, non-renewable oocyte stores established prior to birth has been challenged. Some studies suggest that adult mammalian ovaries possess pluripotent germline stem cells (GSCs) that can differentiate into oocytes, as well as other cell types. Non-mammalian organisms, such as *Drosophila*, do possess ovarian GSCs. Whereas the existence of spermatogonial cells in the adult human testis that give rise to pluripotent GSCs is well accepted, there is considerable evidence that disputes the existence of mammalian adult ovarian GSCs. At this point, there is not sufficient evidence to prove that mammalian oogenesis occurs after birth (Hanna, 2014).

Ovarian Folliculogenesis

The primary oocyte is surrounded by a single layer of granulosa cells in a unit referred to as the **primordial follicle**. Even in the absence of stimulation by gonadotropins, some primordial follicles will develop into **primary** (or preantral) **follicles**, at which stage multiple layers of granulosa cells surround them. Development of follicles to this stage appears to be relatively independent of pituitary control but is probably influenced by intraovarian, nonsteroidal processes that remain to be understood. Development to this stage occurs during the nonovulatory stages of childhood, pregnancy, oral contraceptive use, as well as during ovulatory cycles.

With formation of an antrum (cavity), the follicle, now referred to as a **secondary** or **antral follicle**, enters the final stages of folliculogenesis characterized by the transition from intraovarian regulation to a major control by the hypothalamic-pituitary unit. This requires the presence of the characteristic increase in FSH that occurs in the early menstrual cycle (see **Menstrual Cycle**, presented later).

The development process from primary follicle (preantral follicle) to secondary or antral follicle, and to a mature preovulatory follicle, the latter during the follicular phase of the cycle, takes about 1 year to complete (Fig. 4.7). Only about 400 follicles complete this process, whereas the majority of follicles undergo programmed cell death. Although little is known about factors controlling growth during the earlier stages, more is known

Figure 4.7 Life history of ovarian follicles: endowment, maintenance, initial recruitment, maturation, atresia or cyclic recruitment, ovulation, and exhaustion. A fixed number of primordial follicles are endowed during early life, and most of them are maintained in a resting state. Growth of some of these dormant follicles is initiated before and throughout reproductive life (initial recruitment). Follicles develop through primordial, primary, and secondary stages before acquiring an antral cavity. At the antral stage, most follicles undergo atresia; however, under the optimal gonadotropin stimulation that occurs after puberty, a few of them are rescued (cyclic recruitment) to reach the preovulatory stage. Eventually, depletion of the pool of resting follicles leads to ovarian follicle exhaustion and senescence. (From McGee EA, Hsueh AJW. Initial and cyclic recruitment of ovarian follicles. *Endocrine Rev.* 2000;21:200-214.)

about the final stage of folliculogenesis during the follicular phase of the menstrual cycle (discussed later).

PHYSIOLOGY

Gonadotropin Receptors

Although the two gonadotropins act synergistically in the female, FSH acts primarily on the granulosa cells of the maturing antral follicle to stimulate follicular growth, whereas LH acts primarily on the theca cells of these follicles to induce steroidogenesis. Binding to and activation of their respective receptors at the cell surface membrane represent the necessary first step in the hormonal function of both FSH and LH.

Gonadotropin receptors are transmembrane G protein-coupled receptors, which possess seven membrane-spanning domains (Fig. 4.8). It is believed that the receptor molecule exists in a conformational equilibrium between active and inactive states, which is shifted by binding of LH or FSH. Upon binding to the gonadotropin, the receptor shifts conformation and mechanically activates the G protein, which detaches from the receptor and activates cyclic adenosine monophosphate (AMP) dependent protein kinases. These protein kinases are present as tetramers with two regulatory units and two catalytic units. Upon binding of cyclic AMP (cAMP) to the regulatory units, the catalytic units are released and initiate the phosphorylation of proteins, which bind to

Figure 4.8 The seven transmembrane α -helix structure of a G protein-coupled receptor, such as that for LH or hCG. (The structure for the GnRH receptor is similar, except that the GnRH-R lacks a carboxy terminus on the intracellular site; see the preceding text.) (From trans-membrane helix of G-protein coupled FSH receptor; from Wikipedia.)

DNA in the cell nucleus, resulting in the activation of genes and leading to the physiologic action (Fig. 4.9).

Ovarian Steroids: Biosynthesis

One primary function of the ovary is the secretion of ovarian steroids, which occurs following binding of both FSH and LH to their respective receptors. The ovary secretes three primary hormones: **estradiol** (the primary estrogen), **progesterone**, and

Figure 4.9 Upon binding to their receptor, the gonadotropins activate cyclic AMP-dependent protein kinases (see text). (Modified from Speroff L, Friz M, eds. *Clinical Gynecologic Endocrinology and Infertility*. New York: Lippincott Williams & Wilkins; 2005:71-72.)

androstenedione. These hormones are the chief secretory products of the maturing follicle, the corpus luteum, and the ovarian stroma. The ovary also secretes, in varying amounts, estrone (a less potent estrogen), pregnenolone, 17-hydroxyprogesterone, testosterone, and dehydroepiandrosterone (DHEA). Because of the lack of the appropriate enzymes, the ovary does not synthesize mineralo- or glucocorticoids.

Steroids are lipids that have a basic chemical structure or nucleus (Fig. 4.10). The nucleus consists of three six-carbon rings (A, B, and C) joined to a five-carbon atom (D) ring. The carbon atoms are numbered as shown in Figure 4.10. Functional groups above the plane of the molecule are preceded by the β symbol and shown in the structural formula by a solid line, whereas those below the plane are indicated by an α symbol and a dotted line.

Figure 4.10 Phenanthrene (top left). Cyclopentanoperhydrophenanthrene nucleus (top right), which incorporates the three six-carbon rings of the phenanthrene ring system (A, B, and C) and a five-carbon ring (D), which resembles cyclopentane. Cholesterol (bottom) is the common biosynthetic precursor of steroid hormones. Numbers 1 to 27 indicate the conventional numbering system of the carbon atoms in steroids. (From Stanczyk FZ. Steroid hormones. In: Lobo RA, Mishell DR, Paulson RJ, Shoupe D, eds. *Mishell's Textbook of Infertility, Contraception and Reproductive Endocrinology*. 4th ed. Malden, MA: Blackwell Science; 1997.)

line. All steroids, whether secreted by the ovary, testis, or adrenal, are derived from **acetate** (a two-carbon compound), which, in a series of complex reactions, is transformed into **cholesterol** (a 27-carbon steroid) (Fig. 4.11.)

The sex steroids (as well as the corticosteroids) are then derived from a stepwise transformation of the cholesterol molecule into steroids with 21 carbon atoms (the corticosteroids, pregnenolone, 17-hydroxy pregnenolone, progesterone, and 17-hydroxyprogesterone), 19 carbon atoms (androgens such as DHEA, androstenedione, and testosterone), and 18 carbon atoms (estrogens such as estradiol and estrone). In the first step, cholesterol is transferred from the outer mitochondrial membrane to the inner membrane, where cytochrome P450 enzyme is located. The latter will split off the cholesterol side chain, which is the first enzymatic step in steroid biosynthesis. Being lipophilic, cholesterol is unable to cross the aqueous phase between these two membranes on its own. It is now believed that steroidogenic acute regulatory protein (StAR) assists in that role. The next steps in steroid biosynthesis require participation of a variety of enzymes, most of which are part of the cytochrome P450 superfamily of heme-based enzymes. First is the transformation of cholesterol into pregnenolone by hydroxylation of C-20 and C-22 and cleavage between these two atoms, reducing the C-27 cholesterol to the C-21 compound pregnenolone. At this point, ovarian steroid biosynthesis proceeds along two major pathways, controlled by specific enzymes at each step: (1) the Δ^5 pathway through 17-hydroxypregnenolone and DHEA to Δ^5 androstenediol and (2) the Δ^4 pathway via progesterone and 17-hydroxyprogesterone to the androgens, androstenedione and testosterone.

Aromatase Enzyme

Androgens are converted to the estrogens estrone or estradiol by the enzyme **aromatase**, through the loss of the C-19 methyl

group and the transformation of the A-ring to an aromatic state (hence the enzyme's name) through oxidation and subsequent elimination of a methyl group. The aromatic (or phenolic) ring is characteristic of the estrogens (Fig. 4.12).

Aromatase is a complex enzyme comprising two proteins. The first, P450arom (also a member of the cytochrome P450 superfamily of genes), catalyzes the series of reactions required for the formation of the phenolic A ring. The second is NADPH-cytochrome P450 reductase, a ubiquitous protein required for transferring reducing equivalents from NADPH to any microsomal form of cytochrome P450 with which it comes into contact. (All microsomal P450 enzymes require this reductase for catalysis. Disruption of this reductase has lethal consequences, as shown in knockout mice.)

The aromatase enzyme is found in many tissues besides the gonads, such as the endometrium, brain, placenta, bone, skin, and others. It is also particularly relevant to note that in humans, in contrast to other species, estrogens are also synthesized in adipose tissue, which in the postmenopausal woman becomes the major site of estrogen biosynthesis. The tissue-specific expression of the *CYP19* aromatase gene is regulated by the use of different promoters. For instance, expression in the ovary uses a promoter element proximal to the start of translation, whereas expression in adipose tissue uses distal elements. Overall, the C_{18} estrogen produced in different tissue sites of biosynthesis is rather specific and dependent on the nature of the C_{19} steroid presented to the aromatase enzyme: in the ovary, the main androgen source is ovarian testosterone and thus the main estrogen product from the ovary is estradiol, whereas in adipose tissue the main androgen source is circulating androstenedione (produced by the adrenals) and hence the principal estrogen produced is estrone. (The greater the amount of fat present, the greater the amount of androstenedione that is converted to estrone via aromatase.)

Mutation of *CYP19* leads to the **aromatase deficiency syndrome**, which is inherited in an autosomal recessive way (Morishima, 1995). In these female patients, accumulation of androgens during pregnancy may lead to virilization at birth. Individuals of both sexes have abnormal pubertal maturation and are tall because of the lack of estrogen to affect epiphyseal closure. Female patients have primary amenorrhea. Aromatase inhibition evidently leads to profound hypoestrogenism. Aromatase inhibitors have become useful in the management of patients with estrogen receptor positive tumors—for example, in breast cancer.

Interconversion between androstenedione and testosterone and estrone and estradiol can occur outside the ovaries. Oxidation of the latter to the former reduces biologic potency because both androstenedione and estrone have weaker biologic activity. Estrone is also converted to estrone sulfate, which has a longer half-life and is the largest component of the pool of circulating estrogens. Estrone sulfate is not biologically active; however, sulfatases in various tissues (such as breast and endometrium) can readily convert it to estrone, which in turn can be converted to the more biologically active estradiol. Steroids are in general insoluble in water but dissolve readily in organic solvents. In contrast, steroids that have a sulfate or glucuronide group attached (conjugated steroids)—such as, for example, estrone sulfate, dehydroepiandrosterone sulfate (DHEAS), or pregnenediol glucuronide—are water soluble.

Ovarian Steroids: Blood Transport and Metabolism

After release into the circulation, sex steroids bind to a steroid-specific transport protein, **sex hormone-binding globulin (SHBG)** (a β -globulin synthesized by the liver), to the non-steroid-specific albumin, or circulate in an unbound or "free" form. (There is a separate steroid-specific protein, corticosteroid-binding protein [CBG; transcortin], which binds primarily adrenal steroids, and to a lesser degree progesterone.) Both SHBG and CBG have a high affinity (by definition) but low capacity for steroids. Albumin, in contrast, has a high capacity but binds with low affinity; thus steroids can readily dissociate from its binding and enter target cells.

The free and loosely albumin-bound steroids are believed to be the most biologically important fractions because the steroid is free to diffuse or be actively transported through the capillary wall and bind to its receptor. (There is also evidence, however, that uptake of protein-bound hormone may also play a role.) SHBG binds primarily dihydrotestosterone, testosterone, and estradiol, in order of decreasing affinity. Thus in premenopausal women, 65% of testosterone is bound to SHBG, 30% to albumin, and 5% is free, whereas 60% of estradiol is bound to SHBG, 38% to albumin, and 2% to 3% is free. The metabolic clearance rate of sex steroids is inversely related to their affinity to SHBG. It is thus important to remember that the level of SHBG, and therefore the level of free active hormone, may be influenced by various clinical conditions. For instance, circulating levels of SHBG are increased by estrogens (oral contraceptives, pregnancy) and by thyroid hormone (hyperthyroidism) and are lowered by androgens and in hypothyroidism.

The major sites of steroid metabolism are the liver and kidney. Steroids are mainly oxidized by cytochrome P450 oxidase enzymes, through reactions that introduce oxygen into the steroid ring, allowing a breakdown by other enzymes to form bile acids as final products. These bile acids can then be eliminated through secretion from the liver. In another process, which involves conjugation, the steroids are transformed from

lipophilic compounds, which are only sparingly soluble in water, into metabolites that are readily water soluble and can be eliminated in urine. Examples are estradiol-17 glucuronide, estrone sulfate, and pregnanediol-3-glucuronide (the major urinary metabolite of progesterone).

Prostaglandins

Prostaglandins (a subclass of eicosanoids and prostanoids) are in general mediators of inflammatory and anaphylactic reactions. Their most abundant precursor is arachidonic acid, itself formed from linoleic acid supplied in the diet. Their biosynthesis can be inhibited by several groups of compounds, including the nonsteroidal anti-inflammatory drugs (NSAIDs) type 1 (aspirin and indomethacin), which inhibit endoperoxide formation (the immediate precursor of eicosanoids), and type 2 (phenylbutazone), which inhibits the action of endoperoxidase isomerase and reductase. Corticosteroids also can inhibit prostaglandins synthesis.

In contrast to steroid hormones, which are stored and act at targets distant from their source, prostaglandins are produced intracellularly shortly before they are released and generally act locally. Specific prostanoids can have variable effects on different tissues, as well as variable effects on the same organ, even when released at the same concentration, hence the difficulty of studying their actions. One important effect is their ability to modulate the responses of endogenous stimulators and inhibitors, such as ovarian stimulation by LH, which is modulated by prostaglandin F 2α (PGF 2α), which in turn regulates ovarian receptor availability.

Prostaglandins play an important role in ovarian physiology. They help control early follicular growth by increasing blood supply to certain follicles and inducing FSH receptors in granulosa cells of preovulatory follicles. Both PGF 2α and PGE 2 are concentrated in follicular fluid of preovulatory follicles and may assist in the process of follicular rupture by facilitating proteolytic enzyme activity in the follicular walls. Many prostanoids are produced in the endometrium. Concentrations of PGE 2 and PGF 2α increase progressively from the proliferative to the secretory phase of the cycle, with highest levels at menstruation. These prostaglandins may help regulate myometrial contractility and may also play a role in regulating the process of menstruation.

COMMUNICATION WITHIN THE HYPOTHALAMIC-PITUITARY-OVARIAN ENDOCRINE AXIS

STEROID RECEPTORS

Gonadal steroids are integrated into every aspect of reproduction, and disruption of their signaling pathways, which obviously require initial binding to their receptors, leads to reduced fecundity and aberrations in multiple organ system. For the sex steroid feedback loops (discussed later) to be active, there must be steroid receptors in the appropriate regions of the hypothalamus and pituitary gland to respond to the ovarian signals.

As opposed to peptide or protein hormone receptors that reside on the cell membrane (discussed earlier), steroid receptors reside in the nucleus or in the cytoplasm, in between which they may shuttle in the absence of hormone (Fig. 4.13). The

Figure 4.13 The steroid receptor activation process. As opposed to protein hormones receptors, which reside on the cell membrane, steroid receptors reside in the nucleus or in the cytoplasm. See the text for details.

cytoplasmic receptor is sequestered (hence in an “inactive” state) within a multiprotein inhibitory complex that includes heat shock proteins. Hormone binding leads to dissociation from the heat shock proteins. The lipophilic steroids freely diffuse across the nuclear membrane to bind to their cognate receptor. This binding leads to conformational changes that transform the receptor into an “activated” state, which allows it to bind to a **hormone responsive element (HRE)**, the specific DNA-binding site to which steroid receptors bind conferring hormone sensitivity within target gene promoters. Nuclear receptors can inhibit or enhance transcription by recruiting an array of co-activator or co-repressor proteins to the transcription complex (Fig. 4.14) (Ellmann, 2009). mRNA is then generated from a segment of nuclear DNA in the process of transcription. Transcription is the most important process regulated by steroid hormones. All genes share a common basic design composed of a structural region in which the DNA encodes the specific amino acids of the protein and a regulatory region that interacts with various proteins to control the rate of transcription. Co-activators and co-repressors modify the chromatin state and recruit/activate or hinder the basal transcriptional machinery. Members of the sarcoma (SRC) family of co-activators, including SRC-1, SRC-2, and SRC-3, and the nuclear receptor co-repressor

(NCoR1), interact with both the estrogen and progesterone receptors (see Fig. 4.14) (Ellmann, 2009; Horwitz, 1996). The mRNA migrates into the cytoplasm, where it translates information to ribosomes to synthesize the required new protein.

Several alternative receptor mechanisms besides the classic one outlined previously appear to exist. Some are plasma membrane steroid signaling events that are mediated through various kinases and second messengers including cAMP. These are independent of nuclear interactions and do not involve direct steroid activation of gene transcription (nongenomic). As opposed to the longer time required by the genomic pathway (hours to days), these alternate mechanisms may be responsible for some of the rapid effects of steroids—for instance, as activated by the negative steroid feedback loop (discussed later), which occurs within minutes.

Members of the steroid receptor superfamily share amino acid homology and a common structure. They contain key structural elements that enable them to bind to their respective ligands with high affinity and specificity and to recognize and bind to discrete response elements within the DNA sequence of target genes with high affinity and specificity. For instance, estrogen receptors will bind natural and synthetic estrogens, but not androgens or progestins. The affinity of a receptor for a steroid also correlates with

Figure 4.14 A connections map for the human estrogen receptor (ER). The ER interacts with a large number of proteins that can either positively or negatively regulate target gene transcription. ER α cofactors interact with different target proteins linking the receptor to other signal transduction pathways. Some of the key connections that positively (+) or negatively (-) regulate ER α transcriptional activity are shown. (From McDonnell DP, Norris JD. Connections and regulation of the human estrogen receptor. *Science*. 2002; 296:1642-1644.)

steroid potency; for example, the estrogen receptor has a greater affinity for estradiol than for estrone and estriol, which are much less potent than estradiol. Overall, the magnitude of the signal to the cell and of the cell response to the steroid depends on the concentration of the hormone and of the receptors, as well as on the affinity of the receptor to the hormone.

In the human, there are actually two estrogen receptors, ER- α and ER- β , which are distinct receptor forms encoded by separate genes. There are also two forms of the progesterone receptor, but these are isoforms (differing only by minor structural differences), which are encoded by the same gene.

OVARIAN-HYPOTHALAMIC-PITUITARY FEEDBACK LOOPS

FSH and LH act on the ovaries to induce morphologic changes and ovarian steroid secretion. Morphologic processes include folliculogenesis (i.e., the cyclic recruitment of a pool of follicles to produce a mature follicle ready for ovulation) and the formation of a corpus luteum. These processes occur in sequence, conferring a monthly rhythm to the reproductive cycle. Granulosa and theca cells within the follicle and luteal cells respond to LH by synthesizing and releasing ovarian steroids, mainly estradiol-17 β and progesterone. The type and amount of hormone released depend on the status of the follicle and the corpus luteum (see [Menstrual Cycle](#), presented later).

Figure 4.15 The rapidly acting negative feedback loop of steroids on GnRH and both gonadotropins release is supplemented by a slower-acting negative feedback loop by the inhibins. (From Hylka VW, di Zerega GS. Reproductive hormones and their mechanisms of action. In: Mishell DR Jr, Davajan V, Lobo RA, eds. *Infertility, Contraception and Reproductive Endocrinology*. 3rd ed. Cambridge, MA: Blackwell Scientific; 1991.)

Feedback communication between the ovaries and the hypothalamic-pituitary unit is an essential component to the physiology of the reproductive cycle. It is important for the brain and pituitary gland to modulate their secretion in response to the minute-to-minute activity status of the ovary. Through their receptors, both in various areas of the hypothalamus and in the anterior pituitary gland, the two ovarian steroids, estradiol and progesterone, play a major role in these feedback communications. More recent evidence shows that several nonsteroidal compounds are also involved in these feedbacks.

Negative Steroid Feedback Loop

As in other endocrine systems, the major ovarian to brain/pituitary feedback loop is inhibitory (the **negative feedback loop**), whereby the steroid secreted by the target organ (the ovary) regulates the hypothalamic-hypophyseal unit to adjust GnRH and gonadotropin secretion appropriately (Fig. 4.15).

Estradiol-17 β is a potent physiologic inhibitor of GnRH and of gonadotropin secretion. The threshold for the negative feedback action of estradiol is such that even small increases in the levels of the hormone induce a decrease in gonadotropins. Levels of LH and FSH during the follicular phase vary in accord with the changes in estradiol concentrations that accompany maturation of the follicle. Thus as circulating estradiol levels increase during the follicular phase, gonadotropin concentrations decrease. In postmenopausal women or women who have undergone ovariectomy or have aromatase enzyme deficiency, all of whom lack estradiol secretion, sustained increases in LH and FSH release occur because of the absence of an active negative feedback loop. In these conditions, administration of physiologic doses of estradiol results in a rapid and sustained decrease in LH and FSH to levels equivalent to those seen during the

menstrual cycle. The estradiol negative feedback loop acts to decrease LH secretion rapidly, mainly by controlling the *amplitude* of each LH pulse. Most evidence suggests that this action is secondary to inhibitory effects on the GnRH pulse, most probably relayed by estrogen-receptive kisspeptin and possibly GABA neurons. Effects on the pituitary gonadotrope, whereby estradiol decreases the gonadotropin response to GnRH, may also take place.

Progesterone, at high concentrations such as those observed during the luteal phase of the cycle, also exerts an inhibitory effect on gonadotropin secretion. In contrast to estradiol, progesterone affects mainly the GnRH pulse generator by slowing the frequency of pulses. This effect is responsible for the significant decrease in LH pulse frequency observed during the luteal phase of the cycle, when high levels of progesterone are present, and which becomes more pronounced as the luteal phase progresses (discussed later).

There is good evidence that the slowing action of progesterone on GnRH-LH pulse frequency is mediated by central β -endorphin. Indeed, brain levels of this opioid peptide, as measured in hypophyseal portal blood in the nonhuman primate, are elevated during the luteal phase (Fig. 4.16, A). Furthermore, naloxone administration (an opiate antagonist) in women during the luteal phase results in a significant acceleration in pulse frequency (see Fig. 4.16, B).

In view of these estradiol and progesterone inhibitory feedback loops, it is not surprising that the characteristics of pulsatile LH secretion vary greatly with the stage of the menstrual cycle. During the estrogenic stage or follicular phase, pulses of high frequency but of low amplitude are seen, whereas during the progesterone stage or luteal phase, there is a progressive reduction in the frequency of the LH pulse, with pulse intervals reaching 200

minutes or more by the end of the luteal phase. This decreased pulse frequency is accompanied by a significant increase in pulse amplitude.

Positive Estradiol Feedback Loop

At higher physiologic concentrations, estradiol can also exert a separate stimulatory effect (**positive feedback loop**) on gonadotropin secretion. This positive feedback is dependent on rapidly rising estradiol levels, in combination with a small but significant progesterone rise, both produced by the mature dominant follicle and responsible for the generation of the pre-ovulatory LH and FSH surge. The positive feedback loop is observed in many species: it serves as the critical signal to the hypothalamic-pituitary axis that the dominant follicle is ready to ovulate. In most species, a GnRH surge precedes the LH surge, suggesting that the positive feedback loop acts centrally. However, there is also ample evidence that high levels of estradiol can increase GnRH pituitary receptors and augment the pituitary response to GnRH, suggesting effects at the pituitary site as well.

Experimentally, late follicular phase estradiol levels infused during the early follicular phase are able to activate the positive feedback loop and release an LH surge, however inappropriate and untimely, because no mature follicle is present at the time (Fig. 4.17).

Ovarian Peptides Feedback Loops

In addition to the negative steroid feedback loop, there is also evidence that nonsteroid ovarian factors exert negative feedback effects on the anterior pituitary. Such are the **inhibins**, which are a family of glycoproteins that consist of a dimer with two dissimilar α and β subunits. The two subunits are coded by different

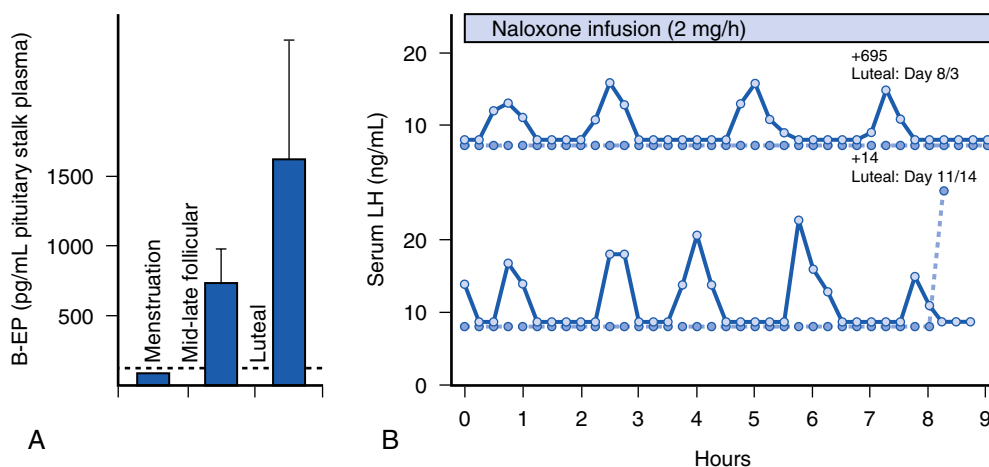

Figure 4.16 The endogenous opiates and the menstrual cycle. **A**, Changes in hypothalamic β -endorphin activity (as determined by its secretion into the pituitary stalk portal vasculature) during the menstrual cycle in the nonhuman primate. In the presence of low ovarian steroids, such as at menstruation, endorphin levels are lowest. They are highest in the presence of progesterone during the luteal phase. **B**, Role of β -endorphin in modulating the negative feedback action of progesterone during the luteal phase; note the dramatic increase in LH pulse frequency after endogenous opiate antagonism by naloxone (dark circles) compared with controls receiving saline (light circles). (**A**, From Van Vugt DA, Lam NY, Ferin M. Reduced frequency of pulsatile luteinizing hormone secretion in the luteal phase of the rhesus monkey: Involvement of endogenous opiates. *Endocrinology*. 1984;115:1095. **B**, From Ferin M, Van Vugt D, Wardlaw S. The hypothalamic control of the menstrual cycle and the role of endogenous opioid peptides. *Rec Prog Horm Res*. 1984;40:441.)

genes. Two forms of the β subunit have been identified, and thus inhibin can exist as α - β A (**inhibin A**) and as α - β B (**inhibin B**) (Fig. 4.18), both of which are detected in serum in women during the reproductive years. The ovaries are the only source of circulating dimeric inhibins.

The inhibins are characterized by their preferential inhibition of FSH over LH through their own negative feedback loop (see Fig. 4.15). This negative feedback loop, however, functions at a significantly slower rate (hours) than that of the steroid negative feedback loop (which is activated within minutes) and is directed mainly at the pituitary gland. It is believed that the decline in FSH after its peak in the early follicular phase of the normal cycle results from a negative feedback action of inhibin B at the pituitary level. At menopause or in premature ovarian failure, data show a decreased secretion of inhibin with reproductive aging, suggesting that inhibin B negative feedback may be an important factor controlling the early monotropic increase

in FSH with aging (reflecting the decreasing number of small antral follicles recruited in each cycle and the consequent insufficient inhibin B production).

The circulating patterns of inhibin A and B during the menstrual cycle are different: plasma concentrations of inhibin B rise rapidly on the day after the intercycle FSH rise (discussed later), remain elevated for a few days, then fall progressively during the remainder of the follicular phase. After a short-lived peak following the ovulatory gonadotropin surge, inhibin B falls to a low concentration during the luteal phase. In contrast, inhibin A concentrations rise only in the later part of the follicular phase and are maximal during the midluteal phase (Fig. 4.19). These different patterns of circulating inhibin B and inhibin A during the human menstrual cycle suggest different physiologic roles (discussed later).

Other dimers of the β subunit have also been described, such as **activin A** (A - β / A - β), which in contrast to the inhibins stimulate FSH release from the pituitary (see Fig. 4.18). This effect is probably not significant because of the irreversible binding of activin to follistatin, which neutralizes activin's bioactivity.

MENSTRUAL CYCLE

The menstrual or ovulatory cycle involves a remarkable coordination of morphologic changes and hormonal secretion occurring not only at several levels of the hypothalamic-pituitary-ovarian axis but also in organs outside of this main axis, such as the uterus and the cervix, and expressed in an orderly sequence of events. The initial stimulus from the brain under the form of GnRH pulses is crucial to proper gonadotropin responses, which in turn instigate folliculogenesis, ovulation, and the formation of the corpus luteum. Essential to the coordination of these events is the communication between the ovaries and the hypothalamic-pituitary unit through the hormonal feedbacks, which provide continuous information of the ovarian status to the brain, which in turn responds with the proper pattern of GnRH pulses and of gonadotropin release. Humans are spontaneous ovulators (as opposed to light or seasonally related) in that the gonadotropin surge, the initiator of ovulation, is triggered by the endogenous changes in estradiol that accompany the maturation of the follicle.

This sequence of events is such that the reproductive process in the human occurs in a cyclic process at about monthly intervals. The primate menstrual cycle is divided into two phases: the follicular phase followed by the luteal phase. These are separated by the ovulatory period. The mean duration of the menstrual cycle is 28 ± 7 days. The length of the follicular phase is more variable, whereas the life span of the corpus luteum is about 14 days. In many women, the length of the follicular phase usually decreases from about 14 days to about 10 days in women over 40 years old. However, menstrual cycle length also varies in an individual woman: it is most variable in the 2 years following menarche and preceding menopause, times of life during which anovulatory cycles are most frequent. The mean age of menarche (the first menstruation) occurs around age 12, whereas menopause (the end of the reproductive phase) usually occurs between ages 45 and 55. Endocrine changes during the menstrual cycle are illustrated in Figure 4.19.

Figure 4.17 GnRH and LH responses to a 3.5-hour estradiol infusion mimicking late follicular phase estradiol levels. After a period of suppression (caused by the rapid estradiol negative feedback), note the large increase in both GnRH and LH (caused by the positive estradiol feedback). (From Xia L, van Vugt D, Alston EJ, Luckhaus J, Ferin M. A surge of gonadotropin-releasing hormone accompanies the estradiol-induced gonadotropin surge in the rhesus monkey. *Endocrinology*. 1992;131:2812-2820.)

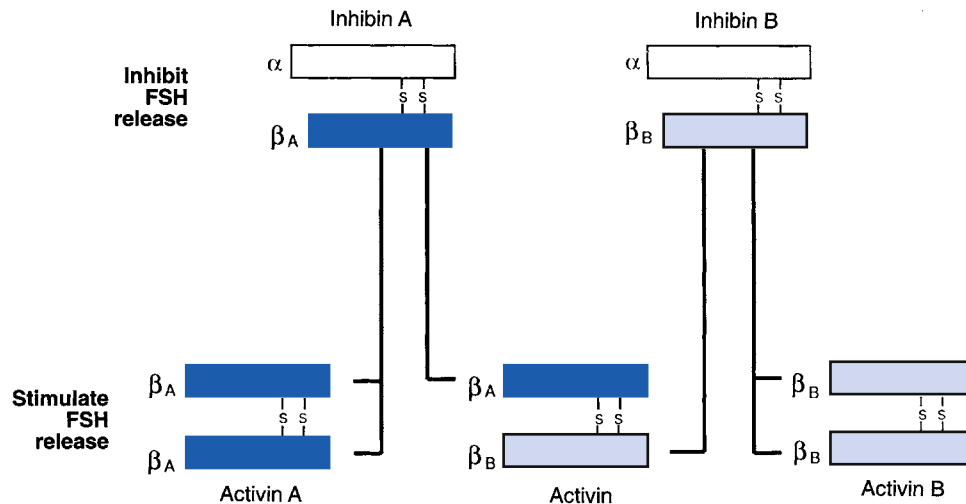

Figure 4.18 Chemical relationships of inhibins and activins. S, Disulfide bond. (From Hylka VW, Di Zerega GS: Reproductive hormones and their mechanisms of action. In: Mishell DR, Davajan V, Lobo RA, eds. *Infertility, Contraception and Reproductive Endocrinology*. 3rd ed. Cambridge, MA: Blackwell Scientific; 1991.)

FOLLICULAR PHASE

The follicular phase can be subdivided into three periods; these denote the successive recruitment of a cohort of antral follicles, the selection of a dominant follicle, and the growth of the selected dominant follicle.

Recruitment of a Cohort of Antral Follicles

When cohorts of growing follicles reach the early antral stage (Fig. 4.20; see also Fig. 4.7), continuing growth requires a proper gonadotropin stimulatory action. **FSH** provides the critical signal for the recruitment of a **cohort** of preantral follicles. This FSH signal (cyclic recruitment) is the major survival factor that rescues the follicles from their programmed death (atresia) and allows them to start growing, increasing in size and beginning to synthesize steroids. In fact, the start of each follicular phase is characterized by a small but significant increase in the FSH:LH ratio (see Fig. 4.19), resulting in the recruitment of a cohort consisting of about three to seven secondary preantral follicles. (Only preantral follicles are able to respond to the FSH signal; follicles at an earlier stage of development lack an independent vascular system so that the signal does not reach them.)

Ovarian reserve is a term used to denote the number of antral follicles in the ovaries and therefore to determine the capacity of the ovary to provide oocytes that are capable of being fertilized. The determination of the ovarian reserve is an important tool in the treatment of infertility. Mainly, it can be assessed by the following means: (1) by a measurement of **FSH** on day 2 to 3 of the cycle: higher FSH levels denote ovarian aging (resulting from a decreased activity of the estradiol negative feedback loop), hence fewer recruitable follicles; (2) by a sonographic **antral follicle count**; (3) by the measurement of **inhibin B** on day 2 to 3 of the cycle, the recruitment of the follicle cohort being reflected by an increase in this hormone produced and secreted by these recruited follicles, thus inhibin B levels provide an early indicator of the number of recruited

follicles and of their secretory activity (see Fig. 4.20); and (4) by the measurement of **anti-müllerian hormone (AMH)** (also named müllerian inhibiting substance [MIS]). AMH belongs to the transforming growth factor- β superfamily. It is a secretory product of granulosa cells in preantral and in small antral follicles. Together with other factors, AMH appears to inhibit the initiation of premature follicle growth. AMH levels decline with age, in parallel with the reduced follicle pool. Data have indicated that in the treatment of infertility, the measurement of AMH in conjunction with sonography offers a more useful assessment of ovarian reserve and a better correlation with the number of oocytes retrieved than that provided by FSH measurement. Unlike FSH, AMH may be measured at any time of the menstrual cycle, with minimal variation. AMH is increasingly used in clinical practice to identify women with premature ovarian insufficiency or polycystic ovary syndrome; very high levels of AMH may reflect polycystic ovary syndrome (La Marca, 2009). Studies show significantly lower age-specific AMH levels in women currently using oral contraceptives with an increase in AMH levels after discontinuation of oral contraceptives (Dolleman, 2013; van den Berg, 2010). It remains to be determined whether AMH measured during oral contraceptive use is an accurate reflection of individual ovarian reserve.

Selection of a Dominant Follicle

Although several primary preantral follicles are recruited at the start of each cycle as part of a cohort, in the primate usually only one (the **dominant follicle**) is selected to complete growth to maturity (see Fig. 4.20), while the other follicles in the cohort become atretic. Although the process of selection is not well understood, it most probably reflects the competitive advantage of the dominant follicle, characterized by a well-vascularized theca layer, allowing a better access of the gonadotropins to their target receptors. This results in a greater local estradiol secretion, which in turn increases the density of gonadotropin receptors and promotes cell multiplication.

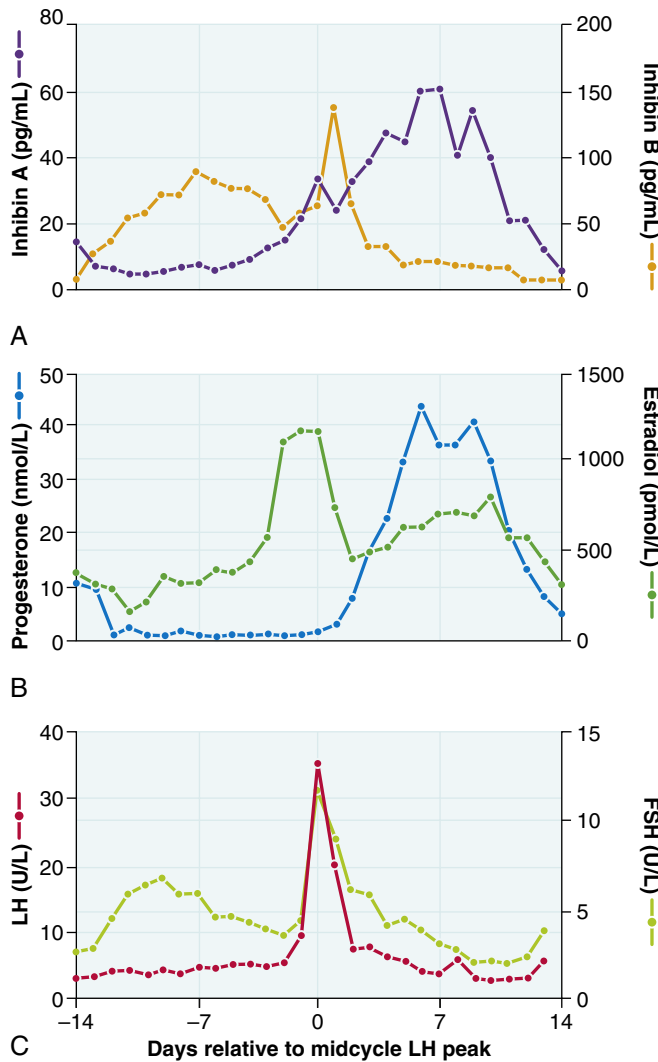

Figure 4.19 Mean plasma concentrations of inhibin A and inhibin B (**A**, upper panel) compared with estradiol and progesterone (**B**, center panel), and LH and FSH (**C**, lower panel) during the menstrual cycle. Day 0 is the day of the LH surge. (From Groome NP, Illingworth PJ, O'Brien M, et al. Measurement of dimeric inhibin B throughout the human menstrual cycle. *J Clin Endocrinol Metab.* 1996;81:1401-1405.)

At the same time, elevation of peripheral estradiol levels will activate the negative estradiol feedback loop and result in a decrease in circulating FSH to a concentration insufficient to sustain growth in the other follicles of the cohort. Experimentally in the nonhuman primate, this process can be overridden by injecting antibodies to estradiol; this prevents the estradiol negative feedback loop from decreasing FSH secretion and results in the maturation of several follicles at the same time. In addition to estradiol, granulosa cells of the recruited follicles also secrete inhibin B (discussed earlier), the action of which selectively suppresses FSH secretion, further decreasing the stimulus to maturation. The dominant follicle, however, continues to grow because of its greater density of FSH receptors and greater vascularization of its theca cell layer, allowing more FSH to reach its receptors.

Figure 4.20 Follicle development. Note that progress beyond the primary or preantral follicle stage depends on FSH stimulation. (From Paulson RJ. Oocytes: from development to fertilization. In: Mishell DR, Davajan V, Lobo RA, eds. *Infertility, Contraception and Reproductive Endocrinology*. 3rd ed. Cambridge, MA: Blackwell Scientific; 1991.)

The process of selection is completed by day 5 of the follicular phase. At this point, if the dominant follicle is experimentally destroyed, no surrogate follicle is available to replace it during that cycle.

Growth of the Dominant Follicle: The Maturing Secondary or Antral Follicle

GnRH pulse frequency at this time of the follicular phase is at its maximum, at about 1 GnRH pulse/90 minutes (**Fig. 4.21, A**). This is the optimal pulse frequency to activate the proper gonadotropin response to increase steroid biosynthesis and the production of estradiol within the ovary. The main role of the gonadotropins and of locally produced estradiol is to continue to stimulate growth of the dominant follicle during the remainder of the follicular phase.

Production of estradiol requires successive events within different locations in the growing follicle (**Fig. 4.22**). **FSH receptors** are located within the avascular **granulosa** cell layer of the antral follicle. Stimulation by FSH of its receptors activates production of the enzyme **aromatase** (responsible for the biosynthesis of estrogens) within these cells. An important change in the structure of maturing follicles is the acquisition of the **theca** cell layer, which surrounds the granulosa layer and rapidly differentiates into the theca interna and the theca externa. The theca layer rapidly becomes well vascularized

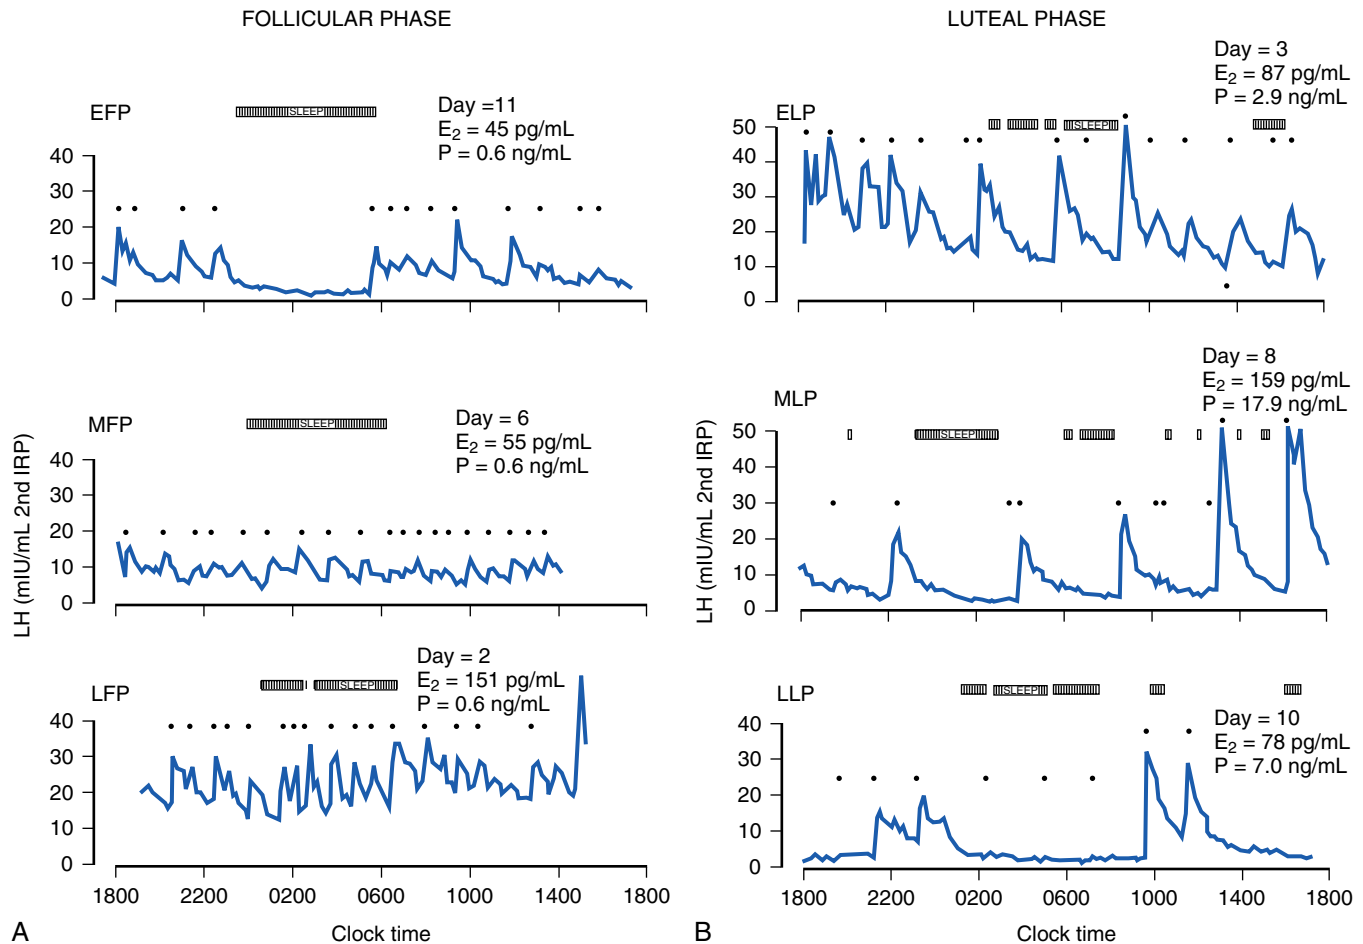

Figure 4.21 Contrasting patterns of pulsatile LH secretion throughout the follicular phase (**A**, left panels) and luteal phase (**B**, right panels) of the menstrual cycle. Representative examples of early (EFP), mid (MFP), and late (LFP) follicular phases are shown. LH pulses are indicated by bullets. E_2 , estradiol; P , progesterone. (Note that in about 20% of volunteers, there is a suppression of pulsatility during deep sleep in EFP. This does not appear to interfere with the normal cycle.) (From Filicori M, Santoro N, Merriam GR, et al. Characterization of the physiological pattern of episodic gonadotropin secretion throughout the menstrual cycle. *J Clin Endocrinol Metab.* 1986;62:1136.)

(in contrast to the granulosa layer, which remains avascular) through an active angiogenesis process, characterized by the presence of several vascular growth-promoting proteins such as vascular endothelial growth factor (VEGF), which stimulates growth of new blood vessels. This allows access of blood, and the hormones and nutrients it carries, to reach the follicle and to diffuse through to the granulosa layer. Circulating FSH now stimulates **LH receptor** synthesis within stromal cells of the **theca interna**. LH, in turn, promotes steroid biosynthesis by theca cells and the production of **androgens**. These androgens, following diffusion into the granulosa layer where the enzyme aromatase is located, are then biotransformed into **estradiol**. This leads to an overall increase in estradiol production, increased intraovarian estradiol levels, and increased estradiol secretion into the peripheral circulation, which parallels follicular parameter (Fig. 4.23).

Thus the growing dominant follicle generates its own estradiol microenvironment. Estradiol, being a mitogenic hormone, in turn directly promotes its exponential growth. (Testosterone,

on the other hand, increases follicular atresia in the absence of adequate aromatase activity, which converts it to estradiol.) Indirectly, estradiol also promotes follicular growth through the activation of several regulatory protein and peptide hormones, such as inhibins, activin, follistatins, insulin-like growth factors (IGFs), and others. For instance, various IGFs have been shown to stimulate granulosa cell proliferation and aromatase activity. Most actions of these factors remain, however, to be elucidated in the primate. By the time the follicle reaches the preovulatory stage, the number of granulosa cells has increased from about 50 at the primordial stage to 5×10^7 . This is accompanied by an exponential increase in peripheral estradiol levels (see Fig. 4.22).

As the dominant follicle grows, an **antrum** (cavity) forms into which follicular fluid accumulates. This fluid contains several steroids, peptide and protein hormones, and nutrients. The growth pattern of the dominant follicle can be documented by ultrasonography, which is well correlated with the endocrine pattern: indeed, increases in both follicle diameter

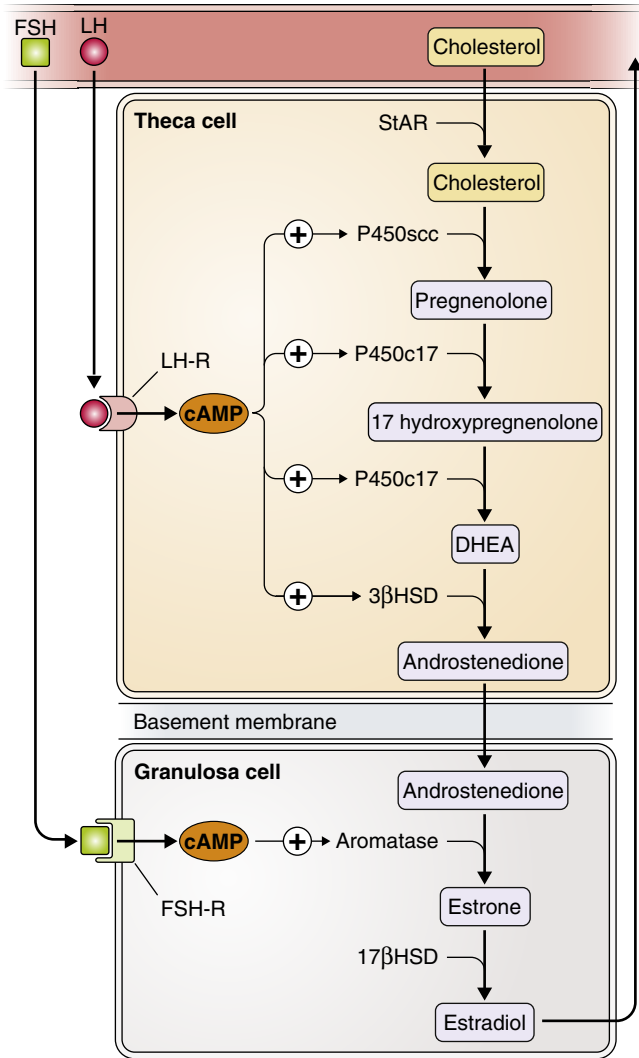

Figure 4.22 Production of estradiol within the growing dominant follicle requires successive events within different locations (see text). FSH receptors are located within the avascular granulosa cell layer, whereas synthesis of LH receptors, stimulated by FSH, occurs within stromal cells of the theca interna. The enzyme aromatase (responsible for the biosynthesis of estrogens) stimulated by FSH originates within the granulosa cells. LH, in turn, promotes steroid biosynthesis by theca cells and the production of androgens. These androgens, following diffusion into the granulosa layer where the enzyme aromatase is located, are then biotransformed into estradiol.

and volume parallel the increase in estradiol levels in blood. At maturation, the dominant follicle reaches a mean diameter range of 18 to 25 mm.

Within the dominant follicle, the oocyte also develops and becomes surrounded by the **zona pellucida**. This is a mucopolysaccharide coat containing specific protein sites that later will allow only spermatozoa to penetrate and fertilize the ovum. Underneath the zona pellucida is the **vitelline membrane** that surrounds the ooplasm. At the end of the follicular phase, the antral follicle contains oocytes that are fully grown but are unable to undergo normal activation if retrieved and fertilized in vitro. Activation will have to await the ovulatory LH surge.

OVULATORY GONADOTROPIN SURGE AND OVULATION

Maturation of the dominant follicle is marked by high blood levels of estradiol. When a threshold is reached, estradiol activates the positive feedback loop, thereby signaling to the hypothalamus and anterior pituitary gland that the follicle is ready for ovulation and that a large gonadotropin surge is to be released (see Fig. 4.17). (A small but significant increase in progesterone is also secreted by the follicle before the LH surge; because administration of a progesterone receptor antagonist delays the timing of the surge, it is thought that these low levels of progesterone help to synchronize the surge.)

In the nonhuman primate, the gonadotropin surge has been shown to be preceded by a surge of GnRH, as measured centrally, suggesting a major hypothalamic site for the positive feedback loop. For reasons unknown, this **GnRH surge** significantly outlasts the LH surge. Because GnRH cannot be measured in the human in peripheral blood, the relative importance of the sites of action of estradiol during the spontaneous surge remains to be established. (Studies in GnRH-deficient women receiving exogenous GnRH replacement in an unchanging 60-minute pulse frequency provide evidence for the relevance of pituitary sensitization to GnRH in the presence of high estradiol, as abrupt LH increases can be observed under this experimental protocol.)

During the ovulatory surge, LH levels increase 10-fold over a period of 2 to 3 days, whereas FSH levels increase about 4-fold. This gonadotropin surge is an absolute requirement for the final maturation of the oocyte and the initiation of the follicular rupture.

The LH surge initiates germinal vesicle (or nucleus) disruption, and the fully grown oocyte resumes meiosis (**meiotic maturation**). Thus it progresses from the diplotene stage of the first meiosis (which was initiated during fetal life; discussed earlier) to metaphase II of the second meiotic division. As the oocyte enters metaphase II, the first polar body appears. (Three haploid polar bodies are produced during the two-step meiosis process, at ovulation and fertilization.) To conserve nutrients, most of the cytoplasm is concentrated into the oocyte or egg. The polar bodies generated from the meiotic events contain relatively little cytoplasm, and the oocyte eventually discards them. At ovulation, meiosis is arrested again (the **second meiotic arrest**). The second meiotic division will only be completed at the time of fertilization. The oocyte's ability to be fertilized coincides with the completion of meiotic maturation and the associated increased secretion of specific proteins such as the IP₃ receptor, glutathione and calmodulin-dependent protein kinase II, and others.

Ovulation (follicle rupture) occurs about 32 hours after the initial rise of the LH surge and about 16 hours after its peak (Table 4.1). Ultrasonographic pictures of ovaries with antral follicles, a preovulatory follicle and a hemorrhagic corpus luteum are shown in Figure 4.24. The LH surge induces a cascade of molecular events and changes in the mature follicle that are associated with ovulation. Studies of these have been complex, with the result that the precise mechanisms underlying ovulation remain to be completely understood. Currently, it is postulated that the LH surge induces an acute inflammatory-like reaction; inflammatory cytokines, such as interleukins, and countless genes are also upregulated. There is

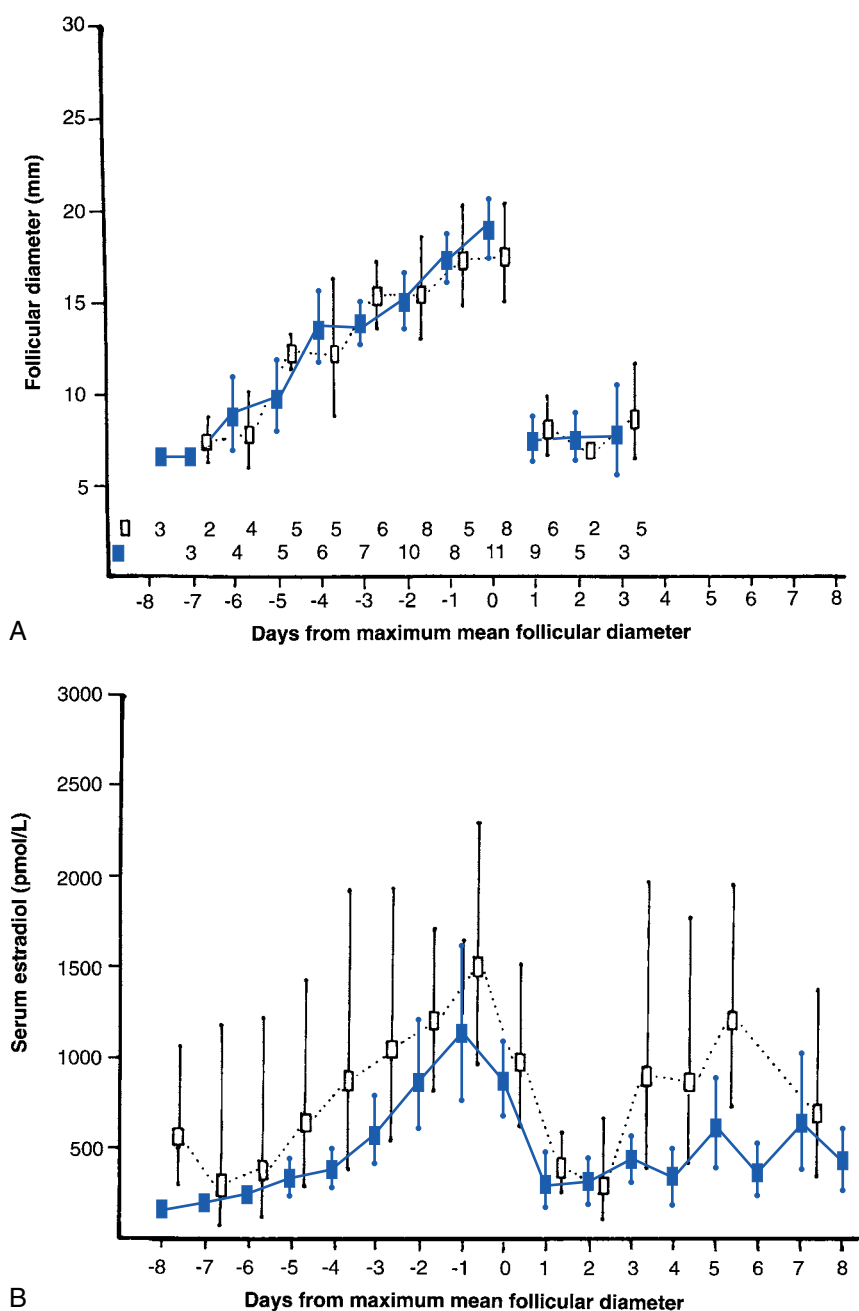

Figure 4.23 Correlation of follicular growth, as indicated by follicular diameter (A), with serum estradiol levels (B), in spontaneous (black bars) and in induced conception (blue bars) cycles. (Modified from Eissa MK, Obhrai Ms, Docker MF, et al. Follicular growth and endocrine profiles in spontaneous and induced cycles. *Fert Ster.* 1986;45:191.)

Table 4.1 Range of Observed Times from Defined Hormonal Events and Time of Ovulation

Hormone	TIME OF OVULATION (HR) FROM RISE TO PEAK			
	First Significant Rise		Peak	
	Median	Range	Median	Range
17β-Estradiol	82.5	48-168	24.0	0-48
LH	32.0	24-56	16.5	0-48
FSH	21.1	8-24	15.3	8-40
Progesterone	7.8	0-32	—	—

Temporal relationships between ovulation and defined changes in the concentration of plasma estradiol-17 beta, luteinizing hormone, follicle-stimulating hormone, and progesterone. I. Probit analysis. World Health Organization, Task Force of Methods for the Determination of the Fertile Period, Special Programme of Research, Development and Research Training in Human Reproduction. *Am J Obstet Gynecol.* 1980;138:383-390.

an increase in cyclooxygenase, which catalyzes the conversion of arachidonic acid into several prostanoids, which include the **prostaglandins** that are produced intracellularly. Prostaglandins then act locally—for instance, to induce the hyperemia and edema seen in the first hours of the process of ovulation and that result from increased blood flow and vascular permeability. Intense protease activity is generated in the follicle. The resultant **proteolytic cascade**, which among others involves collagenases and plasminogen activator (which converts plasminogen into the proteolytic enzyme plasmin), leads to the degradation of the follicular layers and wall, which plays an essential role in follicle rupture. Plasmin helps in detaching the cumulus cell-enclosed oocyte from the granulosa cells, which initiates the process of extrusion of the oocyte and cumulus when the follicle ruptures. (It is worthwhile to point out that

Figure 4.24 Ovary and corpus luteum during a natural menstrual cycle. **A**, On day 12 after menstruation, a dominant follicle is visualized in the central portion of the image and several subordinate follicles from the wave (2 to 5 mm) are observed in the left lateral aspect of the ovary. **B**, Color flow Doppler image demonstrating perfollicular vascularity around a preovulatory follicle. **C**, A blood-filled corpus luteum, called a *corpus hemorrhagicum*, demonstrating thick walls of peripheral luteal tissue and a central hemorrhagic clot with an interspersed fibrin network. **D**, Color flow Doppler image of a recently ovulated follicle/new luteal glands on the day of ovulation. (From Chizen D, Pierson R. Transvaginal ultrasonography and female infertility. *Glob Libr Women's Med* [ISSN: 1756-2228]. 2010.)

the LH surge paradoxically stimulates the expression of both proteolytic enzymes and their inhibitors. This allows for a tight regulation of proteolytic activity during both the follicle rupture process and the formation of the corpus luteum out of the remaining follicle.)

LUTEAL PHASE

After the oocyte is extruded from the mature dominant follicle, the amount of follicular fluid is markedly reduced, the follicular wall becomes convoluted, and the follicular diameter and volume greatly decrease. As a result, a new ovarian structure evolves from the ovulated follicle, the **corpus luteum**.

The corpus luteum is the result of two important events initiated at ovulation. First, granulosa and theca cells hypertrophy, take up increasing amounts of lipids, and acquire organelles associated with steroidogenesis. Simultaneously, tissue-specific

gene transcription results in the activation of new key steroidogenic enzymes; the hallmark of the human corpus luteum is its secretion primarily of **progesterone**. Although there is a significant drop in estradiol and androgen secretion at ovulation, 17-hydroxylase and aromatase are present in the corpus luteum, so it also secretes 17-hydroxyprogesterone and estradiol. Significant amounts of inhibin A are also produced. Second, the basal lamina, which separated the granulosa and theca cell layers, is disrupted, and capillaries from the theca interna now invade the granulosa layer (which up to now had been avascular) to form an extensive capillary network. The result is that each steroidogenic cell within the corpus luteum is in close proximity to blood vessels.

Like the dominant follicle, growth and development of the corpus luteum occur rapidly. Vascular growth plays a central role in this process. Angiogenic factors, such as vascular endothelial growth factor (VEGF), are present in high quantity in

the forming and developing corpus luteum. In nonhuman primates, experimental treatment that interferes with normal VEGF activity in the early and midluteal phase of the cycle suppresses vascular development and hence luteal growth; luteal function is compromised, as indicated by a marked fall in plasma progesterone levels.

Endocrine Factors and the Corpus Luteum

Normal function of the corpus luteum depends primarily on LH stimulation throughout the luteal phase. This has been demonstrated in hypophysectomized women, in whom ovulation was induced by LH treatment. In these patients, continuing injections of small amounts of LH were essential to maintain the secretory viability of the corpus luteum. Other studies have shown that GnRH antagonist treatment (by interrupting LH secretion) readily disrupts luteal cell morphology and suppresses plasma progesterone levels.

Progesterone dominance in the luteal phase results in a significant activation of the **progesterone negative feedback loop** on the GnRH pulse generator, which acts to decrease GnRH pulse frequency. Thus during the luteal phase, there is progressive slowing down of LH pulse frequency, from 1 pulse/90 minutes at the beginning of the luteal phase to 1 pulse/3 hours or even less toward the later luteal phase (see Fig. 4.21, *right panel*). This negative progesterone feedback effect is not directly exerted on the GnRH pulse generator as it is mediated by central **β -endorphin** (an endogenous opioid peptide). β -endorphin neurons are preferentially concentrated in the arcuate nucleus, in close proximity to GnRH neurons. Studies in the nonhuman primate have shown that β -endorphin release from the hypothalamus is significantly increased in the presence of progesterone, such as in the luteal phase, and lowest in its absence, such as after ovariectomy or at menstruation. Experimental administration of a competitive β -endorphin antagonist, such as naloxone, is particularly effective in accelerating LH pulse frequency when given in the luteal phase (see Fig. 4.16, *right panel*).

Progesterone dominance during the luteal phase also affects the hypothalamic thermoregulatory center, such that a small increase in **basal body temperature** (BBT) reflects increased progesterone secretion during the luteal phase. Thus the typical BBT curve of the ovulatory menstrual cycle is biphasic (i.e., elevated during the duration of the luteal phase). (This small temperature rise does not, however, reflect the quantity of progesterone increase in that it occurs when progesterone reaches the low threshold level of 2 to 3 ng/mL.)

Corpus Luteum Regression (Luteolysis)

In primates, the life span of the corpus luteum is limited to a period of about 14 days. Histologically and biochemically, the corpus luteum reaches maturity 8 to 9 days after ovulation, after which time luteal cells start to degenerate and its secretory capability begins to decline. Thus after a progressive increase in progesterone, estradiol, and inhibin A levels in the first half of the luteal phase, the period after the midluteal peak is paralleled by a decline in these hormones. (Only rapidly rising concentrations of **chorionic gonadotropin** [hCG] [secreted by the syncytiotrophoblast] following conception can rescue the corpus luteum and maintain the production of progesterone.)

Structural luteolysis is a complex process responsible for the elimination of the corpus luteum, and little progress has been made in defining the factors responsible for luteolysis in the primate. Steroidogenic luteal cells undergo characteristic degenerative changes, with intense cytoplasmic vacuolization and invasion by macrophages. It has been postulated that regression of the corpus luteum may be related to an alteration in age-dependent luteal cell responsiveness to LH and is dictated by various luteotropic and luteolytic agents, the existence and dynamics of which remain to be investigated in the human. (Although uterine prostaglandin $F_{2\alpha}$ seems to be an important luteolytic signal in nonprimate species, the primate uterus is not the source of luteolytic agents because hysterectomy does not result in a prolonged luteal phase in the human.) Degradation of the luteal cells terminates in a perimenstrual apoptotic wave, and menstruation follows ovulation by 13 to 15 days, unless conception has occurred ("the missed menses").

LUTEAL-FOLLICULAR TRANSITION

The end of the luteal phase is characterized by a dramatic decrease in progesterone, estradiol, and inhibin A. This is accompanied by a characteristic divergence in the FSH:LH ratio, now favoring a specific rise in FSH (see Fig. 4.19). The increase in the FSH:LH ratio heralds a new menstrual cycle and the recruitment of a new cohort of follicles.

The increase in the FSH:LH ratio most probably reflects the following interacting phenomena: (1) a rise in FSH may be the result of the rapid decline in estradiol accompanying the demise of the corpus luteum because FSH seems to be slightly more sensitive to the estradiol negative feedback loop than LH; (2) the end of the luteal phase is also characterized by a decline in inhibin A, a hormone that specifically suppresses FSH; and (3) the rise in FSH also reflects the differential effects of GnRH pulse frequency on the synthesis of LH and FSH: the lower GnRH pulse frequency throughout the luteal phase favors FSH β -subunit synthesis over that of the LH β -subunit (discussed earlier), and thus a larger pituitary pool of FSH is available for release at the end of the luteal phase. The naturally occurring slowing of GnRH pulse frequency during the luteal phase is very relevant to a timely passage to a new cycle: indeed, imposed changes in the normal pulse frequency of this hypophysiotropic signal during the luteal phase results in significant disturbances in cyclicity.

The decrease in progesterone levels at the end of the cycle results in decreased activity in central β -endorphin, and consequently there is a resultant increase in GnRH pulse frequency. The return to a 1/pulse/90-minute frequency is essential to create the optimal conditions for the new menstrual cycle.

MENSTRUAL CYCLE AND THE ENDOMETRIUM

Integration and synchronization between cyclic changes within the hypothalamic-pituitary-ovarian axis and the endometrium is an essential prerequisite for viable reproduction. The primary goal is to ensure an appropriate environment for the implantation of the developing conceptus.

Figure 4.25 Diagram of changes in normal human ovarian and endometrial cycles. (From Shaw ST, Roche PC. Menstruation. In: Finn CA, ed. *Oxford Review of Reproductive Endocrinology*. vol 2. London: Oxford University Press; 1980.)

Human endometrium (the glandular part of the uterus) is made up of two major layers: (1) the stratum basale, which lies on top of the myometrium (the muscle part of the uterus), consists of primordial glands and densely cellular stroma, which change little during the menstrual cycle and do not desquamate at menstruation; and (2) the stratum functionale, which lies between the basale and the lumen of the uterus, is composed of two layers. The superficial layer (stratum compactum) consists of the neck of the glands and densely populated stromal cells. The lower layer (stratum spongiosum) consists primarily of glands with less populated stroma and large amounts of interstitial tissue. Differences in structure in the two layers reflect different biologic functions: whereas the upper layer serves as the site of blastocyst implantation and provides the metabolic environment for it, the lower layer maintains the integrity of the mucosa. Changes in hormones during the menstrual cycle affect mainly the stratum functionale. A diagrammatic representation of endometrial changes during the menstrual cycle is presented in Figure 4.25.

ENDOMETRIUM IN THE PROLIFERATIVE (FOLLICULAR) PHASE

Immediately after menstruation, the endometrium is only 1 to 2 mm thick and consists mainly of the stratum basale and a few glands. As estradiol levels increase with the growth and maturation of the dominant follicle, the number of estradiol receptors in the endometrium increases and the stratum functionale proliferates greatly by multiplication of both glandular and stromal cells. Synthesis of DNA is increased, and mitoses are numerous. Toward the late follicular phase, the straight glands become progressively more voluminous and tortuous. At the time of onset of the LH surge and before ovulation, subnuclear

vacuoles appear at the base of the cells lining the glands. This is the first indication of an effect by progesterone, reflecting the small but significant increase in progesterone seen at that time. Sonography during the follicular phase shows that endometrial thickness, including both anterior and posterior layers, increases from a mean of about 4 mm in the early follicular phase to about 12 mm at the time of ovulation. Examples of structural changes of the endometrium during the menstrual cycle are shown in Figure 4.26.

ENDOMETRIUM IN THE SECRETORY (LUTEAL) PHASE

After ovulation, the proliferative endometrium undergoes a rapid **secretory** differentiation: well-developed subnuclear glycogen-rich vacuoles appear in every cell of a given gland. This correlates with a total lack of mitoses in all glands. Both effects can be attributed to rising levels of postovulatory progesterone. Progesterone antagonizes the mitotic action of estradiol by decreasing estrogen receptors and by increasing the progesterone-specific enzyme 17 β -hydroxydehydrogenase, which converts estradiol into the much less active estrone.

As progesterone levels increase during the first part of the luteal phase, the glycogen-containing vacuoles ascend progressively toward the gland lumen. Soon thereafter, the contents of the glands are released into the endometrial lumen. The peak of intraglandular content and its release into the lumen coincides well with the arrival of the free-floating blastocyst, which reaches the uterine cavity by about 3.5 days after fertilization. This release of glycogen-rich nutrients is crucial in that it provides energy to the energy-starved free-floating blastocyst.

Appropriately timed exposure to estrogen and progesterone alters gene transcription in the endometrium resulting

Figure 4.26 Histology of proliferative (A) and secretory (B) endometrial tissue.

in a “receptive endometrium” that is prepared to engage in a molecular dialog with the blastocyst. The window of implantation (WOI) is typically defined as days 20 to 24 of a 28-day menstrual cycle, with implantation occurring about 1 week after fertilization. Multiple signaling pathways are activated in the endometrium to ensure successful embryo implantation (Fig. 4.27) (Cha, 2012). Several proteins, including glycodeclin, insulin-like growth factor binding protein 1 (IGFBP-1), homeobox A10, and leukemia inhibitory factor, are produced by secretory phase endometrium and may play integral roles in endometrial function.¹⁵ Glycodeclin is also known as *PP14* or *progesterone-associated endometrial protein*. Although it has also been referred to as *pregnancy-associated endometrial alpha-2-globulin*, it is actually not a placental protein but rather a major secretory product of the glandular endometrial epithelium during the secretory phase. Circulating levels of glycodeclin correlate well with serum progesterone levels. Glycodeclin is a glycoprotein of which there are three distinct forms, with identical protein backbones but different glycosylation profiles. These glycoproteins appear to have essential roles in producing a uterine environment suitable for pregnancy and in the timing and occurrence of the appropriate sequence of events in the fertilization process.

After the first week of the luteal phase, changes in the stroma rather than in the glands become more important and relevant. The stroma becomes more edematous as a result of increased capillary permeability. Endothelial proliferation results in the coiling of capillaries and vessels, particularly in the upper

functionale level producing vascular clusters. (These changes have been postulated to be mediated by prostaglandin F_{2α} [PGF_{2α}] and prostaglandin E [PGE₂], the production of which is stimulated by estradiol and progesterone.) These changes are essential in the steps that will lead to the predecidual transformation of stromal cells.

Predecidual stromal cells are precursor forms of gestational decidual cells. (These cells are not involved in the implantation process because they develop after implantation.) In the nongestational endometrium, predecidual cells are engaged in phagocytosis and digestion of extracellular collagen matrix. These cellular activities may contribute to the breakdown of the endometrium at menstruation. (Predecidual cells also have metabolic functions related to pregnancy; for example, they secrete prolactin, which is related to osmoregulation of amniotic fluid. These cells also play a supportive role to the endometrial mucosa and appear to control the invasive nature of the normal trophoblast: in their absence, the trophoblast may invade the myometrium leading to placenta accreta.) Decidualization succeeds predecidualization if pregnancy occurs.

Clinically, the measurement of hormonal levels in parallel with the use of quantitative morphometric endometrial measurements produce a significant correlation with chronologic dating of the length of the luteal phase. Clinical dating of the endometrium, however, is somewhat subjective and is rarely carried out today. Sonography shows that endometrial thickness remains at the same level reached at ovulation (8 to 14 mm) throughout the luteal phase.

Figure 4.27 Signaling network for uterine receptivity and implantation. This is a hybrid cartoon based on mouse and human studies, portraying compartment- and cell-type-specific expression of molecules and their potential functions necessary for uterine receptivity, implantation, and decidualization. (From Cha J, Sun X, Dey SK. Mechanisms of implantation: strategies for successful pregnancy. *Nat Med*. 2012;18:1754-1767.)

MENSTRUATION

If implantation of the blastocyst does not occur in the late luteal phase and hCG is not produced to maintain the corpus luteum, the endometrial glands begin to collapse and fragment. Subsequently, polymorphonuclear leukocytes and monocytes infiltrate the glands and stroma, autolysis of the stratum functionale occurs, and desquamation begins.

Current data support the contention that cyclic elimination of the endometrium functional layer through menstrual bleeding results from intense tissue breakdown by proteolytic enzymes, mainly members of the matrix **metalloproteinase** family (**MMPs**), and that these enzymes are stimulated by the products of an inflammatory process. A number of MMPs, capable of degrading both interstitial matrix and basement membrane components, have been localized to perimenstrual endometrium, and the focal nature of their production suggests local regulation. There are probably important relationships between

cells of the immune system (such as mast cells, eosinophils, neutrophils, and macrophages) and the local production and activation of MMPs.

The degrading actions by MMPs lead to the loss of integrity of blood vessels, the destruction of endometrial interstitial matrix, and the resultant bleeding characteristic of menstruation. Regular menstruation usually lasts for 3 to 5 days, but anywhere from 2 to 7 days is considered normal. Menstrual intervals vary depending of age and time of initiation of the premenopausal period (Fig. 4.28). The average blood loss is 35 mL with 10 to 80 mL considered within the normal range. A similar volume of nonhematogenous fluid is also shed during menstruation. Many women also notice shedding of the endometrial lining that appears as tissue mixed with the blood. (Sometimes, this may be erroneously thought to indicate an early term miscarriage of an embryo.) The enzyme plasmin tends to inhibit the blood from clotting. Because of the blood loss, premenopausal women have higher dietary requirements for iron to prevent iron deficiency.

Figure 4.28 Normal curve contours for the distribution of menstrual intervals in three zones of menstrual life. (From Treloar AE, Boynton RE, Brown BW. Variation of the human menstrual cycle through reproductive life. *Int J Fert.* 1967;12:77.)

MENSTRUAL CYCLE AND THE CERVICAL GLANDS

The cervix plays a substantial role in fertility. Changes in the production and property of mucus secreted by the cervical glands are closely correlated to changes in estradiol and progesterone during the menstrual cycle. Enhanced production of cervical mucus and the presence of crypts within the endocervix facilitate the transport and storage of spermatozoa around midcycle. Cervical mucus is produced in copious amounts in response to high estradiol levels at the end of the follicular phase: it has a clear, water-like appearance, which is acellular, takes the aspect of a “fern” when it dries as viewed under the microscope, and is “stringy,” referred to as “spinnbarkeit” (i.e., cervical mucus that can stretch on a slide at least 6 cm). So characteristic are these findings that the appearance of this type of mucus signifies the “fertile period” in women practicing natural family planning methods. In contrast, one of the actions of progesterone (as seen after ovulation during the luteal phase or as used in the “minipill”) is to thicken the cervical mucus, thereby making it less conducive for sperm transport, thus providing a contraceptive effect.

From a fertility testing perspective, postcoital tests examining spermatozoa within the cervical canal at midcycle to rule out a

cervical factor are seldom used in today’s practice. The subjective nature of this testing makes it not highly predictive of the ability to conceive.

HORMONE ASSAY TECHNIQUES

IMMUNOASSAYS

No other method has had such an impact on the measurement of hormones as immunoassay methods. These techniques provide ways of measuring very small amounts of hormone in small quantities of serum or plasma rapidly and relatively specifically. The use of these techniques, pioneered by Yalow and Berson, has indeed increased the knowledge of reproductive endocrinology exponentially since the 1960s. Immunoassays and their variants have rapidly replaced previously used cumbersome bioassays. They are comparatively much faster and much easier to perform, have a much enhanced sensitivity, and usually require far less than 1 mL of serum or plasma. It should be kept in mind, however, that these techniques measure the immunologic property of a hormone, not its biologic activity (as tested by bioassays). These two effects may differ in magnitude under certain physiologic or pathologic conditions.

The basic principle of an immunoassay involves the competition between an unlabeled antigen (the hormone in the blood sample) and a labeled antigen, both of which are present in excess, for binding sites on a limited amount of antibody. The following is a brief description of the several steps required in the creation of such an assay. Even though the availability of commercial assays for a large number of hormones has greatly facilitated the measurement of hormones, proper interpretation of the generated data requires a general knowledge of these steps.

Preparation of Antibodies

The first step in setting up an immunoassay is the production or availability of an antibody to the analyte (here, the hormone) to be measured. Antibodies used in immunoassays are either polyclonal or monoclonal. **Polyclonal antibodies** are usually produced following the injection of the hormone in larger animals such as sheep or rabbits. For many **protein hormones**, this means injecting the purified hormone, which the host will recognize as foreign. In the natural immune reaction that follows, the host will produce polyclonal antibodies against the hormone. In contrast to protein hormones, **steroid hormones** are too small to produce an immune reaction on their own (haptens) and are not recognized as foreign because they are the same in most species. To become antigenic, they must be attached to a carrier protein (usually bovine serum albumin). This conjugated compound is now perceived as a foreign body to the host animal and large enough to induce antibody formation.

Even with the injection of a purified antigen, polyclonal antibodies may “cross-react” with other closely related hormones and thus in some assays may lack specificity to the concerned hormone. To increase assay specificity, one may now choose to produce **monoclonal antibodies**, which provide unique specificity by recognizing only one epitope (antigenic determinant). These antibodies are produced by first injecting the antigen into a mouse to induce an immunogenic reaction in its spleen. The spleen cells are then screened to identify and separate those clones capable of secreting a single antibody type. These cells are then fused with a myeloma cell from the same species to form a hybrid cell (hybridoma), which can then be maintained in culture. Because of its immortality, the hybridoma continues to produce homogenous antibodies as long as the culture is maintained.

Choice of Assay Markers

The second step in preparation for an immunoassay is the availability of a **labeled analyte** (hormone) in the competitive immunoassay or a **labeled second antibody** to the analyte in a reagent excess immunoassay. The choice of labels to be attached to the analyte or antibody is multiple.

In the initially developed radioimmunoassays, these labels were radioactive, such as iodine I^{125} . Although these assays were initially the norm, they mostly have been replaced by new types of immunoassays, which do not require the use of radioactive elements and thus avoid the attendant problems related to their use and to radioactivity disposal.

Major advances in the identification of nonradioactive labels and of new measurement equipment to detect and quantitate these have occurred. Presently, most current assays use nonradioactive labels. Enzyme immunoassays (enzyme-linked immunosorbent assays, or ELISA; immunometric assays) use enzymes

as labels, such as horseradish peroxidase or alkaline phosphatase. Chemiluminescent immunoassays (CIA) use luminol. Fluorimetric immunoassays (FIA) use fluorescent compounds (such as fluorescein) as labels.

Separation of Bound and Unbound Antigen

The third step requires a method to separate antibody-bound antigen from unbound antigen in order to determine how much antigen is bound to the antibody. In commercial assays, antibodies can be attached to solid surfaces such as to plastic tubes, beads or plates, or cellulose particles. Separation can then be ensured by washing off the unbound antigen.

Separation can also be performed by the use of a second antibody-label conjugate, which is directed against an antigenic site different from that recognized by the first antibody (see sandwich assays, discussed later).

Immunoassay Reaction

In step 1, a specific antibody (ab) to the hormone (which served as the antigen, ag) binds in the patient's blood sample to the antigen during a fixed period of incubation. A set amount of labeled form of the hormone (ag^x) is added to compete with the unlabeled hormone to bind to the antibody, resulting in the following reaction:

In this competitive reaction, the amount of labeled antigen bound to the antibody will be inversely proportional to the amount of antigen (hormone) present in the blood sample. For measurement, the bound antigen is then separated from the free antigen by washing or other approaches.

Immunometric assays (also referred to as “sandwich assays”) use a labeled second antibody, which is usually attached to a solid phase, such as the assay tube or assay plate, in the following reactions. The second antibody is directed against an antigenic site different from that recognized by the first antibody:

Because the sandwich assay depends on occupancy of the binding sites rather than competition for these sites, an excess of reagents is used.

Standard Curve

To allow for the actual measurement of the hormone levels in the blood sample, a standard curve must accompany each assay. A standard preparation of the hormone to be measured is used at various increasing or decreasing concentrations, and each concentration is then processed as for the measurement of the sample with unknown concentrations. A standard curve is then constructed by plotting the measured end points. The result for each unknown sample is then located on the ordinate of the standard curve. By drawing a perpendicular line to the abscissa, the amount of hormone present in the unknown sample can be determined. Currently, these determinations are rapidly computed.

Standard curves require varying amounts of pure preparations of hormone. This is no problem for steroid hormones, which are

available in chemically pure preparations. Thus the amount added to construct the standard curve to determine the amount in the patient's sample can be expressed in terms of absolute mass or weight, such as nanograms (ng; 10^{-9} gram) or picograms (pg; 10^{-12} gram). Sometimes, the results may be expressed in nanomoles (nmol). For most steroids, 1 ng/mL is equivalent to about 3 nmol/L.

Because proteins have higher molecular weights and are more complex, it is not always possible to obtain these in their pure form. In these cases, the results are usually expressed in terms of the amounts of a standard reference preparation used for the standard curve. Standard preparations are obtained by extracting the hormone from large collections of blood, urine, or tissues (such as the pituitary gland for FSH and LH). These protein standards are then most often an international reference preparation with the results expressed as international units. However, because of the use of different standard preparations, data obtained from different laboratories or assays may not agree. Thus clinicians should be aware of the normal levels reported by each laboratory reporting to them. Further complicating interpretation is the observation that protein hormones may also circulate in several forms varying slightly by amino acid or carbohydrate content.

ASSAY EVALUATION

When evaluating the value, accuracy, and relevance of an assay, four items must be examined:

1. **Sensitivity** measures the least hormone that can be measured with accuracy. This will set the lower limit of the assay.
2. **Specificity** is the ability of the assay to measure only the specific hormone of interest. Frequently with polyclonal antibodies, results may be altered by the presence of other cross-reacting substances also recognized by the antibody, although usually at lower levels of detection. This is important to know because cross-reaction may influence the precise measurement of the hormone of interest. In such instance, a preassay separation of the cross-reacting hormones may be necessary.
3. **Accuracy** is the ability to measure the exact amount of the hormone present in the sample. Controls containing varying low and high amounts of the hormone must be always assayed alongside the patient's samples in each assay.
4. **Precision** is the ability of the assay to consistently reproduce the same results. Precision is determined by two measurements. The first, the **intraassay coefficient of variation (intraassay CV)** measures the within assay variation. It is calculated by determining the results obtained from measuring a known sample in a number of replicates (usually 10) in the same assay. The second measurement is the **interassay coefficient of variation (interassay CV)**, which is calculated by measuring known samples in multiple assays.

MASS SPECTROMETRY ASSAYS

There has been an increase in the use of mass spectrometry (MS) assays in both clinical and research laboratories. A particular strength of MS assays is the ability to measure large numbers of structurally similar compounds. MS assays have high specificity, sensitivity, and throughput.¹⁶ MS is the most powerful assay method for defining defects in steroid hormone metabolism. In larger reference laboratories, these assays have replaced the conventional radioimmunoassays, which are cumbersome and time-consuming, and direct immunoassays, which lack specificity or sensitivity. The MS technology has been implemented successfully for routine analysis of steroid hormones in major clinical diagnostic laboratories. Although the high cost of MS instrumentation, related operating costs, and the requirement for technical expertise have prohibited smaller laboratories from using this instrumentation for routine testing of steroid hormones, this situation is changing and MS assays are becoming much more widely used.

KEY POINTS

- GnRH analogues are synthesized by substitution of amino acids in the parent molecule at the 6 and 10 positions. The various agonists have greater potencies and longer half-lives than the parent GnRH.
- LH and FSH have the same α subunit of thyroid-stimulating hormone (TSH) and human chorionic gonadotropin (HCG). The β subunits of all these hormones have different amino acids and carbohydrates, which provide specific biologic activity.
- LH acts on the theca cells to produce androgens, which are then transported to the granulosa cells, where they are aromatized to estrogens.
- Pregnenolone, 17-hydroxypregnenolone, progesterone, 17-hydroxyprogesterone, and corticosteroids have 21 carbon atoms; androgens (testosterone and androstenedione) have 19 carbon atoms; estrogens have 18 carbon atoms and a phenolic ring A.
- Kisspeptin (KISS1) plays a key role in the regulation of GnRH release.
- Because the ovaries lack 21-hydroxylase, 11- β -hydroxylase, and 18-hydroxylase reductase activity, they are unable to synthesize mineralocorticoids or glucocorticoids.
- Sex hormone-binding globulin (SHBG) primarily binds dihydrotestosterone, testosterone, and estradiol. About 65% of circulating testosterone is bound to SHBG and 30% to albumin. Approximately 2% remains unbound or free.
- Estrogen stimulates the synthesis of both estrogen and progesterone receptors in target tissues, and progestins inhibit the synthesis of both estrogen and progesterone receptors.
- With ultrasound it has been found that there is a steady increase in follicular diameter and volume that parallels the rise in estradiol. The dominant follicle has a maximal mean diameter of about 19.5 mm, with a range of 18 to 25 mm just before ovulation. The mean maximal follicular volume is 3.8 mL, with a range of 3.1 to 8.2 mL.
- Ovulation occurs about 24 hours after the estradiol peak, as well as 32 hours after the initial rise in LH, and about 12 to 16 hours after the peak of LH levels in serum.

KEY POINTS—cont'd

- Progesterone levels in serum are less than 1 ng/mL before ovulation and reach midluteal levels of 10 to 20 ng/mL.
- After menstruation, regeneration of the endometrium comes from cells in the spongiosum that were previously a portion of the secretory endometrium and not from the stratum basale as previously believed.
- Enzyme-linked immunosorbent assay (ELISA), or “sandwich,” techniques have been developed to measure

protein hormones (e.g., LH, FSH, HCG) with the use of monoclonal antibodies against the α and β subunits. The end point is a color reaction and can be read in a spectrophotometer.

- There are four characteristics of hormone assays that establish their reliability: sensitivity, specificity, accuracy, and precision.

Evidence-Based Medicine and Clinical Epidemiology

Jonathan R. Foote, Laura J. Havrilesky

Hippocrates, whom most consider to be the “father of western medicine,” introduced the notion that an individual’s disease originated from natural causes that could be observed and described within the environment. Medicine has come a long way since the era of Hippocrates, but his idea of diseases having natural causes was the first consideration that the practice of medicine and the treatment of diseases should be based on evidence. The idea of evidence-based medicine is no longer just an idea; it is the foundation of western medicine. Since the 1960s, there has been an explosion of research and knowledge in the basic and clinical sciences. The main goal of this research is to gain knowledge of disease processes, identify cause and effect of disease states, and develop and assess treatments, interventions, and their efficacy. The leap from the lab to clinical practice has presented a unique challenge to researchers and clinicians. Published results do not necessarily translate into meaningful clinical utility, namely related to constraints inherent in research study design. This chapter discusses traditional clinical study designs and explores modern research constructs, comparative effectiveness research (CER), and health services research (HSR).

INTRODUCTION TO EVIDENCE-BASED MEDICINE

Evidence-based medicine aims to guide clinical decision making using our full body of knowledge from well-designed and conducted research. Research evidence rarely applies directly to a particular individual or clinical problem. Clinical decisions must be formulated within a specific context of patient care, integrated with clinical expertise, and coincide with the values and wishes of a particular patient. Clinical decision making must incorporate the most recent and valid information regarding disease prevention, diagnosis, prognosis, and treatment.

The basis for clinical evidence-based studies and the practice of evidence-based medicine starts with epidemiologic studies. The World Health Organization (WHO) defines epidemiology as “the study of distribution and determinants of health-related states or events (including disease), and the application of this study to the control of disease and other health problems” (www.who.int). More simply stated, epidemiology studies the cause and effect of a particular disease within a defined

population. The basic purpose of an epidemiologic study is to estimate the relationship between an exposure and an outcome in order to assess an association or causality.

One of the most influential studies in gynecology, the Women’s Health Initiative, began after epidemiologic data exhibited an association between the use of hormone replacement therapy (HRT) and the prevention of coronary heart disease and osteoporosis. The collection of this observational data led to one of the largest randomized controlled trials and U.S. prevention studies with more than 160,000 postmenopausal women enrolled. Interestingly, this trial did not demonstrate a cardio-protective effect of HRT, but rather showed an increased risk of coronary heart disease. It also demonstrated an increased risk of venous thromboembolism, stroke, and breast cancer, which were unexpected results ([Rossouw, 2002](#)). This study presents a good example of the limitations of observational epidemiologic study design. It also demonstrates the importance of developing well-designed experimental clinical trials to test, when plausible, prior observations and associations.

Epidemiologic studies can be classified as either observational or experimental. The three most common types of observational epidemiologic studies include cohort, case-control, and cross-sectional studies. Case series can also be included among these, although their data are of lower quality. The gold standard of experimental study is the randomized control trial (RCT), largely due to its ability to control for confounding variables through the process of eligibility criteria and randomization. Although the RCT is the gold standard, it often does not directly represent the therapeutic population seen in the real world. Since the early 2000s, comparative effectiveness research (CER) has created a niche to help bridge the gap between research and clinical practice. CER is geared toward assisting “consumers, clinicians, purchasers, and policy makers to make informed decisions that will improve health care at both the individual and population levels” ([Iglehart, 2009](#)). Another field of research emerging in modern medicine is health services research (HSR), which examines how patients get access to care, the cost and quality of that care, and ultimately the result of delivery of care. A particular area of interest developing within HSR is health economic analysis. There are several forms of economic analysis with the most common being cost-effectiveness

analysis (CEA), which is used to compare the relative cost and effectiveness of alternative strategies, usually using a standard willingness-to-pay threshold. In the sections that follow, we will review both traditional clinical study design and emerging clinical research methods.

TRADITIONAL CLINICAL STUDY DESIGN

Traditional clinical study designs are not created equal when it comes to their quality of evidence. Table 5.1 demonstrates a grading system assessing clinical study design and evidence quality. Blinded, randomized controlled trials offer the highest quality of evidence. Some authorities advocate that systematic reviews and meta-analyses of these types of trials produce an equal quality of evidence, although the validity of such studies relies on the quality and validity of the chosen articles (Grondin, 2011). The next level of evidence comes from cohort studies and case-control studies. The lowest quality of study design can be found in case series, case reports, and expert opinion. Table 5.2 compares the advantages, limitations, and statistical considerations of each study design. Whether experimental or observational, these clinical studies are invaluable to modern medicine and impact our day-to-day care of patients. This section will discuss each clinical study design.

Table 5.1 Levels of Evidence in Clinical Study Design

Level	Evidence
1a	Systematic review (with homogeneity) of randomized controlled trials
1b	Individual randomized controlled trials
2a	Systematic review (with homogeneity) of cohort studies
2b	Individual cohort study
2c	"Outcomes research" and ecological studies
3a	Systematic review of case-control studies
3b	Individual case-control study
4	Case series
5	Expert opinion without explicit critical appraisal, or based on physiology, bench research, or "first principles"

Modified from Oxford Centre for Evidence Based Medicine: Levels of Evidence, 2009, www.cebm.net.

Table 5.2 Comparison of Traditional Clinical Study Designs

Study Design	Advantages	Limitations	Statistical Analysis
Randomized controlled trials	Gold standard; prospective; multiple study groups; randomization; can determine causality or a treatment advantage; time-consuming; expensive; internal validity	Selection bias; confounding factors; performance bias; detection bias (RCT can control for confounding factors and biases with double-blinding and randomization); limited external validity	Relative risk (RR); absolute or attributable risk (AR); confidence interval (CI); number needed to treat (NNT)
Cohort studies	Prospective; can assess many outcomes over time	Take many years to complete; expensive; selection bias; confounding factors; patients can be lost to follow-up; changing exposure profile	Incidence; relative risk (RR); absolute or attributable risk (AR)
Case-control studies	Efficient; inexpensive; can study multiple exposures; can study rare disease	Retrospective; recall bias; sampling bias; confounding factors; good external validity	Odds ratio (OR)
Cross-sectional studies	Can determine the frequency of disease or outcomes; highlights possible associations; efficient	Capture one moment in time; cannot determine incidence or causality; sampling bias; participation bias; recall bias	Prevalence
Case series	Descriptive of rare or new entities; hypothesis generating	Lack of comparison group; no clinical conclusions	No statistical analysis

OBSERVATIONAL STUDIES

The term *observational study* describes a wide range of study designs. Observational studies can be classified as analytic or descriptive. Analytic studies contain a control group for comparison, which includes nonrandomized prospective and retrospective cohort studies, case-control studies, and cross-sectional studies. Descriptive studies lack a control or comparison group and consist of case reports and case series. Observational studies play an important role in evidence-based medicine and provide an important source of information when randomized controlled trials cannot be performed. The descriptive aspect of all observational studies is an invaluable attribute in clinical research, providing statistics about incidence, prevalence, and mortality rates of diseases in particular populations. Observational studies provide clinicians with the context of a disease within a population. However, observational studies cannot determine causality, regardless of how logical or plausible an association may seem. They are unfit to test hypotheses or answer etiologic questions, but they play a major role in generating new hypotheses to be tested by a more formal, experimental study design.

Case Reports and Case Series

The basic element or unit of observational studies, as described by Grimes and Schulz, is the case report (Grimes, 2002). Case reports and case series are the least methodologically robust. This is not to say that case reports are not valuable. Case reports often describe rare or new entities in medicine and offer an opportunity to describe characteristics about a disease and allow for the postulation of hypotheses of pathophysiology. It was through case reports of unusual infections and disturbed immunity that AIDS was first described (CDC, 1981). Case reports can describe infrequent adverse events associated with medications or drugs. They can also report on the plausibility and early use of novel treatment methods or surgery. The biggest limitation of this study design is the lack of a comparison group, which does not allow for any clinical conclusions to be drawn. The scientific audience is led to use historical controls or other less robust objective considerations in order to interpret the meaning of noted observations. Case reports, or case series, should be considered no more than "the first step toward more sophisticated research" (Gehlback, 2002).

Cross-Sectional Studies

Cross-sectional studies examine the relationship between exposure and the outcomes of interest in a defined population at a single point in time. In other words, cross-sectional studies are prevalence studies. *Prevalence* is defined as the number of cases in a population at a given point in time. It is a ratio, or proportion, of affected individuals in relation to a pooled population. Cross-sectional studies cannot determine incidence, or the number of new cases in a population over a period of time. They are snapshots of a disease and a population. With reference to only a designated moment in time, these studies are not able to provide causal evidence. Case reports and cross-sectional studies can highlight possible associations that deserve additional evaluation, but they cannot determine causality.

One advantage of cross-sectional studies is efficiency. Because the study population is examined at one moment in time, conclusions can be generated at the same time as data collection. There is no waiting for outcomes or observations. However, cross-sectional studies also have their disadvantages. They capture only a moment in time and thus cannot determine the incidence of disease nor a true association or causality. It is the age-old question, “Which came first, the chicken or the egg?” Population selection, participation bias, and recall bias are all possible limitations. If a tertiary care center or major referral center is conducting a research study and the study population is taken from patients who present to these facilities, they are unlikely to accurately represent the general population, or even a more specific population of patients with a particular disease undergoing therapy within the community. In 1990, Gayle and colleagues published data regarding the prevalence of HIV among university students, examining more than 17,000 specimens from 19 universities (Gayle, 1990). Thirty students, or 0.2%, had detectable HIV antibodies, which was higher than prior studies within the public. The media sensationalized these data, reporting that more than 25,000 college students across the nation may be infected with HIV. However, patient selection in this study was poor, as specimens collected for examination were not random but rather represented those students who presented to student health whose condition warranted a blood sample. Researchers must be careful that patients selected for cross-sectional studies are to be representative of the study population desired. Participation bias arises when selected subjects do not participate, such as in survey studies. If 100,000 surveys are sent out, but only 10,000 are filled out, participation bias becomes an issue. The minority of patients who respond may not be representative of the desired study population. Recall bias becomes an issue when self-reporting, as in survey studies, is a part of study design. Patients often report inaccurate information regarding certain exposures or events. However, well-conducted cross-sectional studies have their place in evidence-based medicine. They are simply prevalence studies and allow us to determine frequencies of disease or outcomes within particular populations or groups.

Case-Control Studies

The purpose of a case-control study is to determine if an exposure is associated with an outcome (i.e., a disease of interest). Study participants are selected on the basis of already having the outcome of interest (the case group) or of not having that outcome (the control group). Case-control studies are always retrospective as they start with an outcome then trace back to

evaluate exposures or habits. Figure 5.1 illustrates the differences in methodologies between case-control studies as compared with cohort studies. Participants in the case group must be carefully defined and should include all cases of new-onset disease drawn from an identifiable population. Controls should be sampled from that same population. The purpose of the control group is to allow for comparison in frequencies of exposures of a case group with the outcome of interest versus the control group without that outcome. In 1971, Herbst and associates published a case-control study of 8 cases and 32 matched controls identifying a strong association between vaginal adenocarcinoma and in utero exposure to diethylstilbestrol (DES) (Herbst, 1971). Although further cohort studies were required to confirm causality, this case-control study allowed for identification of a suspected culprit (exposure) for the development of vaginal adenocarcinoma in young women (outcome of interest).

Case-control studies offer the advantages of being relatively inexpensive, simple to conduct, and efficient. They are retrospective and thus do not require a prolonged period of data collection. They are able to study multiple exposures as they relate to a particular outcome of interest, and they offer the ability to study rare diseases. The quality of the results from these studies is dependent on uniform, meticulous selection of cases, control groups, and data collection among the groups. There are also disadvantages to case-control studies. Recall bias is a particular issue, as cases and controls are likely to recount historical exposures differently. Patients or families coping with an illness may recall in great detail all events they believe might be associated with the illness, whereas healthy controls may not remember similar exposures. Recall bias may also occur when information on the case group is obtained by chart review, whereas information on the control group is obtained either by interview or mail survey. It may ultimately be impossible to eliminate recall bias. Sample selection, or sampling bias, is also an issue, and it arises if the cases selected do not appropriately represent a particular disease or outcome. This is similar to sample selection issues in cross-sectional studies. Sampling bias can also occur within the control group if a representation of the desired general population either underestimates or overestimates exposures. Matching, or selecting control group participants similar in characteristics to the case group, helps to decrease bias in the selection of controls. Matching also helps to decrease possible confounding. Confounding occurs when factors relate both to the measured outcome and measured exposures. “Confounding is the epidemiologist’s eternal triangle.... Are we seeing cause and effect, or is a confounding factor exerting its unappreciated influence?” (Gehlback, 2002). Controlling sample selection and

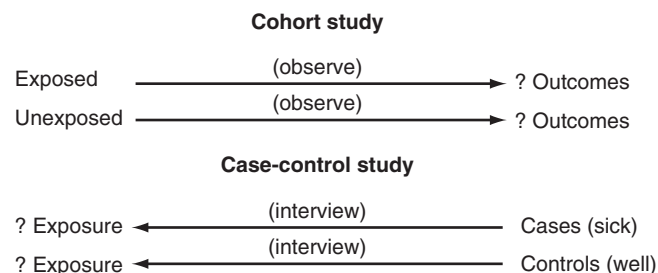

Figure 5.1 Schematic diagram of clinical study design comparing cohort studies and case-control studies.

confounding factors allows for external validity, or the generalizability of the study to the desired population. Often statistical techniques, such as multivariate analysis and logistic regression, are used to help eliminate confounders.

Because case-control studies are by design retrospective, they are limited in their statistical analysis. They cannot provide data on incidence, relative risks, or attributable risks between an exposure and a measured outcome. Case-control studies report an odds ratio, which is the odds that an individual affected by the specific disease being studied has been exposed to a particular risk factor (case group) divided by the odds that the control group has been exposed. It is loosely considered a reasonable estimate of relative risk, but it is not a true calculation of relative risk.

Cohort Studies

A cohort study selects a group of individuals at risk for an outcome of interest and divides them into subgroups based on the presence or absence of one or more exposures to be studied. Subgroups are then followed prospectively, watching for the development of the outcome of interest. Cohort studies are unique in that the study participants select their exposure, rather than having the investigator select an exposure. In experimental research, the investigator selects, either knowingly or unknowingly, the exposure. An excellent example is the Nurses' Health Study (NHS). The NHS was started in 1976 to survey more than 120,000 female nurses regarding medical history, hormonal use, and many other points of interest. The investigators have updated the study every 2 years by mailing out questionnaires to the original enrolled patients. In 2001, Grodstein and coworkers published data regarding the use of postmenopausal hormone therapy and the secondary prevention of coronary events (Grodstein, 2001). The results demonstrated a short-term increased risk of coronary events in patients with a history of coronary disease, whereas the study showed a decreased risk in long-term hormonal use.

A strength of cohort studies is the possibility of assessing many different outcomes over time and also being able to calculate incidence rates, relative risks, and attributable risks. Incidence is defined as the number of new outcomes of interest in a given population over a set period of time. In cohort studies, incidence can be calculated for the population as a whole, but it is most often calculated for populations with and without an identifiable risk factor. Relative risk (RR), or risk ratio, can be calculated from these incidence rates. RR should be thought of as a simple ratio. It is a ratio of the probability of an outcome (disease) occurring within an exposed population as compared with a nonexposed population. It is calculated as the ratio of the incidence in a population exposed to the risk factor over the incidence in the unexposed population. Attributable risk, or absolute risk, represents the absolute additional risk in the exposed population over what may be considered the baseline occurrence in the population. It is determined by calculating the difference between the incidence in the exposed population and that in the unexposed population.

Cohort studies also have their disadvantages. They are often time consuming, take many years to complete, and often become costly. The NHS is a clear example of the time and money it takes to complete a prospective cohort study. As with all analytic-observational studies, subject selection is important

to control for selection bias and confounding factors. Matching of patients in control and study groups will help limit these issues. To the extent that information is collected about known or suspected confounding factors, it is also possible to control for their effect in the statistical analysis. Adjustment techniques can work only for confounding variables that an investigator knows about and measures. Participants may also be lost to follow-up given these studies take years to complete. Investigators must be diligent in keeping accurate follow-up records of each subject. In the same manner, researchers should be aware that patient habits may change over time, and thus their exposure risks may change.

EXPERIMENTAL STUDIES: RANDOMIZED CONTROLLED TRIALS

Randomized controlled trials (RCTs) are considered the gold standard of clinical study design. Within the constructs of epidemiologic studies, RCT is another type of analytic study. In cohort studies, the patient controls the exposure to a factor of interest, whereas in RCTs, the clinical investigator controls exposure to the factor of interest. RCTs are designed to establish evidence of causal associations. They are characterized by the prospective assignment of study participants to a study group (who receive the factor of interest, typically a new treatment) or a placebo, no treatment, or standard care group. Although there are often only two study arms or groups within an RCT, investigators frequently develop designs involving multiple study groups. These groups are followed over time to evaluate for differences in outcomes. Outcomes of interest may include prevention or cure of a disease, reduction in severity of a condition, or differences in costs, quality of life, or side effects between treatments. An example is the Women's Health Initiative already mentioned, which examined the use of hormone replacement therapy (HRT) and the prevention of coronary heart disease, osteoporosis, and the like. The trial did not demonstrate a cardioprotective effect of HRT, but rather showed an increased risk of coronary heart disease. Although it did demonstrate protection against osteoporosis and colon cancer, it showed an increased risk of venous thromboembolism, stroke, and breast cancer (Rossouw, 2002).

RCTs have key design features that make them the gold standard. One of the main features is randomization, a feature that eliminates selection bias and allows for better control of known and unknown confounding factors. Confounding factors are also controlled with strict eligibility criteria, eliminating possible interference from any contributing factors. This is also referred to as *internal validity*, or the ability to control for confounding factors to demonstrate a true causal association. An additional feature of most RCTs is blinding. Performance bias is encountered when systemic differences exist in the care delivered to subjects. In other words, performance bias is when a patient receives less or more therapy based on knowing what particular group or treatment a patient is receiving on trial. Detection bias occurs when systemic differences exist in assessment of a particular outcome. It arises when patients are evaluated more intensely as a result of being in the study group of interest. The double-blinded RCT is a superior study design, as the blinding of both subjects and investigators is preferred to control for any performance or detection bias while also controlling for selection bias and confounding factors. Despite the theoretic design superiority of the RCT approach, these studies provide the best evidence

only if the study has been thoughtfully designed, implemented, analyzed, and reported.

Although RCTs remain the gold standard of research design and evidence quality, they are not without their own limitations. Both ethical and practical considerations may limit the use of RCTs to answer clinical questions. It is clearly unethical to expose patients to potential disease-causing factors just to learn about their negative effects on a particular outcome of interest. Additional ethical concerns arise when designing treatment groups to be studied. A placebo control group is often most efficient to study the effect of a given treatment. However, if an effective treatment already exists, it is not ethical to use a placebo control group, causing harm to patients with the lack of a known, effective treatment. The concept of *primum non nocere*, or “first, do no harm,” also applies in clinical research. If a condition is mild, the treatment period is brief, or effective treatment is not generally available, most investigators believe that a placebo control group is ethical. Most often in RCTs, study groups will be similar, or at least balanced with regard to benefits and harms. The question at hand is, what treatment is preferred? Is there an advantage of one treatment over the other? This uncertainty can be defined as therapeutic equipoise. It is a general uncertainty of the benefits and harms of competing treatments and is often the reason for conducting RCTs. It provides patients with an equal chance to undergo at least “standard of care” treatment versus a possible improved treatment plan. In this nature, RCTs allow an unbiased assessment of determining a preferred treatment. RCTs are also ideal to study outcomes over short periods of time. RCTs intended to study long-term or rare outcomes are much more difficult to carry out. They are time consuming and ultimately cost prohibitive. As already discussed, cohort studies may be more appropriate to evaluate rare outcomes. Unfortunately, for many clinical questions, the time, effort, and expense involved in carrying out an RCT become prohibitive.

A practical consideration in RCTs is that subjects and controls among groups are often special populations that may not be generalizable to the public, or even a specific subset of the public. In 1971, Cochrane noted this issue, stating “Between measurements based on RCTs and benefit...in the community there is a gulf which has been much under-estimated” (Cochrane, 1971). Although the RCT’s strength of design is a strong internal validity, it often lacks strong external validity. External validity is the ability of a result to be generalizable in the real world. Often, the more complex the study protocol, the greater the difference between RCT results and general clinical outcomes. RCTs also often use surrogate markers to substitute for clinical outcomes. A surrogate marker is “an outcome measure that substitutes for a clinical event of true importance...an intermediate measure...commonly laboratory measurements or imaging studies thought to be involved in the causal pathway to a clinical event of interest” (Grimes, 2005). An ideal surrogate marker is a measurable event that is necessary along the pathway to the clinical end point. For example, Skaznik-Wikiel and colleagues demonstrated in a retrospective analysis of 124 women that normalization of cancer antigen 125 (CA-125) levels in ovarian cancer after three cycles of chemotherapy has been associated with an improved overall survival (Skaznik-Wikiel, 2011). However, this is a retrospective analysis, and there are no studies demonstrating an association between the response of CA-125 and overall survival, or any other clinical outcome. Researchers must be careful when

using surrogate markers, as they may not always equate with the disease process being assessed. For example, the effects of a medication on lowering cholesterol are not necessarily the same as preventing heart attacks, which is the desired clinical end point. When interpreting randomized trials, surrogate markers must be used with caution. Grimes and Schulz have emphasized that surrogate markers should, among other characteristics, have similar confounders and influences, and they should show a near identical response to a treatment as the desired clinical end point. They cite an example of fluoride treatments, which improve a surrogate marker, bone mineral density, but increase fractures, which is the true clinical end point of interest. Occasionally, authors will use a “combined outcome,” which includes a surrogate marker and a valid clinical outcome. This combined outcome should be interpreted cautiously because the relative effect of treatments on the various components is unknown.

Researchers may also report “secondary outcomes,” or subgroup analyses, within an RCT. These outcomes may or may not have similar validity as the set of primary outcomes. RCTs are designed to test hypotheses on primary outcomes, controlling for confounding variables that affect the primary outcome. Often, secondary outcomes were not considered in the study design, and thus confounding factors affecting secondary outcomes were not controlled for. Many epidemiologists suggest results of secondary outcomes be interpreted with caution and as hypothesis generating, unless the original study design had internal validity regarding these subgroups. This is particularly true when secondary outcomes and subgroup analyses are incorporated into a meta-analysis, which will be addressed later.

STATISTICAL INTERPRETATION

Epidemiologic studies use a quantitative approach to describing both exposures and outcomes. Whether an RCT, cohort study, or case-control study, all of these studies attempt to present their results as a single number, usually referred to as the *point estimate*, that quantifies the relationship between the exposure and the outcome. This number is an estimate of the truth rather than the truth itself, because each study, however large, includes only a sample of all the people who are affected by the exposure-outcome relationship. The point estimate expresses the strength of the association between the exposure and outcome. In an RCT or a cohort study, the point estimate is the relative risk (RR). Risk in the study subjects is the number of cases or outcomes that occur over time. The RR is simply the risk of disease (or other outcome) among the exposed or treated subjects divided by the risk in the unexposed subjects. As already discussed, case-control studies do not measure risk directly but rather an odds ratio (OR), which is generally considered a rough estimate of RR. The point of any study design is to show a strong association or causality.

Interpretations of RR and OR are similar. As the ratio approaches 1.0, there is little to no association. For both RRs and ORs, the further away the value is from 1.0, the stronger the relationship between the exposure and the outcome. Values less than 1.0 represent a negative association, or a decreased risk of an exposure-outcome relationship. Values greater than 1.0 represent a positive association, or a greater risk of an exposure-outcome relationship. A strong positive RR may be greater than 2.0 and a strong negative RR may be less than 0.5. Weaker associations

can often be explained by confounding variables. However, enthusiastic investigators, worried patients, or sensationalistic media frequently overinterpret weak associations. One must also remember that an OR or RR is based on results of a specific study group and may not represent the general population. This possible difference is understood as a sampling error, or the possible difference in statistics of a study compared with the actual unknown statistics within a population. As a result, investigators will use a confidence interval (CI) to express the precision of a point estimate. Researchers do not rely solely on the traditional *P* value to detect whether a study's findings are due to a chance occurrence, especially when discussing ratios and risks. Confidence intervals represent with high probability (95%) the values within which the actual population point estimate would fall. A narrow CI indicates strong precision and is most often found with larger studies or studies with very little variance. A wide CI indicates poor precision and may be representative of an underpowered study or considerable variance among results. It must be stated that a CI does not address uncertainty in the results because of confounding factors or poor study quality. As well, a wide CI does not mean there is no association between the exposure and the outcome. A CI is a measure of precision. Even an imprecise point estimate remains the best explanation of the relationship until a larger or better study is performed. With regard to understanding graphic representation of confidence intervals, they are most often drawn as a straight line around a point estimate to show the width of their range. This is a poor representation of the actual true point estimate, as it is better understood as a bell-shaped curve centered on the point estimate. Figure 5.2 demonstrates examples of point estimates and their respective confidence intervals.

Calculating RR does not take into account the incidence or the importance of the problem being evaluated. A relative risk of 4 says that the outcome increases 400% in exposed individuals compared with unexposed individuals. However, the relative risk must be interpreted in the context of the frequency of the

Figure 5.2 Schematic diagram of point estimates (open circles) with varying confidence intervals (lines with crossbars). X-axis represents interpretation of respective point estimate and confidence interval. If the confidence interval crosses 1.0, the change in risk is statistically insignificant.

outcome. For instance, the incidence of venous thromboembolism (VTE) in young women while not using oral contraceptives is about 1 in 10,000 and the incidence while using oral contraceptives is 4 in 10,000; thus the relative risk is 4. However, the absolute risk of VTE is still low in both groups of women with a difference in risk of 3 in 10,000. This difference in risk is considered the absolute risk, or attributable risk (AR). It is very useful for putting large relative risks into a clinically useful perspective. It can also be reported as the absolute risk reduction when a benefit is identified or the absolute risk increase when a harm is identified.

An alternative calculation to AR looks at a complementary concept: how many patients need to be treated to observe one benefit or one adverse event? This concept is referred to as the *number needed to treat* (NNT), or the number of patients who need to be treated to achieve an additional positive outcome. It is the reciprocal of the absolute risk reduction (the risk difference for good outcomes). If the effect is dangerous, the value is called the *number needed to harm* (NNH). The number of patients who, if they received the treatment, would lead to one additional patient being harmed, compared with patients not receiving the treatment, is the reciprocal of the absolute risk increase (the risk difference for bad outcomes). Thus using the example of oral contraceptives, with an AR risk of VTE of 3 in 10,000, the number needed to harm (NNH, that is, to experience one extra VTE) is 3,333. It is simply the reciprocal of 3 in 10,000. Calculations of NNT and NNH are essential to determine the potential benefits and harm of therapies, preventive services, and screening tests. Another benefit of these calculations is that they allow us to compare benefits and harm across different treatment strategies. A caution about NNT and NNH is that the number may vary over time. The data from which an NNT is calculated are often specific and may not be generalizable to a person's lifetime or the course of a disease. NNT and NNH derived from a meta-analysis should be viewed with caution. If the studies are from varied populations or used slightly different methods, the NNT and NNH may not always apply to an individual patient or be a simple arithmetic summation.

COMPARATIVE EFFECTIVENESS RESEARCH

Pervasive problems in the quality of delivered care, a lack of high-quality evidence to guide clinical practice and health policy, and concerns about health care spending led to a major initiative, comparative effectiveness research (CER). The Institute of Medicine has defined CER as follows:

The generation and synthesis of evidence that compares the benefits and harms of alternative methods to prevent, diagnose, treat, and monitor a clinical condition or to improve the delivery of care. The purpose of CER is to assist consumers, clinicians, purchasers, and policy makers to make informed decisions that will improve health care at both the individual and population levels (IOM, 2009).

The formal process of developing a CER focus was initiated in the 2003 Medicare Modernization Act, which appropriated \$50 million to conduct research to address the needs and priorities related to improve outcomes, clinical effectiveness, and appropriateness of certain services and treatments. Data from

these earlier efforts were first integrated into coverage for these interventions in 2006, when the Centers for Medicare and Medicaid Services (CMS) provided support to the concept of including evidence-based decision making and research into coverage determination policies (Havrilesky, 2013a). Analysis of costs linked to health-related quality of life was later included as part of CER. In its 2007 definition of CER, the Congressional Budget Office (CBO) included costs as a factor relevant to comparison of different interventions but took a narrow view of interventions by focusing solely on treatment for individual medical conditions (CBO, 2007). CER studies often incorporate different practice settings, a wide range of subgroups, and patient-reported outcomes. Several aspects of CER are depicted in Figure 5.3 and discussed in this section.

META-ANALYSES, SYSTEMATIC REVIEWS, AND EVIDENCE-BASED GUIDELINE DEVELOPMENT

Meta-analyses were developed in response to the problem of conflicting and inconclusive results of individual studies. Uncommon diseases or conditions are hard to study because of the small numbers of patients, which often leads to studies lacking sufficient numbers of patients and power to report significant results. In a meta-analysis, a researcher combines the results of multiple studies to enlarge the group of patients being studied. The ultimate goal of a meta-analysis is to produce a more precise result with a tighter confidence interval. However, not all meta-analyses are created equal. A meta-analysis involving well-constructed and well-performed RCTs is ideal. Meta-analyses of observational studies must be interpreted with extreme caution. Each individual study varies in population, entry criteria, case definition, and exposure definitions, which makes combining data in observational studies problematic. This is particularly true if the analysis combines data from published tables rather than combining the raw data from the original studies. Meta-analyses differ from pooled analyses in that a pooled analysis reexamines the original raw data from multiple individual studies for statistical consideration, whereas a meta-analysis does not reexamine the raw data. If the results from individual studies disagree in direction or report very different results, then the meta-analysis is

not an appropriate tool to answer the question. A pooled analysis can control for heterogeneity by controlling for confounding factors in the original data. A meta-analysis can provide the same type of control by inclusion of similar, high-quality studies. One can argue that the main value of a meta-analysis is the rigorous approach to collecting and evaluating all of the relevant data on a particular clinical problem from multiple sources. A risk of meta-analysis is evaluating many published studies that are small and finding a significant effect that is not accurate. Hennekens and colleagues have suggested that when multiple studies are analyzed together to produce a new finding, the results should be interpreted with caution and viewed as hypothesis generating until a large RCT with adequate power can be performed (Hennekens, 2009). This is particularly true when the additional reported results are secondary outcomes. Neither meta-analyses nor pooled analyses are appropriate for conclusions regarding secondary outcomes, although meticulous examination of original raw data can generate associations for further study.

The clinical need for good evidence and the need for synthesis of evidence that goes beyond opinion have led to the development and use of additional approaches to reviewing evidence. Evidence-based systematic reviews include a comprehensive review and evaluation of the literature. A systematic review is a review of a clearly formulated question that uses systematic and explicit methods to identify, select, and critically appraise relevant research, and to collect and analyze data from the studies that are included in the review (Higgins, 2011). Systematic reviews are reported using a standardized format that must include a detailed description of the search strategy used to identify the relevant literature and the results of the search. Systematic reviews also carry out critical appraisal of the studies they evaluate. Critical appraisal employs a rigid standardized assessment of the relevance and quality of each study. The goal of systematic reviews is to examine the literature regarding a specific clinical question and to use an approach that will minimize bias and random error. Systematic reviews are often performed in conjunction with a meta-analysis.

In 1996, to address the suboptimal reporting of meta-analyses, an international group of researchers released the Quality of Reporting of Meta-analyses (QUOROM) statement to improve standards. In 2009, the guideline was updated to address several conceptual and practical advances in the science of systematic reviews and was renamed PRISMA (Preferred Reporting Items of Systematic reviews and Meta-Analyses). PRISMA provides a 27-item checklist that describes the content of a systematic review including the title, abstract, methods, results, discussion, and funding, as well as a flow diagram that represents the flow of information through the different phases of a systematic review. It characterizes information about the number of records identified in the literature searches, the number of studies included and excluded, and the reasons for exclusions (<http://www.prisma-statement.org/statement.htm>). For example, in 2013, Havrilesky and coworkers published a systemic review and meta-analysis of the use of oral contraceptive pills (OCPs) as primary prevention for ovarian cancer (Havrilesky, 2013b). This study employed methodology that followed PRISMA guidelines. In a flow diagram, the authors described literature searches, abstract screening, number of studies included and excluded, as well as explanations for exclusions. It also illustrates the advantage of systemic review and meta-analysis, which is to provide an answer

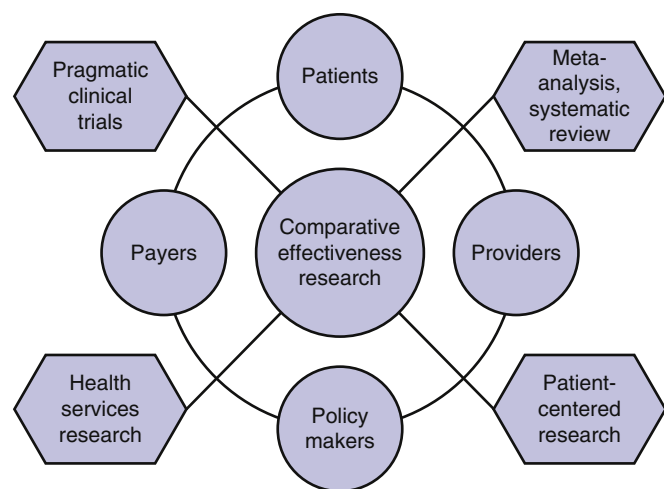

Figure 5.3 Schematic diagram of comparative effectiveness research (CER).

to focused research questions through a rigorous and transparent form of literature review. In this case, the authors confirmed previous large studies demonstrating a duration dependent protective effect of OCP use on the incidence of ovarian cancer.

The Cochrane Collaboration is a major source of systematic reviews (www.cochrane.org). This international organization aims to help people make well-informed decisions about health care by preparing, maintaining, and promoting the accessibility of systematic reviews of the effects of health care interventions. Cochrane funding comes from proceeds from the Cochrane Library and other Cochrane products, along with donations from national and international governments, private foundations, and private funders. Of note, the organization does not accept commercialized donations to prohibit undue commercial influence.

The Agency for Healthcare Research and Quality (AHRQ) also works with a number of partners to publish systematic reviews. The AHRQ lists its mission as “producing evidence to make health care safer, higher quality, more accessible, equitable, and affordable, and to work within the U.S. Department of Health and Human Services and with other partners to make sure that the evidence is understood and used.” The AHRQ also works in conjunction with the U.S. Preventive Services Task Force (USPSTF) to perform systematic reviews regarding clinical preventive services. These are published in both book form and, increasingly, electronic form. Many professional groups issue practice guidelines to help translate these often lengthy reviews into briefer, clinically useful documents, ultimately assisting clinicians in making patient care decisions. An electronic collection of such guidelines is now available at the National Guideline Clearinghouse (NGC; www.guideline.gov).

PRAGMATIC CLINICAL TRIALS

As noted earlier, the RCT is the gold standard for evaluating the effects of treatment; however, RCTs are often not generalizable due to the tightly controlled environment in which they are carried out. In recent years, clinicians and policy makers have made a concerted effort to distinguish between the *efficacy* and the *effectiveness* of an intervention. RCTs are efficacy trials (explanatory trials) whose purpose is to determine whether an intervention produces the expected result under ideal circumstances. On the other hand, pragmatic clinical trials (PCTs) are effectiveness trials, measuring the benefit of treatment under real-world circumstances or routine clinical practice. In 1967, Schwartz defined a PCT as a trial “for which the hypothesis and study design are formulated based on information needed to make a decision” (Schwartz, 1967). PCTs address real questions of cost, risk, and benefits that arise in everyday clinical practice, providing direct, useful information to providers, patients, payers, and other decision-makers (Roland, 1998). They resemble RCTs in the use of randomization, but PCTs do not place strict constraints on the setting of the trial, target patients, or intervention delivery. Traditional RCT approaches prioritize internal validity and efficacy, testing whether the intervention has the intended effect in ideal, highly controlled settings. In contrast, PCTs prioritize external validity, or generalizability to the public. Pragmatic trials test effectiveness, or the degree of beneficial effect in everyday clinical practice.

In a document released by the AHRQ and the Patient Centered Medical Home (PCMH), there are five ways in which

PCTs differ from RCTs: They (1) compare clinically relevant alternatives, (2) enroll diverse study populations, (3) recruit from a variety of practice settings, (4) measure a broad range of outcomes, and (5) adapt the intervention being tested to the local context. However, even PCTs have disadvantages. Although PCTs have excellent external validity, there is a tradeoff for internal validity. Effects of a particular treatment may be lessened or heightened, as the results were obtained in a more real-world setting. It also may be more difficult to determine what component of an intervention is responsible for a certain outcome, as the interventions can be heterogeneous. PCTs also require a great number of resources to keep meticulous records of implementation and to be sure that the study design is upheld. Regardless, the PCT is an excellent alternative to the traditional RCT in certain clinical settings. An example of the benefits of this study design is a study that examined the standard care of atrial fibrillation versus atrial fibrillation-specific management strategy (the SAFETY trial). This trial was designed as a pragmatic, randomized controlled trial. The standard group received routine primary care as well as hospital discharge follow-up. The SAFETY group included a home visit, a Holter monitor for 7 to 14 days, prolonged follow-up by a specialized cardiac nurse, and multidisciplinary support as needed. The SAFETY group was associated with more days alive out of the hospital, but no change in prolonged event-free survival (Stewart, 2015). This trial demonstrates the nature of PCTs focusing on the generalizability of an intervention to patients in the community, while holding true to RCT study design. It also demonstrates the amount of planning and support required to conduct a PCT. As the use of the PCT continues to grow, clinicians and researchers will have to learn where it will fit into our understanding of quality of evidence.

PATIENT-CENTERED OUTCOMES RESEARCH INSTITUTE

The Patient-Centered Outcomes Research Institute (PCORI) is an independent nonprofit, nongovernmental organization established by the 2010 Patient Protection and Affordable Care Act. PCORI's purpose is to assist patients and clinicians in making informed health decisions by advancing the quality and relevance of evidence concerning a broad range of health conditions. PCORI directs research to improve prevention, diagnosis, management, and monitoring of disease in varied patient subpopulations (Patient Protection and Affordable Care Act, 2010). Patient-centered outcomes research (PCOR) differs from CER in its primary target. The institution's primary goal is to inform individual patient decision making rather than targeting a wider range of audiences such as payers and policy makers. According to a working definition approved in March 2012 by the PCORI board of governors, the purpose of PCOR is to help patients and their providers communicate and make informed health care decisions by allowing the patient's voice to be heard in assessing the value of health care options. One way that PCORI operationalizes the focus on individuals in PCOR is through examination of outcomes “that people notice and care about such as survival, function, symptoms, and health related quality of life” (D'Arcy, 2012). PCORI aims to achieve this mission by producing and promoting the use of high-integrity, evidence-based information stemming from research guided by patients, caregivers, and the broader health care community.

PCORI funds comparative clinical effectiveness research and supports work that will improve the methods used to conduct such studies.

HEALTH SERVICES RESEARCH

The AHRQ defines health services research (HSR) as a

multidisciplinary field of scientific investigation that studies how social factors, financing systems, organizational structures and processes, health technologies, and personal behaviors affect access to health care, the quality and cost of health care, and ultimately, our health and well-being.

In 1993, the National Institutes of Health (NIH) Revitalization Act created a National Information Center on Health Services Research and Health Care Technology (NICHSR), which had the following goal:

To make the results of health services research, including practice guidelines and technology assessments, readily available to health practitioners, health care administrators, health policy makers, payers, and the information professionals who serve these groups; to improve access to data and information needed by the creators of health services research; and to contribute to the information infrastructure needed to foster patient record systems that can produce useful health services research data as a by-product of providing health care (<http://www.nlm.nih.gov/hsrinfo>).

As the cost of health care in the United States continues to increase, amounting to almost \$3 trillion in 2013, HSR has the ability to make major contributions to the future of medicine. Clinical research has long shaped the practice of medicine, but HSR looks to study the infrastructure of practicing medicine. The following sections contain examples of HSR.

DATA REGISTRY STUDIES

Large national and state registries provide the patient health care data needed for HSR. In 1971, the National Cancer Act provided funding to the National Cancer Institute (NCI) to detect, treat, and perform research on cancers in the United States. In 1973, the Surveillance, Epidemiology, and End Results (SEER) Program of NCI was established as the first national cancer registry. The SEER registry “collects and publishes cancer incidence and survival data from population-based cancer registries...on patient demographics, primary tumor site, tumor morphology and stage at diagnosis, first course of treatment, and follow-up for vital status” (<http://seer.cancer.gov>). The SEER database is updated annually and provided to the public. Since 1998, the Centers for Disease Control and Prevention (CDC), the American Cancer Society (ACS), the NCI, and the North American Association of Central Cancer Registries have collaborated on the Annual Report to the Nation on the Status of Cancer. Countless researchers and clinicians, along with legislators and policy makers, use SEER data. In 2015, Dinkelspiel and colleagues published SEER data on ovarian cancer from 1988 to 2012 comparing the causes of death by stage, age, and interval time after diagnosis (Dinkelspiel, 2015). SEER and CMS have also partnered to form the SEER-Medicare database. SEER continues to collect clinical and demographic

information, whereas CMS provides Medicare claims for covered health care services of patients with Medicare eligibility until death. The linkage of these two data sources allows for a unique collaboration incorporating epidemiologic and health services research. Forde and associates used the SEER-Medicare database to examine the cost of treatment for elderly women with ovarian cancer in the Medicare population. Neo-adjuvant chemotherapy (NACT) and primary debulking surgery (PDS) were compared for cost and effectiveness (Forde, 2015). NACT and PDS were comparable in stage IIIC disease, whereas PDS was associated with a 12% increase in cost in stage IV disease. In both groups, NACT was associated with a decreased 5-year overall survival (OS) with hazard ratio (HR) of 1.27 and 1.19, respectively. Although cancer registries have been mentioned here, there are a number of data registries for patients. CMS and the National Institute of Diabetes and Digestive and Kidney Disease (NIDDK) have collaborated on the United States Renal Data System (USRDS) to collect and analyze data on patients with end stage renal disease (www.usrds.org).

QUALITY IMPROVEMENT

Quality improvement (QI) is a unique format of HSR, encompassing both research and QI program development to improve the quality of health care. The Institute of Medicine (IOM) defines quality in health care as a direct correlation between the level of improved health services and the desired health outcomes of individuals and populations (www.iom.edu). QI projects can be developed and conducted within small practices, in large hospital systems, or on a much larger national and international scale. The Health Resources and Services Administration (HRSA) under the U.S. Department of Health and Human Services provides a toolkit to help QI programs develop and implement QI projects (www.hrsa.gov). There are numerous organizations and committees whose sole purpose is to examine the issue of health care quality. In 1990, the National Committee for Quality Assurance was founded as a not-for-profit organization to help build consensus around important health care quality issues. It has a simple formula: “measure, analyze, improve, repeat” (www.ncqa.org). The National Quality Forum (NQF) is a not-for-profit, nonpartisan, membership-based organization whose mission is to “lead national collaborations to improve health and healthcare quality through measurement” (qualityforum.org). Its vision is “to be the convener of key public and private sector leaders to establish national priorities and goals to achieve healthcare that is safe, effective, patient-centered, timely, efficient, and equitable.” The American Medical Association (AMA) also convenes the Physician Consortium for Performance Improvement (PCPI). It is a physician-led program with a mission “to align patient-centered care, performance measurement and quality improvement” (www.ama-assn.org). The U.S. Centers of Medicare and Medicaid Services (CMS) Physician Quality Reporting System (PQRS) is a quality reporting program on the care given to Medicare beneficiaries. In 2015, the CMS will begin applying a negative payment adjustment to providers and groups who did not meet requirements of reporting data to PQRS. In 2018, PQRS will begin using these reported quality measures to make reimbursement decisions based on quality of care given to Medicare beneficiaries. The role of quality improvement is also felt heavily in surgical specialties.

CMS and other payers are increasingly refusing to pay for complications of surgery that are deemed preventable. The American College of Surgeons National Surgical Quality Improvement Program (ACS NSQIP) helps surgeons and hospitals identify preventable surgical complications. Data are collected directly from patients' charts by a surgical clinical reviewer (SCR), in contrast to collecting data from billing codes. In 2009, Hall and colleagues published data on 118 hospitals nationally participating in ACS NSQIP from 2006 to 2007 reporting that 82% of hospitals had improved risk-adjusted complication rates and 66% of hospitals had improved risk-adjusted mortality as compared to their own prior rates reported the year prior (Hall, 2009). By the end of 2007, ACS NSQIP had enrolled 183 hospitals, reporting that participating hospitals avoided on average 52.5 complications per year. ACS NSQIP helps identify and rectify preventable surgical outcomes; QI projects are a necessity for all health care providers and health care institutions.

COST-EFFECTIVENESS ANALYSIS

The term *cost-effectiveness analysis* has become a catch phrase referring to all health economic analyses. As the cost of health care continues to rise in the United States, now expected to exceed \$3 trillion in 2015, health economic analysis is more relevant than ever. There are four methods of health economic analysis, with cost-effectiveness analysis (CEA) being one of the more commonly used methods. The other three methods include cost-utility analysis (CUA), cost-minimization analysis (CMA), and cost-benefit analysis (CBA). CEA and CUA are used most often. CEA is most often used among economic analysis tools and is a comparison of relative costs and outcomes of varying treatments. It is a measure of cost per unit of effectiveness (additional survival time, number of adverse events, etc.). It determines incremental cost-effectiveness ratio (ICER), or the ratio of the difference in costs to the difference in effectiveness between two strategies. It is most often used in the allocation of resources for treatment or intervention. CUA takes into account the quality of life associated with each intervention. The number of quality-adjusted life years (QALY) is the most common metric used for comparison and represents the differences in survival and quality of life between interventions. CUA is an important effectiveness measure when morbidity and mortality are affected by an intervention. CMA assumes comparable effectiveness among intervention strategies and thus is just a comparison of the mean cost of each intervention. CBA incorporates not only the monetary expense of intervention but also the costs of the consequences of each intervention.

In CEA an intervention has traditionally been considered cost-effective if the ICER is less than \$50,000 per QALY, with some leeway. It is important to understand that the term "cost-effective" does not represent that an intervention saves money but rather means that the additional cost of that intervention is worthwhile based on the improved effectiveness achieved. In 2009, Kim and coworkers published a CEA on the addition of the human papillomavirus (HPV) vaccination to routine cervical cancer screening in women older than 30 years in the United States. The estimated ICER for the addition of the vaccine ranged from \$116,950 to 381,590 per QALY, which greatly exceeds the standard threshold of \$50,000. It was concluded that the addition of the HPV vaccination to routine

screening in women over the age of 30 years in the United States is not cost effective (Kim, 2009). These types of studies are flourishing as the cost of health care in the United States continues to rise. They are an integral part of understanding the costs and quality of health care.

NEW HORIZONS: VALUE IN HEALTH CARE

The discussion of value in health care is currently gaining interest. Value in health care is defined as "the health outcomes achieved per dollar spent" (Porter, 2006). Outcomes are inherently linked to the medical condition of interest, whereas the dollar spent represents the total amount spent during a cycle of care, not the cost of individual service. Porter argued:

The proper unit for measuring value should encompass all services or activities that jointly determine success in meeting a set of patient needs. These needs are determined by the patient's medical condition, defined as an interrelated set of medical circumstances that are best addressed in an integrated way...and that value should be measured for everything included in that care (Porter, 2010).

Large clinical societies are getting involved with defining the value of health care. The American Society of Clinical Oncology (ASCO) is developing a conceptual framework to assess the value of cancer treatment options (Schnipper, 2015). As the cost of new treatments for cancer continues to rise, the value of this care is an important question. Value in health care is in its infancy but shows promise in navigating the ever-increasing costs of health care.

ACKNOWLEDGMENT

The authors wish to acknowledge the contributions of Dr. Vern Katz, the author of the previous edition of this chapter.

KEY POINTS

- Evidence-based medicine seeks to improve the care of patients and the delivery of care to patients.
- Descriptive-observational studies, including cross-sectional studies and case series, help generate hypotheses and characterize the context of disease.
- Cohort studies allow us to study many outcomes over time.
- Case-control studies allow us to study rare diseases and evaluate for a wide range of exposures.
- RCTs are considered to be the gold standard of experimental clinical study design.
- PCTs are designed to study the effectiveness of an intervention in the real world.
- CER encompasses patient-centered research, PCTs, meta-analyses, systematic reviews, evidence-based guidelines, and health services research to study the benefits and harms of an intervention to improve patient care on the individual and population level.
- Estimating the value of health care involves an assessment of the quality and integration of care, as well as the overall cost to provide all services included in that care.

Medical-Legal Risk Management

James M. Kelley III, Gretchen M. Lentz

The word *malpractice* evokes guttural responses in physicians and health care providers. This is perhaps most true in the areas of obstetrics and gynecology, where the physical damages are often catastrophic and the economic damages reach the millions of dollars. The fear of being unjustly involved in litigation and judged by nonphysicians as liable—despite having provided reasonable and appropriate care—seems unavoidable to many conscientious health care providers. The little known reality, however, is that the growing consensus of empirical data on outcomes of malpractice actions shows that the legal system actually works for the health care provider more often than it does not. Understanding how the system works and making minor practice modifications can greatly minimize the risk of legal exposure by avoiding claims and adverse outcomes.

A medical negligence case is composed of three basic elements: a deviation from the standard of care, proximate causation, and damages. Each of these elements is required to be proved by way of “competent” expert testimony. The definition of “competent” varies state to state, but all states are uniform in requiring a physician to agree that malpractice occurred and that it directly resulted in injury. A deviation from the standard of care, though a cumbersome legal phrase, is simply a failure to act reasonably as compared with another health care provider in the same or similar clinical circumstance. A deviation from the standard of care can be an act (intraoperative bowel perforation, administration of the wrong medication, etc.) or an omission (failure to run the bowel intraoperatively if a bowel injury is possible or failure to review laboratory results in a timely manner).

Proximate causation is often a more medically complex component of a malpractice action. The law requires that the deviation from the standard of care be *a* direct, proximate cause of injury to the plaintiff. It is important to note that the deviation does not have to be *the* exclusive cause of injury, but rather need only be *a* direct proximate cause. Proximate cause, legally, merely means that with appropriate or reasonable treatment, the injury would not have occurred.

The final element of a malpractice claim is damages. Damages can be both economic and noneconomic. Economic damages include easily quantifiable losses as past and future medical bills and past and future wage losses. Noneconomic damages contemplate factors such as past and future physical pain, emotional suffering, and, in certain instances, wrongful death. To be successful, the plaintiff must prove each of these elements to a probability, through expert testimony, in order to

win. A failure on any one of the elements will result in a verdict for the defendant.

As mentioned, many health care providers will be surprised to learn what the growing consensus of empirical data reflects regarding medical claims. A review of approximately 1400 closed malpractice claims from five different liability carriers showed that only 3% of claims filed had no verifiable medical injuries to justify a claim. Additionally, 37% of the 3% did not involve errors but rather would be what a physician would commonly refer to as “frivolous.” Despite common perceptions about runaway juries and lottery verdicts levied against faultless physicians, the study demonstrated that 84% of the claims that did not involve errors nonetheless resulted in nonpayment. Conversely, approximately six times that rate of claims resulted in nonpayment to the plaintiff, despite the presence of medical errors and verifiable injuries (Studdert, 2006) (Box 6.1).

Although these data should be heartening for health care providers, they do little to eliminate burdens of excessive litigation costs, time away from practice and families, and the stress of participating in litigation. The goal for conscientious providers must be one focused on risk management: balancing improved patient care and minimizing medical legal risk.

A safe health care system must further incorporate efficient redundancies that promote safety without being cost prohibitive. “Errors can be prevented by designing systems that make it hard for people to do the wrong thing and easy to do the right thing” (IOM, 2000).

Realizing lawsuits will inevitably occur, what follows is a brief historical overview along with practical insights aimed at helping one enhance patient care and communication, minimize the risk of involvement in meritless litigation, and provide the best defense in the event a claim is made.

Box 6.1 What Constitutes Medical Practice?

To successfully maintain a medical malpractice action, a plaintiff must be able to establish three distinct elements of his or her case by way of expert testimony:

1. *Deviation from the standard of care:* The health care provider deviated from what a reasonable provider would have done in the same or similar circumstances.
2. *Causation:* The deviation was a direct cause of the injury suffered.
3. *Damages:* Economic and noneconomic damages were suffered as result of the injury.

HISTORICAL PERSPECTIVE

A doctor who knows nothing of the law and a lawyer who knows nothing of medicine are deficient in essential requisites of their professions.

—DAVID PAUL BROWN 1795-1872

British North America inherited its law, as its language, from England. Most European countries originally occupied by the Romans adopted a form of law based on the Roman law codes. That law is called *civil law*. England's law, on the other hand, was based mainly on Scandinavian (Danish) law with a dose of folk law of undetermined origin thrown in. It was called the *common law*. One should not be deceived by its name. It was not law designed to protect the common man. It takes its name from the fact that it was the law that was common to all of England by about the year 1240. The two forms of law differ significantly.

Civil law is a codified system of laws. That is, the laws are spelled out in a series of written statutes adopted by the jurisdiction. Civil law therefore tends to be fairly static. Common law is largely law made by judges. It may incorporate some statutory elements on specific issues, but even statutes are subject to judicial interpretation. Judges in the civil law are academics specially trained for their positions and act as prosecutor, judge, and jury. Civil law is therefore inquisitorial in nature and heavily dependent on the written word. In contrast, common law is an adversarial system in which the oral argument between the parties plays a much larger role. Judges are chosen from the practicing bar and are not usually academics. The judge is essentially a referee and instructs the jury, which makes the ultimate decision on the merits of the case. In common law, the law is made by judges who hear a disputed case on appeal. Those decisions become precedent for future cases. However, higher appellate courts or future appellate courts of the same level can overturn or overrule a prior decision if circumstances change or new information develops. Therefore change, albeit slow and irregular, is a constant element of the common law.

Under the early common law to bring a civil action a King's Writ was needed, therefore little attention was paid to compensating the individual for personal wrongs (tort law). Doctors were essentially immune from suit for malpractice. Technically some suits might have been pursued as contract suits, but written contracts were highly unusual between a physician and his patient, and without the written document such suits became almost impossible for the plaintiff to win.

In 1346 the bubonic plague arrived in Italy. It spread over Europe rapidly but did not reach England until 1348. The major effect of the epidemic occurred between 1348 and 1351, but the bubonic plague became endemic and continued more or less uninterrupted until 1381. It is estimated that between 1348 and 1351, 50% of the population died, and by 1381 two thirds of the English population was decimated by the epidemic. (Because there was no accurate census at the time, such figures are estimates based on church records, burial records, tax rolls, and contemporary accounts.)

The loss of manpower was a major blow to the English economy. Overnight, people became as important as real property (land) and personal property (including livestock) in the English economy. Therefore a physician's mistake that deprived the economy of a worker became an important enough matter to be

brought before the courts. Physicians suddenly lost their immunity for practice errors. Actually it was an even worse scenario: the physician became strictly liable for an unfavorable outcome, and because there was no tort law (law compensating the individual for personal wrongs), the physician was prosecuted under the criminal law for mayhem. By 1364, it had become obvious that this was too draconian a remedy, and two property terms that had been previously used in livestock cases were introduced to permit civil malpractice cases. *Trespass* (trespass by force and arms) was charged for direct injury and *trespass on the case* for indirect injury.

These same concepts, refined over the centuries, were brought to the North American colonies and adopted almost entirely by the American court system after independence. In the early 1800s the modern concept of negligence replaced trespass and trespass on the case. In the period of rapid industrialization following the Civil War, American courts refined these claims. The four elements of a cause of action for medical negligence are as follows:

1. *Duty*: The obligation created through physician patient relationship.
2. *Breach*: A deviation from the "standard of care" for a reasonable practitioner in the same clinical circumstance.
3. *Proximate causation*: A direct and foreseeable connection between breach and injury.
4. *Damages*: Economic (medical costs, wage loss, etc.) and non-economic (physical and emotional pain and suffering).

There is no greater asset in risk management for the clinician than a strong physician-patient relationship. Patients are typically trusting and respectful of their providers, which gives the best opportunity to avoid litigation. The typical patient will become a plaintiff when he or she loses trust in the provider or fails to get understandable answers to the complex medical issues surrounding a less than optimal outcome. "I don't know or understand either what happened or how this happened?" is the question that begins nearly all inquiries into the quality of care. This chapter provides insights that will allow the physician to supply answers to the patient, to document appropriately, and to participate more functionally in a medical-legal claim while maintaining a high level of care and professionalism.

REPRODUCTIVE MEDICINE AND THE COURTS

No area of medicine receives more court scrutiny, legal scholarly review, or social commentary (even including presidential directives) than the fields of obstetrics and gynecology. In addition, it is common that the most expensive category of malpractice claims arise from the obstetrician/gynecologist's practice (pregnancy/birth claims, failure to diagnose breast cancer, failure to diagnose cervical cancer). Practically speaking, nearly every malpractice issue that has been litigated in American courts deserves a volume of its own to discuss and dissect adequately. Indeed, a single chapter in a general textbook of gynecology can do little but cover the generalities and touch on the more important issues the courts have addressed. Overall, applying the four elements noted previously to most claims, a malpractice case is typically a review of case facts applied to the "standard of care" and "proximate cause" through medical testimony to determine if care was simply "reasonable." It

is important to note that the care does not have to be perfect nor do all decisions have to be correct. Instead, if care is attentive and the decisions rational, the provider will have a strong defense position regardless of outcome.

PRACTICAL INSIGHT

Medical-legal risk management, at its core, centers on communication in both the written and verbal form. Awareness of the common pitfalls in the processes employed in communicating information to patients, as well as concurrent and subsequent care providers, will be invaluable if problems or litigation arise. The medical record, institutional policies and guidelines, and information communicated to patients (prospective plaintiffs) will be the only information attorneys, claim representatives, and reviewing expert physicians have available to judge the validity of a potential malpractice claim. The following discussion examines good practices to improve communications with patients (both before and after treatment), improve the accuracy of the medical records, and provide useful information about navigating the litigation process to your best outcome.

COMMUNICATION WITH THE PATIENT

Physicians well understand that the relationship with a patient is in large measure a relationship of trust. More often than not, a perceived breach of that trust is the impetus for a patient to seek the advice of an outsider for explanations about unfortunate medical outcomes. It must become a routine practice for physicians to thoroughly and carefully discuss potential problems with their patients prior to treatment. Taking the time necessary to assess a patient's understanding of the procedures and possible outcomes, and answering all questions the patient may have, are critical to managing and controlling expectations. Concurrent notations in the record that you have in fact reviewed all risks and benefits of a potential treatment, thoroughly explained alternative treatments or procedures, and answered all patient questions will provide important evidence of careful and appropriate treatment, should it later become necessary (Box 6.2).

The eleven words in the sample progress note are an invaluable resource in the event of a complication or litigation. Although this is brief documentation, it does indicate the physician personally reviewed the critical elements mentioned earlier and allowed for questions. This note portrays the provider discussing the case with the patient, which will supplement the standard preprinted consent that is more "legalese" than substantive.

POOR OUTCOME

In the unfortunate event of a poor outcome, it is imperative for the physician to communicate more, not less, with the patient or the patient's family where appropriate. Health care providers often dramatically change—or end entirely—their relationship

with patients following a maloccurrence. For example, in situations in which the patient may have ongoing care issues but is transferred to a tertiary center or a different specialist, there is often minimal or no ongoing relationship. Despite what may be the urge to distance yourself from an unpleasant or uncomfortable interaction, keep in mind that your patient and his or her family members will begin to assess whether you are forthcoming with them at this very time. If there is an attempt to avoid interaction it can, and likely will, be misperceived as an attempt to avoid explaining the cause or causes of the bad outcome. It is important that your trust relationship with the patient and the patient's family continues at this crucial time and that they feel you are willing to answer all questions.

When discussing the outcome or problem, revisit the discussion of risks and outcomes at the time of the informed consent. Reiterate the information you previously provided, and explain how this result is related to the risks previously discussed, if appropriate. Finally, it is also important that you are involved in establishing the plan for care going forward, even if it is outside of your specialty. Remaining involved preserves the physician-patient relationship. Patients are far less likely to file claims against physicians with whom they have an ongoing, trusting relationship. It is therefore important to make yourself available as long as is necessary to assure the patient and his or her family that you are answering all of their questions. Absence or avoidance will create suspicion by the patient or another family member and can ultimately lead them to seek answers to their questions from an outside source, most often an attorney.

Once again, it is imperative you write contemporaneous and accurate notes. The timing of such notes, combined with their detail and clarity, will begin to establish a good defense in the event the records are reviewed for a possible claim. It is easy to defend conscientious care, regardless of outcome, if the record supports you (Box 6.3).

CANCELLATIONS AND "NO SHOWS"

Cancellations and "no shows" of patients' follow-up appointments are often ignored in the busy clinic or office. They can be, and are, frequently responsible for subsequent malpractice suits. Each cancellation or no show should be documented in the chart. The treating physician should then review the chart and, where appropriate, a letter or phone call should be made to the patient. All efforts to communicate with the patient should be documented.

COVERAGE ARRANGEMENTS

As mentioned earlier, improper coverage arrangements may lead to charges of abandonment. Poor communication among coverage groups frequently leads to offended patients and can be the first step on the path to a malpractice suit.

Box 6.2 Practice Tip

Sample Progress Note

Risks/benefits/alternatives discussed with patient. All questions answered in full.

Box 6.3 Practice Tip

Communication with the patient when a problem occurs is an opportunity to explain how the poor outcome happened, despite vigilance. Patients will naturally have questions, and most who contact a malpractice attorney are doing so to get answers to questions they feel were not sufficiently answered by the health care provider.

MEDICATION ERRORS

About 1.5 million people are injured each year in the United States due to medication errors, the Institutes of Medicine of the National Academy of Sciences revealed in a 2006 review of medication management in the U.S. health care system (IOM, 2007). The study reveals medication errors make up a large share of medical malpractice cases. The results can range from minor allergic response to death. Medications pose risk to both the institution and the provider for liability.

The reasons behind this include, but are not limited to, the frequency with which patients are being prescribed medication, the popularity of at-home prescription administration, and the many look-alike, sound-alike, drugs. The Institute of Medicine report states, “The extra medical cost of treating drug-related injuries occurring in hospitals alone conservatively amounts to \$3.5 billion a year, and this estimate does not take into account lost wages and productivity or additional health care costs” (IOM, 2007).

Medication errors are always preventable, through system and personal practice modifications. Data show that 400,000 preventable drug-related injuries occur each year in hospitals (IOM, 2007). Another report states that adverse drug events cause more than 770,000 injuries and deaths each year and cost up to \$5.6 million per hospital (AHRQ, 2015).

The National Coordinating Council for Medication Error and Prevention has approved the following definition of medication error:

Any preventable event that may cause or lead to inappropriate medication use or patient harm, while the medication is in the control of the health care professional, patient, or consumer. Such events may be related to professional practice, health care products, procedures, and systems including: prescribing; order communication; product labeling, packaging and nomenclature; compounding; dispensing; distribution; administration; education; monitoring; and use (FDA, 2016).

Practical Tip

The reality of practice is that many orders are verbal, telephonic, or standing. Verbal or telephonic orders should always be read back to the provider to verify drug, dosage, frequency, and method of administration. This minimizes the likelihood of a communication lapse. Furthermore, telephonic orders are frequently later signed after the medication is administered. Closely review these to be sure you are not validating the error as your own order. Litigation is often more than a year later, and memory of the details will be a challenge with a record that is inconsistent. If upon review an error is noted, correct it in the record with a single line and the corrected information at the side. Time and date your correction as well.

Be aware of your orders as well as those of other providers, anesthesia, infectious disease, and so on to be aware of interactions of medications also. Standing orders often pose a risk in this circumstance.

COMMUNICATION THROUGH MEDICAL RECORDS

Once the litigation process has commenced, a plaintiff attorney's best friend is inaccurate or inconsistent documentation of the

care provided. Inaccurate documentation can stem from a genuine standard-of-care issue; however, inaccuracies can also arise from use of inappropriate nomenclature. In either situation, the health care provider will be in the untenable position of attempting to defend a narrative note or deposition testimony that is factually inconsistent with literature, policies, or objective data in the medical record. Needless to say, in a courtroom, inconsistencies never favor the inconsistent party. Careful attention to record keeping will not only demonstrate attentive care and rationally based treatment decisions but will ultimately become a provider's best defense in a courtroom.

Within your hospital, facility, office, and charts, you must use nomenclature designed to standardize the verbiage utilized among providers. Unfortunately, despite the attempts at standardization, many health care providers have been slow to adapt. This is often based on variable levels of education by authors and is also generational. This increases not only the risk of inaccurate communication between health care providers but also the risk of a medical record replete with inconsistencies. Inconsistencies can be easily used to portray a provider as incompetent or disingenuous.

From a medicolegal risk management standpoint, it is critical to keep in mind when a plaintiff's counsel attempts to determine whether medical malpractice may have occurred, the medical record is the primary (and often the only) source of information available to evaluate the potential claim. Any narrative notes supplied will be read against subsequent health care providers' notes and the objective data such as lab results and imaging. As stated earlier, clearly noted and accurate recognition and description of reassuring and nonreassuring findings in the record will demonstrate attentive and competent care. However, inaccurate terminology, when read against the objective data, could result in the commencement of litigation.

Beyond the initial review phase of a potential claim, inconsistent and inaccurate nomenclature and record keeping will continue to present obstacles to a favorable resolution of the claim during the testimonial phase of trial. When a witness employs modified or nonstandardized nomenclature, other health care providers, including expert medical witnesses, do not necessarily understand the full extent of what is meant. This unclear communication can result in actual medical errors among providers or, at a minimum, the appearance of errors within a medical record (Box 6.4).

The example shows how the inappropriate and inconsistent nomenclature forced the physician to be critical of the nurse's actions, while the nurse attempted to separate herself from her own charting. This is not only a difficult posture to defend, but also it reflects poorly on the competency and truthfulness of the parties involved. Simply employing appropriate, consistent nomenclature would have provided an easy defense (Box 6.5).

ALTERATION OF RECORDS

A medical malpractice case can go from defensible to indefensible immediately with an alteration of the record. An alteration is typically defined as an entry added to or redacted from the record to avoid culpability. An alteration in many states is a basis for punitive damages (noninsured). Furthermore, it may invalidate coverage under some professional policies. Most providers do not add for the purpose of deceit but to make the record more

Box 6.4 Factual Scenario

In a previous deposition, a physician was questioned regarding a nursing narrative note:

- Q. Dr. Doe, do you expect the nurse to relay to you if there are any postoperative changes?
- A. Any relevant postoperative changes should be relayed to me, particularly if there are more than one.
- Q. By relevant change, do you mean if any vital signs manifest persistent change?
- A. I do not understand what that means. However, if a nurse sees vitals change, I want to know about it immediately, especially if it persists.

The narrative notes within the case included the nurse describing labile blood pressures. Utilizing charting terminology such as *labile* created a scenario in which the physician had expectations of being told immediately and a medical record suggesting the call should have been made. Further testimony demonstrated that no information regarding these changes was relayed. The nurse testified as follows:

- Q. Did you relay to Dr. Doe that the blood pressures were labile?
- A. No.
- Q. Why not?
- A. Because I felt it was not necessarily significant and may be routine post-op fluctuations.
- Q. So you felt it was unstable but not labile?
- A. Yes.
- Q. So when you chart the word *labile*, you want the jury to believe it doesn't mean labile?
- A. I guess.

Box 6.5 Practice Tip

The consistent use of appropriate nomenclature not only minimizes risk in the defense of a medical legal action but also allows the physicians and nurses to communicate clearly by ensuring they are discussing the same findings and placing the same significance.

“complete” after an unfortunate outcome. Accordingly, it is not typical to chart after a shift has passed. In the event it is necessary, clearly note the entry as a “late entry” and date when it is entered and to when it refers. There is nothing wrong with a late entry if you accurately describe it as such. Today, technology can discern the sequence through impression as to when notes were written and if the ink is the same through infrared light. A record that can be alleged to be altered will cause a loss of credibility with any jury and may expose you to personal liability.

COMMUNICATION CONSISTENT WITH INSTITUTIONAL POLICIES

Published institutional policies and procedures should be reviewed regularly and integrated into your daily practice. The purpose of the policies or protocols is not merely for JCAHO, or to fill shelf space, but to effectuate patient care and create a consistent safe administration of the medication and care to patients. However, each individual patient obviously deserves individual care and modifications to the policy or protocol as may be necessary. Policies and protocols relevant to the issues that are the

Box 6.6 Factual Scenario

Many gynecologic cases involve the failure to recognize postoperative bowel perforations or significant bleeding. Total abdominal hysterectomy usually carries with it a specific physician's postoperative orders or, more commonly, a hospital's postoperative policy or protocol. It is of critical importance that the nurse and physician both have an understanding of the specific details of the policy or protocol prior to executing care and prior to testifying regarding these issues. The following example highlights why this is important:

- Q. Are you aware as to whether or not there is a postoperative policy at this facility?
- A. I don't know. I guess there probably is.
- Q. Do you agree that you, as a reasonable nurse, have a duty to follow the policy here at the facility?
- A. I don't really know what the policy says, but I'm sure it's reasonable and yes I should probably follow it.
- Q. If you failed to follow the policy, can we agree that you would have been acting unreasonably and beneath the accepted standards of care?
- A. I probably should follow a policy if it exists. I guess if I didn't, I was beneath the standard of care.

The nurse went on to define terms differently from the definition contained in the policy and testified that the physician with whom she was working was aware of her actions. When the physician was questioned, he testified as follows:

- Q. Do you expect the nurses to follow your specific orders and, when orders are not present specific to the chart, to follow policies or protocols that are in place for the delivery of health care to patients?
- A. Absolutely.
- Q. For this patient, did you write a specific postoperative order?
- A. No.
- Q. Your order says, “post total abdominal hysterectomy protocol”?
- A. Yes.
- Q. Does that mean the nurse should follow the hospital's policy or protocol?
- A. Absolutely.
- Q. Is a reasonable nurse allowed to deviate from that policy or protocol without calling you first?
- A. No.

bases of any litigation should be familiar to you *before* providing sworn testimony under oath. Because these written policies can form the basis of an accepted standard of care in your institution, any testimony or records inconsistent with these policies can be viewed by a jury as being outside the standard of care, or negligent (Box 6.6).

In the boxed example, a lack of familiarity with the standard policy within the hospital created a scenario in which the physician and nurse were uncertain as to what the hospital expected. Compounding matters, the lack of familiarity with the policy and protocol prior to deposition created a scenario in which not only did the nurse provide testimony that she deviated from the policy but also she was forced to acknowledge a total lack of familiarity with the same. In short, knowledge of and compliance with institutional policies, guidelines, and resources can demonstrate the implementation of appropriate care and documentation can be the shield of your defense; conversely, ignorance of and deviation from such policies can provide a documented deviation from the standard of care that will be the sword of the plaintiff.

WHEN A CLAIM IS MADE

The institution of a claim varies from state to state and is defined differently among various insurance policies. It is imperative that you have an understanding through your institution, insurance policy, and within your state as to what constitutes knowledge or notice of a claim. When notice of a claim is received, it is imperative that you immediately notify your hospital or group administrator and your insurance company. A failure to timely notify individuals can jeopardize insurance coverage or compromise your defense, and in a worst-case scenario may potentially result in a default judgment for failure to timely respond. Although the legal system does move slowly, there are certain parameters, and timely responses are mandatory at the beginning of litigation.

Participation in a claim is aggravating, frightening, and an imposition on your professional or personal time. However, it is critical to avoid procrastination or de-prioritization of the claim regardless of the level of merit or damages perceived by you. A lawsuit is typically commenced by the filing of a legal pleading known as a “complaint.” Thereafter, there will be a statutory amount of time for an “answer” to be filed on your behalf. The first portion of litigation is thereafter referred to as “discovery.” This is where each side exchanges information either through documents or sworn testimony between the sides—first regarding factual information, then regarding expert opinions in the claim. A deposition is simply the opposing attorney’s opportunity to ask questions under oath that are reasonably calculated to lead to relevant discoverable evidence.

Your deposition is an obligation, not an opportunity. In that regard, it is critical that you meet with your attorney in advance of your deposition so that you can be prepared for the relevant issues. A critical review of your care with your attorney is important so that you that can anticipate all areas of questioning and avoid surprise questioning under oath. The answers you give under oath are sworn testimony in the case, and often depositions circulate through the legal community even after the case closes. It is recommended that you meet at least 1 week in advance of your deposition with counsel for a preparatory session, which will allow you adequate time in the event your practice requires rescheduling that meeting, before you actually give your testimony at deposition. Additional preparation could include a mock deposition, or simulation in a question-and-answer format, with another attorney to give you a sense of the actual deposition. This can be very useful to isolate and review medically complex issues and to enhance your preparation for giving sworn testimony.

Your deposition testimony, along with that of the other factual witnesses, will supplement the medical record for the expert witnesses retained by all parties to litigation to utilize in formulating their opinions and testimony. All of which, in turn, will ultimately become the evidence jurors will use to judge which positions they find most reasonable. Accordingly, just as accurate, concise, and consistent communication in your medical record is a priority, so too should it be within your deposition.

Following discovery, cases are usually scheduled for jury trials based on individual court docket systems. You should plan on attending each day of your trial and participating in the trial all day and some evenings. Although it is no physician’s desire to take time away from his or her practice to be in a courtroom, it is imperative that when you arrive, you have an accurate medical

Box 6.7 Practice Tip

1. Secure and isolate the patient’s complete medical record.
2. Make no additions, modifications, or alterations to that chart.
3. Immediately notify either your institutional administrative or insurance representative of the claim, in order to preserve malpractice coverage.
4. Participate fully—and as a priority—in the defense of the quality of your care.

record and deposition to support the reasonableness of the decisions you made at the time that you made them (Box 6.7).

FRAUD AND ABUSE

In 1972, as part of the first amendments to the Medicaid and Medicare rules and regulations, Congress passed antifraud and abuse regulations. The first such laws were hardly more than a slap on the wrist. However, in 1977 Congress made those laws draconian. False statements include the following:

1. Knowingly and willfully making or causing to be made any false statement or representation of a material fact in seeking to obtain any benefit or payment
2. Fraudulently concealing or failing to disclose information affecting one’s rights to a payment
3. Converting any benefit or payment rightfully belonging to another
4. Presenting or causing to be presented a claim for a physician’s service knowing that the individual who furnished the service was not licensed as a physician

These also encompass false claims, bribes, kickbacks, rebates, or “any remuneration” and are felonies with a maximum penalty of 5 years in jail and a \$25,000.00 fine possible for each such offense. (The law states that any provider who knowingly and willfully solicits, pays, offers, or receives any remuneration, in cash or in kind, directly or indirectly, overtly or covertly, to induce or in return for arranging for or ordering items or services that will be paid for by Medicare or Medicaid will be guilty of a felony.) These rules and regulations essentially made it impossible to practice without violating some aspect of the fraud and abuse laws. It was, however, 10 years before the laws were refined in the Medicaid-Medicare Patient Protection Act of 1987, which provided some safe harbors to free normal course-of-business procedures. Since 1987, the government has pursued fraud and abuse cases with ever-increasing vigor. In 2003, settlements in fraud and abuse cases netted the government close to \$2 billion (WSJ, 2004). The real danger to the physician is not the fine that may force him or her into bankruptcy or the unusual imposition of jail time (to date, the government has seemed more interested in recovering cash and calling a halt to illegal practices than it has in jailing doctors), but the felony conviction that may result in the automatic loss of the license to practice. Thus Medicare/Medicaid fraud and abuse is a far more dangerous hazard than is malpractice.

Practical Tip

Have your patients sign in regardless of whether they have come for an office visit or just a procedure. If you are worried about privacy issues, use a privacy sign-in sheet to prevent subsequent signers from seeing previous signers. (Colwell Publishing

provides several styles of such sheets, and they are likely supplied by local firms as well.)

Do not unbundle procedures that are supposed to be bundled on a physician's visit. Do not unbundle surgical procedures. Do not charge for procedures done by another licensed provider or charge for a physician's services if the physician is not physically present. Send your personnel to an accredited coding course, and make sure your coding is being done in an accurate manner. Do not be tempted to code up. Time studies and statistics are against you. Finally, beware of the "coding consultant" who promises to increase your accounts receivable.

LABORATORY TESTS

In my experience, one of the most common reasons for malpractice suits is the unreported abnormal laboratory or x-ray finding. The usual story is that the pathologist or radiologist returns the report and the efficient clerk, receptionist, or nurse staples it in the medical record and then files the record. The alternative story is that the report is never sent and there is no follow-up. Of course, normal clerical errors do occur in any business; nevertheless, the physician's fiduciary duty extends to communicating the results and meanings of all abnormal tests to the patient. Therefore the failure to communicate the results of an abnormal Pap smear, glucose tolerance test, or mammogram to a patient can have disastrous legal consequences.

Practical Tip

A gynecologist must have a system to track and document all laboratory and diagnostic tests and imaging studies ordered. There is no totally satisfactory way to do this. Old-fashioned "tickler" files are the least efficient, but they are better than nothing. Some office-generated computer programs have been highly successful, and some of the commercially available programs even generate an automatic notification letter. In any case, the physician must track all ordered tests and make every reasonable effort to notify the patient. The notification and follow-up must be documented. Telling the patient to call for the test results does not relieve the physician of his or her duty to notify. Finally, use the information you secure. Do not order laboratory or other diagnostic tests and then ignore or belittle those results.

CAP STRATEGY

CAP (communication, anticipation, and preparation) should be the cornerstone of simple practice philosophies that, when effectively put into practice by qualified, trained health care providers in a safe medical system, will increase patient safety and thereby "cap" exposure to liability (Fig. 6.1).

The optimal health system will assimilate CAP between and among the care providers within any given institution or health system. Applying the principles of CAP will ensure, by employing efficient written, verbal, and policy guidelines, that the right health care providers will have the correct information necessary to effectuate optimal care. There is no single greater way to reduce medical liability than to increase patient safety.

Next we will review how these simple, sound, and commonsense approaches can be incorporated to increase patient safety. Errors have and will continue to occur in any system that involves people

Figure 6.1 Communication + Anticipation + Preparation = Patient safety and reduced medicolegal risk.

performing duties or tasks. "The most extensive study of adverse events is the Harvard medical practice study, a study of more than 30,000 randomly selected discharges from 51 randomly selected hospitals in New York State in 1984. Adverse events, manifested by prolonged hospitalization or disability at the time of discharge, or both occurred in 3.7% of the hospitalizations. The proportion of adverse events attributed to errors (i.e., preventable adverse events) was 58% and the proportion of adverse events due to negligence was 27.6%." These data were corroborated in the 1992 studies in Colorado, Utah, and New York state (IOM, 2000). Errors can be diagnostic, treatment based, preventive, or other (Leape, 1993).

The American College of Obstetrics and Gynecology (ACOG) Committee Opinion 447 further placed patient safety in obstetrics and gynecology on the forefront (ACOG, 2009). The committee opinion set forth that a culture of safety should be the framework for any effort to reduce medical errors. The goal is to encourage obstetricians and gynecologists to adopt and develop safe practices that will reduce the likelihood of system failures that can cause adverse outcomes in their patient populations.

COMMUNICATION

As explained previously, communication is the bedrock of safety and efficiency in every high-risk organization. Health care communications can be written in the medical record, published as guidelines and literature, treated as verbal communications, and accepted as cultural norms within an institution. In its analysis of sentinel events, The Joint Commission found that almost two thirds of the events involved communication failure as a root cause (TJC, 2004). Communication training is now becoming increasingly recognized as the cornerstone of any patient safety program. AHRQ developed the TeamSTEPPS trademark program to address this issue (AHRQ, 2015). Obvious times for increased risk in communication slipped through the cracks at patient handoffs, patient transfers, or shift changes. ACOG found that an increased awareness of the importance of clear

communication between all members of the health care team will measurably enhance the safety of the care delivered by obstetricians and gynecologists. Training around these issues for all health care providers is highly recommended.

Communication requires, first, a basic understanding of roles and responsibilities. Team members must be clearly trained in their roles and familiar with the appropriate policies, guidelines, or procedures for delivering routine and emergent care. Through enhanced communication, and clear communication, medical errors can be avoided.

ANTICIPATION

Anticipation is defined as an expectation or prediction. Within each patient's clinical presentation there are varying degrees of a health care provider's ability to anticipate outcomes. Anticipation assists in ensuring the right people and necessary equipment are in place to provide appropriate and safe care when needed. Anticipation requires an understanding of the patient's clinical presentation, hospital resources, and any likely encumbrance to the delivery of safe and effective care.

PREPARATION

The Joint Commission has recommended and mandated, at various levels, simulation programs or training. Simulations are a way for institutional practices to be perfected prior to one's handling of life-threatening emergencies. The concept of a simulation, though basic and simple, requires more than just the simple actions that day. The preparation required includes appropriate staffing; reasonable, updated, and appropriately disseminated policies and guidelines that include definitions of roles and responsibilities; and planned simulations of foreseeable emergencies.

CONCLUSION

In the broadest sense, medical malpractice is defined by whether or not conduct and decisions were reasonable. The fear

of all physicians is that they will be judged ultimately by lesser-trained individuals who identify more with the patient than with the provider. The tests of reasonableness they will utilize are often as simple as asking the question, based on the care and the testimony you provided. Would the jurors be comfortable being treated by you? If the answer to that question is yes, regardless of the complications, decision making, and outcomes, then the most likely jury verdict will be in favor of the defendant physician. However, if the care appears to be inattentive or inconsistent and the records or depositions are inaccurate, the chance to explain your decision and the reasonableness you feel is behind it may be lost through no one's fault but your own.

Breakdowns in the systems of communication—with patients, care providers, or through the medical records—can create a host of problems for physicians, nurses, and health care institutions in the event of an unfavorable treatment outcome. By focusing attentively on both system-wide and individual best practices for accurate and contemporaneous communications, many problems can be avoided or quickly resolved. Awareness that your patients will have serious questions about unexpected, often life-altering, outcomes is integral to avoiding legal problems. Only when patients feel that they have not received satisfactory answers from their care providers will they seek those answers elsewhere—most likely from an attorney.

Focusing on communication, anticipation, and preparation will ensure the appropriate people are in the appropriate place with the appropriate information to deliver health care within a timely manner. The concept of capping one's liability is far too often looked at retrospectively through litigation or discussed after an error occurs. In reality, the best ways to cap liability is through enhanced communication and the development of a cohesive system of health care, which are both patient focused and health care provider friendly.

Balancing practice modifications that become oppressive or interfere with the delivery of reasonable and efficient health care can be challenging. However, ensuring adequate layers of redundancies and safeguards to make certain a single or perhaps even two human errors are protected by a well-designed cohesive system will prevent an undesirable outcome or patient harm (Fig. 6.2).

Figure 6.2 Swiss cheese model system errors and benefits of redundancies.

History, Physical Examination, and Preventive Health Care

Vicki Mendiratta, Gretchen M. Lentz

The first contact a physician has with a patient is critical. It allows an initial bond of trust to be developed on which the future relationship may be built. The patient will share sensitive medical, reproductive, and psychosocial information. The physician will gain her confidence and establish rapport by the understanding and nonjudgmental manner in which he or she collects these data. Today's obstetrician/gynecologist (OB/GYN) will care for women from around the globe, with varying cultural, social, and religious beliefs and values. Women will be of differing socioeconomic status, may have physical or mental disabilities, and may identify as lesbian, bisexual, or transgender. Open communication, with an awareness of and sensitivity to the vast diversity of our patient population, will help to create a collaborative environment in which to explore health issues.

The annual well-woman visit is a crucial part of general medical care. During this visit, the health care provider can attend to current gynecologic concerns, promote disease prevention, assess risks for potential disease, and provide the indicated physical examination or tests. This annual health encounter should include healthy lifestyle counseling, as well as screening and immunizations as appropriate, based on the patient's age and risks.

The first visit generally involves taking a complete history, performing a complete physical examination, and ordering appropriate screening or laboratory tests. The physician practicing obstetrics and gynecology should not assume that others are caring for the patient's general medical needs. It may be appropriate to assume the role of her primary physician, with your care including attention to preventive health services, depending on the physician's training and skills. In other circumstances, a referral to a primary care provider may be more appropriate to better serve the patient.

This chapter focuses on the appropriate manner that an obstetrician/gynecologist should use to conduct a history and physical examination and discusses the appropriate ingredients of ongoing health maintenance.

DIRECT OBSERVATIONS BEFORE SPEAKING TO THE PATIENT (NONVERBAL CLUES)

When meeting a patient, it is important to *look* at her even before speaking. Differing cultural backgrounds and belief systems may

greatly affect the information transfer and challenge effective communication. The general demeanor of the patient should be evaluated. Many new patients are apprehensive about meeting a new physician and the pelvic examination. This apprehension may create barriers to an open and positive first encounter.

By observing nonverbal clues, such as eye contact, posture, facial expressions, or tone of voice, the physician can determine the appropriate approach for conducting the interview. The act of greeting the woman by name, making eye contact, and shaking hands is a formal but friendly start to the visit.

Four qualities have been recognized as potentially important in caring communication skills: comfort, acceptance, responsiveness, and empathy. Despite the busy demands of clinical practice, effective communication skills enhance patient satisfaction and patient safety and decrease the likelihood of medical liability litigation. [Box 7.1](#) lists some components of effective physician communication.

ESSENCE OF THE GYNECOLOGIC HISTORY

CHIEF COMPLAINT

The patient should be encouraged to tell the physician why she has sought help. The chief complaint is a concise statement describing the woman's problem in her words. Questions such as "What is the nature of the problem that brought you to me?" or "How may I help you?" are good ways to begin.

HISTORY OF THE PRESENT ILLNESS (HPI)

The patient should be able to present the problem as she sees it, in her own words, and should be interrupted only for specific clarification of points or to offer direction if she digresses too far. During the interview the physician should face the patient with direct eye contact and acknowledge important points of the history. This approach allows the physician to be involved in the problem and demonstrates a degree of caring to the patient. Now that electronic medical records (EMRs) are almost universally utilized, the ability to sit and just listen to the patient and provide that direct eye contact can be challenging, as providers are often documenting while the patient is sharing her

Box 7.1 Components of Effective Physician Communication

Be culturally sensitive.
 Establish rapport.
 Listen and respond to the woman's concerns (empathy).
 Be nonjudgmental.
 Include both verbal and nonverbal communication.
 Engage the woman in discussion and treatment options (partnership).
 Convey comfort in discussing sensitive topics.
 Abandon stereotypes.
 Check for understanding of your explanations.
 Show support by helping the woman to overcome barriers to care and compliance with treatment.

story. When the patient has completed the history of her current problem, pertinent open-ended questions should be asked with respect to specific points. This process allows the physician to develop a more detailed database. Directed questions may be asked where pertinent to clarify points. In general, however, the patient should be encouraged to tell her story as she sees it rather than to react with short answers to specific questions. Under the latter circumstance, the physician may get the answers he or she is looking for, but they may not be accurate answers. When the HPI is documented in the medical record, it represents a chronological history of the current concerns.

A general outline for a gynecologic and general history is given in **Box 7.2**. The outline is given in a specific order for general orientation. The information, however, may be collected through any comfortable discussion with the patient that seems appropriate in the circumstances. It is important that all aspects be covered.

PERTINENT GYNECOLOGIC HISTORY

A pertinent gynecologic history can be divided into several parts. It begins with a menstrual history, in which the age of menarche, duration of each monthly cycle, number of days during which menses occurs, and regularity of the menstrual cycles should be noted. The dates of the last menstrual period should be obtained. In addition, the characteristics of the menstrual flow, including the color, the amount of flow, and accompanying symptoms, such as cramping, nausea, headache, or diarrhea, should be noted. In general, menstruation that occurs monthly (range 21 to 35 days), lasts 4 to 7 days, is bright red, and is often accompanied by cramping on the day preceding and the first day of the period are all characteristics of an ovulatory cycle. Menstruation that is irregular, often dark in color, painless, and frequently short or very long may indicate lack of ovulation. Often adolescents or premenopausal women have **anovulatory cycles** with resultant irregular menstruation. Any vaginal bleeding not related to menses (intermenstrual bleeding) should be noted, as well as its relationship to the menstrual cycle and to other events, such as coitus (postcoital bleeding), the use of tampons, or the use of a contraceptive device. For the postmenopausal woman, the age at last menses, history of hormone replacement therapy, and any postmenopausal bleeding should be noted.

The second pertinent point in the gynecologic history is that of previous pregnancies. The woman should be asked specifically to list all pregnancies, including chemical pregnancies, all

Box 7.2 History Outline

- I. Observation—nonverbal clues
- II. Chief complaint
- III. History of gynecologic problem(s)
 - A. Menstrual history—last menstrual period, previous menstrual period
 - B. Pregnancy history
 - C. Vaginal and pelvic infections
 - D. Gynecologic surgical procedures
 - E. Urologic history
 - F. Pelvic pain
 - G. Vaginal bleeding
 - H. Sexual status
 - I. Contraceptive status
- IV. Significant health problems
 - A. Systemic illnesses, including bleeding problems
 - B. Surgical procedures
 - C. Other hospitalizations
- V. Medications, habits, and allergies
 - A. Medications taken
 - B. Medication and other allergies
 - C. Smoking history
 - D. Alcohol usage
 - E. Illicit drug usage
- VI. Family history
 - A. Illnesses and causes of death of first-order relatives
 - B. Congenital malformations, mental retardation, and reproductive loss
- VII. Occupational and avocational history
- VIII. Social history
- IX. Review of systems
 - A. Constitutional—such as fever, fatigue
 - B. Head, eyes, ears, nose, mouth, throat
 - C. Cardiovascular—such as chest pain
 - D. Respiratory—such as cough or shortness of breath
 - E. Gastrointestinal—such as constipation, bloating, diarrhea, abdominal pain
 - F. Genitourinary—such as incontinence, urinary frequency or urgency
 - G. Musculoskeletal—such as back pain
 - H. Skin
 - I. Neurologic
 - J. Psychiatric—such as sadness, feeling down or anxious; a short depression screening inventory can be administered; a frequently utilized inventory is the Patient Health Questionnaire 9
 - K. Endocrine—such as significant weight gain or loss
 - L. Hematologic—easy bleeding from gums or nose
 - M. Allergic/immunologic
- X. Physical abuse
 - A. Sexual abuse—incest, rape, sexual touching

abortions (spontaneous and induced), molar and ectopic pregnancies. For deliveries, the following information should be obtained: year of birth, gestational age at delivery, the type of delivery, infant birth weight, and any complications that may have occurred. For all other pregnancies, the circumstances under which they took place, the method by which they were concluded (dilation and curettage [D&C], methotrexate, etc.), and any complications should be obtained.

Next, a history of vaginal and pelvic infections should be obtained. The patient should be asked what types of infection she has had, what treatment she received, and what complications

Box 7.3 United States Preventive Services Task Force Definitions of High Risk for HIV and Gonorrhea

Gonorrhea Risk

History of previous gonorrhea infection
Treatment or presence of other STDs
New or multiples sexual partners
Inconsistent condom use
Sex trade work
Drug use

HIV Risk

Men and women having unprotected sex with multiple partners
Past or present injection drug use
Women who exchange sex for money or drugs or who have partners who do
Women whose past or present partners were/are HIV-infected, bisexual or intravenous drug users
Women being treated for STDs
Women with a history of blood transfusion between 1978 and 1985
Women receiving health care in a high prevalence or high-risk clinical setting

Modified from Campos-Outcalt D. US Preventive Services Task Force: the gold standard of evidence-based prevention. *J Fam Pract.* 2005;54:517-519. STDs, Sexually transmitted diseases.

she experienced. Risk factors for human immunodeficiency virus (HIV) infection, such as intravenous drug abuse or coitus with drug abusers or bisexual men, should be sought by direct questioning and HIV screening offered where appropriate (Box 7.3). The 2013 U.S. Preventive Services Task Force (USPSTF) report states with “high certainty that the net benefit of screening for HIV infection in adolescents, adults and pregnant women is substantial” (Moyer, 2013). Part of this rationale stems from the fact that 20% to 25% of individuals living with HIV infection are unaware they are infected. All hospitalizations should be reviewed as to cause and outcome.

The physician should obtain a Pap smear screening history, including the date of the last Pap smear, the frequency of screening, and any abnormal tests and the treatment. The patient’s human papilloma virus (HPV) vaccination status should be determined.

The woman’s contraceptive history should be investigated, including methods used, length of time they have been used, effectiveness, and any complications that may have arisen.

All instances of gynecologic surgical procedures should be noted, including office procedures, such as endometrial biopsies; vulvar, vaginal, or cervical biopsies. For any minor or major procedures, such as laparoscopy or laparotomy, the following data should be collected: dates, types of procedures, diagnoses, and significant complications. In cases where pertinent, past records, particularly operative and pathology reports, should be sought.

A complete sexual history should be obtained (Box 7.4), and specific problems should be evaluated. The history should include whether the patient is currently sexually active or has been in the past. Patients should be asked if they have one or more current partners and if they have sex with men, women, or both. The provider should also inquire about any sexual dysfunction such as dyspareunia or anorgasmia.

Symptoms of pelvic pain or discomfort should be discussed fully. Six common questions should be asked about the pain:

Box 7.4 Important Points of Sexual History

1. Sexual activity (presence of)
2. Types of relationships
3. Individual(s) involved
4. Satisfaction? Orgasmic? Desire/interest?
5. Dyspareunia
6. Sexual dysfunction
 - a. Patient
 - b. Partner

location; timing; quality, such as throbbing, burning, colicky; radiation to other body areas; intensity on a scale of 1 to 10, with 10 being the worse pain imaginable; and duration of symptoms. Additional questions about what causes the pain to worsen or subside; the context of the pain symptoms; and associated triggers, signs, and symptoms may be helpful. The pain should be described, noting the presence or absence of a relationship to the menstrual cycle and its association with other events, such as coitus or bleeding and bladder and bowel symptoms.

GENERAL HEALTH HISTORY

The woman should be asked to list any significant health problems that she has had during her lifetime, including all hospitalizations and operative procedures. It is reasonable for the physician to ask about specific illnesses, such as diabetes, hypertension, or heart disease, that seem likely based on what is known about the woman or about her family history. Many physicians use a history checklist of the most common conditions.

Medications taken and reasons for doing so should be noted, as should allergic responses to medications. The woman should be encouraged to bring all medications, both prescription and over-the-counter drugs, including herbal preparations, to subsequent health maintenance visits. Most women who use complementary and alternative medicines do not offer this information to physicians.

A history of smoking should be obtained in detail, including amount, length of time she has smoked, and attempts at quitting smoking. She should be questioned about the use of illicit drugs, including heroin, methamphetamines, cocaine, and prescription drug abuse with narcotics. Any affirmative answers should be followed by specific questions concerning length of use, types of drugs used, and side effects that may have been noticed. Her use of alcohol should be detailed carefully, including the number of drinks per day and any history of binge drinking or previous therapy for alcoholism.

FAMILY HISTORY

A detailed family history of first- and second-degree relatives (parents, siblings, children, aunts, uncles, and grandparents) should be taken and a family tree constructed if relevant (Fig. 7.1). Serious illnesses or causes of death for each individual should be noted. If the woman desires fertility now or in the future, an inquiry should be made about any congenital malformations, mental retardation, or pregnancy loss in either the woman’s or her spouse’s family. Such information may offer clues to hereditarily determined causes of reproductive problems.

Figure 7.1 Family tree of typical gynecologic patient.

Occupational and Social History

The woman should be asked to detail her occupation. A non-judgmental way to approach this could be to ask if she is currently working outside of the home. It is very important to determine if she is currently exercising, what type of activity she engages in, and the frequency of exercise.

Additional information that may be relevant include hobbies and other avocations that may affect health or reproductive capacity, where and with whom the woman lives, other individuals in the household, areas of the world where the woman has lived or traveled, or unusual experiences that may affect her health.

SAFETY ISSUES

The patient should be questioned about safety matters. She should be asked about the use of seat belts and helmets (if she rides a bicycle, motorcycle, or horse). She should be asked whether there are firearms in her household and, if so, whether appropriate safety precautions are taken. A question about intimate partner violence is appropriate and can be asked in a nonthreatening manner, such as “Has anyone in your household threatened or physically hurt you?” Sexual violence is a widespread problem, and as more is being learned about prevention, providers should be knowledgeable about resources (Senn, 2015).

NUTRITIONAL AND DIETARY ASSESSMENT

It is important to inquire about dietary choices that our patients make. Assessment of folic acid is important in reproductive-aged women. Asking about fruits and vegetables as well as calcium-containing foods should be standard. Vegetarians and vegans may need additional discussion about adequate protein and vitamin/mineral intake. A referral to a certified nutritionist may be a valuable addition to routine preventive health care.

REVIEW OF SYSTEMS

A complete review of systems (ROS) should be obtained and documented. (See Box 7.2 for comprehensive ROS and some relevant examples.)

ESSENCE OF THE ANNUAL EXAMINATION

The scope of services and examination provided by an OB/GYN in the ambulatory setting will vary from practice to practice. In 2014, the American College of Obstetricians and Gynecologists (ACOG) reaffirmed its recommendation that the annual examination include obtaining vital signs, determining body mass index (BMI), palpating the abdomen, palpating inguinal lymph nodes, and making an overall assessment of the patient's health (ACOG Committee Opinion, No. 534, 2014). The extent to which additional examination is performed is based on many factors, such as age, patient concerns, family history, and whether the patient has a primary care provider whom she also sees for routine and concern-driven care. Not all women will require a clinical breast exam or pelvic exam at each annual visit. Refer to Table 7.1 for examination and screening recommendations.

PHYSICAL EXAMINATION

The patient should disrobe completely and cover herself with a hospital gown that ensures warmth and modesty. During each step of the examination she should be allowed to maintain personal control by being offered options whenever possible. These options begin with the presence or absence of a chaperone. The chaperone, a third party, usually a woman, serves a variety of purposes. She may offer warmth, compassion, and support to the patient during uncomfortable or potentially embarrassing portions of the examination. She may help the physician to carry out procedures and in some cases act as a witness to the doctor-patient interaction. Although the presence of a chaperone is not imperative in every physician-patient relationship, one should be immediately available for any encounter.

The examination should begin with a general evaluation of the patient's appearance and affect. Her weight, height, and blood pressure should be taken initially. A body mass index (BMI) should be calculated and is an important “vital sign” to track over time. Most currently used electronic medical records (EMRs) will automatically calculate BMI when height/weight data are entered. Postmenopausal women should have their height measured routinely to document evidence of osteoporosis, which causes loss of height from vertebral compression fractures. Some institutions require a pain scale reporting at each visit and consider it a fourth vital sign.

Most gynecologists will not perform a comprehensive screening head, eye, ears, neck, and throat (HEENT) examination. The American Academy of Ophthalmology (AAO) recommends that adults with no signs or risk factors for eye disease should receive a baseline comprehensive eye evaluation at age 40 and then every 2 to 4 years until age 55; every 1 to 3 years through age 64; and yearly to every other year for individuals 65 years old or older (AAO, 2015).

The thyroid gland should be palpated for irregularities or increase in size (goiter). Discrete areas of enlargement, hardness,

Table 7.1 Examination, Screening, and Immunization Recommendations for the Annual Health Maintenance Visit

	AGE (YEARS)

Additional data from American the Congress of Obstetricians and Gynecologists (ACOG). Well-woman care: assessment and recommendations (<http://www.acog.org/wellwoman>).

*No evidence supports or refutes the annual pelvic exam, speculum, bimanual exam for low-risk, asymptomatic patients. Decisions about the examination for this group should be shared between patient and provider (ACOG Committee Opinion, #534).

[†]The American College of Gastroenterology recommends African Americans initiate screening at age 45 due to a higher earlier incidence of colorectal cancer. Colonoscopy is preferred but other methods include fecal occult blood testing, flexible sigmoidoscopy, double contrast barium enema, computed tomography colonography, stool DNA (interval for testing varies based on method utilized).

[‡]Per ACS/ACOG, however USPSTF: start age 50 and q 2 years.

[¶]CDC: Advisory Committee on Immunization Practices.

[¶]CDC recommends "routine" testing in all patients, frequency to be determined by patient and provider.

General recommendations for low-risk populations. High-risk populations may have more recommended vaccines.

High-risk groups based on lifestyle, concurrent medical conditions, and family history may have other testing or intervals for testing. Chart represents recommendations for the general populations.

BMI, Body mass index; BP, blood pressure; HIV, human immunodeficiency virus; Ht, height; hx, history; q, every; Wt, weight.

and tenderness should be described. The patient's neck should be palpated for evidence of adenopathy along the supraclavicular and posterior auricular chains.

In a comprehensive preventive health examination, both the chest and cardiac systems should be evaluated. Whether this is necessary in an annual well-woman visit for a healthy woman is at the discretion of the provider. A nongynecologic primary care provider or subspecialist will likely care for women with medical conditions such as hypertension or diabetes. When performing the chest exam, the chest should be inspected for symmetry of movement of the diaphragm and observed for respiratory effort. This is followed by palpation, percussion, and auscultation.

The heart should be examined by palpation for points of maximum impulse, percussed for size, and auscultated for irregularities of rate and evidence of murmurs and other adventitious sounds. The patient's heart should be auscultated in both the lying and the sitting positions. An older woman's neck should be auscultated for evidence of vascular bruits.

BREAST EXAM

There is no evidenced-based recommendation for when to begin clinical breast exam (CBE) screening in the low-risk, asymptomatic woman. ACOG, American Cancer Society (ACS), and National Comprehensive Cancer Network (NCCN) all recommend CBE every 1 to 3 years for women ages 20 to 39 and yearly

thereafter (ACOG Committee Opinion, No. 534, 2014). A careful breast examination should be carried out in a systematic fashion. To summarize a detailed clinical breast examination, refer to Box 7.5. Research has shown the following factors are associated with a high-quality breast examination: longer duration, thorough coverage of the breast, a consistent exam pattern, use of variable pressure with the finger pads, and use of the three middle fingers. ACOG, ACS, and NCCN all recommend the teaching of breast self-awareness, including teaching breast self-examination. Women are no longer instructed to examine their own breasts monthly but rather if they feel or see any concerning symptom or abnormality such as redness, pain, skin changes, or a mass.

ABDOMINAL EXAM

The abdomen should first be inspected for symmetry, scars, masses, distension, and visible organomegaly. The hair pattern should be noted. The typical female escutcheon is that of an inverted triangle over the mons pubis. A male escutcheon involves hair growth between the area of the mons pubis and the umbilicus, also known as a *diamond pattern*, and may indicate excessive androgen activity in the patient (Fig. 7.2).

The physician should listen (auscultation) for bowel sounds. Hypoactive or absent bowel sounds may imply an ileus caused by peritoneal irritation of the bowel. Hyperactive bowel sounds

may imply intrinsic irritation of the bowel or partial or complete bowel obstruction.

Next, abdominal percussion affords the ability to differentiate fluid waves and to outline solid organs and masses. Localized percussion tenderness may suggest peritoneal inflammation.

Finally, the abdomen should be palpated for organomegaly, particularly involving the liver, spleen, kidneys, and uterus, and for adnexal masses, which may be palpated abdominally, if large. Palpation affords the possibility of noting a fluid wave, which would suggest either ascites or hemoperitoneum. Palpation also yields evidence for rigidity of the abdomen, which would imply spasm in the rectus muscles secondary to intraabdominal irritation. Where the irritation is caused by intraabdominal hemorrhage or infection, this rigidity is often evidence of an acute abdomen. During the palpation of the abdomen, the physician should elicit the phenomenon of *rebound*, which also signifies intraabdominal irritation, by gently pressing the abdomen and then releasing. The release may cause pain either under the spot (direct rebound) or in a different portion of the abdomen (referred rebound). It should be noted, however, that sudden, deep pressure may cause pain even in a normal patient. Gentle pressure carried out systematically may elicit painful “trigger points.” With the woman straining or simulating an abdominal

sit-up, an abdominal or incisional hernia may be visualized and the fascial defect palpated.

The groin should be palpated for adenopathy and inguinal hernias.

PELVIC EXAMINATION

In 2014, ACOG continues to recommend that the pelvic exam, including an external genital evaluation, speculum exam, and bimanual exam, be performed yearly in adult women (ACOG Committee Opinion, No. 534, 2014). However, also in 2014, the American College of Physicians published their own new guidelines based on a systematic review of the literature obtained since the 1950s. The authors concluded that annual screening pelvic exams in asymptomatic, nonpregnant adult women do not offer benefit and can, in fact, cause harm. They recommended against such examinations (Qaseem, 2014). This new guideline certainly prompted much debate among physician leaders in all primary care fields. The decision to perform this exam and the frequency of the exams remain in the hands of the provider together with the patient. All symptomatic women should have a pelvic exam.

The pelvic examination is conducted with the patient lying supine on the examining table with her legs in stirrups and a sheet draped across her. The physician should be sure the patient is as relaxed as possible and should take a few minutes to describe the procedure and allow the patient to prepare herself. Suggesting that the patient allow her legs to fall wide apart and concentrate on relaxing her abdominal muscles may be helpful.

Box 7.5 Clinical Breast Examination Elements

1. With patient sitting up, position her hands at her hips and ask her to gently push inward. Visualize for symmetry. Ask patient to put hands together above head and press inward. Visualize for symmetry. With arms at side, palpate axilla bilaterally, feeling for lymph nodes.
2. In the supine position, ask patient to place arms above her head. Pay attention to entire breast tissue from midsternum to the posterior axillary line and from the inframammary crease to the clavicle.
3. Inspection and palpation (a variety of palpation techniques exist):
 - Skin flattening or dimpling
 - Skin erythema
 - Skin edema
 - Nipple retraction
 - Nipple eczema
 - Nipple discharge
 - Breast fixation
 - Tissue thickening
 - Palpable masses
 - Tenderness

INSPECTION

The vulva and introitus should be carefully inspected beginning with the mons pubis. The quality and pattern of the hair on the mons and the labia majora should be noted. During the inspection of the pubic hair, the physician should look for evidence of body lice (pediculosis). Next, the skin of the vulva/perineum is inspected for erythema, excoriation, discoloration, or loss of pigment and for the presence of vesicles, ulcerations, pustules, warty growths, or neoplastic growths. In addition, pigmented nevi or other pigmented lesions should be noted, as should varicose veins. Skin scars denoting previous episiotomy or other obstetric lacerations should be noted.

Next, the specific structures of the vulva should be systematically evaluated. The clitoris should be noted and its size and

Figure 7.2 Normal female pubic hair pattern (*right*) and hair pattern of female showing male (androgenized) pattern (*left*).

Figure 7.3 Normal female perineum. (Modified from Krantz KE. *Anatomy of the female reproductive system*. In: Benson RC, ed. *Current Obstetric and Gynecologic Diagnosis and Treatment*. 5th ed. Los Altos, CA: Lange Medical; 1984.)

shape described. Normally it is 1 to 1.5 cm in length. Any irregularities or abnormalities of the labia majora or minora should be noted and carefully described. At times these areas are injured by trauma related to coitus, accidental injury, or childbearing. The patient should be questioned about evidence of trauma when appropriate.

The introitus should be observed closely. Whether the hymen is intact, imperforate, or open and whether the perineum gapes or remains closed in the usual lithotomy position should be noted.

The perineal body, the area at the posterior aspect of the labia where the muscles of the superficial perineal compartment come together, should be inspected. It represents the focal point of support for the perineum and is between the vagina and the rectum. The perianal area is then inspected for evidence of hemorrhoids, sphincter injury, warts, and other lesions (Fig. 7.3).

PALPATION

The next step in the examination of the perineum involves palpation. The labia minora are gently separated, and the urethra is inspected and the length of the urethra is palpated and “milked” with the middle finger. In this way, irregularities and inflammation of Skene glands (periurethral glands), expressed pus or mucus, or a suburethral diverticulum can be noted. Any pus expressed from the urethra should be submitted for Gram stain and cultured, because it is occasionally found to contain gonococci. Next, the area of the posterior third of the labia majora is palpated by placing the index finger inside the introitus and the thumb on the outside of the labium. In this way, enlargements or cysts of Bartholin glands are noted. This exam should be performed on each side.

The opening of the vagina should be inspected. The presence of a cystocele or a cystourethrocele should be noted. This would be seen as a bulging of vaginal mucosa downward from the anterior wall of the vagina. The presence of this abnormality may be noted either by simply observing or by asking the patient to bear down (Fig. 7.4). Likewise, the posterior wall should be observed

Figure 7.4 Side and direct views of cystocele. (Modified from Symmonds RE. *Anatomy of the female reproductive system*. In: Benson RC, ed. *Current Obstetric and Gynecologic Diagnosis and Treatment*. 5th ed. Los Altos, CA: Lange Medical; 1984.)

Figure 7.5 Side and direct views of rectocele. (Modified from Symmonds RE: *Relaxations of pelvic supports*. In: Benson RC, ed. *Current Obstetric and Gynecologic Diagnosis and Treatment*. 5th ed. Los Altos, CA: Lange Medical; 1984.)

for a bulging upward, which would represent a rectocele (Fig. 7.5). A cystic bulge in the cul-de-sac may represent an enterocele (Fig. 7.6). Also, with the patient bearing down, the cervix may become visible, indicating prolapse of the uterus (Fig. 7.7). Each of these observations is evidence for relaxation of the pelvic supports. Accurate evaluation of pelvic organ prolapse is improved by examining the woman standing with her legs spread apart and with a Valsalva maneuver. Pelvic organ prolapse and pelvic floor dysfunction are defined and extensively discussed in Chapter 20.

SPECULUM EXAMINATION

After palpation, the physician chooses the appropriate speculum for the patient. The most commonly utilized are the Grave and the Pederson specula. The Pederson speculum is narrower and may be more appropriate for virginal or nulligravid women, women with a history of sexual abuse, vaginal pain or

dyspareunia, or postmenopausal women. Each is available in several sizes corresponding to length of the blades (small, medium, large, extra large) (Fig. 7.8).

The speculum should be warmed, either by a warming device or by being placed in warm water, and then touched to the patient's leg to determine that she feels the temperature is appropriate and comfortable. Judicious use of a water-based lubricant can facilitate a more comfortable exam for the patient. The speculum is then inserted by placing the transverse diameter of the blades in the anteroposterior position and guiding the blades through the introitus in a downward motion with the tips pointing toward the rectum. Because the anterior wall of the vagina is backed by the pubic symphysis, which is rigid, pressure upward causes the patient discomfort. This is avoided by following the described method of introducing the speculum. Also, in the resting state the vagina lies on the rectum and actually extends posteriorly from the introitus. Placing two fingers into the introitus and pressing down may facilitate the procedure.

Once the blades are inserted, the speculum should be turned so that the transverse axis of the blades is in the transverse axis of the vagina. The blades should be inserted to their full length and then opened so that the physician may inspect for the position of the cervix. If the cervix cannot be visualized with repositioning of the speculum, the physician should inspect for the position of the cervix with his or her finger and then reinsert the speculum accordingly. Once the blades are inserted and the cervix is visualized, the speculum should be opened and the introitus widened so that the cervix can be adequately inspected and any indicated specimens obtained.

The physician then inspects the vagina and cervix. The vaginal canal is inspected during the insertion of the speculum and upon its removal. The vaginal epithelium should be noted for

Figure 7.6 Lateral view of enterocele. (Modified from Symmonds RE: Relaxations of pelvic supports. In: Benson RC, ed. *Current Obstetric and Gynecologic Diagnosis and Treatment*. 5th ed. Los Altos, CA: Lange Medical; 1984.)

Figure 7.7 Depiction of prolapse of uterus. (Modified from Symmonds RE: Relaxations of pelvic supports. In: Benson RC, ed. *Current Obstetric and Gynecologic Diagnosis and Treatment*. 5th ed. Los Altos, CA: Lange Medical; 1984.)

Figure 7.8 Graves (left) and Pederson (right) specula.

evidence of erythema or lesions. Vaginal lesions, such as areas of adenosis (see [Chapter 11](#)), clear cystic structures (Gartner cysts), or inclusion cysts on the lines of scars or episiotomy incisions, should be noted.

Any concerning fluid discharge is collected for wet mount and potential culture. Saline wet mount allows for visualization of normal vaginal epithelial cells as well as any abnormal findings such as motile *trichomonads*, clue cells (vaginal epithelial cells studded with adherent coccobacilli, indicative of bacterial vaginosis), or polymorphonuclear leukocytes (indicative of inflammation).

A potassium hydroxide wet mount includes the whiff-amine test, which, if positive for a distinct fishy odor, may indicate bacterial vaginosis. In addition, inspection of the slide may reveal hyphae and budding yeast, indicative of *Candida* vaginitis.

In many instances, particularly with women younger than 26 years, it is appropriate to screen for chlamydia and gonorrhea using swabs that sample secretions from the endocervical canal or the vagina. The gold standard is **nucleic acid amplification testing (NAAT)** of the urine or vaginal/cervical discharge, rather than a culture. Yearly chlamydia testing is recommended for all sexually active women up to age 25 ([ACOG, Well-Woman Care, 2014](#)) (see [Chapter 23](#)).

Next, the cervix is inspected. It should be pink and without lesions. In a nulliparous individual, the external os should be round. When a woman is parous, the external os takes on a slitlike appearance, and if there have been cervical lacerations, healed stellate lacerations may be noted ([Fig. 7.9](#)). Normally, the transformation zone (i.e., the junction of squamous and columnar epithelium) is just barely visible inside the external os. Occasionally, glandular epithelium may be present on the **portio vaginalis**, moving the transformation zone onto the portio. This is common in teenage girls, women who have been exposed to diethylstilbestrol in utero, some women with vaginitis, or women immediately postpartum or postabortion. Generally, this is cleared by a process of **metaplasia**, in which squamous epithelium covers the columnar epithelium. This process, however, may leave small areas of irregularities and inclusion cysts, called **nabothian cysts**, which may be seen in various sizes and shapes. They are typically translucent and range from a few millimeters to up to 3 cm in size. These cysts are common benign findings and require no additional evaluation or treatment.

Cervical ectropion occurs when the endocervical epithelium is exposed to the vaginal environment and takes on a reddish appearance, similar to granulation tissue. This **ectropion** is not a pathologic condition.

Any lesions of the cervix should be noted and, where appropriate, a biopsy should be performed. In a patient with acute herpes simplex, vesicles or ulcers may be noted. In a patient infected with human papillomavirus, warts (condylomata acuminata) on the cervix may also be observed.

Figure 7.9 Nulliparous, parous, and stellate lacerations of cervix.

PAPANICOLAOU SMEAR

At this point in the examination a Pap smear is usually taken, if indicated. In 1943, Papanicolaou and Trout published their now classic monograph demonstrating the value of vaginal and cervical cytology as a screening tool for cervical neoplasia. With the use of the Pap smear in screening programs, the incidence of invasive cervical cancer has been reduced by 50%. In 2012, ACOG together with ACS and U.S. Preventive Services Task Force (USPSTF) recommended that initial screening should begin at age 21 regardless of sexual activity. For women ages 21 through 29, screening should occur every 3 years. Women ages 30 to 65 can either have co-testing (Pap plus high-risk human papillomavirus [HPV] testing) or just a routine Pap test. Repeat co-testing occurs every 5 years, whereas Pap testing alone continues on an every 3-year basis. Pap smear screening is no longer recommended in women after age 65, if she has had normal adequate testing over the past 10 years and she has not been treated for high-grade dysplasia within the past 20 years. Exceptions to the above schedule include HIV seropositive women, immunosuppressed women, and women exposed to DES in utero, all of whom should be screened annually (Saslow, 2012). It is crucial to educate women that this extended interval between Pap smears is based on long-term, excellent analysis of the existing data. The importance of this cancer screening should continue to be highlighted during annual preventive visits, as we know that 50% of cervical cancer cases develop in women who have never had a Pap test, and an additional 10% occur in women who have been underscreened (Saslow, 2012). No Pap smear screening is necessary after a complete hysterectomy done for benign conditions. However, if a supracervical hysterectomy was performed, the same screening guidelines pertain as if there had been no hysterectomy, since the cervix remains in situ.

The goal of the Pap smear is to collect cells from the transformation zone of the cervix. The presence of adequate endo- and ectocervical cells ensures that this area is captured in the specimen. After excess mucus is gently removed (routine swabbing may cause insufficient cells to be sampled), the endocervical canal is sampled with a Cytobrush, which is placed into the canal and rotated. A spatula is then used to collect ectocervical cells ([Figs. 7.10 and 7.11](#)). A single broomlike sampling device can also be used to collect both populations of cells in a single step. The collected material is placed in the liquid preservative solution. HPV testing can be concurrently ordered from the collected sample, as indicated (Video 7.1).

Figure 7.10 Obtaining cells from endocervix using a Cytobrush.

Figure 7.11 Obtaining cells from transformation zone using Ayers spatula.

Chapter 28 discusses cervical dysplasia, classifications of abnormalities, surveillance, and treatment options.

BIMANUAL EXAMINATION

The bimanual examination allows the physician to palpate the uterus and the adnexa. The lubricated index and middle fingers of the dominant hand are placed within the vagina, and the thumb is folded under so as not to cause the patient distress in the area of the mons pubis, clitoris, and pubic symphysis. The fingers are inserted deeply into the vagina so that they rest beneath the cervix in the posterior fornix. The physician should be in a comfortable position at this point, generally with the leg on the side of the vaginal examining hand on a table lift and the elbow of that arm resting on the knee. The opposite hand is placed on the patient's abdomen above the pubic symphysis. The flat of the fingers are used for palpation. The physician then elevates the uterus by pressing up on the cervix and delivering the uterus to the abdominal hand so that the uterus may be placed between the two hands, thereby identifying its position, size, shape, consistency, and mobility. In the normal and nonpregnant state, the uterus is approximately 6 cm × 4 cm and weighs approximately 60 g. It may be somewhat larger in a woman who has had children (Fig. 7.12).

Enlargement of the uterus should be described in detail. Size may be estimated in centimeters or by comparing with weeks of normal gestational age. The majority of women will have a uterus that is anteverted with the uterine fundus tipped forward. In the anteverted uterus, the fundus points anteriorly as well. The uterus may be retroverted, in which the entire uterus tips posteriorly, and may also be retroflexed, in which the fundus points posteriorly as well. If it is positioned in a straight line with the vagina, it is said to be midposition or neutral. A markedly retroverted uterus that cannot be brought forward by manipulation is best inspected by rectovaginal examination, which is described later in the chapter. The general shape of the uterus is that of a pear, with the broadest portion at the upper pole of the fundus. Generally, the uterus is mobile, and if it fails to move, it may be fixed by adhesions. The surface should be smooth; irregularities may indicate the presence of uterine leiomyomas (fibroids).

The shape of the uterus should also be described in detail. The consistency of the uterus is generally firm but not rock hard, and this should be noted in the examination. Any undue tenderness

Figure 7.12 Bimanual examination of uterus.

Figure 7.13 Bimanual examination of adnexa.

caused by palpation or movement of the uterus should be noted, because it may imply an inflammatory process.

Attention is then turned to examination of the adnexa. If the right hand is the pelvic hand, the first two fingers of the right hand are then moved into the right vaginal fornix as deeply as they can be inserted. The abdominal hand is placed just medial to the anterior superior iliac spine on the right, the two hands are brought as close together as possible, and with a sliding motion from the area of the anterior superior iliac spine to the introitus, the fingers are swept downward, allowing for the adnexa to be palpated between them. A normal ovary is approximately 3 × 2 cm (about the size of a walnut) and will sweep between the two fingers with ease unless it is fixed in an abnormal position by adhesions. When the adnexa are palpated, its size, mobility, and consistency should be described. When the right adnexa has been palpated, the left adnexa should be palpated in a similar fashion by turning the vaginal hand to the left vaginal fornix and repeating the exercise on the left side (Fig. 7.13). Adnexa are usually not palpable in postmenopausal women because of involution and retraction of the ovary to a position higher in the pelvis. A palpable organ in such an individual may need further investigation for ovarian pathology if enlarged, although they are mostly benign or no disease is found.

Figure 7.14 Rectovaginal examination.

RECTOVAGINAL EXAMINATION

Historically, the rectovaginal (RV) exam has been a part of the annual examination. In fact, however, the sensitivity of the RV examination in detecting pathology is very low, limiting its capacity as a screening test. The RV exam should therefore only be performed as indicated based on patient symptoms or complaints or based on findings from the pelvic examination.

After completing the vaginal portion of the bimanual examination, the middle finger is relubricated with a water-soluble lubricant and placed into the rectum. The index finger is reinserted into the vagina. In this fashion the rectovaginal septum is palpated between the two fingers, and any thickness or mass is noted. The finger should also attempt to identify the uterosacral ligaments, which extend from the posterior wall of the cervix posteriorly and laterally toward the sacrum. Any thickening or nodularity of these structures may imply an inflammatory reaction or endometriosis. If the uterus is retroverted, that organ should be outlined for size, shape, and consistency at this point. It may be examined appropriately using the fingers inserted into the vagina and the rectum, as well as using the abdominal hand (Fig. 7.14).

RECTAL EXAMINATION

The USPSTF and the ACS find that a digital rectal exam, by itself, is not adequate screening for colorectal cancer. Furthermore, testing a single stool specimen for fecal occult blood is also inadequate. Therefore, routine assessment of the rectum is not recommended during female pelvic exams. Colon cancer screening recommendations are described later in this chapter.

Like the RV exam, a rectal examination should only be performed based on patient symptoms, concerns, or findings on the pelvic examination. As noted earlier, simple inspection of

the perianal area can reveal abnormalities such as genital warts, hemorrhoids, or skin lesions.

The rectum is then palpated in all dimensions with the rectal examining finger. It should be possible to palpate as many as 70% of distal bowel lesions with the rectal finger. The physician should also note the tone of the anal sphincter and any other anal abnormalities, such as hemorrhoids, fissures, or masses. At the end of the examination the physician should give the patient some tissue or a washcloth so that she may remove the lubricating gel from her perineum before she dresses.

It is important that each step of the examination be explained to the patient and that she is reassured about all normal findings. Wherever possible, abnormal findings should be pointed out to the patient either by allowing her to palpate the pathologic condition or by demonstrating it to her using a hand mirror. It may also be appropriate to demonstrate normal structures to the patient, such as the cervix and portions of the vagina that she may be able to see with her hand mirror. The physician should use the examination as a vehicle for teaching the patient about her body.

ANNUAL VISIT

The annual visit is important for both health maintenance and preventive medicine reasons. Although the visit varies in emphasis depending on the patient's age, the long-term goals should be to maintain the woman in the best health and functional status possible, to promote high-quality longevity, and to aid in early detection of disease. Long-term continuity of care may improve health status. Major preventable problems must be discussed because patient behavior can make a difference. Various medical groups update recommendations for primary and preventive screening services regularly. Much of this chapter utilizes guidelines from the United States Preventive Services Task Force (USPSTF), American College of Obstetricians and Gynecologists (ACOG), Centers for Disease Control and Prevention (CDC), Morbidity and Mortality Weekly Report (MMWR), other subspecialty guidelines, and the Agency for Healthcare Research and Quality. The latter is a clearinghouse of evidence-based guidelines that allows comparison of differing recommendations, as many societies do not always agree on these guidelines. Their websites can be checked for updates.

It is important not to confuse screening with diagnosis. Screening is looking for a condition in an asymptomatic woman. Diagnostic tests are performed to clarify the etiology of a woman's complaints (symptoms) and are not screening. So when one of the organizations such as the USPSTF makes a recommendation for screening for chlamydia yearly up to age 25, it does not mean you should not test a 26-year-old woman who has symptoms of vaginal discharge or a new sexual partner. Furthermore, screening recommendations must be considered in light of local prevalence of disease and additional risk factors an individual patient might present. The USPSTF also makes recommendations that are qualified by a grade: A = strongly recommends, B = recommends, C = no recommendation for or against, D = recommends against, and I = insufficient evidence to recommend for or against.

A 2004 article published in the *Journal of the American Medical Association* estimated the root causes of American deaths and

attributed 18% to tobacco, 15% to poor diet and physical inactivity, 3.5% to alcohol, 4% to microbial agents, 1% to illicit drug use, 2% to toxic agents, 1.2% to firearms, 1.8% to motor vehicles, and 1% to sexual behavior (Mokdad, 2004). Obviously, patients taking an active role in changing their behavior can alter many of these factors, and physicians have the opportunity to advise them at the annual visit. Although the gynecologist may or may not function as the sole primary care provider for women, the annual visit is an opportunity to discuss patient choices, lifestyle, and habits. It offers a perfect environment to provide education about healthy lifestyle and prevention strategies to reduce harm and improve health. In 1618, an English clergyman observed, "Prevention is so much better than healing because it saves the labor of being sick." In 1973, Belloc reported that in a study of women past the age of 45, the life expectancy was 7 years greater for those who routinely practiced six of seven important health habits as compared with those who practiced three or fewer (Box 7.6) (Belloc, 1973). These recommendations hold true today according to a 2009 report from the Agency for Healthcare Research and Quality (AHRQ). During the annual visit, physicians should therefore discuss nutrition regarding (1) proper caloric intake to maintain the patient's weight near her optimum and avoid obesity, (2) restricting saturated fat and cholesterol, and (3) understanding the need for adequate calcium and vitamin D in the diet.

At each checkup the physician should also encourage the patient to develop an exercise program appropriate for her abilities and taking into account her overall health status and recommendations from any other health care providers. Table 7.2

Box 7.6 Good Health Habits

Eat moderately
 Eat a healthy diet focusing on fruits, vegetables, whole grains, and foods low in saturated fats*
 Eat breakfast
 Be tobacco free
 Exercise regularly; 30 minutes or more on most days of the week
 Use alcohol in moderation or not at all
 Sleep 7 to 8 hours per night
 Stay at a healthy weight†

*Modified from original according to AHRQ recommendations.

†Added to original according to AHRQ recommendations.

presents the CDC recommendations for types/duration of exercise by age group.

For patients who smoke, benefits of reduction and cessation should be addressed and resources provided. Tobacco use is a leading preventable cause of death in the United States. It is the most important modifiable risk factor associated with adverse pregnancy outcomes, and pregnancy is often a time when a woman will be motivated to quit smoking. The nonreproductive negative health effects of smoking include cancer, coronary artery disease, peripheral vascular disease, respiratory disorder, peptic ulcer disease, and osteoporosis. The five "A"s of smoking cessation are important for providers to know: ask (about use), advise (about use), assess (willingness to quit), assist (in planning and counseling), and arrange (regular contact and follow-up). Counseling strategies have been published and show that 5 to 15 minutes of motivational interviewing and problem-solving strategies will result in a 5% to 10% quit rate. More intensive options to aid in smoking cessation include pharmacotherapy with nicotine replacement, bupropion, or varenicline.

Any alcohol or drug use and potential abuse should also be discussed. Short alcohol use screening questionnaires such as CAGE are utilized in many primary and specialty care clinics.

The physician should discuss possible stressors in the patient's life, such as her relationship with her husband or partner and other family members, her satisfaction or dissatisfaction with her job, and other social problems that she may be experiencing. It is appropriate to ask questions that assess her sexual activity and gratification and questions that detect abuse or intimidation in her life. As OB/GYNs continue to care for women well past menopause, it may also be appropriate to discuss the physical and emotional implications of loss and grief. Everyone suffers loss during his or her lifetime, and the older the patient the more likely that this is the case. Grief may be the result of a loss of a spouse or loved one, a pet, a job, a body part, or the ability to perform activities the patient has enjoyed (see Chapter 9).

The patient should provide updated information about all medications/supplements that she takes. This will give the physician the opportunity to review with the patient why she is taking each one and also to assess for potential adverse drug interactions. It may also be possible to tie specific drug use to an undesirable symptom the patient may be experiencing.

Table 7.2 CDC Exercise Recommendations

Age (Years)	MINIMUM EXERCISE		
	Option 1	Option 2	Option 3
18-64	2.5 hours moderate-intensity aerobic activity/week* and muscle-strengthening† activities 2+ days/week	75 minutes vigorous-intensity aerobic activity/week† and muscle-strengthening activities 2+ days/week	Equivalent mix of moderate and vigorous aerobic activity and muscle-strengthening† activities 2+ days/week
65+	2.5 hours moderate-intensity aerobic activity/week* and muscle-strengthening† activities 2+ days/week	75 minutes vigorous-intensity aerobic activity/week† and muscle-strengthening activities 2+ days/week	Equivalent mix of moderate and vigorous aerobic activity and muscle-strengthening† activities 2+ days/week

Data from Centers for Disease Control and Prevention (CDC). Physical activity basics. How much physical activity do adults need? 2015. Available at <http://www.cdc.gov/physicalactivity/basics/adults/index.htm> and Centers for Disease Control and Prevention (CDC). Physical Activity Basics. How much physical activity do older adults need? 2015. Available at <http://www.cdc.gov/physicalactivity/everyone/guidelines/olderadults.html>.

*Moderate-intensity aerobic activity: brisk walking, water aerobics, pushing lawn mower.

†Vigorous-intensity aerobic activity: running, swimming laps, basketball.

‡Muscle-strengthening activities: weight lifting, resistance bands, pushups, heavy gardening, yoga. Older adults need to adjust both type and intensity of exercise.

Increasing overall time of aerobic exercise beyond the minimal recommendations further increases health benefits.

The annual visit is an opportunity for the physician to screen for a variety of illnesses affecting not only the reproductive organs but also all of the organ systems. The visit should include an interim health history and an age-appropriate physical examination. The weight, height, and blood pressure measurements with calculated BMI should be obtained. A neck and abdominal exam should be performed. Whether the breast, pelvic, and speculum exams are performed depends on the patient's age, concerns, and agreement between the provider and the patient (see [Table 7.1](#)).

In 2013, the American College of Obstetricians and Gynecologists published online the *Well-Woman Care: Assessments & Recommendations*, which recommended screening examinations, immunizations, and laboratory tests for the annual visit for women in different age groups (see [Table 7.1](#)). Women with concurrent medical conditions such as obesity or hypertension, women with certain lifestyle choices such as tobacco use, and women with certain family history will be directed to screening that may be sooner or more frequent than that recommended for the general population. The USPSTF and ACOG recommend referral for genetic counseling and evaluation for the breast cancer susceptibility gene (*BRCA*) for women whose family history is associated with an increased risk for deleterious mutations in the *BRCA1* or *BRCA2* genes. Ninety percent of breast cancers are sporadic, but 10% are due to inherited disorders. The prime findings in the history include multiple family members with breast or ovarian cancer, breast and ovarian cancer in a single individual, or early age of breast cancer onset. With women having a one out of eight chance of developing breast cancer in their lifetime, it makes sense to counsel even low-risk women about healthy lifestyle interventions that can lower their risk of cancer, including eating a healthy diet, exercising, and maintaining a normal body weight.

In 2009, the USPSTF published substantial changes in the mammography recommendations that have been extremely controversial. Routine screening mammography was no longer recommended in women 40 to 49 years old. Instead, the decision about when to begin regular screening should be individualized. This received a “C,” which means the organization did not recommend for or against. Reasons for this change are that while breast cancer mortality does decrease with screening in this age group, it is a small net benefit. Furthermore, there were concerns about the potential harm of mammography in terms of excess radiation exposure, excess need for additional imaging and breast biopsies (false-positive tests), and patient worries and anxiety about the testing. The recommendation does leave room for an open a discussion with the individual woman. ACOG and ACS continue to recommend mammography screening yearly starting at age 40.

In 2009, screening for ages 50 to 74 was also changed from annual to biennial with a “B” recommendation by the USPSTF. In 2015, the USPSTF issued new draft guidelines regarding screening mammography (USPSTF, 2015).⁸ Final updated guidelines should be available in the later half of 2015. ACOG and ACS still recommend yearly mammograms for women 50 and older. Mammograms are reported with the Breast Imaging Reporting and Data System (**BI-RADS**), which classify abnormalities identified by mammography with standardized reporting (see [Chapter 15](#)).

A variety of other screening tests are recommended during annual gynecologic visits. See [Table 7.1](#) for ACOG recommendations. Important screening includes tests for diabetes, hyperlipidemia, thyroid disorders, osteoporosis, HIV, and colorectal cancer. The 2008 American College of Gastroenterology guidelines stated that the preferred test for colorectal cancer screening is colonoscopy every 10 years. The alternatives include fecal occult blood testing, flexible sigmoidoscopy, double contrast barium enema, CT colonography, and stool DNA (interval for testing varies based on the method utilized) ([Levin, 2008](#)). African Americans should begin routine screening at age 45. A family history of polyps does not evoke earlier onset of screening unless the polyps were advanced adenomas. If a single first-degree relative had colorectal cancer diagnosed after age 60, routine screening is recommended. Otherwise, 10 years before the age at which the family member developed colorectal cancer is the time to begin screening.

Other screening tests, such as tests for hepatitis C and tuberculosis, should certainly be considered for women in high-risk groups, with comorbid medical conditions, or with certain family histories. The USPSTF also recommends offering one-time screening for hepatitis C in adults born between 1945 and 1965.

Cancer screening besides breast, cervix, and colorectal are more symptom based. Endometrial cancer recommendations for early detection consist of advising women at menopause of their risk factors and the symptoms of endometrial cancer. Those symptoms include unexpected vaginal bleeding or spotting. Even in women known to be at increased risk of endometrial cancer, there is insufficient evidence to recommend screening (unopposed estrogen treatment, tamoxifen therapy, late menopause, nulliparity, infertility or anovulation, obesity, hypertension, and diabetes). Women at very high risk should have an annual endometrial biopsy starting at age 35 (known hereditary nonpolyposis colorectal cancer, genetic mutation carrier, or strongly suspected carrier). Regular health exams to include the thyroid, ovaries, lymph nodes, oral cavity, and skin should be offered, but no special recommendations have been made.

The best source of updated recommendations for adult immunization schedules is the CDC's MMWR website (see [Table 7.1](#)). All women should have a Tdap booster once in their adult lifetime and in each third trimester of pregnancy to facilitate some passive immunity to the fetus against *Bordetella pertussis*. Then, every 10 years, the regular TD (tetanus-diphtheria) booster is given. Influenza vaccination is recommended annually as well.

Three highly efficacious human papillomavirus (HPV) vaccines are available. In 2006, the Advisory Committee on Immunization Practices (ACIP) and then ACOG recommended vaccinating all girls and young women ages 9 to 26 with the quadrivalent vaccine Gardasil. The U.S. Food and Drug Administration (FDA) approved this in 2009. Then in 2011, ACIP recommended this vaccination for boys and young men as well. A second HPV vaccine, Cervarix, was ACIP approved in 2009. Most recently, a third HPV vaccine, the 9-valent HPV vaccine, Gardasil 9, became available. This vaccine was FDA approved in December 2014 and recommended by ACIP in February 2015. This vaccine contains virus-like particles not only for HPV types 6, 11, 16, and 18 but also for five more high-risk strains of HPV: 31, 33, 45, 52, and 58. This vaccine has been approved for females ages 9 to 26 and males ages 9 to 15. This vaccine affords more

thorough coverage against the top HPV virus strains that can lead to cervical, vaginal, and vulvar cancer. Ideally, the vaccine should be administered before the onset of sexual activity to prevent cervical dysplasia and cancer and other diseases caused by low and high-risk strains of HPV. Both vaccines have excellent safety profiles and contain virus-like particles (VLPs), but no infectious virus, and are given in a three-dose series. The bivalent vaccine contains VLPs for HPV types 16 and 18, which protect against 70% of cervical cancer cases. The quadrivalent vaccine contains VLPs for HPV types 16, 18, 6, and 11. HPV types 6 and 11 cause 90% of genital warts. Because both vaccines prevent new infection against the vaccine containing VLP types but are not effective in preventing disease in individuals already exposed to these types, every effort should be made to target HPV-naïve individuals. A new 9-valent vaccine will likely be available after this printing. See the discussion of intraepithelial neoplasia of the cervix in [Chapter 28](#) for further details.

For women in high-risk groups, MMR and hepatitis B vaccine should be given if indicated. Pneumococcal vaccine should be offered to women with chronic lung, liver, or cardiovascular disease; diabetes; asplenia; cochlear implants; and immunocompromising conditions. Herpes zoster vaccine (for shingles) is recommended for women age 60 and over. For women who are 65 and older, the pneumococcal vaccine should be given once.

In addition, women in all age groups should be offered appropriate immunizations and vaccinations when they travel to other countries. The hepatitis A vaccine is available and should be offered to women of all ages. In particular, the hepatitis A vaccine should be given to women who are traveling to areas with a high or intermediate endemicity of hepatitis A, use injection drugs, have chronic liver disease, receive clotting factor concentrates, or work with primates infected with hepatitis A.

Physicians should discuss risk behavior annually with their patients. In line with injury prevention, the patient should be reminded about the use of seat belts and helmets and other safety concerns mentioned earlier in this chapter. Fall precautions can be discussed with elderly patients.

Exposure of the skin to ultraviolet radiation and proper precautions to avoid overexposure should be discussed. Regular dental checkups should be encouraged. Adequate calcium and vitamin D intake for proper bone health and age-appropriate intake recommendations should be reviewed at the annual visit ([Table 7.3](#)).

Many women will ask their physician about prophylactic aspirin use. The U.S. Preventive Services Task Force ([USPSTF, 2009](#)) recommends that women with no history of heart disease or stroke aged 55 to 79 years use aspirin to prevent stroke when the benefit of aspirin use outweighs the potential harm of gastrointestinal hemorrhage or other forms of serious bleeding. The latest research suggests that most healthy women under age 65 should not take aspirin, as the risk of gastrointestinal bleeding outweighs the benefits ([van Kruijsdijk, 2014](#)). A woman's individual risk factors must be weighed.

Promoting good health is a continuing responsibility for both the physician and the patient. It represents a challenge

Table 7.3 Recommended Intakes of Calcium and Vitamin D

Age (Years)	Intake Calcium (mg)	Intake Vitamin D (IU)
14-18	1300	600
19-50	1000	600
51-70	1200	600
71+	1200	800
Pregnancy and lactation	1000	600

From Institute of Medicine, Food and Nutrition Board. *Dietary Reference Intakes for Calcium and Vitamin D*. Washington, DC: National Academy Press; 2010. Available at <http://iom.nationalacademies.org/Reports/2010/Dietary-Reference-Intakes-for-Calcium-and-Vitamin-D/DRI-Values.aspx>.

that includes education and observation on the physician's part and motivation on the patient's part. The U.S. Department of Health and Human Services has a division devoted to women's health titled the Office on Women's Health. Its website (www.womenshealth.gov) offers accurate patient information on screening recommendations for both healthy and at-risk women. Furthermore, the website lists symptoms of serious health conditions for heart attack and stroke as well as for reproductive, breast, lung, digestive, bladder, skin, mental health, and muscle or joint problems. ACOG similarly has a comprehensive document for providing screening and prevention suggestions for women (www.acog.org/wellwoman).

SPECIAL POPULATIONS

The 2010 United States Census data estimated there were 56 million noninstitutionalized people with a self-care disability. Women with disabilities have some unique barriers to gynecologic care. Aside from communication obstacles and non-availability of facilities with exam tables to make routine pelvic exams easily performed, there may be ignorance or negative attitudes about a woman's life with disabilities. Women with disabilities undergo screening for cervical and breast cancer less often than recommended. Contraception, sexuality issues, childbearing plans, and abuse issues may all have to be addressed.

Data from the 2006-2008 National Survey of Family Growth revealed that 1.1% and 3.5% of women identify as lesbian or bisexual, respectively. ACOG reflects that women in this group face barriers to health care, including discriminatory attitudes and treatment, confidentiality and disclosure concerns, limited health care access, and perhaps limited understanding of their risks. Physicians should not assume all women are heterosexual, and asking about sexual activity can be done in a sensitive manner. Physicians sometimes conclude, incorrectly, that lesbian women do not need sexually transmitted infection or Pap screening because they are considered low risk. Fertility services should not be influenced by sexual orientation. ACOG has developed a committee opinion with background and recommendations ([ACOG, Committee Opinion #525, 2012](#)). Other populations that may encounter problems accessing gynecologic care include transgendered individuals and incarcerated, abused, or drug-addicted women.

KEY POINTS

- Strive to become a culturally sensitive and aware physician with a nonjudgmental approach to women regardless of race or ethnicity, age, faith, disabilities, profession, sexual orientation, or activities.
- Menstrual history includes age of menarche, number of days of cycle, number of days of flow, presence of bleeding between menstrual periods, the date of the last menstrual period, and the date of the previous menstrual period.
- A complete gynecologic evaluation should always include a sexual history, contraceptive history, and history of physical or sexual abuse.
- The specific components of the annual exam will be based on patient age, health concern, and risk factors. Whether to perform breast or pelvic exams is a joint decision between individual providers and their patients.
- Cervical cytology screening should begin at age 21 regardless of the onset of sexual activity.
- Pap smears should be performed every 3 years until age 29, then either every 3 or 5 years, depending on the addition of HPV testing. Screening should continue until between age 65 and 70, at which time adequately screened women and those with negative screening can stop undergoing cervical cancer screening.
- Sexually active women should be evaluated at appropriate intervals for sexually transmitted diseases, with annual chlamydia screening for women age 26 and under. Counseling women on safe sex practices to avoid contracting sexually transmitted diseases is important.
- Goals of preventive medicine include maintaining good health and function and promoting high-quality longevity.
- The physician should maintain an immunization record for each patient and offer appropriate vaccinations as recommended by public health guidelines.

Interaction of Medical Diseases and Female Physiology

Sarah K. Dotters-Katz, Fidel A. Valea

This chapter highlights the interactions and influences of female physiology on major medical disease processes. The chapter also reviews how medical diseases affect female physiology. Many disease processes act directly; for example, renal failure commonly induces abnormal uterine bleeding. Other diseases act indirectly through their therapies, such as cancer chemotherapy, which may lead to ovarian failure. Multiple chapters in this text discuss important aspects of female physiology. This chapter serves as an addendum to those discussions. When considering specific drug interactions and doses, the clinician is encouraged to review current pharmacologic literature.

In general, the impact of female physiology on medical disease is primarily via the effects of estrogen and to a lesser extent progesterone. Other hormones, such as prolactin, oxytocin, and gonadotropins, play minor roles. Estrogen and progesterone affect almost all major organ systems in both tonic and cyclic modes. The effects of the female hormones are mediated directly through receptors (estrogen alpha, estrogen beta, progesterone) as well as indirectly through their effects on other organ systems, such as smooth muscle relaxation and changes in prostaglandin levels. The responses induced by estrogen and progesterone may be theorized, in a teleologic sense, as promoting successful reproduction. Pathology occurs when the normal hormonal effects overlap a disease process that is already present.

Medical diseases affect female physiology at all levels of the hypothalamic-pituitary-ovarian-genital axis, from anovulation to vaginal atrophy. Medical diseases also affect female physiology in a horizontal manner, throughout every stage of a woman's life. Thus medical diseases must be seen in both a vertical and a horizontal context (i.e., a three-dimensional manner). The gynecologist acts as a consultant to other health professionals. As such, we are frequently asked to help with complications stemming from gynecologic issues. Though different clinicians direct the treatment of lupus, multiple sclerosis, or epilepsy, modulating the effects of female physiology on these disease processes is the role of the gynecologist.

PULMONARY DISEASE

Asthma is more common in boys up until puberty. After puberty, the ratio reverses with women more prone to asthma until

menopause. Asthma is one of several major diseases in which the severity of symptoms is increased around the time of menses ([Box 8.1](#)). Premenstrual asthma is well described, affecting up to 40% of reproductive-age women who have asthma, with symptoms including increasing cough, wheezing, and shortness of breath. Up to 50% of hospitalizations for asthmatic women in their 20s will occur around the time of menses. Women with premenstrual asthma have been shown to have a measurable decline in respiratory function with the end of the cycle ([Dratva, 2010](#)). Data suggest that combination oral contraceptives (OCs) may blunt this effect and mildly decrease the severity of the asthma ([Dratva, 2010](#)). The variability of symptoms between cycles may be caused by the hormonal fluctuations from one cycle to the next.

There are several mechanisms by which hormones can affect symptoms. One theory is that the increased symptomatology is related to the estrogen and progesterone-mediated increase in both serotonin and histamine release from granulocytes and mast cells ([van den Berge, 2009](#)). Estrogen also increases eosinophilic adhesion to the bronchial lining. In addition, progesterone induces degranulation of eosinophils. Interestingly, both estrogen and progesterone also have anti-inflammatory properties, and it may be that the withdrawal of estrogen and progesterone at the end of the cycle contributes to the fluctuation in prostaglandin levels that lead to increased bronchial reactivity and premenstrual asthma.

Regarding the effects of asthma on female physiology, a few small series have noted an increased incidence of abnormal menstrual cycles in women with severe asthma ([Real, 2007](#)). Whether this is due to glucocorticoid medications or whether this is a direct effect from severe pulmonary disease on the hypothalamus is unclear. It should be noted that multiple studies have found that women with early menarche have twice the risk of asthma in early adulthood ([Fida, 2012](#)). Women who are taking inhaled glucocorticoids may be at an increased risk for osteopenia and osteoporosis ([Aljubran, 2014](#)). Clinicians who care for women with asthma beyond their third decade should obtain vitamin D levels and counsel the women about adequate calcium intake. There are conflicting reports about the effect of menopause and hormone replacement therapy on asthma symptoms and severity; some have noted an improvement in symptoms, whereas others have noted a worsening ([Tam, 2011; van den Berge, 2009](#)).

Box 8.1 Major Diseases in Which Menstrual Hormonal Changes Affect Symptoms

Asthma
Atopic reactions
Epilepsy
Eating disorders
Irritable bowel syndrome
Menstrual migraines
Mental health disorders
Multiple sclerosis
Inflammatory bowel disease
Rheumatoid arthritis
Supraventricular tachycardia
Sickle cell disease
Type 1 diabetes

It is now common for women with cystic fibrosis (CF) to reach reproductive age. Tsang and colleagues, in a review of reproductive problems, noted that women with cystic fibrosis tend to have shorter stature, delayed puberty with delayed growth spurts, and delayed menarche (Tsang, 2010). The degree of delay is related to the severity of the disease. Additionally, due to the effects of estradiol on mucin production, periods of the menstrual cycle with high estradiol levels are associated with worse lung function (Tam, 2011). Girls with cystic fibrosis tend to be as sexually active as their peers; however, they tend to have less counseling regarding contraception than their peers. Estrogen-based contraceptives are acceptable for women with cystic fibrosis as long as they do not have pulmonary hypertension, active liver disease, or a history of thromboembolism (Tsang, 2010). Long-acting reversible contraception (LARCs), including the progesterone intrauterine devices (IUDs) or progesterone implants, are also safe, effective, and a practical option for these young women. Issues of sexuality may be problematic for young women with severe cystic fibrosis because of poor body image secondary to chronic disease, infections, and gastrointestinal disturbances from pancreatic problems, as well as sometimes enlarged rib cages from chronic hyperventilation. Thus counseling on sexuality should occur in conjunction with contraceptive counseling.

There is an emerging body of evidence suggesting that fertility is affected in women with cystic fibrosis. Cervical mucus is thicker in women with cystic fibrosis and may lead to altered fertility. Oligomenorrhea, amenorrhea, and ovulatory dysfunction are increased in women with cystic fibrosis related to the degree of severity of disease. Finally, alterations in uterine levels of bicarbonate, which affects sperm capacitation, also affect fertility in women with cystic fibrosis (Ahmad, 2013). Though a full discussion of the management of subfertility and infertility treatment options is beyond the scope of this chapter, intrauterine insemination, intracytoplasmic sperm injection, and in vitro fertilization have all been successfully performed in women with CF.

IMMUNE AND ALLERGIC DISEASE

The profound effect that female physiology has on immunity is best exemplified by the remarkably increased survival of women compared with men from infectious causes. Estrogen and progesterone have multiple effects on the immune processes,

Box 8.2 Effects of Estrogen and Progesterone on Cellular Processes of the Immune System

B Cell

Inhibited bone marrow B-cell lines with high concentrations of estrogen
Increased antibody production through inhibition of T-cell suppression
Enhanced interleukin-10 response

T Cell

Lower doses of estrogen are stimulatory, higher doses of estrogen are inhibitory, primarily through TNF
Stimulation of inhibitory T-cell pathways and T-cell cytokines
Low-level stimulation of interleukins

Monocytes

Increased monocyte apoptosis inhibiting differentiation
Inhibited dendritic cell differentiation (in vitro)
Inhibited migration of inflammatory cells with decreased migration at higher estrogen levels

Mast Cells and Granulocytes

Estrogen increases serotonin and histamine release through estrogen alpha-receptors
Progesterone promotes IgE production

General Inflammation

Increased presence of estrogen beta-receptors over estrogen alpha receptors with generalized inflammation
Increased sensitization of sensory neural tissue leading to increased neurogenic inflammation
Increased fibroblast activity and improved wound healing
Increased stimulation of the hypothalamus-pituitary-adrenal axis
Increased anaphylaxis* and allergic reactions

*Includes drug-induced and radiologic contrast media induced.

Data from Chen A, Rogan WJ. Isoflavones in soy infant formula: a review of evidence for endocrine and other activity in infants. *Annu Rev Nutr.* 2004;24:33-54; Lang JT, McCullough LD. Pathways to ischemic neuronal cell death: are sex differences relevant? *J Transl Med.* 2008;6:33; Straub RH. The complex role of estrogens in inflammation. *Endocr Rev.* 2007;28(5):521-574.

through numerous cellular sites. This is manifest in multiple disease processes (Box 8.2). In most women the effects are mild, but in women constitutionally or genetically predisposed to atopic reaction or autoimmune disease, the effects can be significant.

The overall effect may be grossly simplified in noting estrogen's effect on the B cell as an immune enhancer (Lang, 2004). In contrast, on T cells, estrogen tends to act as an inhibitor (Lang, 2004). Importantly, estrogen effects vary by the level and type of estrogen. At lower levels, as in most of the menstrual cycle, estrogen stimulates immune responses. However, at high estrogen levels such as with pregnancy, estrogen generally inhibits immune cellular responses. The effects of estrogen on inflammation have important implications for wound healing. Women heal much better than men because estrogen stimulates fibroblast activity and nerve growth. Estrogen's positive effect on reepithelialization lasts until several years after menopause (Straub, 2007). Interestingly, hormone replacement therapy improves wound healing (Peržel'ová, 2016).

B-cell-dominated autoimmune diseases have a higher incidence and severity in women (Straub, 2007). Estrogen enhances the hypersensitivity responses from both B-cell activity and granulocyte action in allergic responses (Chen, 2008). Women are more prone than men to eczema, atopic irritations, hypersensitivity, and

Table 8.1 Medical Disorders with Contraindicated Contraceptive Options

Medical Disorder	Contraindicated Contraception	Rationale/Complication
Systemic lupus erythematosus with antiphospholipid antibodies or thrombosis	Estrogen-containing contraception* (ECC)	Increased venous thrombosis (VTE) risk
Crohn disease	Any oral contraception ECC†	Decreased absorption Increased VTE risk
Severe dyslipidemia	ECC	Increased VTE risk
Hypertension with risk factors‡	ECC	Increased VTE, stroke, and myocardial infarction risk
Renal transplant	ECC	Increased VTE risk Increased metabolism
Thrombophilias	ECC	Increased VTE risk
Diabetes with risk factors§	ECC	Increased VTE risk
Malabsorptive bariatric surgery	Any oral contraception	Decreased absorption
Migraine with aura	ECC	Increased VTE
Epilepsy on enzyme-inducing antiepileptic drugs	Progestosterone-only oral contraception Progestosterone implant	Increased metabolism

Modified from Centers for Disease Control and Prevention. U.S. medical eligibility criteria for contraceptive use, 2010. *MMWR Recomm Rep.* 2010;59(RR-4):1-86.

*Includes combined oral contraception, vaginal ring, and the transdermal patch.

†In cases of extensive or active disease, prior bowel resection, very active disease, corticosteroid use, or immobilization.

‡Risk factors include: poor control, tobacco use, age >35, other chronic medical condition leading to vascular degradation, end organ damage, use of anti-hypertensives.

§Risk factors include end-organ damage, vascular disease, hyperlipidemia, poorly controlled disease.

anaphylaxis from foods, medications, radiologic contrast media, and anesthesia (Chen, 2008). Granulocytes, eosinophils, mast cells, and basophils are enhanced by estrogen (Chen, 2008). Estrogen also enhances serotonin and histamine release. In contrast, cellular-mediated immune mechanisms, primarily controlled through T cells, tend to be functionally inhibited by estrogen. At high, pregnancy levels of estrogen, there is functional inhibition of T-cell function, leading to improvement of T-cell-mediated autoimmune diseases during pregnancy such as rheumatoid arthritis or multiple sclerosis (Straub, 2007). During periods of estrogen withdrawal, late luteal phase, menstruation, postpartum, and early menopause, there are often clinical rebounds and an increase in disease flares with the release of T-cell suppression.

For the gynecologist asked to consult on women with autoimmune diseases, important strategies include ensuring that any pregnancy is planned, not only to allow time for medication optimization balancing disease stability with fetal risk but also because the best pregnancy outcomes occur when autoimmune diseases are quiescent. Thus effective contraception is essential. Estrogen-containing contraceptives (ECCs) (including the vaginal ring, the transdermal patch, and combined oral contraceptive pills) are acceptable for women with systemic lupus erythematosus (SLE), if they do not have antiphospholipid antibody syndrome or a history of thrombosis (Table 8.1) (Centers for Disease Control and Prevention [CDC], 2010). Women with SLE are also prone to menstrual irregularities, thus hormonal contraceptive may also help with cyclic regulation (Tseng, 2011). However, LARC methods are also safe, have similar benefits as far as cyclic regulation, are more effective contraceptives, and are less susceptible to user error than all ECCs, but especially OCPs. ECCs have not been shown to increase the severity of disease or the number of flares in premenopausal women with SLE (Sanchez-Guerrero, 2005).

In general, most of the autoimmune diseases are not worse around the time of menses. For the women with menstrual exacerbation, hormonal contraceptives may help to decrease periodic variability. SLE does not seem to affect menses or the timing of menopause. However, some anti-inflammatory medications,

Table 8.2 Antineoplastic and Chemotherapeutic Agents That May Produce Ovarian Failure

Major Risk	Moderate Risk	Minimal Risk
Cyclophosphamide	Cisplatin	Methotrexate
Melphalan	Adriamycin	5-fluorouracil
Busulfan	Paclitaxel*	Vincristine
Chlorambucil		Bleomycin
Procarbazine		Actinomycin
Nitrogen mustard		

Modified from Sonmezer M, Oktay K. Fertility preservation in young women undergoing breast cancer therapy. *Oncologist.* 2006;11(5):422-434.

*Unquantified risk at this time.

including glucocorticoids and antineoplastic agents, will affect not only the hypothalamic-pituitary-ovarian (HPO) axis but the ovarian follicles as well (Table 8.2). Women with severe end-organ disease may develop down-regulation of the HPO axis (see Chapter 26). Hormone replacement therapy (HRT) has been shown to increase the number of mild, but not severe, flares in lupus patients (Sammaritano, 2012).

Multiple sclerosis (MS), is another autoimmune condition that merits discussion. Women are more frequently affected but usually have a less severe disease course than men (Ghezzi, 2008). Evidence is mixed regarding the effects of menstruation in disease flares. However, for women with cyclic disease flares, hormonal contraceptives are safe (Ghezzi, 2008). Women with severe multiple sclerosis have an increased risk of sexual dysfunction. Though data are limited, HRT may be useful for postmenopausal women with MS.

GASTROINTESTINAL DISEASE

Estrogen and progesterone are critical in the modulation of the gastrointestinal tract. Estrogen plays a role in the secretory and absorptive function in gut epithelium, affects the gut's

microbiome composition, and has receptors on enteric neurons, which regulate neurogenic reflexes (Mulak, 2014). Progesterone is known to affect the motility of the gut, as well as the growth and metabolism of the bacteria in the gastrointestinal tract (Mulak, 2014). Thus it is no surprise that many gastrointestinal disease processes affect women differently than they affect men.

Irritable bowel syndrome (IBS) is perhaps the best example of this effect. With a female-to-male prevalence as high as 5:1, up to half of women with IBS will have exacerbations of symptoms with menses. The rapid progesterone withdrawal at the end of the luteal phase and the increase in systemic prostaglandins both lead to exacerbations of symptoms, including bloating and abdominal pain (Mulak, 2014). OCPs have been shown to decrease symptoms in women with IBS. For women in whom menstrual effects become debilitating, the use of GnRH agonists or continuous OCPs has been suggested. The incidence of IBS tends to decrease after menopause.

Celiac disease, like other autoimmune diseases, tends to preferentially affect women. Females are at twice the risk for developing celiac disease (Liu, 2014). Women with undiagnosed or poorly controlled celiac disease have more irregular menstrual cycles and secondary amenorrhea. A meta-analysis regarding fertility and celiac disease suggested that women with unexplained infertility should be tested for celiac disease, but that women with well-controlled disease do not have decreased fertility compared with women without celiac (Tersigni, 2014).

Women with Crohn disease and ulcerative colitis tend to have symptomatic exacerbations around the time of menses, specifically worsening nausea, constipation, and diarrhea. Inflammatory bowel disease (IBD) has also been shown to have a negative effect on body image and sexuality (Moleski, 2011). Dyspareunia is common, especially in those with Crohn disease. Women also cite abdominal pain, fear of incontinence, and diarrhea as reasons for decreased levels of sexual activity (Moleski, 2011). Effective contraception is important for women with IBD, as unplanned pregnancy in the setting of active disease is associated with worse maternal and fetal outcomes (Moleski, 2011). Though OCPs are not associated with disease relapse, there are some data suggesting decreased absorption in women with Crohn disease as well as in those women with increased intestinal transit secondary to previous bowel resection. For women with IBD who are at an increased risk for venous thrombosis (VTE), including those with extensive or active disease, corticosteroid use, vitamin deficiencies, or immobilization, ECCs are not recommended (CDC, 2010). LARC methods are considered safe and very effective in women with IBD, independent of disease severity, and thus often are preferred over oral contraceptive options and ECCs. It is also important to note that women with IBD are at increased risk for osteoporosis and osteopenia, and they should be screened accordingly.

Estrogen has been noted to have a protective effect on the development and progression of liver disease. Women with hepatitis C have a better response to therapy and a slower rate of disease progression than men (Rodríguez-Castro, 2014). Research also suggests estrogen plays a significant role in preventing carcinogenesis in the liver (Zhang, 2013). As such, hepatocellular carcinoma is less common in women. Some reports have also detailed the use of hormone replacement in postmenopausal women to inhibit liver fibrosis (Zhang, 2013). In contrast, autoimmune-mediated liver diseases, such as primary

biliary cirrhosis and autoimmune hepatitis, are more common in women. It is also important to note that for women with cirrhosis or severe liver disease, estrogen-containing contraceptive options are contraindicated.

VASCULAR AND HYPERTENSIVE DISEASES

In general, estrogens have a positive effect on the vascular system through improved lipid profiles. The presence of estrogen is associated with lower rates of atherogenic dyslipidemia, cardiovascular disease, and metabolic syndrome (Pellegrini, 2014). This effect is lost in postmenopausal women. However, women with dyslipidemias may have complications with estrogen because of its procoagulant effects, especially after the third or fourth decade. Women with a dyslipidemia should avoid estrogen-based contraceptives and hormone replacement therapy. However, progesterone-based contraceptives, including LARC methods, are safe and effective for these women, independent of age.

In contrast, vascular and hypertensive diseases have important effects on women. Studies indicate that women with hypertension have much higher than expected levels of sexual dysfunction with impaired genital congestion and decreased arousal (Doumas, 2006). Data regarding the effects of antihypertensive medications on sexual function are mixed. Though beta-blockers are consistently associated with worsening sexual function, multiple studies have noted that adequate blood pressure control with medication leads to an improvement in sexual function (De Franciscis, 2013; Doumas, 2006; Fogari, 2004). Women with coronary artery disease, as well as survivors of myocardial infarction, have less sexual activity and increased sexual dysfunction (Basson, 2007). Thus it is helpful for gynecologists to inquire about sexual issues in women with cardiovascular disorders.

Hormonally based contraceptives may be problematic in women who are taking antihypertensive medications or those with poorly controlled hypertension. If there is no associated thrombosis, guidelines from the American College of Obstetricians and Gynecologists (ACOG) suggest that women may use ECCs as long as their blood pressures are well controlled (ACOG, 2006; World Health Organization [WHO], 2015). A return office visit 2 or 3 months after initiation of any ECC to assess blood pressure and potential side effects is appropriate. Studies have shown a small increase in stroke and myocardial infarction in women on oral contraceptives with hypertension, but the absolute risk is quite small (ACOG, 2006; WHO, 2015). It should also be noted that women with a history of pregnancy-related hypertension who are currently normotensive are also at a slightly increased risk for myocardial infarction and VTE, though again, the absolute risk is small (ACOG, 2006; WHO, 2015). As long as a woman does not use tobacco or does not have other aspects of vascular disease besides mild hypertension, ECCs may be reasonable. However, LARC methods are preferable, especially after age 35.

Cardiac arrhythmias are also affected by gender, though the exact pathophysiologic reasons for this are unclear. Atrioventricular nodal reentrant tachycardia occurs twice as frequently in women as in men, though Wolff-Parkinson-White syndrome is more common in males (Curtis, 2012). Supraventricular tachycardias and ectopic ventricular beats occur more frequently and last longer in the luteal phase of the menstrual cycle (Curtis, 2012). The QT interval tends to be longer in women, increasing

the risk for torsades de pointes. Though rates of atrial fibrillation are lower in women, women with atrial fibrillation are less likely to be anticoagulated, undergo ablative procedures, and are more likely to suffer a stroke (Curtis, 2012). Sudden cardiac death affects both genders equally.

Renal Disease

Women with end-stage renal disease (ESRD) have high prolactin levels as well as gonadotropin-mediated disruption of the luteinizing hormone (LH) surge (Guglielmi, 2013). These hormonal alterations result in anovulatory cycles, amenorrhea, oligomenorrhea, menorrhagia, infertility, and decreased libido. The effects of chronic disease (see Chapter 26) on the HPO axis also contribute to an increased likelihood of anovulatory bleeding in this population. Though many women with ESRD or on dialysis have irregular menstrual cycles and problems with infertility, many are sexually active, and thus contraception should be discussed with them.

Women with end-stage renal disease have higher rates endometrial hyperplasia, likely related to anovulatory cycles. There is also an increased incidence of cervical dysplasia, thought to be due to increased susceptibility to human papillomavirus (HPV) infection. Mammography can be challenging in this population due to increased vessel calcifications. To avoid unnecessary procedures, the patient's history should be provided to the radiologist (Holley, 2007). Ca-125 is also often falsely elevated in this population and should be interpreted with caution (Holley, 2007). Women with ESRD or who have undergone renal transplant have been shown to have a higher risk of surgical complications during gynecologic procedures (Heisler, 2010).

Up to 70% of women who are on hemodialysis, with chronic renal disease, and those who have had renal transplants have some degree of sexual dysfunction, including arousal disorders, decreased libido, and decreased genital blood flow, issues with lubrication, and orgasm problems. This may be related to lower levels of circulating estrogen. These women also go through menopause at an earlier age, 47 compared with 51 in nondialyzed females, further exacerbating problems with sexual dysfunction (Guglielmi, 2013).

Peritoneal dialysis has many specific considerations in women. Fertility in this population is lower than in women receiving hemodialysis, likely related to a disruption in the ovum's path to the fallopian tube (Guglielmi, 2013). Additionally, these women may experience cyclic hemoperitoneum, usually related to retrograde menstruation (Guglielmi, 2013). The hemoperitoneum is often asymptomatic, though rarely may cause obstruction to the dialysis catheter (Guglielmi, 2013). If the hemoperitoneum is recurrent or problematic, it may be treated with tubal ligation or hormonal suppression of ovulation (Guglielmi, 2013). Finally, women who undergo peritoneal dialysis may be at increased risk for uterine prolapse possibly related to changes in intraabdominal pressure associated with the dialysis.

HEMATOLOGIC AND THROMBOTIC DISEASES

Estrogen affects hematologic diseases primarily through its prothrombotic effects. Progesterone decreases smooth muscle venous tone, which leads to increased clotting potential. Routine screening for thrombophilias in women without a history of

thrombosis, prior to the use of ECCs or hormone replacement, is not indicated. Women with a personal history of thrombosis related to estrogen should avoid estrogen-containing medications (WHO, 2015). Women with known thrombophilias are great candidates for LARC methods but can also use progesterone-based oral contraceptives. Because supplemental estrogen is contraindicated in women with thrombophilias, these women may be more prone to osteoporotic problems over time. These women should be regularly screened for a dietary history of calcium intake as well as serum levels of vitamin D, with appropriate supplementation given.

Women with sickle cell disease (SCD) tend to go through menarche at a later age but do not have an increased rate of irregular cycles (Smith-Whitley, 2014). The menstrual cycle is often associated with increased pain crises. Progesterone stabilizes red-cell membranes and significantly decreases the frequency of sickling crises, thus women with SCD may benefit from progesterone-containing contraceptives. Injectable medroxyprogesterone acetate has been used in women with frequent crises as an adjunct therapy with very good results (Smith-Whitley, 2014). The pain-mediating effects of progesterone-based IUDs and implants have not yet been well documented, though these are considered a safe contraceptive option for women with SCD. ECCs and HRT do not improve sickling but are not contraindicated (WHO, 2015).

Women who receive oral anticoagulants (OA), for either treatment or prophylaxis, experience increased vaginal bleeding, menorrhagia, and metrorrhagia (Huq, 2011). One series of women noted that after starting the OA, the duration of bleeding increased, the percentage of women reporting heavy bleeding increased to almost 75%, and the number of women seeking medical treatment nearly doubled (Sjalander, 2007). Anovulatory cycles may be particularly troublesome for these women. Progesterone-based IUD or progesterone supplementation for the 14 days at the end of the cycle may be necessary to decrease heavy bleeding. Estrogen-containing contraceptives are not recommended for women on anticoagulation (CDC, 2010). Though the copper-containing IUD does not increase the risk of thrombosis, it is also generally not recommended given its associated increased menstrual bleeding (Huq, 2011). Women on OA are also at an increased risk for ovulation bleeding and associated hemoperitoneum.

The most common inherited bleeding diathesis is von Willebrand disease. The association of von Willebrand disease and vaginal bleeding is discussed in Chapter 26. LARC methods are safe in these women. However, because estrogen increases von Willebrand factor, ECCs may be advantageous for women with excessive bleeding or ovarian cysts (Committee on Adolescent Health Care, 2013). Women with rare bleeding disorders fall into similar categories, and ECCs may be helpful for them. A consensus report discussed other therapies including endometrial ablation or hysterectomy as potential options in women with bleeding disorders who do not desire fertility (James, 2009).

ENDOCRINE DISEASE

Women with type 2 diabetes or who are obese have increased rates of anovulation, infertility, and endometrial hyperplasia. ECCs are acceptable in women with isolated diabetes (type 1 or 2) without end-organ damage, as are progesterone-based

contraceptives (CDC, 2010). However, because many women with diabetes have coexisting vascular disease or hyperlipidemia, it is recommended that ECCs be limited to women who are non-smokers and younger than 35 with no other significant pathology. LARC methods are safe, effective, and recommended for women with diabetes. In addition to the contraceptive effects, LARC methods also protect the endometrium in women who are anovulatory (ACOG, 2010).

Studies of sexuality in women with diabetes have noted increased sexual dysfunction, particularly for those with type 1 diabetes and those with long-standing disease. Sexual dysfunction is due to end-organ disease, with decreased genital blood flow, decreased lubrication, and orgasmic dysfunction. Young women with type 1 diabetes are also more likely to suffer from longer menstrual cycles and heavier menses when compared with nondiabetic women (Gaete, 2010). Though these issues are worse in women with higher HbA1cs, the problems persisted in women with well-controlled disease (Gaete, 2010). It should also be noted that insulin requirements and glycemic control vary with the hormonal fluctuations of the menstrual cycle, especially in the luteal phase and around menses. Discussion of this normal variation with younger women is important.

Obese women present an interesting conundrum regarding contraceptive options. Most studies related to contraceptive efficacy exclude morbidly obese and super morbidly obese women. Thus existing data have limited generalizability to this population, though the evidence that does exist is reassuring that efficacy of many contraceptive options is maintained (Robinson, 2013). It should also be stated that given the increased risks of pregnancy in this population, some contraceptive effect is better than no contraception. The progestin-based IUD or progestin-based implant have the highest success rate, independent of weight, and should be considered a first-line treatment in the obese population (Robinson, 2013). Given the increased incidence of anovulation with obesity, the local effects of the progestin-based IUD are especially protective against endometrial hyperplasia as well. However, OCPs are also an acceptable option in the population (Robinson, 2013). There are some data suggesting decreased efficacy of transdermal contraception in obese patients; thus other methods are preferred. Obese women also describe higher rates of sexual dysfunction than normal weight-women. However, this seems to improve with weight loss and improvement in body image (Kolotkin, 2012). This is true with both natural weight loss and bariatric surgery.

Obese women undergoing bariatric surgery should also be counseled about contraception and pregnancy planning. Malabsorptive procedures, specifically the Roux-en-Y procedure, have the potential to affect absorption of all oral contraception, including emergency contraception, and thus these methods should be discouraged in women who are undergoing or have undergone this sort of operations (Robinson, 2013). The efficacy of nonoral methods is not affected by bariatric surgery; thus the LARC methods are a good option for this population. After surgery, women may transition from being anovulatory to regular ovulation with improved glucose control. It is recommended that women wait 12 to 18 months prior to attempting pregnancy after bariatric surgery, another reason that the LARC methods are a good choice for these women (Mody, 2014).

Women with congenital adrenal hyperplasia (CAH) are usually treated with glucocorticoid replacement. These women are

exposed to an androgenic environment throughout their lives, thus hormonally based contraceptives, including OCPs, are a good form of contraception. Though many of these women have increased problems with hirsutism, they should not be treated with spironolactone because it may affect mineralocorticoid regulation. Infertility secondary to chronically increased progesterone and androgen levels may occur, though this condition is correctable with steroid maintenance therapy (Reichman, 2014). Women with more severe phenotypes may need mineralocorticoid as well as progesterone suppression (Reichman, 2014). Women with CAH may also have problems with dyspareunia, vaginal stenosis, and lower sexual satisfaction (Nordenstrom, 2011). Sexual counseling for these women is helpful. Of note, thyroid disease is discussed in detail in Chapter 26.

CENTRAL NERVOUS SYSTEM DISEASE

SEIZURE DISORDERS

Estrogen and progesterone have significant effects on a woman's susceptibility to seizures. Estrogen is a pro-convulsant, decreasing seizure threshold. Estrogen increases neuronal excitability directly on nerve cells, as well as secondarily through inhibition of the GABA system. More potent, though, are the effects of progesterone, which acts primarily via its metabolite allopregnanolone, a neurosteroid. Allopregnanolone acts rapidly and directly on the GABA receptors to enhance their activity, producing potent neural inhibition throughout the central nervous system (CNS). Withdrawal of progesterone (even in small amounts such as periovulatory) leads to a significant decline in seizure threshold and an increase in seizure frequency and severity.

More than 1 million women in the United States are affected with seizure disorders, and many have increased seizure activity related to changes in menstrual hormones. Catamenial epilepsy (from the Greek *katomenios*, meaning "monthly") has been defined as seizures that occur from 3 days prior to 4 days after the onset of menses. Pure catamenial epilepsy affects 10% of all women with epilepsy (Crawford, 2009). However, nearly 80% of women have an increase in seizure activity related to menstrual cycles (Crawford, 2009). Progesterone-based contraceptives or a small amount of progesterone add-back during menses has been used to decrease seizure frequency. Continuous OCPs with an every-3-month withdrawal may also be helpful. It is unclear if the progesterone-based IUD produces systemic progesterone levels high enough to affect the seizure threshold.

Though hormonal contraception is acceptable for women with seizure disorders, estrogen affects metabolism of some antiepileptic drugs (AEDs) (Table 8.3). Women who experience menstrual-related seizures should have serum levels of their anticonvulsant medications checked during menses. Some of these women will benefit from perimenstrual adjustments of their medications. In contrast, some antiepileptic drugs, referred to as *enzyme-inducing AEDs* (see Table 8.3), affect the metabolism of hormonal contraception. For women on this family of AEDs, progesterone-only pills have decreased efficacy and are not recommended (Crawford, 2009). Similarly, progesterone implants are contraindicated in this population (Luef, 2009). Emergency contraception can be used in women with epilepsy, but those on enzyme-inducing AEDs may need a higher dose (Crawford, 2009).

Table 8.3 Interactions of Anticonvulsants (AEDs) and Oral Contraceptives

Enzyme-Inducing AEDs	Non-Enzyme-Inducing AEDs
Barbiturates	Gabapentin
Carbamazepine	Lamotrigine
Phenytoin	Valproic acid
Topiramate	Ethosuximide
Vigabatrin	Levetiracetam

Modified from the American College of Obstetricians and Gynecologists (ACOG) Practice Bulletin #72, 2006, Use of Hormonal Contraception in Women with Coexisting Medical Conditions.

Almost one third of women with epilepsy exhibit some degree of sexual dysfunction, ranging from decreased interest to orgasmic dysfunction (Crawford, 2009). Thus providers caring for women with epilepsy should query patients regarding sexual function and satisfaction. Epilepsy may predispose women to earlier menopause. Seizures often increase in the perimenopausal transition, then decrease after menopause, especially in women who suffer from catamenial epilepsy (Luef, 2009). HRT is associated with an increase in seizure frequency. Finally, women with epilepsy are at increased risk for osteoporosis related to the effects of AEDs on bone metabolism (Erel, 2011). Calcium and vitamin D supplements are recommended in this population as well as monitoring of bone mineral density (Crawford, 2009).

MIGRAINE HEADACHES

In general, women have three times more migraines than men. Fourteen percent of all women with migraines have pure menstrual migraines; 46% have exacerbation of severity and frequency of their migraines during menses. Approximately 17 million women are affected by this problem. A menstrual migraine is defined as a migraine headache, without aura, occurring within the last 2 days of the menstrual cycle and the first 3 days of menses and affecting two of every three cycles (Brandes, 2012). After menopause, the incidence of migraines decreases by two thirds, and women and men have equal frequencies.

The etiology of menstrual migraines is related to estrogen withdrawal. Migraines are primarily vascular headaches, and the withdrawal of the estrogen leads to a relative vascular instability (Mathew, 2013). Estrogen also affects the CNS serotonin receptors. The change in serotonin metabolism as estrogen is withdrawn affects the brain stem, which controls cerebral blood flow. Serotonin uptake is blocked by triptans, and triptans are noted to be extremely effective for both abortive treatment of menstrual migraines as well as short-term prophylaxis (prevention) (Mathew, 2013). When menstrual migraines and menstruation-related migraines are diagnosed, therapeutic choices include modifying estrogen withdrawal with therapies such as the continuous OCPs, transdermal patches, or small amounts of estrogen add-back in the appropriate time window (Brandes, 2012). Preventive therapies include tricyclic antidepressants, beta-blockers, and other medications (Brandes, 2012).

Women who have migraines with aura are more susceptible to stroke, and thus the use of estrogen-containing contraceptives in women with migraines with aura is contraindicated (WHO, 2015). However, progestin-only contraception and LARC methods are safe in this population.

Box 8.3 Emotional Symptoms Affected by Changes in Estrogen and Progesterone

Anger
Anxiety
Appetite change
Decreased self-esteem
Depression
Feelings of phobia
Increased sense of fatigue
Inhibited control of limbic system sensations
Irritability
Loss of pleasure
Memory problems
Mood lability
Temperature fluctuations
Vulnerability

Modified from Pinkerton JV, Guico-Pabia CJ, Taylor HS. Menstrual cycle-related exacerbation of disease. *Am J Obstet Gynecol.* 2010;202(3):221-231.

MENTAL HEALTH ISSUES

Changes in estrogen and progesterone levels have profound effects on psychiatric and psychological symptomatology and on psychiatric diseases (Box 8.3). Estrogen and progesterone are neuromodulators, thus exacerbation of mental health conditions may occur with menstrual hormonal fluctuations. Premenstrual exacerbation has been shown to occur with anxiety disorder, panic disorder, obsessive-compulsive disorder, bipolar disease, eating disorders, and psychotic disorders (Pinkerton, 2010). Women without mental health disorders handle these fluctuations well, but women who have a predisposition to mental health disorders may be strongly affected by the hormonal fluctuations.

Premenstrual dysphoric disease (PMDD) affects up to 5% of women and is discussed in Chapter 37. Other mental health disorders are best managed by mental health providers. However, the gynecologist may help to provide hormonal stability. Continuous combined oral contraceptives can help improve depression that occurs around the time of menses (Pinkerton, 2010). Sexual dysfunction may be a symptom of depression, but it can also be a side effect of antidepressant medications, including the serotonin reuptake inhibitors (SSRIs).

New onset depression or worsening of known depression often occurs during the menopausal transition. Studies suggest this occurs in as many as half of all women (Pinkerton, 2010). Screening for depression in this age group is important given the high incidence of disease. Treatment with antidepressant medications is the first-line therapy for moderate to severe depression in the menopausal transition (Pinkerton, 2010). If there are only mild to moderate symptoms and the woman is an appropriate candidate, estrogen-containing HRT may be helpful (Pinkerton, 2010). Black cohosh and St. John's wort may also be beneficial in the treatment of perimenopausal depression, though they should be used with caution as safety data and production regulation are limited (Pinkerton, 2010).

CANCER

The gynecologist can play a valuable role in improving quality of life for women with cancer. Sexuality in cancer patients should

be addressed from the beginning of cancer therapy. Issues of depression and sexual dysfunction are enhanced by ovarian failure, loss of hair, changes in body image, and changes in relationships (Lamb, 1995). Abnormal vaginal bleeding in the first few cycles of chemotherapy is frightening, and the role of the gynecologist is important at this phase of treatment.

Chemotherapy produces toxic effects on ovarian function that are related to dose, duration, and type of chemotherapy. Agents that are particularly toxic to the ovary are listed in Table 8.2. Of these, alkylating agents are the most toxic to the ovaries, but women who receive antineoplastic agents for control of severe autoimmune disease can also develop ovarian failure. Young women treated with oophorotoxic agents often become amenorrheic, but their menses and ovarian function may return after a few or several months (Sonmezer, 2006). They generally undergo menopause earlier. For older women, their chemo-induced menopause is usually permanent. Radiation to the ovaries greater than or equal to 20 Gy may also produce ovarian failure, though oophoropexy to remove the ovaries from the field of radiation may mitigate this reaction (Mahajan, 2015).

In addition to the effects that chemotherapy has on the ovaries, the effects on the bone marrow, thrombocytopenia specifically, can lead to gynecologic issues. GnRH analogues have been shown to be effective in reducing episodes of severe vaginal bleeding associated with thrombocytopenia, without the potential risks associated with the estrogen-based options, especially venous-thromboembolism (Bates, 2011). GnRH analogues may be used as prophylaxis for menorrhagia/menstrual suppression in women with expected thrombocytopenia for more than 30 days (Bates, 2011). Acute menorrhagia in women undergoing treatment for most cancers can be treated with tranexamic acid, relying on hormonal therapies as second-line agents (Bates, 2011).

Young women wishing to preserve ovarian function and fertility need consultation prior to treatments. Mature oocytes are the most susceptible to chemotherapy, whereas immature oocytes in the prepubertal females are somewhat resistant. Thus investigators have used GnRH antagonists to suppress follicular maturity and attempt to preserve ovarian function. The results are mixed, though a Cochrane review supports their usage (Chen, 2011). Other potential options to save oocyte function and preserve fertility include in vitro fertilization with freezing of embryos, harvesting/freezing of mature oocytes after ovarian stimulation, and ovarian cryopreservation, which is still in the investigational stage. The American Society of Clinical Oncology currently recommends discussion of both embryo and oocyte cryopreservation as methods of fertility preservation (Loren, 2013). The options should be reviewed in light of the patient's needs, fertility desires, and clinical situation. Early and urgent referral to a reproductive endocrinologist with expertise in potential therapies to preserve fertility is important (McLaren, 2012).

SUMMARY

The interaction of female physiology and medical disease is complex. The gynecologist has several roles in the treatment of these women. All providers who address women's health should regularly discuss issues of sexual function, particularly in the setting of coexisting disease. Additionally, the exacerbation of symptoms

around the time of menses should be reviewed. Hormonal changes that increase the symptoms of women will change over the course of a woman's reproductive life. Disease manifestation in a woman's 20s will not be the same as symptoms in her 40s or in her 60s. There are many treatment options that can improve quality of life. Though gynecologists may not be the primary providers for nongynecologic diseases, they are best suited to act as consultants for adjunctive therapy, which may enhance the efficacy and treatment of medical disease.

KEY POINTS

- LARC methods are safe, effective, and have minimal risk of user error, thus they have become the recommended option for most women with complicated chronic illnesses.
- The severity of asthma symptoms increases around the time of menses.
- Many women with IBS and IBD will have exacerbations of symptoms with menses.
- Women with chronic renal disease often experience menorrhagia.
- Estrogen-containing contraceptives are not recommended in women with hypertension who are over 35, use tobacco, have poorly controlled disease, or are on medications for hypertension.
- Progesterone stabilizes red cell membranes and significantly decreases the frequency of sickling crises.
- Withdrawal of progesterone (even in small amounts such as periovulatory) leads to a significant decline in the seizure threshold and an increase in seizure frequency and severity.
- Women who have migraines with aura are more susceptible to stroke, and thus the use of ECC in women with migraines with aura is contraindicated.
- Early referral of women with cancer to a reproductive endocrinologist with expertise in potential therapies to preserve fertility is important.

Emotional Aspects of Gynecology

Depression, Anxiety, Posttraumatic Stress Disorder, Eating Disorders, Substance Use Disorders, “Difficult” Patients, Sexual Function, Rape, Intimate Partner Violence, and Grief

Deborah S. Cowley, Gretchen M. Lentz

Gynecologists follow women across the life cycle, from puberty through old age. The gynecologist may be a woman's primary health care provider for much of this time and thus is in an important position to help her to navigate normal developmental stages and challenges, to share in critical life events from adolescence to late life, and to provide or obtain counseling for her as she works her way through emotional adjustments and problems. Normal development includes challenges such as building an identity and self-esteem; dealing with sexuality and sexual development; forming meaningful relationships; pregnancy and motherhood; life roles and transitions; and inevitable losses, such as loss of relationships, loss of important career and life roles, loss of physical or mental abilities through illness or accident, and loss of loved ones through separation or death. In addition to these normal developmental transitions and challenges, a woman may have to deal with trauma related to difficult early childhood experiences, abuse, rape, or intimate partner violence. Psychiatric disorders such as depression, anxiety, posttraumatic stress disorder, and eating disorders are common in women, and conditions such as alcohol and drug use disorders often have a different presentation and course in women compared with men.

This chapter reviews common psychiatric disorders occurring in gynecologic patients, sexual function and disorders, and psychosocial issues and traumas that may arise during a woman's lifetime, and it offers suggestions as to how the physician can aid the patient.

DEVELOPMENTAL ISSUES IN CHILDHOOD AND ADOLESCENCE

Self-esteem begins to develop in early childhood and is affected by the positive efforts of parents and others in the child's immediate environment. Continuous reinforcement of a child's worth as an individual, by verbal and nonverbal means, should be encouraged. Praise for the child's positive actions and setting consistent, predictable limits that are socially acceptable within the framework of the family are reasonable steps. Punishment

should be limited to reinforcing the needs for the limits that have been set. Intimidation by verbal or physical means should be avoided. The physician may have the opportunity to suggest help for parents by offering reading material, discussing issues directly with them, or referring them to parenting classes. In general, positive reinforcement of the child's worth as an individual, mixed with appropriate warmth and love, tends to build self-esteem, whereas negative statements or actions tend to tear it down. A child has little basis for comparison, and if she is given negative information about herself, she will tend to believe it.

Girls and women, starting in childhood, often are highly invested in maintaining relationships, caring for others, not being “selfish” in pursuing their own goals and desires, and striving for ideal standards of appearance and behavior. These characteristics make it difficult, throughout life, to effectively and constructively express anger, be appropriately assertive, and know or pursue individual goals, and they may predispose girls and women to conditions such as depression and eating disorders, which are discussed later in the chapter. The physician can help by recognizing these characteristics and conditions early and providing support and referrals for mental health treatment as needed.

Physical, sexual, or emotional abuse in childhood and adolescence can have serious consequences for the child's development. Evidence of abuse must be addressed vigorously. The health care professional should communicate to the child or adolescent that she is a victim and is in no way responsible for what has happened. Reporting to child protective services may be legally mandated. Issues of abuse are discussed more fully later in this chapter.

DEPRESSION

Major depression is common in women, with a lifetime prevalence of 20% to 25%. Although boys and girls are equally likely to experience depression, major depression is about twice as common in women as in men, starting in adolescence. Worldwide, depression is one of the leading causes of functional impairment and disability. The diagnosis of major depression refers to persistent

sadness or lack of interest or pleasure in usual activities, lasting for at least 2 weeks, and accompanied by symptoms such as changes in eating habits, trouble sleeping, lack of energy and motivation, poor memory or concentration, and feelings of guilt, worthlessness, hopelessness, and despair. In severe cases, depression may lead to suicidal thoughts and attempts. The diagnostic criteria for major depression are listed in [Box 9.1](#). The Patient Health Questionnaire (PHQ-9) ([Table 9.1](#)) is a useful screening tool for

Box 9.1 Diagnostic Criteria for Major Depressive Episode

- Five or more of the following symptoms have been present during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure.
1. Depressed mood most of the day, nearly every day, as indicated by either subjective report (e.g., feels sad or empty) or observation made by others (e.g., appears tearful)
 2. Markedly diminished interest or pleasure in all, or almost all, activities
 3. Significant weight loss (when not dieting) or weight gain, or decrease or increase in appetite
 4. Insomnia or hypersomnia
 5. Psychomotor agitation or retardation observable by others
 6. Fatigue or loss of energy
 7. Feelings of worthlessness or excessive or inappropriate guilt
 8. Diminished ability to think or concentrate, or indecisiveness
 9. Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation, or a suicide attempt or specific suicide plan
- Symptoms cause clinically significant distress or impairment.

Modified from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. (DSM-5). Washington, DC: American Psychiatric Association; 2013:160-161.

major depression, can be filled out quickly by the woman in the waiting room or in the office prior to a visit, and helps in identifying depression, monitoring effects of treatment, and educating the woman about her own characteristic symptoms of depression. Scores of 5, 10, 15, and 20 are cutoff scores indicating mild, moderate, moderately severe, and severe depression, respectively.

The cause of major depression is unclear. It may occur without a clear stress or precipitant, especially in women with a strong family history of depression who are genetically predisposed. A family history of depression, a prior depressive episode, and older age are all risk factors for depression. In addition, environmental stressors such as loss of relationships and loved ones, divorce, role transitions, interpersonal conflicts, medical illness, or feelings of being trapped in a stressful situation without a way to escape or cope can precipitate depression. The cause of depression in a particular person may be uniquely determined by individual factors, such as family relationships while growing up and past experiences that are highly meaningful and evoke negative feelings and memories triggered by current situations or events.

Loss of a parent during childhood is an important factor predisposing to later depression. Although there is conflicting literature—confounded by other consequences of parental loss such as financial problems, the nature of substitute caregiving, and potential family disruption—it appears that both boys and girls are at heightened risk for later depression if they lose their primary caregiver in childhood. That risk is higher if the lost caregiver is of the same gender as the child.

The increased rate of depression in women starting at menarche has also been thought to result from hormonal factors. There are clear increases in risk for depressive symptoms premenstrually, with some women only experiencing mood symptoms

Table 9.1 Patient Health Questionnaire (PHQ-9)

Over the past 2 weeks, how often have you been bothered by any of the following problems?				
	Not at All	Several Days	More than Half the Days	Nearly Every Day
1. Little interest or pleasure in doing things	0	1	2	3
2. Feeling down, depressed, or hopeless	0	1	2	3
3. Trouble falling or staying asleep, or sleeping too much	0	1	2	3
4. Feeling tired or having little energy	0	1	2	3
5. Poor appetite or overeating	0	1	2	3
6. Feeling bad about yourself—or that you are a failure or have let yourself or your family down	0	1	2	3
7. Trouble concentrating on things, such as reading the newspaper or watching television	0	1	2	3
8. Moving or speaking so slowly that other people could have noticed, or the opposite—being so fidgety or restless that you have been moving around a lot more than usual	0	1	2	3
9. Thoughts that you would be better off dead or of hurting yourself in some way	0	1	2	3
Total Score	_____	+ _____	+ _____	+ _____
If you checked off any problems, how difficult have these problems made it for you to do your work, take care of things at home, or get along with other people?				
____ Not difficult at all ____ Somewhat difficult ____ Very difficult ____ Extremely difficult

at this time and others noting a worsening of underlying depression in the week or two prior to menses (for a discussion of premenstrual dysphoric disorder, see [Chapter 37](#)). The postpartum period is a high-risk time for depression and is the highest risk time in a woman's life for psychiatric hospitalization. There is also an increase in depressive symptoms at the time of menopause and the menopausal transition.

The differential diagnosis of major depression includes adjustment disorder, persistent depressive disorder (dysthymia), depression related to drugs and alcohol or secondary to a medical condition, and bipolar disorder. Adjustment disorder is a stress-related, short-term emotional or behavioral response to a stressful life circumstance. Depressive symptoms begin within 3 months of the onset of the stressor and resolve within 6 months once the stressful circumstance ends. The symptoms do not meet criteria for major depression. The physician can help a woman with an adjustment disorder by helping her to problem solve and cope with the situation she is in or by referring her for short-term therapy or counseling.

Persistent depressive disorder (previously called *dysthymic disorder*) is a chronic, low-grade depression, with symptoms present more than half the time for at least 2 years and no more than 2 months without depressive symptoms during that time. The best treatment is antidepressant medication and psychotherapy, but this condition is often harder to treat than major depression because of its chronicity. Symptoms of major depression can also be caused by alcohol or drug use, or by medical conditions, such as hypothyroidism, vitamin B₁₂ deficiency, anemia, or cancer (most classically pancreatic cancer). Women presenting with depression should be screened for medical disorders and asked about use of alcohol and drugs.

Probably the greatest dilemma in deciding to prescribe antidepressants is the concern that if the woman has bipolar disorder, antidepressants can cause a "switch" into a manic episode. Manic episodes are characterized by feelings of euphoria or irritability and increased energy or goal-directed activity, with symptoms such as decreased need for sleep, increased activity or agitation,

talkativeness, racing thoughts, grandiose and unrealistic plans, and impulsive and risky behavior. If a woman has been hospitalized for mania or has had such symptoms for a week or more in the past, the diagnosis may be clear. However, people often do not recall their manic symptoms or have little insight into them, or they may have had briefer periods of a few days (hypomania) that still predispose them to mania with antidepressants. It is often difficult to make the diagnosis of bipolar disorder, especially just from the woman's report. Any suspicion of this condition is an indication for psychiatric consultation, because bipolar depression requires treatment with a mood stabilizer instead of, or combined with, an antidepressant.

Treatment of major depression can include antidepressant medication, psychotherapy, or both. Because both antidepressant medication and psychotherapy are effective, the initial choice of treatment can be made according to the woman's preference, although for more severe depression medication is indicated. Commonly prescribed antidepressant medications and dosages are listed in [Table 9.2](#). A 2009 meta-analysis by Cipriani and associates suggested that the best combination of efficacy and tolerability is for sertraline or escitalopram ([Cipriani, 2009](#)). Because of their more benign side effect profiles, it is reasonable to start a selective serotonin reuptake inhibitor (SSRI) as the first antidepressant in most cases. SSRI side effects include gastrointestinal symptoms (nausea, diarrhea, vomiting), which are minimized by taking the medication with a meal. Other common side effects include initial dizziness and headaches, as well as sexual dysfunction, most commonly delayed orgasm or anorgasmia. Doses of the SSRI citalopram exceeding 40 mg daily (>20 mg/day age 60 or higher) are not recommended due to the risk of QT prolongation. SSRIs may also cause uncomfortable withdrawal symptoms if discontinued suddenly. Withdrawal symptoms can include gastrointestinal symptoms, headache, dizziness, and "electric shock" sensations. Fluoxetine, an SSRI with a long half-life, is not generally associated with withdrawal symptoms and women discontinuing other SSRIs can be switched to fluoxetine to minimize withdrawal. Fluoxetine also has the strongest

Table 9.2 Commonly Prescribed Antidepressants

Antidepressant	Dose Range (mg/day)	Comments
Serotonin Reuptake Inhibitors (SSRIs)		
Citalopram	20-40	FDA warning of QT prolongation at doses >40 mg/day (>20 mg /day age 60 or higher) S-enantiomer of citalopram Long half-life; unlikely to cause withdrawal symptoms with discontinuation or missed doses; best evidence base for use in children and adolescents High rate of withdrawal symptoms
Escitalopram	10-20	
Fluoxetine	20-80	
Paroxetine	20-50 (25-62.5 controlled release)	
Sertraline	50-200	
Serotonin and Norepinephrine Reuptake Inhibitors (SNRIs)		
Duloxetine	60-120	May also be effective for neuropathic pain, urinary incontinence Risk of elevated blood pressure
Venlafaxine	75-375	
Other		
Bupropion	300-450	Elevated risk of seizures, especially at doses above 450 mg/day; contraindicated in patients with bulimia; may be effective for comorbid attention deficit disorder; activating; does not cause sexual dysfunction or weight gain; effective for smoking cessation Sedating; causes weight gain Sedating; used as adjunctive treatment for insomnia
Mirtazapine	15-45	
Trazodone	25-100 (for insomnia)	

evidence base for treatment of major depression in children and adolescents.

Serotonin and norepinephrine reuptake inhibitors (SNRIs) include venlafaxine and duloxetine. Venlafaxine is associated with a dose-related risk for gradual onset of hypertension, and blood pressure should be monitored carefully on this medication. SNRI side effects include gastrointestinal side effects, headaches, dizziness, anorgasmia, activation, and anxiety. Bupropion appears to exert its therapeutic effect by enhancing effects of dopamine and norepinephrine. It increases energy and can cause insomnia, increased anxiety, headaches, and gastrointestinal side effects. Bupropion also lowers the seizure threshold, especially at doses above 450 mg daily, and should not be used in women with a history of a seizure disorder or bulimia. Mirtazapine is an α_2 -adrenergic, 5-HT₂, and 5-HT₃ receptor antagonist, which also has antihistaminic effects. Its common side effects include sedation and weight gain. Trazodone is a highly sedating serotonergic antidepressant that is used primarily at low doses (25 to 100 mg at bedtime) for insomnia. Tricyclic and monoamine oxidase (MAO) inhibitor antidepressants are infrequently prescribed currently because of side effects, in addition to dietary restrictions and the risk of hypertensive crisis with MAO inhibitors. It is important to warn women that antidepressant medication can take up to 4 to 6 weeks to work, and to schedule a follow-up visit within that time to monitor treatment adherence, side effects, and therapeutic response. The Food and Drug Administration (FDA) has required black box warnings regarding increases in suicidal ideation with antidepressants, especially in adolescents and young adults. The mechanism for this is unclear but may be in part an increase in energy and motivation before improvement in mood. Women should be warned of this potential phenomenon and instructed to stop the medication and call the provider if this occurs. Overall, antidepressants reduce depression and risk for suicide, but this potentially serious side effect is another indication for close follow-up early in treatment.

Effective psychotherapies for depression include cognitive behavioral therapy (CBT) and interpersonal therapy (IPT). Cognitive behavioral therapy addresses the negative, distorted thinking that is characteristic of depression, such as the belief that things are bad now, have always been bad, and will always be bad, or thoughts of worthlessness and guilt. In addition, behavioral activation, or scheduling activities that provide a sense of accomplishment, mastery, or pleasure, is helpful in depression, and exercise has been shown to decrease depressive symptoms. Interpersonal therapy addresses the life changes and interpersonal challenges that contribute to depression, especially in women. These include grief, conflicts in interpersonal relationships including marital or intimate partner conflicts, transitions in roles within work or the family, and social isolation with a lack of supportive relationships. These therapies are usually weekly for an hour for 3 to 4 months. In cases of clear-cut couple's issues, couples therapy may be indicated, especially after the woman has recovered from depression sufficiently to participate in such therapy. Other nonmedication treatments for depression include morning light for seasonal or winter depression, and electroconvulsive treatment (ECT) or repetitive transcranial magnetic stimulation (rTMS) for depression that does not respond to medication and psychotherapy.

Both medication and psychotherapy are significantly more effective than placebo for treatment of major depression, with response rates varying between about 50% and 70%, depending on the patient population. Combined treatment with both psychotherapy and medication is more effective and is indicated for more severe depression.

The goal of treatment for depression is complete remission, or resolution of all depressive symptoms, as even mild residual symptoms increase the risk of relapse. There are several measures that can increase rates of remission (Cameron, 2014). First, close follow-up, with visits every 1 to 2 weeks at first and then every 2 to 4 weeks, will enhance adherence and response rates. One third of people prescribed an antidepressant discontinue the medication within 30 days. There is considerable stigma associated with taking psychotropic medication or having a psychiatric diagnosis, so addressing the woman's concerns that depression is a weakness or a character flaw can be helpful. Frequent visits also allow early identification of side effects that decrease adherence. Patient education about the lag in response to antidepressants and the need to take the medication every day for at least 6 to 12 months is important. Tracking symptoms with a scale such as the PHQ-9 is helpful in monitoring progress and identifying residual symptoms. If there is little response in 2 to 4 weeks, a dose increase should be considered, and only partial response at 8 weeks should prompt reassessment of the diagnosis, ensuring that the patient is taking the maximal tolerated dose of the antidepressant, and consideration of switching medications, adding an augmentation agent such as lithium, an atypical antipsychotic, or triiodothyronine (T₃), or referral to a psychiatrist. Women who have had three or more episodes of major depression should be continued on maintenance antidepressant treatment.

Suicide is a feared and tragic outcome of depression and other mental health conditions. In the United States, there were 41,149 suicide deaths in 2013, 5.5 per 100,000 women and 20.2 per 100,000 men committed suicide, and suicide was the 10th leading cause of death. Rates of suicide are highest among people aged 45 to 64 years compared with other age groups and in whites, Native Americans, and Native Alaskans compared with other ethnic groups. There are 12 to 25 suicide attempts per every suicide death. Risk factors for suicide include depression or other mental health disorders, substance use disorders, a prior suicide attempt, a family history of psychiatric or substance use disorders, family violence including physical or sexual abuse, access to means such as firearms in the house, and exposure to suicidal behavior by others such as family members, peers, or celebrities. All depressed women should be asked about suicidal thoughts. This can include asking about whether the woman feels hopeless, has had thoughts that life is not worth living, or thoughts of ending her life, followed by more specific questions about whether she has made specific plans and how far she has gone to carry these out. Active suicidal thoughts and plans are a psychiatric emergency. The woman should not be left alone. The physician or staff should call 9-1-1 to have her taken to the nearest emergency room. Even in less acute cases, it is important to engage family members and other supportive people as possible, to remove firearms and other means of suicide from the home, to have someone else supervise the woman's medication, and to seek psychiatric or other mental health consultation as soon as possible.

EATING DISORDERS

Anorexia nervosa, bulimia nervosa, and binge eating disorder are the major eating disorders and have a lifetime prevalence of 0.6%, 1%, and 3%, respectively (for a review of eating disorders, see [Treasure, 2010](#)). Eating disorders primarily affect younger people and have their peak onset between the ages of 10 and 19. In a report from the [Centers for Disease Control and Prevention \(2011\)](#), 61% of female high school students reported they were trying to lose weight. In the preceding 30 days, 11% had not eaten in 24 hours or more, 5% took diet pills, powders or supplements, and 4% took laxatives or induced vomiting to avoid weight gain. These disorders are more common in women than in men. Many young women with eating disorders are secretive about their disorder, do not view it as a problem, and do not seek treatment for it. Gynecologists

Box 9.2 SCOFF Screening Questionnaire for Eating Disorders

1. Do you make yourself sick because you _____ Yes _____ No
feel uncomfortably full?
2. Do you worry you have lost control _____ Yes _____ No
over how much you eat?
3. Have you recently lost more than one _____ Yes _____ No
stone (14 pounds) in a 3-month period?
4. Do you believe yourself to be fat when _____ Yes _____ No
others say you are too thin?
5. Would you say that food dominates _____ Yes _____ No
your life?

Two or more “yes” answers indicate that the patient may have an eating disorder.

Modified from Morgan JF, Reid F, Lacey JH. The SCOFF questionnaire: assessment of a new screening tool for eating disorders. *BMJ*. 1999;319:1467-1468.

may see such girls or women for related problems, such as amenorrhea, menstrual dysfunction, low bone density, sexual dysfunction, infertility, anxiety, depression, hyperemesis gravidarum, or other pregnancy complications. Because the woman may not volunteer information about disordered eating, it is important to have a high index of suspicion for eating disorders. A simple, five-question self-rating scale, the “SCOFF” ([Box 9.2](#)), is highly sensitive and specific in detecting eating disorders in primary care settings, and thus is a useful screening tool. The *Diagnostic and Statistical Manual, Fifth Edition (DSM-5)*, diagnostic criteria for anorexia nervosa, bulimia nervosa, and binge eating disorder are listed in [Box 9.3](#). Of note, the DSM-5 diagnosis of anorexia nervosa is also specified by current severity, with a body mass index (BMI) of 17 kg/m² being mild, 16 to 16.99 kg/m² moderate, 15 to 15.99 kg/m² severe, and less than 15 kg/m² extreme.

Anorexia nervosa is characterized by a disturbed body image; fears of becoming fat or gaining weight, even though the woman's body weight is less than expected; and amenorrhea. Weight loss is achieved by restricting food intake, over-exercising, self-induced vomiting, or use of laxatives, emetics, and diuretics. Anorexia is most common in white teenage girls in industrialized Western societies. Societal pressures and standards of attractiveness for women, which emphasize thinness, have long been considered to increase the risk for anorexia nervosa, and a preoccupation with dieting is common in girls at menarche. Increasing evidence indicates, however, that there is clearly a significant genetic contribution to anorexia nervosa and other eating disorders, with heritability estimates of 50% to 80%. Other risk factors include a history of childhood sexual abuse and psychological traits of low self-esteem, perfectionism, and obsessive thinking.

Medical signs and symptoms associated with anorexia nervosa include bradycardia, hypotension, hypothermia, leukopenia, hair loss, skin changes, and constipation. Vomiting

Box 9.3 Diagnostic Criteria for Eating Disorders

Anorexia Nervosa

- A. Restriction of energy intake relative to requirements, leading to a significantly low body weight in the context of age, sex, developmental trajectory, and physical health. *Significantly low weight* is defined as a weight that is less than minimally normal or, for children and adolescents, less than that minimally expected.
- B. Intense fear of gaining weight or becoming fat, or persistent behavior that interferes with weight gain, even though at a significantly low weight.
- C. Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or persistent lack of recognition of the seriousness of the current low body weight.

Coding note: The ICD-9-CM code for anorexia nervosa is **307.1**, which is assigned regardless of the subtype. The ICD-10-CM code depends on the subtype (see below).

Specify whether:

(F50.01) Restricting type: During the last 3 months, the individual has not engaged in recurrent episodes of binge eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas). This subtype describes presentations in which weight loss is accomplished primarily through dieting, fasting, and/or excessive exercise.

(F50.02) Binge-eating/purging type: During the last 3 months, the individual has engaged in recurrent episodes of binge

eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas).

Specify if:

In partial remission: After full criteria for anorexia nervosa were previously met, Criterion A (low body weight) has not been met for a sustained period, but either Criterion B (intense fear of gaining weight or becoming fat or behavior that interferes with weight gain) or Criterion C (disturbances in self-perception of weight and shape) is still met.

In full remission: After full criteria for anorexia nervosa were previously met, none of the criteria have been met for a sustained period of time.

Specify current severity:

The minimum level of severity is based, for adults, on current body mass index (BMI) (see below) or, for children and adolescents, on BMI percentile. The ranges below are derived from World Health Organization categories for thinness in adults; for children and adolescents, corresponding BMI percentiles should be used. The level of severity may be increased to reflect clinical symptoms, the degree of functional disability, and the need for supervision.

Mild: BMI ≥ 17 kg/m²

Moderate: BMI 16-16.99 kg/m²

Severe: BMI 15-15.99 kg/m²

Extreme: BMI < 15 kg/m²

Continued

Box 9.3 Diagnostic Criteria for Eating Disorders-cont'd**Bulimia Nervosa**

A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:

1. Eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than most individuals would eat in a similar period of time under similar circumstances.
2. A sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating).

B. Recurrent, inappropriate compensatory behaviors in order to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, or other medications; fasting; or excessive exercise.

C. The binge eating and inappropriate compensatory behaviors both occur, on average, at least once a week for 3 months.

D. Self-evaluation is unduly influenced by body shape and weight.

E. The disturbance does not occur exclusively during episodes of anorexia nervosa.

Specify if:

In partial remission: After full criteria for bulimia nervosa were previously met, some, but not all, of the criteria have been met for a sustained period of time.

In full remission: After full criteria for bulimia nervosa were previously met, none of the criteria have been met for a sustained period of time.

Specify current severity:

The minimum level of severity is based on the frequency of inappropriate compensatory behaviors (see below). The level of severity may be increased to reflect other symptoms and the degree of functional disability.

Mild: An average of 1-3 episodes of inappropriate compensatory behaviors per week.

Moderate: An average of 4-7 episodes of inappropriate compensatory behaviors per week.

Severe: An average of 8-13 episodes of inappropriate compensatory behaviors per week.

Extreme: An average of 14 or more episodes of inappropriate compensatory behaviors per week.

Binge-Eating Disorder

A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:

1. Eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than what

most people would eat in a similar period of time under similar circumstances.

2. A sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating).

B. The binge-eating episodes are associated with three (or more) of the following:

1. Eating much more rapidly than normal.
2. Eating until feeling uncomfortably full.
3. Eating large amounts of food when not feeling physically hungry.
4. Eating alone because of feeling embarrassed by how much one is eating.
5. Feeling disgusted with oneself, depressed, or very guilty afterward.

C. Marked distress regarding binge eating is present.

D. Binge eating occurs, on average, at least once a week for 3 months.

E. The binge eating is not associated with the recurrent use of inappropriate compensatory behavior as in bulimia nervosa and does not occur exclusively during the course of bulimia nervosa or anorexia nervosa.

Specify if:

In partial remission: After full criteria for binge-eating disorder were previously met, binge eating occurs at an average frequency of less than one episode per week for a sustained period of time.

In full remission: After full criteria for binge-eating disorder were previously met, none of the criteria have been met for a sustained period of time.

Specify current severity:

The minimum level of severity is based on the frequency of episodes of binge eating (see below). The level of severity may be increased to reflect other symptoms and the degree of functional disability.

Mild: 1-3 binge-eating episodes per week.

Moderate: 4-7 binge-eating episodes per week.

Severe: 8-13 binge-eating episodes per week.

Extreme: 14 or more binge-eating episodes per week.

From American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed, DSM-5. Washington, DC: American Psychiatric Association; 2013, pp 338-339, 345, 350.

or laxative use may cause hypokalemia. Endocrine changes include low estrogen and testosterone levels, amenorrhea, decreased libido, hypercortisolemia, and low bone density. Prolonged QT interval is a serious sequela of anorexia nervosa and has been associated with sudden death. The mortality rate of anorexia nervosa from all causes is 5% to 6% per decade of illness.

Psychiatric symptoms associated with anorexia nervosa include depression, anxiety, social difficulties, sleep disturbance, agitation, poor emotion regulation, rigidity, obsessional thinking, and compulsive behaviors. Interestingly, these symptoms occur in individuals without anorexia nervosa during starvation and resolve with weight gain and so are most likely caused, or at least exacerbated, by the illness.

Anorexia nervosa is difficult to treat. Women do not usually seek help themselves but instead are brought to treatment

by concerned family members. They fear gaining weight, do not see their illness as a problem, are frequently nonadherent to treatment, feel isolated and do not engage with treatment providers, and may have multiple relapses. About one third recover completely, but this may take a number of years. Early recognition and treatment improve outcome. Family members often become frustrated with the woman's multiple relapses, lack of insight, and apparent lack of cooperation with treatment and may need support themselves in dealing with her illness.

The best treatment for anorexia nervosa involves referral to a multidisciplinary team, with medical, nutritional, psychological, and psychiatric expertise in this area. The focus is on gradual refeeding to achieve weight gain, and outpatient treatment, with hospitalization only for acute, dangerous medical or psychiatric complications. In adolescents, family therapy or,

in nonintact families, adolescent-centered individual psychotherapy is most effective (Lock, 2010). There is little evidence supporting any specific type of psychotherapy in adults, but treatment by a therapist with expertise in anorexia nervosa is more effective than support from a nonspecialist. From one randomized controlled trial (RCT), focal psychodynamic therapy seemed to help recovery at 1 year and enhanced cognitive behavioral therapy was more effective with speed of weight gain and improvement in eating disorder thinking (Zipfel, 2014). There is no clear evidence supporting treatment with psychotropic medications. An early study showing efficacy of fluoxetine to maintain weight gain has not been replicated. Preliminary trials of atypical antipsychotics, with the goal of addressing distorted thinking about weight and body shape, have shown initial promise.

Bulimia nervosa is characterized by binge eating, combined with inappropriate compensatory mechanisms to avoid weight gain, such as self-induced vomiting, misuse of laxatives or diuretics, or fasting or excessive exercise. Binge eating and compensatory behaviors occur an average of once a week for 3 months (see Box 9.3 for full diagnostic criteria). Bulimia, like anorexia, is most common in young women, has a significant genetic component, may follow teasing or criticism about the woman's weight or shape, and is thought to involve disturbances in hunger-satiety pathways, the drive system and rewarding characteristics of food, or self-regulation. Comorbidity with mood and anxiety disorders, addictions, and suicidal thoughts and behaviors is common. All-cause mortality rates, including suicide rates, are elevated, with a mortality rate of 3.9% over 8 to 25 years of follow-up.

Women with bulimia nervosa and purging may develop hypokalemia, hyponatremia, hypochloremia, a metabolic alkalosis as a result of vomiting, or a metabolic acidosis with laxative abuse. Recurrent self-induced vomiting can result in loss of dental enamel, parotid gland enlargement, or calluses and scars on the dorsal aspect of the hand. Rare but serious complications include esophageal tears, gastric rupture, rectal prolapse, and cardiac arrhythmias.

There is strong evidence for the efficacy of cognitive behavioral therapy for bulimia nervosa, although complete remission of bingeing and purging occurs in only 30% to 40%. Other therapies that have some evidence for efficacy are interpersonal therapy, dialectical behavior therapy focusing on emotion regulation, and family therapy in adolescents. Antidepressants are superior to placebo in treatment of bulimia, with the agent of choice being fluoxetine 60 mg daily. Of note, the antidepressant bupropion is contraindicated in women with a history of bulimia because of an elevated risk of seizures, presumably because of electrolyte abnormalities. The outcome of bulimia is full recovery in 45%, significant improvement in 27%, and a chronic, protracted course in about 23%.

In binge eating disorder, the woman binge eats (as in bulimia nervosa) an average of once a week for at least 3 months, but she does not engage in compensatory behaviors such as purging, fasting, or excessive exercise. As a result, she may also develop obesity but does not develop the medical complications associated with purging or low weight. Treatment for binge eating disorder includes nutritional consultation, diet, physical activity, education, and specific psychotherapies. There is strong evidence

for the efficacy of cognitive-behavioral therapy in binge eating disorder and other psychotherapies, such as dialectical behavior therapy (DBT) and interpersonal therapy (IPT), are also effective. Medication treatments include antidepressants such as SSRIs. Weight loss agents, topiramate, and stimulants may also be effective.

OBSESITY

The prevalence of obesity has dramatically increased in the United States. The World Health Organization (WHO) definitions for body weight are shown in Table 9.3. Weight classification by body mass index (BMI) is outlined in Table 9.4. Based on this definition, more than 35% of U.S. adults are obese and 69% are overweight or obese. The prevalence of obesity is higher in middle-aged adults, minority women, and low-income women and varies by geographic regions. In particular, African American and Hispanic women are at double the risk of non-Hispanic white women. WHO describes a global epidemic of obesity, which is a major burden to worldwide chronic disease and disability. Of note, women taking psychotropic medications, especially antipsychotics, are at heightened risk for obesity and metabolic syndrome.

There is a strong relationship between mortality and increased BMI above 25 kg/m² (and below 20 kg/m²) (Fig. 9.1). Even in healthy people who have never smoked, at age 50 years, there is still an elevated risk of death for persons whose BMIs are between 25 and 30 (Adams, 2006). The risk of death increased 20% to 40% in the overweight group and by two to three times among obese persons. Severe obesity is a health hazard that carries a 12-fold increase in mortality. Increased central adiposity is associated with increased risk of morbidity and mortality as well as BMI, so waist circumference can easily be measured. Using a tape measure at the level of the iliac crest, the waist circumference is taken. For women with a BMI of 25 to 34.9 kg/m², a waist circumference of over 35 inches is associated with heart disease and diabetes mellitus. Because of these risk factors, many organizations, including the American College of Obstetricians and Gynecologists, recommend screening for obesity.

Often these individuals suffer complicating factors, such as hypertension, diabetes mellitus, dyslipidemias, heart disease, stroke, arthritis, increased operative morbidity and mortality, and compromised pulmonary function (sleep apnea). Obesity has been linked to multiple obstetric and gynecologic problems, including spontaneous abortion, endometrial hyperplasia, and endometrial and breast cancer, to name a few. One meta-analysis of increased BMI and cancer risk found a strong association between a five-point BMI increase and endometrial cancer (relative risk [RR] 1.59, $P < .0001$), gallbladder cancer (RR 1.59, $P = .04$), esophageal adenocarcinoma (RR 1.51, $P < .0001$), and renal cancer (RR 1.34, $P < .0001$). A weaker positive association was found with postmenopausal breast, pancreatic, thyroid and colon cancer plus leukemia, multiple myeloma, and non-Hodgkin lymphoma. The mechanisms of cancer association with obesity may be linked to hormone systems like insulin, insulin-like growth factor, sex steroids, adipokines, and other substances.

Diet, exercise, and behavior modification provided by lay supervision is appropriate for those suffering from mild obesity; diet, exercise, and behavior modification under medical

Evidence Report of Clinical Guidelines on the Identification, Evaluation, and Treatment of Overweight and Obesity in Adults, 1998, http://www.ncbi.nlm.nih.gov/books/NBK2003/pdf/Bookshelf_NBK2003.pdf.

supervision is appropriate for those suffering from moderate obesity; and operative intervention is appropriate for those suffering from severe obesity if conservative measures have failed. Patients suffering from severe obesity almost always have medical complications, and these often improve with weight reduction. Unless behavior is modified, weight loss is usually not maintained. One study of 145 patients who were approximately 60% overweight and divided them into three groups. Treatment continued for 6 months, and there was at least 1 year of follow-up in 99% of those who completed the therapy. Group 1 underwent behavior modification using Ferguson's *Learning to Eat* manual. They lost an average of 11.4 kg and regained only 1.8 kg during the follow-up year. Group 2 received medication therapy with an appetite suppressant, fenfluramine hydrochloride (Pondimin). They lost an average of 14.5 kg but regained 8.6 kg during the follow-up period.

Table 9.4 Weight Classification by Body Mass Index (BMI)

Weight	BMI*
Normal weight	18.5-24.9
Overweight	25.0-29.9
Obesity	>30
Class I	30.0-34.9
Class II	35.0-39.9
Class III	>40

*BMI calculation = weight in kilograms/height in square meters.

The third group was treated with a combination of behavior modification and medication and lost an average of 15 kg but regained 9.5 kg during the follow-up period. The authors concluded that behavior modification without medication was the most appropriate therapy for moderate obesity. Setting goals is important in

Figure 9.1 Relation between mortality and body mass index in men and women who have never smoked. (Data from Calle EE, Thun MJ, Petrelli JM, et al. Body-Mass Index and mortality in a prospective cohort of U.S. adults. *N Eng J Med.* 1999;341:1097-1105.)

behavior therapy, and a 5% to 10% loss of total body weight is realistic over 6 months and can decrease the severity of comorbid diseases. A systematic review of 12 trials, involving 3893 participants supported these findings with intensive behavioral counseling, diet (reducing intake by ≥ 500 kcal/day) and exercise (≥ 150 minutes of walking/week) leading to clinically meaningful weight loss of 0.3 kg to 6.6 kg over 6 months (Wadden, 2014).

Many individuals embrace fad diets and look for magic cures. However, if placed on a nutritionally appropriate limited-caloric diet, they generally do well if their attitudes toward eating and response to various stimuli are modified. Lay groups, such as Weight Watchers or Take Off Pounds Sensibly (TOPS), may be successful for motivated individuals. Tracking calorie intake, utilizing a smart phone app for weight loss, avoiding food binges, avoiding eating at night, and practicing stress reduction or mindfulness-based training could benefit some women. In a meta-analysis of named diet programs, 48 randomized trials were reviewed and reported the largest weight loss was associated with the low-carbohydrate diets and low-fat diets (Johnston, 2014). The differences in weight loss between the programs were minimal. It is more important to find a healthy diet that a person can adhere to long term. One study suggested that if these structured weight loss programs could be provided free of charge to participants, both retention and average weight loss may be far better than when participants pay for these programs. Many diet programs prescribe or sell low-fat foods in an attempt to achieve a diet containing about 20% to 30% fat. Because fat represents 9 Cal/g and protein and carbohydrate represent 4 Cal/g, it is possible by changing eating habits to allow a patient a considerable quantity of food without high numbers of calories. The use of portion-controlled servings has been demonstrated to be effective for weight loss because obese persons tend to underestimate the amount of food they consume. Educating patients to change eating habits in this fashion is the

key not only to losing weight but also to maintaining the weight loss. Weight loss done sensibly takes a long time. Setting a realistic goal of 5% loss of body weight over 6 months is helpful. The major problem with such individuals is maintaining weight loss, and, in fact, most do not maintain the weight loss.

Exercise is a useful addition to diet regimens. Several studies have demonstrated that although similar weight loss can be obtained by both diet alone and diet plus exercise programs, the latter will allow for a greater loss of fat stores while maintaining muscle mass. To maintain this advantage, exercise programs must be maintained. Although exercise alone is not a good method for losing weight, studies indicate exercise is very beneficial for long-term weight management and overall health. One study looked at amount of physical activity and weight gain in women and concluded that physical activity is inversely related to weight gain in women of normal weight, but not in women who are overweight (Lee, 2010). Getting more active might be manageable for some women via their work commute. A United Kingdom study found that people who commuted to work by active (bike or walk) or public transport had significantly lower BMI and percentage body fat than people who used private transportation (Flint, 2014). Presumably, utilizing public transportation required more walking each day.

The FDA has approved medications for weight loss, although there have been many concerns about safety. Generally the medication must be continued for sustained benefit or weight gain recurs. Medications are mainly recommended for BMI >30 kg/m² or BMI >27 kg/m² when comorbid conditions are present. Orlistat inhibits dietary fat absorption and is considered first-line treatment because of its better safety profile than other medications. Most subjects can expect about 3% loss of initial weight. It has side effects of fecal urgency, flatulence, and oily stools. Sibutramine inhibits reuptake of neurotransmitters and affects satiation. Adverse effects include increases in heart rate

Table 9.5 Guide to Selecting Treatment

Treatment	BODY MASS INDEX CATEGORY				
	25-26.9	27-29.9	30-34.9	35-39.9	>40

Pharmacotherapy		With comorbidities	+	+	+
Surgery			With comorbidities	With comorbidities	With comorbidities

From The Practical Guide: Identification, Evaluation, and Treatment of Overweight and Obesity in Adults. National Heart, Lung, and Blood Institute and North American Association for the Study of Obesity. Bethesda, MD: National Institutes of Health; 2000.
The + represents the use of indicated treatment regardless of comorbidities.

and blood pressure, so sibutramine was removed from the market. Lorcaserin is a serotonin 2c receptor agonist, which reduces appetite. It is a more selective serotonin agent so is thought to be less likely to cause cardiac valve problems. Over 1 year, about 50% of patients lost at least 3% of their body mass. Side effects include headache, dizziness, fatigue, nausea, and constipation. More patients (67% to 70%) will lose weight on phentermine plus topiramate-extended release and up to 9% weight loss for the top dose (Yanovski, 2014). Warnings include metabolic acidosis, increased heart rate, anxiety, insomnia, and increased creatinine levels. Both lorcaserin and phentermine-topiramate have warnings about memory, attention, and depression. All these medications have limited long-term safety and efficacy data. Another option is metformin for women with type 2 diabetes. A guide to selecting treatment for obesity is given in Table 9.5.

Eligible candidates for bariatric surgery include those with a BMI >40 kg/m² or a BMI >35 kg/m² if serious comorbid conditions are present, if nonsurgical weight loss measures have failed, if the woman is motivated and well-informed, and there is acceptable surgical risk. One meta-analysis found the majority of postsurgical obesity patients have resolution or improvement in comorbid conditions such as diabetes, hypertension, dyslipidemia, and obstructive sleep apnea (Puzziferri, 2014). In looking at 29 studies and 7971 patients, gastric bypass had better outcomes than gastric banding for long-term weight loss, type 2 diabetic control and remission, hypertension, and hyperlipidemia. Gastric bypass and sleeve gastrectomy reported weight loss exceeding 50% and only 31% in gastric band studies. Surgical options can provide long-term weight loss but are not without complications. Bariatric procedures used (gastric bypass, laparoscopic gastric band, vertical banded gastroplasty, and biliopancreatic diversion and switch) result in a 20% complication rate and 1% mortality. A patient with a BMI of 35 to 39 kg/m² appears to do better with surgery as well as the morbidly obese. In fact, there is even one randomized trial on laparoscopic adjustable gastric banding in adults with a BMI of 30 to 35 kg/m². The surgery was significantly more effective at reducing weight, resolving the metabolic syndrome, and improving quality of life at 2 years after the intervention.

Obesity in adolescence is a variant of the problem in the general population. The percentage of young people who are overweight has more than tripled since 1980. Seventeen percent of young people (2 to 19 years old) are obese, although this did not change between 2003-2004 and 2011-2012. Being overweight in adolescence is a more powerful predictor of morbidity from cardiovascular disease than being overweight in adulthood. Because the risk for progression with increasing morbidity and mortality is

great, prompt support and behavior modification are most important. School and parental involvement are important aspects of controlling the problem. Where an obese parent is also present, best results seem to be achieved when both the parent and the child undergo therapy but in separate counseling sessions. One study of 42 obese adolescents, ages 12 through 16, divided them into three groups and used 16 weeks of treatment. When the child alone attended group therapy, there was an average 3.3-kg weight loss; when the child and mother were treated together, there was an average 5.3-kg weight loss; and when the child and mother were both treated but separately, there was an 8.4-kg weight loss. After 1 year of follow-up, the group in which the mother and child were treated separately maintained their weight loss at a mean of 7.7 kg, whereas the other two groups had regained their previous baseline levels. The Cochrane Collaboration reviewed interventions for treating obesity in children in 2009, and although 64 randomized controlled trials were found, the data quality was limited. However, combined behavior lifestyle modifications with dietary changes, physical activity, or behavioral therapy were favored over standard or self-care for meaningful weight control. In obese adolescents, pharmacologic treatment warranted consideration in addition to the combined lifestyle modifications.

The Centers for Disease Control and Prevention (CDC) mentions the following promising approaches for preventing obesity: (1) breastfeeding, which is associated with a reduced risk of overweight children; (2) regular physical activity; (3) increasing physical activity in overweight people to prevent the complications associated with obesity; and (4) decreasing children's time watching television. Beyond the individual, population-based strategies and policies are being studied.

ANXIETY DISORDERS, OBSESSIVE-COMPULSIVE DISORDER, AND POSTTRAUMATIC STRESS DISORDER

Anxiety disorders are the most common psychiatric disorders in the general population. They usually have their onset in childhood, adolescence, or early adulthood and are more common in women than in men. Anxiety is a normal, adaptive response to danger or threat and is associated with physical symptoms (e.g., increased heart rate, sweating, shaking) and cognitive symptoms (e.g., worry, fear). Increases in anxiety are common with life stressors, including medical appointments, diagnoses, and procedures. In addition, anxiety may result from a number of drugs (e.g., caffeine, cannabis, cocaine, methamphetamine, withdrawal of alcohol or opiates), medications (e.g., theophylline, steroids),

Box 9.4 Specifier for a Panic Attack

Note: Symptoms are presented for the purpose of identifying a panic attack; however, panic attack is not a mental disorder and cannot be coded. Panic attacks can occur in the context of any anxiety disorder as well as other mental disorders (e.g., depressive disorders, posttraumatic stress disorder, substance use disorders) and some medical conditions (e.g., cardiac, respiratory, vestibular, gastrointestinal). When the presence of a panic attack is identified, it should be noted as a specifier (e.g., “posttraumatic stress disorder with panic attacks”). For panic disorder, the presence of panic attack is contained within the criteria for the disorder and panic attack is not used as a specifier.

An abrupt surge of intense fear or discomfort that reaches a peak within minutes, and during which time four (or more) of the following symptoms occur:

Note: The abrupt surge can occur from a calm state or an anxious state.

1. Palpitations, pounding heart, or accelerated heart rate
2. Sweating
3. Trembling or shaking
4. Sensations of shortness of breath or smothering
5. Feeling of choking
6. Chest pain or discomfort
7. Nausea or abdominal distress
8. Feeling dizzy, unsteady, lightheaded, or faint
9. Chills or heat sensations
10. Paresthesias (numbness or tingling sensations)
11. Derealization (feelings of unreality) or depersonalization (being detached from oneself)
12. Fear of losing control or “going crazy”
13. Fear of dying

Note: Culture-specific symptoms (e.g., tinnitus, neck soreness, headache, uncontrollable screaming or crying) may be seen. Such symptoms should not count as one of the four required symptoms.

From American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*, 5th ed, DSM-5. Washington, DC: American Psychiatric Association; 2013, p.214.

or medical conditions (e.g., asthma, arrhythmias, temporal lobe epilepsy). Some people experience primary anxiety disorders, involving excessive anxiety that interferes with daily functioning, without apparent explanation or out of proportion to any stressor. Primary anxiety disorders include panic disorder, generalized anxiety disorder (GAD), social anxiety disorder, and specific phobias. Obsessive-compulsive disorder (OCD) and posttraumatic stress disorder (PTSD), although categorized separately from anxiety disorders in DSM-5, also involve significant anxiety and fear.

Panic disorder is characterized by sudden, intense attacks of fear (Katon, 2006). The symptom criteria for a panic attack are shown in Box 9.4. People with panic disorder have recurrent, unexpected panic attacks, with at least one of the attacks followed by a month or more of persistent concern about having additional attacks or worry about their consequences (e.g., losing control, having a heart attack, going crazy) or a maladaptive change in behavior because of panic attacks (e.g., avoiding certain situations for fear of having an attack). About one third of people in the general population have at least one panic attack during their lives, so that a woman presenting with a single panic attack can be reassured that this is very common. Panic attacks can be precipitated by frightening situations or heightened stress, in which case they are called *situational panic attacks*. People with only situational

panic attacks are not diagnosed with panic disorder. Panic attacks without apparent precipitant are called *spontaneous*.

Panic disorder occurs in 1% to 2% of the population and is about twice as common in women than in men. Risk factors include a family history of panic disorder and significant life stress in the year before the development of symptoms. The disorder has a genetic component, with a heritability of about 30%. Complications include depression in about two thirds of people, and one third are depressed at the time of clinical presentation. Especially as panic attacks are unpredictable, they frequently lead to anticipatory anxiety (anxiety about having the next panic attack) and phobic avoidance, or avoidance of situations in which the person has had or would fear having a panic attack. These situations commonly include crowds, being in lines or in the middle of an audience, driving (especially in tunnels, over bridges, or in freeways), or other situations in which the woman would feel trapped, unable to get out, or publicly embarrassed. With time, the fear and avoidance surrounding panic attacks often become significantly more distressing and disabling than the attacks themselves and may lead to agoraphobia, or avoidance of multiple situations and activities. Panic disorder, like other anxiety disorders, is also associated with an increased rate of alcohol abuse as a form of self-medication. Finally, panic and other anxiety disorders are associated with an increased risk for suicide attempts. Thus even though a woman presents with anxiety and does not endorse depression, she should be asked about hopeless or suicidal thoughts.

The treatment of panic disorder includes reassurance, education, general measures, medication, and psychotherapy. Fortunately, treatment response rates are high, so it is possible to be optimistic that the woman has a highly treatable condition. She may fear that she is dying, has a life-threatening or serious medical illness, or that she is “going crazy,” and she can be reassured that, although panic attacks are terrifying, none of these fears is true. Presenting a model of panic attacks as being the body’s natural, healthy “alarm system” that is malfunctioning and being triggered for no reason is often helpful. As general measures, the woman should be counseled to avoid exacerbating factors, such as caffeine, alcohol, stimulants, or other illicit drugs and to examine possible modifiable sources of increased life stress.

Panic disorder responds well to both medication and psychotherapy (Roy-Byrne, 2006). In more severe cases or with significant comorbid phobic avoidance, a combination of both treatments is preferable. However, because both are effective, the approach to treatment can be determined by the woman’s preference. The first-line medication treatment for panic disorder is serotonin reuptake inhibitor antidepressants (SSRIs). There are two important differences in prescribing these medications for panic disorder versus for depression. First, people with panic disorder are frequently very sensitive to medication side effects. Because panic attacks involve feeling out of control of physical sensations and one’s own body, side effects can initially increase anxiety and panic. Thus although ultimately doses need to be similar to antidepressant doses, it is wise to start treatment at a low dose (e.g., a daily dose of 12.5 mg sertraline, 5 mg citalopram), increasing the dose rapidly after a few days if the woman has no side effects. Second, whereas antidepressants take 4 to 6 weeks or less to relieve depression, they can take up to 12 weeks to have their full effect on panic and anxiety, with some effect expected by 6 weeks. It is important to educate the woman about this delayed and gradual onset of action. Many women present in distress and ask about something that will act

more rapidly. In cases of disability resulting from panic attacks (e.g., inability to function, work, or go to school), it is reasonable to prescribe a benzodiazepine along with an SSRI, with the expectation that the SSRI will be the long-term treatment and the benzodiazepine will be tapered after at most 12 weeks. A benzodiazepine such as clonazepam, which has a longer half-life, requires only twice a day dosing, and maintains more constant blood levels, is preferable to shorter-acting agents such as alprazolam. For women with a history of substance use disorders or who need to avoid the potential slowed reflexes, psychomotor impairment, and cognitive slowing associated with benzodiazepines, other alternative adjuncts to reduce anxiety and panic quickly could include hydroxyzine or gabapentin. Buspirone has not been proved effective for panic disorder. In women who do not tolerate SSRIs, most other antidepressants (e.g., venlafaxine, mirtazapine) are also effective for the long-term treatment of panic disorder, with the exception of bupropion, which increases anxiety symptoms.

Psychotherapy is a highly effective treatment for panic disorder. The best established therapy treatment is cognitive behavioral therapy (CBT), which focuses on addressing the catastrophic thoughts associated with panic attacks (e.g., “I’m dying,” “I’m going to crash my car and kill myself and other people”), learning coping and anxiety reduction strategies (e.g., relaxation, paced breathing to combat hyperventilation), and gradual approach to feared situations to decrease disability. CBT for panic disorder is a weekly therapy for about 12 to 16 weeks, has significant improvement rates equal to or better than the 70% response rate with medication, yields long-term benefits after therapy is over, and increases the patient’s sense of mastery and control, which is valuable in a disorder that makes people feel out of control. CBT can also help patients tolerate medication side effects and benzodiazepine withdrawal symptoms.

Overall, of the varied symptoms of panic disorder, panic attacks are the easiest to treat and quickest to resolve with both medication and therapy. Phobic avoidance and anticipatory anxiety usually linger for a longer time, because of the unpredictability of panic attacks. People with panic disorder in most cases have a relapsing and remitting condition that requires long-term medication treatment (at least a year and frequently longer) and may recur in periods of increased stress.

In contrast with the sudden attacks of fear in panic disorder, generalized anxiety disorder (GAD) is characterized by excessive anxiety and worry about a number of life situations (e.g., work, school, family members) occurring more days than not for at least 6 months. The patient experiences her worries as excessive and difficult to control and as causing significant distress or trouble functioning. In addition, she has three or more of the following symptoms associated with her anxiety and worry: restlessness, insomnia, muscle tension, fatigue, trouble concentrating, or irritability. GAD usually begins early in life, is about twice as common in women than in men, has a genetic component, and has a lifetime prevalence of 5%. This is often a chronic disorder, with other lifetime psychiatric diagnoses (depression, other anxiety disorders, substance use disorders) superimposed in up to 90% of people. The restlessness and trouble concentrating associated with GAD and anxiety in general may lead to a misdiagnosis of attention deficit disorder.

The treatment of GAD often depends on the need to treat comorbid psychiatric conditions, which may have actually led the woman to seek medical help. In general, though, GAD responds to general measures such as avoiding caffeine, alcohol, and illicit drugs; medication; and psychotherapy.

Antidepressants are effective for GAD, and the first-line long-term medication treatment is an SSRI. Buspirone 30 to 60 mg daily is effective for GAD and has few side effects. Hydroxyzine and beta-blockers have been shown to be effective, as are benzodiazepines. However, given the chronic, often life-long course of GAD, benzodiazepines are not recommended. Psychotherapy for GAD focuses on addressing and coping with worry (“What if” thoughts).

Social anxiety disorder (or social phobia) refers to anxiety in and avoidance of social situations, where the woman is or feels the center of attention and fears humiliation, embarrassment, or being judged negatively by other people (for diagnostic criteria, see Box 9.5). Symptoms of social anxiety disorder can include full-blown panic attacks, but these are provoked by social situations and are not spontaneous. In many cases, social anxiety disorder is restricted to specific situations, most often public speaking or other public performances. Some women have a more pervasive form of this disorder, in which fears and avoidance relate not just to public performance but to most social situations and interactions, such as meeting new people, parties,

Box 9.5 Diagnostic Criteria for Social Anxiety Disorder (Social Phobia)

- A. Marked fear or anxiety about one or more social situations in which the individual is exposed to possible scrutiny by others. Examples include social interactions (e.g., having a conversation, meeting unfamiliar people), being observed (e.g., eating or drinking), and performing in front of others (e.g., giving a speech).

Note: In children, the anxiety must occur in peer settings and not just during interactions with adults.

- B. The individual fears that he or she will act in a way or show anxiety symptoms that will be negatively evaluated (i.e., will be humiliating or embarrassing; will lead to rejection or offend others).
- C. The social situations almost always provoke fear or anxiety.

Note: In children, the fear or anxiety may be expressed by crying, tantrums, freezing, clinging, shrinking, or failing to speak in social situations.

- D. The social situations are avoided or endured with intense fear or anxiety.
- E. The fear or anxiety is out of proportion to the actual threat posed by the social situation and to the sociocultural context.
- F. The fear, anxiety, or avoidance is persistent, typically lasting for 6 months or more.
- G. The fear, anxiety, or avoidance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- H. The fear, anxiety, or avoidance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.
- I. The fear, anxiety, or avoidance is not better explained by the symptoms of another mental disorder, such as panic disorder, body dysmorphic disorder, or autism spectrum disorder.
- J. If another medical condition (e.g., Parkinson’s disease, obesity, disfigurement from burns or injury) is present, the fear, anxiety, or avoidance is clearly unrelated or is excessive.

Specify if:

Performance only: If the fear is restricted to speaking or performing in public.

From American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed, DSM-5. Washington, DC: American Psychiatric Association; 2013, pp 202-203.

initiating and maintaining conversations, dating, group projects, speaking with authority figures, or asserting oneself.

In epidemiologic studies, the lifetime prevalence of social anxiety disorder ranges from 3% to 13%. Age of onset is usually early in life, and women are more commonly affected than men. In Asian cultures, social anxiety frequently focuses on fears of giving offense to other people—for example, through making inappropriate eye contact, body odor, flatulence, or blushing. There is evidence for a genetic or familial risk for this condition. Women with social anxiety disorder may have associated poor self-esteem, difficulty asserting themselves, depression, or alcohol abuse. Social anxiety disorder exists on a continuum with, and may be difficult to differentiate from, normal shyness, although by definition social anxiety disorder involves marked distress or impairment in functioning.

Treatment of social anxiety disorder also includes medication and psychotherapy (Stein, 2008). Serotonin reuptake inhibitors (SSRIs) are the first-line medication treatment and, as in other anxiety disorders, may take up to 12 weeks to have their full therapeutic effect. MAO inhibitors, though effective, bring with them dietary restrictions and risk of hypertensive crisis. Beta-blockers are helpful for performance anxiety but not for more generalized social anxiety disorder. Benzodiazepines are effective but should be used with caution because of the chronicity of this disorder and the comorbidity with alcohol use disorder. There is some evidence for efficacy of gabapentin. Women with social anxiety restricted to public speaking may benefit from attending Toastmasters and thus practicing public speaking in a safe setting. Cognitive behavioral therapy (CBT) for social anxiety disorder is very effective. CBT includes individual treatment focusing on distorted thoughts about social situations (e.g., thoughts that the patient will make

a fool of herself, has embarrassed herself, and that this will have catastrophic consequences) and on problem solving around and role-playing feared situations. Surprisingly, group cognitive behavioral therapy is also effective for social anxiety disorder.

Specific phobias occur in up to 20% of the general population and include fears of specific animals (e.g., snakes, spiders), phenomena (e.g., lightning), or situations (e.g., heights, flying in airplanes, driving, medical or dental procedures). People usually come to medical attention for specific phobias when these interfere with daily life or with their medical treatment. For example, people may develop specific phobias related to repeated medical events like chemotherapy treatments or to necessary aspects of their daily life, such as driving or traveling by plane. The best treatment for a specific phobia is desensitization, or gradually confronting the feared situation with the aid of an anxiety reducing strategy such as relaxation or imagery. In an acute situation, a benzodiazepine may help the woman to get through the particular event, but this will not reduce her future fear of the same situation.

Obsessive-compulsive disorder (OCD) is characterized by persistent, repetitive thoughts, ideas, or images that the patient finds irrational and intrusive (obsessions), with repetitive behaviors or rituals (compulsions) designed to decrease the anxiety caused by obsessions. Common obsessions include fears of contamination, dirt, germs, and illness; doubts (e.g., about having locked the door, turned off the oven, run over someone in one's car); needing to have things in order; and sexual or religious images or preoccupations. Compulsions include repetitive and excessive washing, cleaning, checking, putting things in order, or asking for reassurance. These obsessions and compulsions are distressing, time-consuming, or interfere with functioning. The full diagnostic criteria are shown in Box 9.6. Although most

Box 9.6 Diagnostic Criteria for Obsessive Compulsive Disorder

A. Presence of obsessions, compulsions, or both:

Obsessions are defined by (1) or (2):

- (1) Recurrent and persistent thoughts, urges, or images that are experienced, at some time during the disturbance, as intrusive and unwanted, and that in most individuals cause marked anxiety or distress.
- (2) The individual attempts to ignore or suppress such thoughts, urges, or images, or to neutralize them with some other thought or action (i.e., by performing a compulsion).

Compulsions are defined by (1) and (2):

- (1) Repetitive behaviors (e.g., hand washing, ordering, checking) or mental acts (e.g., praying, counting, repeating words silently) that the individual feels driven to perform in response to an obsession or according to rules that must be applied rigidly.
- (2) The behaviors or mental acts are aimed at preventing or reducing anxiety or distress, or preventing some dreaded event or situation; however, these behaviors or mental acts are not connected in a realistic way with what they are designed to neutralize or prevent, or are clearly excessive.

Note: Young children may not be able to articulate the aims of these behaviors or mental acts.

- B. The obsessions or compulsions are time-consuming (e.g., take more than 1 hour per day), or cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- C. The obsessive-compulsive symptoms are not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.

D. The disturbance is not better explained by the symptoms of another mental disorder (e.g., excessive worries, as in generalized anxiety disorder; preoccupation with appearance, as in body dysmorphic disorder; difficulty discarding or parting with possessions, as in hoarding disorder; hair pulling, as in trichotillomania [hair-pulling disorder]; skin picking, as in excoriation [skin-picking] disorder; stereotypies, as in stereotypic movement disorder; ritualized eating behavior, as in eating disorders; preoccupation with substances or gambling, as in substance-related and addictive disorders; preoccupation with having an illness, as in illness anxiety disorder; sexual urges or fantasies, as in paraphilic disorders; impulses, as in disruptive, impulse-control, and conduct disorders; guilty ruminations, as in major depressive disorder; thought insertion or delusional preoccupations, as in schizophrenia spectrum and other psychotic disorders; or repetitive patterns of behavior, as in autism spectrum disorder).

Specify if:

With good or fair insight: The individual recognizes that obsessive-compulsive disorder beliefs are definitely or probably not true or that they may or may not be true.

With poor insight: The individual thinks obsessive-compulsive disorder beliefs are probably true.

With absent insight/delusional beliefs: The individual is completely convinced that obsessive-compulsive disorder beliefs are true.

Specify if:

Tic-related: The individual has a current or past history of a tic disorder.

From American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed, DSM-5. Washington, DC: American Psychiatric Association; 2013, p 237.

people with OCD realize that their obsessions and compulsions are irrational, some have poor or absent insight and think that their OCD-related beliefs may be true.

Obsessive-compulsive disorder has a lifetime prevalence of 2% to 3% and is more common in monozygotic than dizygotic twins and in first-degree relatives of affected individuals than in the general population. Rates are similar in men and women. However, males have an earlier peak age of onset than females (6 to 15 years old vs. 20 to 29 years old) and a higher comorbidity with Tourette's syndrome and tic disorders. In people with OCD, the incidence of Tourette's is 5% to 7% and of tics is 20% to 30%. Other conditions commonly associated with OCD, in both genders, include major depression, anxiety disorders, hypochondriacal concerns, and excessive use of alcohol and sedatives.

Treatment of OCD includes both medications and psychotherapy (Grant, 2014). The first-line treatment is serotonergic antidepressants, specifically SSRIs and clomipramine, which is a highly serotonergic tricyclic antidepressant. People with OCD may require higher doses of these medications than do depressed patients and take about 12 weeks for a full response. Response rates tend to be lower than in anxiety disorders and are generally 40% to 60%. It is uncommon for a patient with OCD to have complete resolution of symptoms, and this is usually a chronic, relapsing, and remitting disorder requiring ongoing treatment. The specific psychotherapy treatment most helpful in OCD is exposure and response prevention. This treatment involves gradually increasing exposure to the feared situation, without performing the compulsive ritual (e.g., exposure to dirt without the ability to wash one's hands). Patients who agree to this treatment must tolerate significant anxiety, which, however, subsides with time after each exposure and diminishes over the course of treatment.

Posttraumatic stress disorder (PTSD) refers to a characteristic set of responses to a traumatic situation that involves exposure to actual threatened death, serious injury, or sexual violence, either to oneself or experienced by witnessing the trauma occurring to others, learning that the trauma has happened to a close friend or family member, or working in a setting with repeated or extreme trauma exposure. The characteristic responses include symptoms of reexperiencing the event, avoidance of stimuli associated with the event, negative thoughts and mood associated with the trauma, and increased arousal. The full diagnostic criteria and lists of symptoms are given in Box 9.7. It is common for people to experience symptoms like this in the first month following a major trauma, in which case the diagnosis is acute stress disorder. After a month, when most people would have recovered, persistent symptoms are then diagnosed as PTSD.

PTSD has an estimated lifetime prevalence of 8% in adults in the United States. Rates of PTSD vary from one third to over half of people exposed to specific traumas, such as combat, rape, or captivity. Risk factors for development of PTSD in people exposed to a specific trauma include female sex, younger age, severity and duration of the event, lack of social support, history of prior trauma, or history of preexisting psychiatric disorders. There is also evidence that people with greater autonomic arousal (higher heart rate and blood pressure) following the trauma are at increased risk. Although PTSD would appear to be a quintessentially environmentally determined disorder, the risk of development of PTSD following trauma appears to be heritable. PTSD is associated with depression, panic attacks and

anxiety, substance abuse and dependence, suicidal thoughts and attempts, and, in severe cases, psychotic symptoms such as hallucinations or paranoia.

Several types of individual and group psychotherapy are effective in the treatment of PTSD. These therapies include coping with current life problems and triggers, gradual exposure and reexperiencing of the trauma with desensitization, and examining any distorted thoughts about the trauma, such as guilt that the woman brought this upon herself or could have done more to prevent or stop it. It is important to recognize that many people are retraumatized and their symptoms worsened by retelling the story of the trauma, especially if this is not in the context of a structured, ongoing psychotherapeutic treatment.

Medications are frequently used to address symptoms of PTSD. For example, SSRIs are effective in reducing depression, anxiety, and emotional numbing. Medications such as valproate may help with impulsivity and anger. Hypnotics may be helpful for insomnia. Prazosin, an alpha-adrenergic antagonist, has been shown to be helpful in reducing trauma-related nightmares and more general PTSD symptoms. Benzodiazepines should be used with caution, given the comorbidity with substance use disorders and reports of increased impulsivity in patients with PTSD given these medications. Acute management immediately following a rape is discussed further later in the chapter.

PSYCHOTROPIC MEDICATIONS AND ORAL CONTRACEPTIVES

The gynecologist frequently sees women who are taking psychotropic medications for one of the disorders described earlier or for other less common psychiatric disorders such as bipolar disorder or schizophrenia and may be called upon to advise them about options for birth control. There are several psychotropic medications that alter the metabolism and efficacy of oral contraceptives (OCs) or whose metabolism is in turn altered by OCs (Oesterheld, 2008).

Induction of the hepatic cytochrome P450 3A4 enzyme can increase OC metabolism and cause contraceptive failure. Psychotropic medications that induce 3A4 and that have been associated with spotting, breakthrough bleeding, or unwanted pregnancy include the mood stabilizers carbamazepine (Tegretol) and oxcarbazepine (Trileptal), topiramate (Topamax; at doses above 200 mg daily), and the wakefulness-enhancing agent modafinil (Provigil). St. John's wort, commonly used over the counter as an antidepressant, also induces 3A4 and can cause contraceptive failure. OC activity may be increased or prolonged by 3A4 inhibitors such as the antidepressants fluoxetine (Prozac) and possibly fluvoxamine (Luvox).

Oral contraceptives are themselves moderate 1A2 and 2C19 inhibitors and mild 2B6 and 3A4 inhibitors. Thus OCs can increase levels and effects of amitriptyline (Elavil), bupropion (Wellbutrin), chlordiazepoxide (Librium), chlorpromazine (Thorazine), clozapine (Clozaril), diazepam (Valium), imipramine (Tofranil), and possibly olanzapine (Zyprexa). Drugs whose clearance is increased with OCs and therefore have lower blood levels include nicotine and the mood stabilizers lamotrigine (Lamictal) and valproic acid (Depakote). Lamotrigine levels have been found to be 84% higher in the week off ethinyl

Box 9.7 Diagnostic Criteria for Posttraumatic Stress Disorder (PTSD)

Note: The following criteria apply to adults, adolescents, and children older than 6 years.

- A. Exposure to actual or threatened death, serious injury, or sexual violence in one (or more) of the following ways:
1. Directly experiencing the traumatic event(s)
 2. Witnessing, in person, the event(s) as it occurred to others
 3. Learning that the traumatic event(s) occurred to a close family member or close friend. In cases of actual or threatened death of a family member or friend, the event(s) must have been violent or accidental
 4. Experiencing repeated or extreme exposure to aversive details of the traumatic event(s) (e.g., first responders collecting human remains; police officers repeatedly exposed to details of child abuse).

Note: Criterion A4 does not apply to exposure through electronic media, television, movies, or pictures, unless this exposure is work related.

- B. Presence of one (or more) of the following intrusion symptoms associated with the traumatic event(s), beginning after the traumatic event(s) occurred:

1. Recurrent, involuntary, and intrusive distressing memories of the traumatic event(s).

Note: In children older than 6 years, repetitive play may occur in which themes or aspects of the traumatic event(s) are expressed.

2. Recurrent distressing dreams in which the content and/or effect of the dream are related to the traumatic event(s).

Note: In children, there may be frightening dreams without recognizable content.

3. Dissociative reactions (e.g., flashbacks) in which the individual feels or acts as if the traumatic event(s) were recurring. (Such reactions may occur on a continuum, with the most extreme expression being a complete loss of awareness of present surroundings.)

Note: In children, trauma-specific reenactment may occur in play.

4. Intense or prolonged psychological distress at exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event(s).
 5. Marked physiologic reactions to internal or external cues that symbolize or resemble an aspect of the traumatic event(s).
- C. Persistent avoidance of stimuli associated with the traumatic event(s), beginning after the traumatic event(s) occurred, as evidenced by one or both of the following:
1. Avoidance of or efforts to avoid distressing memories, thoughts, or feelings about or closely associated with the traumatic event(s).
 2. Avoidance of or efforts to avoid external reminders (people, places, conversations, activities, objects, situations) that arouse distressing memories, thoughts, or feelings about or closely associated with the traumatic event(s).
- D. Negative alterations in cognitions and mood associated with the traumatic event(s), beginning or worsening after the

traumatic event(s) occurred, as evidenced by two (or more) of the following:

1. Inability to remember an important aspect of the traumatic event(s) (typically due to dissociative amnesia and not to other factors such as head injury, alcohol, or drugs).
 2. Persistent and exaggerated negative beliefs or expectations about oneself, others, or the world (e.g., "I am bad," "No one can be trusted," "The world is completely dangerous," "My whole nervous system is permanently ruined").
 3. Persistent, distorted cognitions about the cause or consequences of the traumatic event(s) that lead the individual to blame himself/herself or others.
 4. Persistent negative emotional state (e.g., fear, horror, anger, guilt, or shame).
 5. Markedly diminished interest or participation in significant activities.
 6. Feelings of detachment or estrangement from others.
 7. Persistent inability to experience positive emotions (e.g., inability to experience happiness, satisfaction, or loving feelings).
- E. Marked alterations in arousal and reactivity associated with the traumatic event(s), beginning or worsening after the traumatic event(s) occurred, as evidenced by two (or more) of the following:
1. Irritable behavior and angry outbursts (with little or no provocation) typically expressed as verbal or physical aggression toward people or objects.
 2. Reckless or self-destructive behavior.
 3. Hypervigilance.
 4. Exaggerated startle response.
 5. Problems with concentration.
 6. Sleep disturbance (e.g., difficulty falling or staying asleep or restless sleep).
- F. Duration of the disturbance (Criteria B, C, D, and E) is more than 1 month.
- G. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- H. The disturbance is not attributable to the physiological effects of a substance (e.g., medication, alcohol) or another medical condition.

Specify whether:

With dissociative symptoms: The individual's symptoms meet the criteria for post-traumatic stress disorder, and in addition, in response to the stressor, the individual experiences persistent or recurrent symptoms of either of the following:

1. **Depersonalization:** Persistent or recurrent experiences of feeling detached from, and as if one were an outside observer of, one's mental processes or body (e.g., feeling as though one were in a dream; feeling a sense of unreality of self or body or of time moving slowly).
2. **Derealization:** Persistent or recurrent experiences of unreality of surroundings (e.g., the world around the individual is experienced as unreal, dreamlike, distant, or distorted).

Note: To use this subtype, the dissociative symptoms must not be attributable to the physiological effects of a substance (e.g., blackouts, behavior during alcohol intoxication) or another medical condition (e.g., complex partial seizures).

From American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed, DSM-5. Washington, DC: American Psychiatric Association; 2013, pp 271-272.

estradiol. Given the risk of Stevens-Johnson syndrome with fluctuating levels of lamotrigine and the likelihood of worsening mood symptoms with variations in blood levels of mood stabilizers such as lamotrigine and valproic acid, it is best to advise women taking these medications to use a continuous daily OC or another form of birth control.

SUBSTANCE USE DISORDERS

Women have lower rates of alcohol and drug use and substance use disorders than men. However, substance use disorders are common in women and the rates are increasing. In the 2013 National Survey on Drug Use and Health, rates of illicit drug use in individuals

12 years and older were 11.5% in men and 7.3% in women. Among pregnant women ages 15 to 44, the rate was 5.4%, compared with 11.4% in nonpregnant women in the same age group. Rates of past-year alcohol use disorder were 8.7% in men and 4.6% in women. In contrast to a male: female ratio for alcohol use disorders of 5:1 in the 1980s, a 2010 survey by Greenfield and colleagues showed a ratio of about 3:1. Alcohol, tobacco, and other drug uses in women are of particular concern to gynecologists, not only because of the risks to the woman but also because of the risks to her children through teratogenic risks and effects on parenting abilities (Albright, 2009).

Women consistently have been noted to have an accelerated progression of substance use disorders, with a shorter time between first use of a substance to onset of dependence and then first treatment. This phenomenon is known as *telescoping* and is best established for alcohol, cannabis, and opiates. Women generally present for treatment with a more severe form of the disorder and more social, behavioral, and medical complications than men, despite a shorter period of heavy use. They are more likely than men to suffer psychosocial consequences, such as violence and victimization, and to have psychiatric comorbidity, especially depression, anxiety, eating disorders, and posttraumatic stress disorder. About 72% of women, as opposed to 57% of men, have coexisting psychiatric disorders, and in women these other disorders are more likely to have preceded, and to exacerbate, the substance use

disorder. Thus it is important to recognize and treat other mental health problems in women with alcohol and drug abuse and dependence. Heavy drinking in women increases general health risks, as it does in men, but also is associated with amenorrhea, anovulation, luteal phase dysfunction, and early menopause. The DSM-5 criteria for alcohol use disorder are shown in Box 9.8, and DSM-5 includes similar criteria for other substances.

Patients frequently do not report excessive alcohol or drug use or may not recognize their use as excessive. As in primary care and mental health settings, patients seeing gynecologists are far less likely to be recognized as having a substance use disorder based on physician assessment and documentation. There are several screening tests that can help identify these disorders (Box 9.9; Bradley, 1998). The CAGE is a brief and widely used screening test. Although it is generally helpful in detecting heavy drinking, it is less sensitive in women and minorities. The T-ACE is a variation on the CAGE, which replaces the “guilt” about drinking item with a question about tolerance. The T-ACE was developed specifically for use in pregnant women, given the high rate of guilt in women who consume any alcohol during pregnancy, and is recommended by the American College of Obstetrics and Gynecology for screening (ACOG, 2011). Another effective screening test in detecting heavy alcohol use in groups of women of mixed ethnicity is the

Box 9.8 Diagnostic Criteria for Alcohol Use Disorder

A problematic pattern of alcohol use leading to clinically significant impairment or distress, as manifested by at least two of the following, occurring within a 12-month period:

1. Alcohol is often taken in larger amounts or over a longer period than was intended.
2. There is a persistent desire or unsuccessful efforts to cut down or control alcohol use.
3. A great deal of time is spent in activities necessary to obtain alcohol, use alcohol, or recover from its effects.
4. Craving, or a strong desire or urge to use alcohol.
5. Recurrent alcohol use resulting in a failure to fulfill major role obligations at work, school, or home.
6. Continued alcohol use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of alcohol.
7. Important social, occupational, or recreational activities are given up or reduced because of alcohol use.
8. Recurrent alcohol use in situations in which it is physically hazardous.
9. Alcohol use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by alcohol.
10. Tolerance, as defined by either of the following:
 - a) A need for markedly increased amounts of alcohol to achieve intoxication or the desired effect
 - b) A markedly diminished effect with continued use of the same amount of alcohol.
11. Withdrawal, as manifested by either of the following:
 - a) The characteristic withdrawal syndrome for alcohol (refer to Criteria A and B of the criteria set for alcohol withdrawal, pp. 499-500).
 - b) Alcohol (or a closely related substance, such as a benzodiazepine) is taken to relieve or avoid withdrawal symptoms.

Specify if:

In early remission: After full criteria for alcohol use disorder were previously met, none of the criteria for alcohol use disorder have been met for at least 3 months but for less than 12 months (with the exception that Criterion A4, “Craving, or a strong desire or urge to use alcohol,” may be met).

In sustained remission: After full criteria for alcohol use disorder were previously met, none of the criteria for alcohol use disorder have been met at any time during a period of 12 months or longer (with the exception that Criterion A4, “Craving, or a strong desire or urge to use alcohol,” may be met).

Specify if:

In a controlled environment: This additional specifier is used if the individual is in an environment where access to alcohol is restricted.

Code based on current severity: Note for the ICD-10-CM codes: If an alcohol intoxication, alcohol withdrawal, or another alcohol-induced mental disorder is also present, do not use the codes below for alcohol use disorder. Instead, the comorbid alcohol use disorder is indicated in the 4th character of the alcohol-induced disorder code (see the coding note for alcohol intoxication, alcohol withdrawal, or a specific alcohol-induced mental disorder). For example, if there is comorbid alcohol intoxication and alcohol use disorder, only the alcohol use disorder is mild, moderate, or severe: F10.129 for mild alcohol use disorder with alcohol intoxication or F10.229 for a moderate or severe alcohol use disorder with alcohol intoxication.

Specify current severity:

305.00 (F10.10) Mild: Presence of 2-3 symptoms.

303.90 (F10.20) Moderate: Presence of 4-5 symptoms.

303.90 (F10.20) Severe: Presence of 6 or more symptoms.

TWEAK. The AUDIT is a longer, 10-item screening test that has been well validated and includes self-reports of quantity and frequency of drinking. Women who score at or above the cutoff score on any of these screening tests, or who endorse use of an illicit drug or tobacco, should be questioned further about the frequency, amount, and consequences of their use of alcohol and illicit drugs. Although women with severe alcohol use disorders may have abnormalities in laboratory tests such as hepatic enzymes (ALT, AST, GGT) or mean corpuscular volume (MCV), questionnaires provide a significantly more sensitive method of detecting problem drinking.

The gynecologist is frequently a woman's primary care provider and is in an ideal position to help the patient seek help for a substance use disorder. The patient may not realize that her use is problematic or dangerous. It can be useful to educate her about "safe" levels of alcohol use, for example. Consuming more than two drinks per day on average is considered heavy drinking for a woman and has been linked to increases in mortality, cirrhosis, and breast cancer. Women may benefit from education about adverse effects of alcohol, tobacco, and drugs to the fetus and newborn.

Once the patient has been educated, her motivation to engage in behavior change or specific substance abuse treatment can be enhanced using motivational interviewing, an efficient and highly effective brief counseling technique that aims to accomplish behavior change by helping people explore and resolve ambivalence. Advice alone is often not sufficient to bring about behavior change, and patients vary in their stage of "readiness to change" (Box 9.10). The goal of motivational interviewing is to move people through the stages of change listed in this box. Motivational interviewing was developed for substance use disorders but is also highly effective in promoting weight reduction, exercise, safe sex practices, and regular use of contraception.

Motivational interviewing emphasizes reflective listening, rather than advice giving. In the context of a trusting relationship, the physician expresses empathy and understanding of the patient's ambivalence and the obstacles to change, avoids arguments, points out discrepancies between the patient's behavior and her goals, helps problem solve ways to succeed in meeting goals, and supports the patient's own motivation and efforts to change. Training in motivational interviewing is readily available. Motivational

Box 9.9 Substance Use Disorder Screening Tests

Audit

The following questions pertain to your use of alcoholic beverages during the past year. A "drink" refers to a can or bottle of beer, a glass of wine, a wine cooler, or one cocktail or shot of hard liquor.

1. How often do you have a drink containing alcohol? (never, 0 points; monthly or less, 1 point; 2-4 times per month, 2 points; 2-3 times per week, 3 points; 4 or more times a week, 4 points)
2. How many drinks containing alcohol do you have on a typical day when you are drinking? (1-2 drinks, 0 points; 3-4 drinks, 1 point; 5-6 drinks, 2 points; 7-9 drinks, 3 points; 10 or more drinks, 4 points)
3. How often do you have 6 or more drinks on one occasion? (never, 0 points; less than once a month, 1 point; monthly, 2 points; weekly, 3 points; daily or almost daily, 4 points)
4. How often during the past year have you found that you were not able to stop drinking once you had started? (same scoring as question 3)
5. How often during the past year have you failed to do what was normally expected from you because of drinking? (same scoring as question 3)
6. How often during the past year have you needed a first drink in the morning to get yourself going after a heavy drinking session? (same scoring as question 3)
7. How often during the past year have you had a feeling of guilt or remorse after drinking? (same scoring as question 3)
8. How often during the past year have you been unable to remember what happened the night before because you were drinking? (same scoring as question 3)
9. Have you or someone else been injured as a result of your drinking? (no, 0 points; yes, but not in the past year, 2 points; yes, during the past year, 4 points)
10. Has a relative or friend, or a doctor, or other health care worker been concerned about your drinking or suggested you cut down? (same scoring as question 9)

Scoring: Add up points; score 0-40; score of 4 or above indicates possible alcohol abuse or dependence for women.

- CAGE**
- C Have you ever felt you ought to cut down on your drinking?
 - A Have people annoyed you by criticizing your drinking?
 - G Have you felt bad or guilty about your drinking?
 - E Have you ever had a drink in the morning (eye opener) to steady your nerves or get rid of a hangover?
- Scoring: 1 point for each "yes"; any yes response warrants further assessment.

- TWEAK**
- T Tolerance: How many drinks can you hold (6 or more indicates tolerance) or how many drinks does it take before you begin to feel the first effects of the alcohol? (3 or more indicates tolerance)
 - W Worried: Have close friends or relatives worried or complained about your drinking in the past year?
 - E Eye opener: Do you sometimes take a drink in the morning when you first get up?
 - A Amnesia: Has a friend or family member ever told you about things you said or did while you were drinking that you could not remember?
 - K Kut down: Do you sometimes feel the need to cut down on your drinking?

Scoring: 2 points each for Tolerance or Worried; 1 point each for others; total Possible = 7 points; 2 points or more warrants further assessment in women.

- T-ACE**
- T Tolerance: How many drinks does it take to make you feel high? (3 or more indicates tolerance)
 - A Annoyed question from CAGE
 - C Cut down question from CAGE
 - E Eye opener question from CAGE

Scoring: 2 points for tolerance, 1 point each for "yes" on other items; 1 or more points warrants further assessment in women.

Modified from Bradley KA, Boyd-Wickizer J, Powell SH, Burman ML. Alcohol screening questionnaires in women: a critical review. *JAMA*. 1998;280:166-171.

Box 9.10 Stages of Readiness for Change

- Precontemplation—The patient does not believe a problem exists. (“I won’t get pregnant!”)
- Contemplation—The patient recognizes a problem exists and is considering treatment or behavior change. (“Maybe I could get pregnant and there are things I could do to prevent this.”)
- Action—The patient begins treatment or behavior change. (“I’ll take that prescription for birth control pills.”)
- Maintenance—The patient incorporates new behavior into daily life. (“I’m taking the pill every day.”)
- Relapse—The patient returns to the undesired behavior. (“The pill makes me sick. I think I’ll stop.”)

From ACOG Committee Opinion. Motivational interviewing: a tool for behavior change. *Obstet Gynecol.* 2009;113:243-246.

interviewing has been shown to be a highly effective intervention, and practicing this technique adds an average of only 3 minutes to a clinic visit. Resources and videos are listed in the [2009 American College of Obstetricians and Gynecologists \(ACOG\) Committee Opinion](#) regarding motivational interviewing.

Once a patient has expressed interest in cutting down use of drugs or alcohol, she may be able to do this on her own. If not, treatments include Alcoholics Anonymous, Women for Sobriety, Cocaine Anonymous, or Narcotics Anonymous; psychotherapy; or outpatient and inpatient substance abuse treatment centers. The Substance Abuse and Mental Health Services Administration (SAMHSA) provides a convenient list of drug and alcohol treatment programs by state and local area at <http://www.samhsa.gov/find-help>.

Specific substances of abuse are associated with particular gender differences in patterns of use and treatment success. Alcohol use in women is associated with the phenomenon of telescoping, or an accelerated course from onset of use to significant alcohol-related problems. Several biologic factors may contribute to this more rapid course, including the lower percentage of body water in women, lower levels of alcohol dehydrogenase in the gastric mucosa and thus decreased first pass metabolism, and slower rates of alcohol metabolism. Women also appear to have different motives for drinking, with a higher likelihood of drinking in response to stress, negative emotions, and underlying primary coexisting psychiatric disorders. Women are less likely to seek treatment, perhaps related to childcare responsibilities, financial resources, and greater stigma related to women’s use of alcohol. Female patients may benefit from women-only treatment settings or groups addressing women’s issues. Effective pharmacologic treatments for alcohol dependence in both genders include naltrexone, acamprosate, and topiramate ([Jonas, 2014](#); [Guglielmo, 2015](#)). Alcohol use during pregnancy is associated with fetal alcohol syndrome and fetal alcohol effects, and most women avoid alcohol once they know that they are pregnant.

In 2013, 31.1% of men, 20.2% of women, and 15.4% of pregnant women in the United States reported using nicotine in the past month. Although rates are higher in men than in women, women are at increased risk for heart attacks, chronic obstructive pulmonary disease, and lung cancer secondary to nicotine ([Benowitz, 2010](#)). Nicotine also is associated with early menopause and with spontaneous abortion, low birth weight, and preterm birth with in utero exposure. Only 3% of smokers

are able to quit in any given year, and women appear to have more difficulty quitting than men. Women have more success quitting in the follicular versus the luteal phase of their cycle, but they are more likely to relapse because of weight gain associated with smoking cessation and have a high rate of relapse (about 65%) even if they have quit during pregnancy. Specific smoking cessation treatments, such as the nicotine patch, bupropion, and varenicline, show equal efficacy in men and women in short-term treatment trials. Bupropion may be particularly useful in women who have comorbid depression.

Cannabis abuse is more common in men, but it has a more rapid progression in women. Cannabis is associated with impaired memory, attention, and motivation; increases risk for the onset of panic attacks; may increase vulnerability to depression and psychotic disorders; and has been associated with shorter gestation, decreased birth weight, and possible impairments in executive functioning with in utero exposure. Treatments such as cognitive behavioral therapy and therapeutic communities appear equally effective for both genders.

Women may be more vulnerable than men to the reinforcing effects of stimulants, especially during the follicular phase when estrogen levels are high. The diagnosis of attention deficit disorder is increasingly being made in women, with a corresponding increase in therapeutic use of stimulants. Illicit use of stimulants more than doubled in the general population in the decade between 1995 and 2005, and about 5% to 10% of college students are estimated to misuse stimulants. The literature regarding stimulant effects during pregnancy is conflicting, but growth restriction, decreased birth weight, decreased gestational age, and maternal hypertension have been reported.

Use of heroin and other intravenous drugs is less frequent in women than in men, and women are more likely to inject drugs if their partner uses IV drugs and introduces them to injection. In contrast, overuse of prescription narcotics is more common in women than in men. Use of opiates, including methadone, during pregnancy is associated with neonatal abstinence syndrome, respiratory depression, preterm delivery, premature rupture of membranes, fetal growth restriction, and meconium-stained amniotic fluid.

“DIFFICULT” PATIENTS

In a study of more than 500 adult patients seen in a primary care clinic, [Jackson and Kroenke \(1999\)](#) found that physicians described more than 15% of their patients as “difficult.” “Difficult” patients were more likely to have a depressive or anxiety disorder, poor level of functioning, unmet expectations, low levels of satisfaction, and higher use of health care services. It is always possible for a physician to have a personality clash with an individual patient, but “difficult” patients are a subset of patients who evoke negative feelings in many, if not most, physicians. These patients may be angry, argumentative, threatening, mistrustful, demanding, dissatisfied; may misuse habit-forming prescribed medications or appear “drug seeking”; may challenge the physician’s approach and not comply with treatment recommendations; or may be difficult to engage in a productive treatment alliance. In a classic 1978 paper, Groves described “hateful patients” as people who “kindle aversion, fear, despair, or even downright malice

in their doctors.” Feeling frustration, anxiety, or dislike in seeing patients significantly reduces a physician’s satisfaction with providing medical care.

“Difficult” patients have also been described as “heartsink” patients, referring to the feeling that the provider has on seeing the patient’s name on his or her schedule (O’Dowd, 1988). This term emphasizes the physician’s response to the patient, rather than attributing the difficulty of the interaction entirely to the patient. Indeed, there are physician characteristics that have been associated with describing patients as “difficult.” A secondary analysis of the Physicians Worklife Survey divided 1391 family medicine, general internal medicine, and medical subspecialty physicians into quartiles based on the percentage of their patients they estimated as being “generally frustrating to deal with.” Those in the top quartile, reporting the highest percentage of frustrating patients, were more likely to be younger (<40 years), to work more than 55 hours per week, to report higher stress, to practice in a medical subspecialty, and to have a higher number of patients with psychosocial problems or substance abuse (Krebs, 2006). Physicians have also related difficult patient encounters to patient factors but also to their own anxiety, perfectionism, need to be loved by patients, defensiveness, and being “overly nice” (Steinmetz, 2001), and physicians with high scores on psychosocial orientation to care find fewer patients to be “difficult.”

A woman may not comply with treatment because of denial and fear of illness; cultural factors; having a different explanatory model of the symptoms, their cause, and their optimal treatment; or a misunderstanding of the diagnosis, treatment, or the physician’s instructions and expectations. In these cases, education, reassurance where appropriate, use of a skilled interpreter, or gaining a better understanding of the woman’s culture and view of her symptoms and illness may be very helpful. In some cases, a formal cultural consultation may be needed. Although such situations may be challenging, their health care providers do not generally experience these women as being “difficult” or “hateful.”

Groves grouped “hateful patients” into four different categories—“dependent clingers,” “entitled demanders,” “manipulative help-rejecters,” and “self-destructive deniers”—and described their behavior patterns and ways in which the physician can intervene to work with them more effectively. In a more recent paper, Strous and associates (2006) revisited Groves’ original categories and suggested an overall framework for approaching these people based on empathy and an understanding of the physician’s own responses. Empathy refers to understanding another person’s feelings, motives, and point of view. It is not synonymous with sympathy, because empathy does not involve pity. Understanding what a woman is experiencing and where the woman is coming from allows the physician to more calmly take a nonblaming, problem-solving approach. In addition, the physician can use his or her own responses to understand the woman better. For example, a woman who is feeling helpless and angry may, by complaining or demanding, evoke similar responses of helplessness or anger in her health care provider, allowing the provider insight into the woman’s state of mind.

Groves’ first group of “hateful patients,” which he called “dependent clingers,” appears insatiable in their escalating demands for medical care and to represent a “bottomless pit.”

They require constant reassurance and inordinate amounts of time and attention, interfering with the rest of the physician’s personal as well as professional life. These women may frequently and intrusively page, e-mail, call the physician at home or on the physician’s cell phone, feeling unable to cope on their own. The physician cannot possibly fulfill all of the woman’s demands, feels overwhelmed and angry, and tries to withdraw from caring for her. Groves suggested intervening as the woman’s demands escalate and setting firm but reasonable limits (e.g., not giving out personal contact information, limiting visits or calls). The physician can empathically understand that the woman feels overwhelmed and unable to cope, but in order to preserve an effective treatment relationship the physician needs to be clear about what he or she realistically can and cannot do for the woman.

The second group, which Groves called “entitled demanders,” is similarly dependent and needy but displays a sense of entitlement, aggressively makes demands of the physician (e.g., for controlled substances, expensive diagnostic tests), and may make implicit or explicit threats, such as threats of litigation. This often leads the physician to feel angry and resist complying with the demands, even if some are reasonable. Groves has recommended validating the woman’s entitlement to good medical care but focusing on a shared therapeutic goal and the woman’s role in working with the treatment team to accomplish that goal. Empathically recognizing the woman’s fear of loss of control may allow the physician to respectfully point out destructive patterns of behavior and attempt to establish a more collaborative decision-making process.

“Manipulative help-rejecters” seek care but do not improve despite extensive workups and multiple attempts at treatment. Groves has suggested that these patients are afraid of losing the relationship with the physician if they improve. He recommended setting up a schedule of regular appointments that do not depend on having acute symptoms, much as one would do with a patient with chronic somatization and multiple physical symptoms of unclear etiology.

Finally, “self-destructive deniers” persist in self-destructive behavior such as drinking, smoking, risky sexual behavior, and use of drugs, despite obvious and significant medical problems that have resulted from this behavior. Groves conceptualized these people as having a form of chronic suicidal behavior and recommended ruling out depression, if needed with the help of a psychiatric consultation. In general, in cases in which the physician feels angry or overwhelmed and does not wish to treat the woman, consultation with colleagues, consultation with a psychiatrist, and having the woman see a psychiatrist, if she is willing to do so, can be very helpful in better understanding and managing the woman and the physician-patient relationship.

Women with the diagnosis of borderline personality disorder are often challenging for physicians to treat, given their chronic suicidal thoughts, self-harm behavior such as suicide attempts and cutting, intense and rapidly changing emotions, anger, and difficulty regulating and controlling their emotions rather than acting on them. Women with borderline personality disorder may also see one or more members of the treatment team as wonderful and other members of the team as being punitive or bad. This can lead to “splitting” within the treatment team, with team members having quite different views of and responses to

the woman and resulting disagreements within the team about how to best manage the woman's care. It is important in these cases for the members of the team to have a unified approach, focusing on the best care of the woman and avoiding being overly punitive or gratifying. Psychiatric consultation can be very helpful, and there are well-validated, effective psychotherapies for people with this condition (for a review of borderline personality disorder, see [Leichsenring, 2011](#)).

Women who seek and misuse habit-forming prescription medications are another class of "difficult" patients and may evoke feelings of anger, helplessness, and confusion in providers. Such women may be quite skilled in presenting plausible reasons for their needing the medication, or they may present as "entitled demanders" and make actual or veiled threats. It is important to have clear limits regarding the circumstances under which the physician will or will not be willing to continue prescribing the medication and to convey these to the woman empathically and with the woman's best interests in mind. It may be necessary to establish a formal treatment agreement with her, spelling out how the medication will be prescribed, in what amounts, and what will happen in the case of lost prescriptions or early refill requests. In an institutional setting, such as a hospital or clinic with multiple providers, it is important to include this treatment agreement in the medical record and make sure that it is consistent with institutional policies and values. Psychiatric consultation and addressing substance abuse or dependence issues directly may be necessary.

An understanding of attachment styles can be useful in interacting with "difficult patients" as well as less extreme problems in delivering the best possible medical care. Attachment theory was first elaborated by John Bowlby, a British psychiatrist, in the 1950s, and it posits that early interactions with caregivers in the first years of life influence an individual's later interpersonal relationships. These relationships include those with health care providers. When people become ill, often they "regress," become more vulnerable and childlike, and are less able to use more effective coping strategies. The position of being ill, with associated worries about loss of control, loss of health, needing to depend on others, and uncertainty about the future, amplifies any maladaptive patterns of attachment and interpersonal interactions stemming from relationships with early caregivers.

[Thompson and Ciechanowski \(2003\)](#) described the application of attachment theory to primary care settings. Most people have secure attachment styles and assume both that they themselves are deserving of care and that others can be trusted. There are three insecure attachment styles that affect relationships with medical providers and the quality of medical care: dismissing, preoccupied, and fearful attachment styles.

People with a dismissing attachment style have not been able to rely on early caregivers, have had to fend for themselves, and are compulsively self-reliant. They deny their own needs, tend to minimize symptoms or disability, have difficulty seeking and complying with medical care, and avoid seeking help or support. Women with this attachment style are hard to engage in regular care, especially for chronic illnesses, and may have worse health outcomes. Patients with diabetes with a dismissing attachment style have been shown to have significantly lower levels of exercise, foot care, and adherence to oral hypoglycemic medications ([Ciechanowski, 2002a](#)). Such patients may either fall through the cracks in a busy practice or be frustrating for the physician

who tries to engage them in more active treatment. Engaging such women requires respecting their need for autonomy and respect, being flexible about appointment frequency and duration, giving them control over their care where possible, and using tracking systems and appointment reminders to make sure that they are being followed appropriately.

A preoccupied attachment style is characterized by compulsive care seeking. These people have received inconsistent responses to their needs in the past and feel they must exaggerate their symptoms and distress to evoke consistent care and support. In a study of 701 female primary care patients ([Ciechanowski, 2002b](#)), those with a preoccupied attachment style reported more physical symptoms, despite comparable medical morbidity, and had the highest health care costs and utilization. Such women respond best to brief, frequent, regularly scheduled appointments and to a physician who is responsive, but calm, consistent, and unflappable.

The main feature of a fearful attachment style is mistrust of oneself and others, usually based on a history of mistreatment or abuse in the past. The woman seeks help, but she mistrusts and may reject it. She seems anxious, demanding, and highly distressed on the one hand, but she misses appointments and is non-adherent on the other. For example, in the study by Ciechanowski and coworkers (2002b) of 701 female primary care patients mentioned previously, women with a fearful attachment style reported considerable distress and symptoms but had the lowest health care costs and utilization. A major challenge in treating these women is to be patient, accept them as they are, and not withdraw from care. [Thompson and Ciechanowski \(2003\)](#) recommended providing care through a number of different clinic providers or a treatment team if possible, so that the woman can develop a relationship with the clinic rather than needing to trust a single person.

Understanding attachment styles and that women's interactions with the health care system reflect earlier formative relationships can be helpful in maintaining a nonpejorative stance toward the woman and in achieving the best health care outcome possible. In general, seeking an empathic understanding of the woman's point of view can allow the physician not to become caught up in the negative feelings these women can evoke. Understanding the woman's fears and wishes does not mean that the physician needs to or should do what the woman wishes. However, it may help the physician to be able to set reasonable limits and expectations and pursue an approach that is in the woman's ultimate best interests, without feeling cruel, withholding, or intimidated. All physicians find some of their patients to be "difficult." Each physician can also increase his or her ability to manage these situations and reduce personal feelings of frustration, anger, or guilt, through consultation with colleagues, participating in a Balint group to discuss the psychological aspects of patient care, collaborating with other team members in discussing and making a plan for dealing with a patient, or consulting with a mental health specialist for or about the patient.

SEXUAL FUNCTION AND DYSFUNCTION

Sexual satisfaction is one of the more important human experiences, yet it has been estimated that as many as 51% of women experience some sexual dissatisfaction or dysfunction. But self-reported distress about a woman's sex life was much less

common, estimated to be 11% (Mitchell, 2013). Although there is a strong physiologic basis for sexual function, it is impossible to separate sexual response from the many emotional, social, and other contributing factors that may influence a relationship. Cultural or religious beliefs have influence on sexual function and dysfunction. For example, many African and some Asian and Middle Eastern countries practice female circumcision to varying degrees. The more extreme genital cutting or the trauma from the experience can result in reduced sexual activity, pain, and lowered frequency of orgasm.

In 1966, Masters and Johnson published their now famous book *Human Sexual Response*, which was a discussion of observations made on the sexual cycles of 700 subjects. It is on this important work that our early understanding of the female sexual response was based. Masters and Johnson described four phases of the sexual response: excitement, plateau, orgasm, and resolution (Fig. 9.2).

The excitement phase may be initiated by a number of internal or external stimuli. Desire may be activated in the hypothalamus with dopaminergic activity. As shown in Box 9.11, physiologically this phase is associated with deep breathing, an increase in heart rate and blood pressure, a total body feeling of warmth associated often with erotic feelings, and an increase in sexual tension. There is generalized vasocongestion, which leads to breast engorgement and the development of a

Figure 9.2 Sexual response cycle defined by Masters and Johnson. (From Masters WH, Johnson VE. *Human Sexual Response*. Boston: Little, Brown; 1966.)

Box 9.11 Characteristics of the Excitement Phase of the Sexual Response Cycle in the Female

- Deep breathing
- Increased pulse
- Increased blood pressure
- Warmth and erotic feelings
- Increased tension
- Generalized vasocongestion
- Skin flush
- Breast engorgement
- Nipple erection
- Engorgement of labia and clitoris
- Vaginal transudation
- Uterine tenting

maculopapular erythematous rash on the breasts, the chest, and the epigastrium, which is called the sex flush. There is also engorgement of the labia majora (seen particularly in multiparous women) and of the labia minora. The clitoris generally swells and becomes erect because of increased genital blood flow and the neurotransmitter nitric oxide, causing it to be tightly applied to the clitoral hood. The dilation of the sinusoidal vascular spaces of the corporal tissue of the clitoris, vestibular bulbs, and spongiosal tissue lead to that engorgement. The vagina “sweats” a transudative lubricant, and the Bartholin glands may secrete small amounts of liquid. With the increasing deep breathing, the uterus may tent up into the pelvis, perhaps as a result of the Valsalva maneuver. There is also a myotonic effect, which is most notable in nipple erection. Much of the response in the excitement phase is caused by stimulation of the parasympathetic fibers of the autonomic nervous system. Dynamic genital magnetic resonance imaging (MRI) studies enable the visualization of the physiologic arousal response that provides the direct observation of the time course and magnitude of this response, along with the variability that appears to occur in women with sexual arousal disorder. In some cases, anticholinergic drugs may interfere with a full response in this stage. A diabetic woman with peripheral neuropathy may complain of poor arousal because of lack of sensation.

Next is the plateau stage, which is the culmination of the excitement phase and is associated with a marked degree of vasocongestion throughout the body. Breasts and their areolae are markedly engorged, as are the labia and the lower third of the vagina. The vasocongestion in the lower third of the vagina is such that it forms what has been called the *orgasmic platform*, causing a decrease in the diameter of the vagina by as much as 50% and thus allowing for greater friction against the penis. At this stage, the clitoris retracts tightly against the pubic symphysis, and the vagina lengthens, with dilation of the upper two thirds. Uteri in the normal antelex position tend to tent up more. Retroverted uteri do not.

The next stage is orgasm, in which the sexual tension that has been built up in the entire body is released. Characteristics of orgasm are listed in Box 9.12. A myotonic response involves muscle systems of the entire body. There is contraction of the muscles surrounding the vagina, as well as the anal sphincter. The uterus may also contract. Muscle contraction occurs 2 to 4 seconds after the woman begins to experience the orgasm and repeats at 0.8-second intervals. The actual number and intensity of contractions vary from woman to woman. Some women observed to have orgasmic contractions are not aware that they are having an orgasm. Masters and Johnson feel that prolonged stimulation during the excitement phase, during masturbation, or in conjunction with the use of a vibrator may lead to more pronounced orgasmic activity. Whereas the excitement phase is under the influence of the parasympathetic portion of the autonomic nervous system, orgasm seems to be related to the sympathetic portion. The release of endogenous opioids, serotonin, prolactin, and oxytocin also has

Box 9.12 Characteristics of Orgasm in the Female

- Release of tension
- Generalized myotonic contractions
- Contractions of perivaginal muscles and anal sphincter
- Uterine contractions

been reported. Medication such as antihypertensive or antidepressant drugs, particularly SSRIs, may affect orgasmic response. A spinal cord injury may result in orgasmic disorder.

The resolution stage is last and represents a return of the woman's physiologic state to the preexcitement level. Although a refractory period is typical of the sexual response cycle in the male, no such refractory periods have been identified in women. Therefore new sexual excitement cycles may be stimulated at any time after orgasm. During the resolution phase, the woman generally experiences a feeling of personal satisfaction and well-being. Increased brain serotonergic activity has been recorded as well as decreased dopamine release.

Alternative models of the human sexual response have been proposed that differ from the linear progression of Masters and Johnson's (1966) model and also incorporate women's motivations and reasons for engaging in sex. Basson (2006) proposed that the phases overlap and may even occur in a different order. She proposed a more intimacy-based, circular model. Women in established relationships may engage in sex, not because of sexual desire but because of a desire for intimacy with their partner (Fig. 9.3).

SEXUAL RESPONSE AND MENOPAUSE

Many factors contribute to sexual changes as a woman enters menopause. Aging in general is associated with the slowing of sexual response and decreases in the intensity of response. Specifically, arousal may be slower and orgasms may be less intense and less frequent. Aging may also lead to psychosocial changes affecting self-esteem in relation to desirability. Of course, hormonal changes are a factor. The postmenopausal woman who is not on hormone replacement therapy (HRT) may experience progressive atrophy of vaginal epithelium, a change in vaginal pH, a decrease in quantity of vaginal secretions, and a decrease in the general circulation to the vagina and uterus. Although estrogen clearly plays a role in maintaining the integrity of the vaginal mucosal epithelium and promotes lubrication, there is no direct link between estrogen levels and sexual desire or symptoms. If quality of life is poor from menopausal vasomotor symptoms and poor sleep, then estrogen can improve overall well-being without directly impacting sexual

desire complaints. Testosterone is the predominant androgen in women. Both the ovaries and adrenal gland produce androgens, even after the menopause and the ovarian production ceases with oophorectomy, which may lead to lower circulating levels of testosterone. Decreased testosterone levels are associated with decreased sexual desire, arousal, sensation, and orgasm, but levels of endogenous androgens do not predict sexual function.

A postmenopausal woman may experience other sexual problems relating to her partner, or if she is single, widowed, or divorced, to her lack of availability of male partners. In addition, her general health and the general health of her partner will play a role in her ability to respond sexually in a satisfactory manner. Pelvic organ prolapse and poor levator ani muscle function may contribute to poorer sexual function. Couples with marital or communication problems may find that menopause is an appropriate excuse to cease sexual activities. A concerned physician can help a couple sort out their needs and desire for sexual compatibility at this stage of life. Frequently, counseling aimed at dealing with problems of the relationship will alleviate sexual response difficulties.

Male partners of older women may suffer from medical conditions or be affected by medications, with a resultant decrease in arousal and difficulties in acquiring or maintaining an erection sufficient for intercourse. The physician should ask women about sexual function, and if male dysfunction is evident, they should make suggestions for appropriate referral to physicians or other health care workers who may deal with male sexual dysfunction.

SEXUAL DYSFUNCTION

Female sexual dysfunction is quite common, particularly the loss of desire for sex. Higher percentages of dysfunction are seen in couples presenting for marital therapy and some women with loss of libido fear losing their partner. Both patient and physician wish for an easy solution, but the problem is often complex and not easily treated with drugs. Physicians caring for women should make a special effort to uncover sexual dysfunction or poor sexual response, as patients often do not bring up the problem unless asked. The Prevalence of Female Sexual Problems Associated with Distress and Determinants of Seeking Treatment (PRESIDE) study (Shifren, 2008) found low sexual desire accompanied by personal distress in 10% of women aged 30 to 39 years, 11% in women aged 40 to 49 years, 13% in women aged 50 to 59 years, and 10% in women aged 60 to 69 years. A 2009 report with the PRESIDE data of 31,581 respondents found the prevalence of a desire disorder was 10%, but reduced to 6.3% for those without concurrent depression. Overall, 40% of those respondents with sexual disorder of desire, arousal, or orgasm have concurrent depression.

Obviously, assembling a careful history by asking general and directed questions is appropriate when dealing with a patient in a gynecologic visit. The patient should be asked if she is sexually active; if she is active with men, women, or both; if intercourse is comfortable and enjoyable (if heterosexual); and if she experiences orgasm. Depending on the answer to these questions, more specific questioning should follow with the objective of outlining the extent of any problem and determining if there is distress related to the problem.

Sexual response problems may be the result of a previous negative sexual experience or may be secondary to emotional or physical illness. Primary medical conditions causing female sexual dysfunction can be hormonal, anatomic, vascular, or neurologic. The problem may also be related to difficulties in the current relationship

Figure 9.3 Blended intimacy-based and sexual drive-based cycles. (From Basson R. Female sexual response: the role of drugs in the management of sexual dysfunction. *Obstet Gynecol.* 2001;98:350-353.)

or to alcohol or drug abuse. Although an occasional alcohol drink may decrease inhibitions and improve sexual response, in general, alcohol is a depressant and decreases the woman's ability to become sexually aroused and to become vaginally lubricated. Drugs with antihypertensive and anticholinergic activity, as well as those active at the α - and β -adrenergic receptors, may decrease arousal or inhibit sexual interest. Narcotics, sedatives, and antidepressant drugs, such as SSRIs, may also depress sexual responsiveness. Finally, decreased arousal or ability to remain aroused may be due to distractions in the woman's life such as concerns for children, job, or other problems that may enter her consciousness during arousal.

Hypoactive sexual desire disorder is the most common sexual dysfunction and is reported by 5% to 14% of women surveyed. This is defined as persistent or recurrent deficiency of sexual desire that causes distress. Because each individual has his or her own libidinal drive, it is not surprising that couples may have some incompatibility of needs. It is important, however, that these needs and desires be discussed openly and that reasons for lack of sexual desire that may involve experiences or problems inherent in the relationship be resolved. At times the problem may be merely a failure to set aside appropriate time and effort for intimacy. The couple should be encouraged to give sexual activity a high priority within their relationship rather than leaving it last on the list of priorities. Couples should be encouraged to use arousal and seduction techniques that are appropriate for their relationship. Satisfactory foreplay of a mutually enjoyable nature should be encouraged. Sexual arousal disorder is characterized by a persistent inability to sense genital arousal. There may be difficulty attaining adequate lubrication and swelling response of sexual excitement. The prevalence of this disorder is uncertain but possibly 5% and often coexists with decreased sexual desire, chronic medical conditions, or vaginal atrophy.

Hormonal levels are frequently obtained in evaluating desire disorders. However, there is no evidence that low testosterone levels distinguish women with sexual desire disorder from others. A report on 1021 women who had androgen levels drawn from a random recruitment in Australia found neither total nor free testosterone nor dehydroepiandrosterone sulfate (DHEAS) levels discriminated between the women with and those without low sexual function. Testosterone testing in women is not recommended because the commonly available tests are not sensitive enough to detect the low concentrations in women, and the normal range in women has not been established.

There is one FDA-approved medication for hypoactive sexual desire disorder called *flibanserin*. It is approved for premenopausal women, and daily use increased satisfying sexual events by only 1 per month. Alcohol must not be consumed. Side effects include drowsiness, hypotension, and syncope. There are no other FDA-approved medications to treat desire disorders other than estrogen for vaginal atrophy. Estrogen may improve sexual desire if hypoestrogenism is causing an overall lack of well-being from nighttime hot flashes and poor sleep or genital discomfort from atrophy. The risks of estrogen are discussed elsewhere. Androgen therapy is not at present FDA approved in women, but randomized controlled trials have noted some benefits in postmenopausal women with hypoactive sexual desire disorders and arousal disorders. Levels of endogenous androgens therapy that increase serum concentrations to the upper limit of normal have consistently been shown to improve female sexual desire and sexual activity. The transdermal testosterone patch has been evaluated with the higher dose patch (300 μ g) showing increases in desire over a 6-month study in selected populations of

postmenopausal women. Improvements are modest. The group that has the most response to testosterone is women who have had surgical menopause. The FDA has not approved the patch, as long-term safety and efficacy data are not available and there are particular concerns about cardiovascular risk. Testosterone use remains controversial. Phosphodiesterase inhibitors have not been found to be effective. Bupropion has shown some effectiveness, even in women without depression, but further studies are needed. Ospemifene is a selective estrogen receptor modulator that is approved for vulvovaginal atrophy and dyspareunia in postmenopausal women. This would be appropriate for women with hypoactive sexual desire disorder thought to be from pain from vaginal atrophy.

Because sex is a biopsychosocial experience, it is not surprising that no one treatment for low libido stands out. Studies narrowly focusing on orgasm, genital function, or frequency of intercourse without addressing satisfaction or quality of life may not get at the essence of the sexual experience. At present, a sound approach to female sexual dysfunction is complex and needs to assess sexual education knowledge, a women's relationship with her partner, all forms of abuse including emotional abuse or traumatic experiences, body image issues, religious or cultural ideals, depression, concerns about sexually transmitted diseases, pain, other medical problems, and everyday fatigues and stresses. Exercise to improve blood flow to the pelvis and decrease fatigue, changing SSRI medication for depression if negative sexual side effects occur, and psychotherapy/sex therapy can all be beneficial.

Sexual arousal disorders have received relatively little scientific inquiry. Masters and Johnson taught women sensate focus using masturbation training and working with the partners with apparently good results. Vaginal or systemic estrogen therapy improves arousal disorder by improving vaginal blood flow and lubrication in postmenopausal women. The FDA-approved EROS-CTD (Clitoral Therapy Device, UroMetrics, Inc., St. Paul, MN) is a cup that sits over the clitoris and a gentle vacuum is applied via a battery-powered device. The EROS-CTD has been reported to improve clitoral blood flow, engorgement, and genital sensation, which is effective in the ability to reach orgasm. Exercise may improve genital blood flow.

Sexual pain disorders include dyspareunia and vaginismus. Vaginismus is a condition in which the woman has difficulties allowing vaginal entry of a penis. It is thought to be secondary to involuntary contraction of vaginal introital and levator ani muscles. Because of this spasm, penetration is either painful or impossible. With time, there can be fear of pain and phobic avoidance. Lamont has attempted to classify the degrees of vaginismus and, in a group of 80 patients, noted that 27 (34%) had first-degree vaginismus, defined as perineal and levator spasm relieved by reassurance during pelvic examination. Another 21 (26%) had second-degree vaginismus, defined as perineal spasm maintained throughout the pelvic examination. Another 18 (22.5%) demonstrated third-degree vaginismus, defined as levator spasm and elevation of the buttocks. A total of 10 (12.5%) had fourth-degree vaginismus, defined as levator and perineal spasm with withdrawal and retreat. Four of the 80 patients refused pelvic examination. These patients frequently complain not only of pain or fear of pain with coitus or pelvic examination but also of difficulty in inserting a tampon or vaginal medication. The condition may be primary, in which case the individual has never experienced successful coitus. This problem is generally based on either early sexual abuse or aversion to sexuality in general. This leads to a form of conversion disorder

studies hard to conduct. Although physicians and women may desire a pharmacologic solution, at present there is a paucity of good quality evidence. In fact, in the clinical trials of drug treatments for female sexual dysfunction, the placebo responses have been substantial. Whether attention to sexual function or changes in sexual behavior during a trial result in the marked placebo response, this definitely complicates the studies and needs to be considered in any treatment offered. Psychosexual counseling is often appropriate, as well as a comprehensive medical evaluation.

LESBIAN, GAY, BISEXUAL, AND TRANSGENDER HEALTH CARE

Before 1990, there was little information in the literature regarding lesbian, gay, bisexual, and transgender (LGBT) health care or health issues. In 2014, the Association of

American Colleges released a comprehensive curriculum to improve the health care of LGBT individuals so that medical schools can be guided in training physicians and faculty. Early uncontrolled studies were the first to suggest increased rates of depression, abuse, and substance abuse (Bradford, 1994). A systematic review and meta-analysis (King, 2008) found an increased rate of depression, anxiety disorders, and substance abuse and dependence in lesbian, gay, and bisexual individuals. The risk for suicide attempts in LGBT youth was four times as likely in comparison with heterosexual peers. Lesbian and bisexual women had a particularly high rate of alcohol and drug dependence and, again, this was more pronounced in adolescents. A number of studies have now documented that lesbian women use mental health services at high rates, with 70% to 80% having been in therapy, primarily for depression and relationship problems. The reasons for the higher rates of mental health and substance use disorders are unclear but may

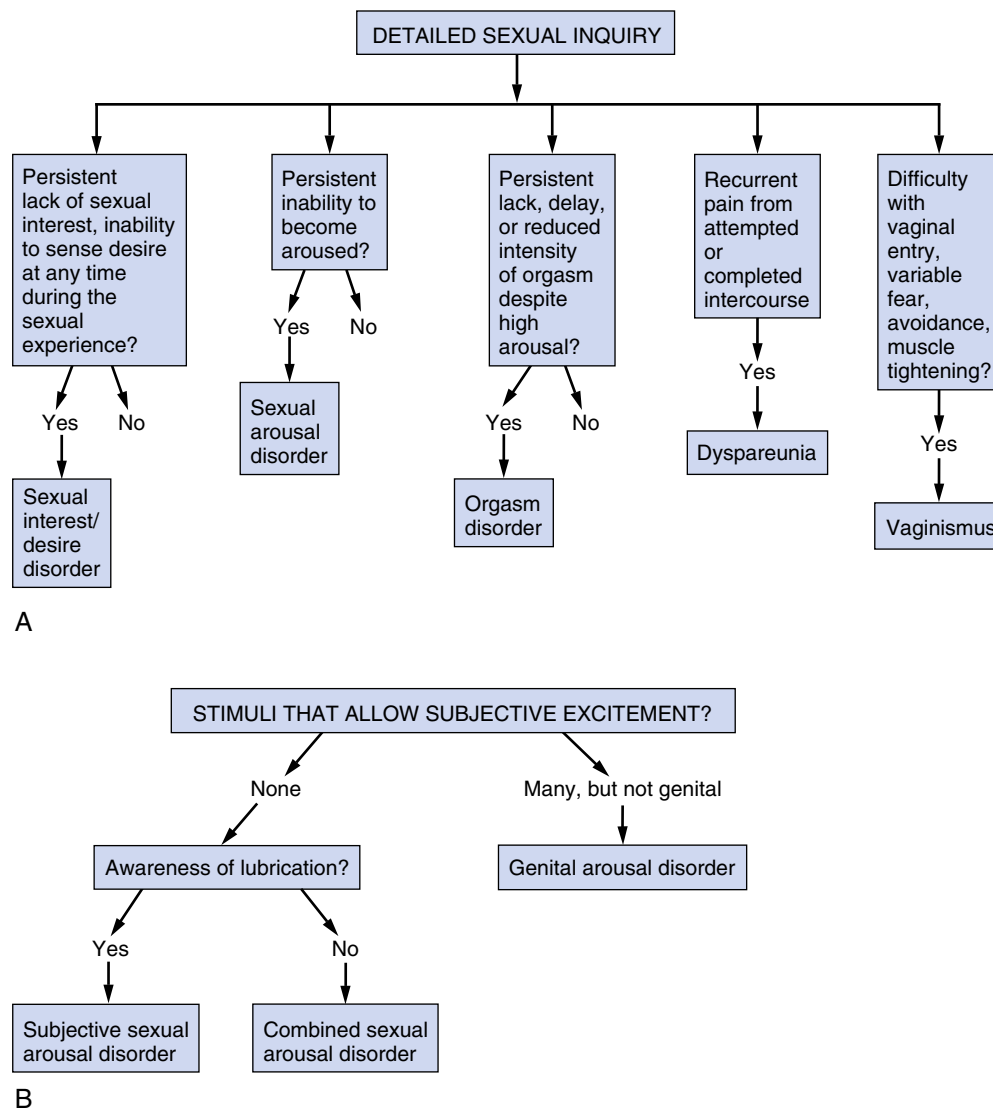

Figure 9.5 **A**, Detailed sexual inquiry. **B**, Further assessment of arousal disorder. (From Basson R, Althof D, Davis S. Summary of the recommendations on sexual dysfunctions in women. *J Sex Med*. 2004;1:24-34.)

include a higher rate of childhood sexual abuse, being a member of a stigmatized minority group, and dealing with conflict and secrecy regarding sexual orientation.

Lesbians have a higher rate of cardiovascular risk factors, such as obesity and smoking. Smoking rates are especially high in lesbian adolescents. Lesbian and bisexual women are twice as likely to be obese as heterosexual women. That may be interrelated with studies showing LGBT youth are less likely to participate in moderate or rigorous sports activities. Since the 1990s, lesbian women have become increasingly willing to disclose their sexual orientation to health care providers and to seek routine physical examinations. Nonetheless, their rates of routine physicals and Pap smears are lower than national guidelines and lower than those of their heterosexual peers, and adolescents in particular have difficulty disclosing their sexual orientation to physicians. LGBT youth report that they think their health care provider should know their sexual orientation to provide the best possible care, but two thirds do not disclose this information. Lesbians prefer female and preferably lesbian health care providers and frequently use alternative health care providers such as nonphysicians, acupuncturists, and massage therapists. Lesbian women are 10 times less likely to be screened for cervical cancer than heterosexual women, even though their risk of developing the disease is comparable. This has been thought to be due to lack of concern and a belief that lesbian women were at low risk for cervical cancer. However, studies show human papillomavirus (HPV) screening and Pap smear frequency should be the same as the recommendations for heterosexual women. Sexually transmitted diseases also occur in lesbian women, particularly those who have had male partners.

Lesbians are increasingly having children through artificial insemination and adoption. Couples wishing to have children through donor insemination have concerns about coming out to their obstetrician, involving the nonpregnant partner, legal issues, family support, and parenting issues. Obstetrician-gynecologists need to be comfortable treating and advising LGBT women and couples, not just for pregnancy but also for general health issues, or should refer them to an appropriate provider.

RAPE, SEXUAL ASSAULT, AND INTIMATE PARTNER VIOLENCE

RAPE

Rape, or the sexual assault of children, women, and men, is a common act. Sexual assault encompasses many acts, including rape and unwanted genital touching. *Rape* is a legal term and refers to any penetration of a body orifice with threat of force or actual force and nonconsent. Sexual violence is defined as any sexual act performed by one person on another without that person's consent. Unfortunately, this is a common problem all over the world. A 2014 worldwide systematic review found 7.2% of women had ever experienced nonpartner sexual violence. The rates were 8% to 13% in North America with higher rates in sub-Saharan Africa and lower in Asia. Another study found 18% of women reported they had experienced attempted or completed rape. In separating out by female age groups, 11% of high school adolescents reported having been forced to have

sex. The percentage increases the younger the adolescent is for involuntary first intercourse. Twenty to 25% of women in college have been victims of actual or attempted sexual assault during college. Among women 18 years of age or older, 31.5% who were raped sustained physical injury, and 36% of injured female victims received medical treatment. Of the rape victims who came to the emergency room, two thirds had general body trauma. This type of crime, however, is often underreported, and the actual incidence may be much higher. Victims are often reluctant to report sexual assault to the authorities because of embarrassment, fear of retribution, feelings of guilt, assumptions that little will be done, or simply lack of knowledge of their rights. Homeless women and women with mental illness are particularly vulnerable to sexual assaults compared with the general population.

In the past, society has held many misconceptions about the rape victim, particularly female victims. These included the notion that the individual encouraged the rape by specific behavior or dress and that no person who did not wish to be raped could be raped. Furthermore, the feeling that rape was an indication of basic promiscuity was widely held. To some extent, many of these societal misconceptions are held today.

Sexual assault happens to people of all ages and races in all socioeconomic groups. The very young, the mentally and physically handicapped, and the very old are particularly susceptible. Although men can be victims of sexual violence, most victims are female. Sexual violence can be unwanted touching and rape, but it also includes nonphysical distressing acts of sexual harassment, threats, peeping, and taking nude photos without consent. The Centers for Disease Control reported in 2006 that high school black (9.3%) and Hispanic (7.8%) students had higher rates of forced sexual intercourse than white students (6.9%). Although the perpetrator may be a stranger, he or she is often an individual well known to the victim. In fact, for first rape experience in women, 30.4% of the time the perpetrator was known to be an intimate partner, 23.7% a family member, and 20% of the time an acquaintance.

Some situations have been defined as variants of sexual assault. These include marital rape, which involves forced coitus or related acts without consent but within the marital relationship, and "date rape." In the latter situation the woman may voluntarily participate in sexual play, but coitus is performed, often forcibly, without her consent. Date rape is often not reported because the victim may believe she contributed by partially participating. This, however, can be a traumatic event and scar her self-esteem.

Almost all states have statutes that criminalize coitus with females under certain specified ages. Such an act is referred to as *statutory rape*. Consent is irrelevant because the female is defined by statute as being incapable of consenting.

During a rape, the victim loses control over his or her life for that period and frequently experiences anxiety and fear. When the attack is life threatening, shock with associated physical and psychological symptoms may occur. [Burgess \(1974\)](#) identified two phases of the rape-trauma syndrome. The immediate, or acute, phase lasts from hours to days and may be associated with a paralysis of the individual's usual coping mechanisms. Outwardly, the victim may demonstrate manifestations ranging from

complete loss of emotional control to a well-controlled behavior pattern. The actual reaction may depend on a number of factors, including the relationship of the victim to the attacker, whether force was used, and the length of time the victim was held against his or her will. Generally, the victim appears disorganized and may complain of both physical and emotional symptoms. Physical complaints include specific injuries or general complaints of soreness, eating problems, headaches, and sleep disturbances. Behavior patterns may include fear, mood swings, irritability, guilt, anger, depression, and difficulties in concentrating. Frequently, the victim will complain of flashbacks of the attack. Medical care is often sought during the acute period, and at this point it is the physician's responsibility to assess the specific medical problems and also to offer a program of emotional support and reassurance.

The second phase of the rape-trauma syndrome involves long-term adjustment and is designated the reorganization phase. During this time, flashbacks and nightmares may continue, but phobias may also develop. These may be directed against members of the offending sex, the sex act itself, or non-related circumstances, such as a newly developed fear of crowds or heights. During this period the victim may institute a number of important lifestyle changes, including job, residence, friends, and significant others. If major complications such as the contraction of a sexually transmitted infections (STIs) or a pregnancy occur, resolution may be more difficult. The reorganization period may last from months to years and generally involves an attempt on the part of the victim to regain control over his or her life. During this time, medical care and counseling must be nonjudgmental, sensitive, and anticipatory. When the physician realizes that the patient is contemplating a major lifestyle change during this period, it is probably appropriate to point out to the patient why the change is being contemplated and the complicating effects it may have on the patient's overall well-being.

In some women, rape, like other trauma, can lead to ongoing, persistent posttraumatic stress disorder (PTSD, discussed earlier in this chapter), with disabling nightmares, flashbacks, hyperarousal, avoidance, depression, anxiety, and panic. Individuals with a prior history of trauma before the rape; greater severity, duration, and life-threatening nature of the assault; poor social support; and a past history of depression or anxiety are more susceptible to developing PTSD. Approximately 15% to 20% of women ages 18 to 50 have chronic pelvic pain of more than a year's duration. An estimated 40% to 50% of those women have a history of physical or sexual abuse.

Physician's Responsibility in the Care of a Rape Victim

Although any individual may become a rape victim, this discussion will be limited to the care of a female, as is appropriate for a gynecology textbook. The physician's responsibility may be divided into three categories: medical, medicolegal, and supportive, as shown in [Box 9.14](#).

Medical

The physician's medical responsibilities are to treat injuries and to perform appropriate tests for, to prevent, and to treat infections and pregnancies. It is important to obtain informed consent before examining the patient and collecting specimens. In addition to addressing legal requirements, it helps the victim

to regain control over her body and her life. After acute injuries have been determined and stabilized, a careful history and physical examination should be performed. It is important to have a chaperone present while taking the history, performing the examination, and collecting the specimen, to reassure the victim and to provide support. The presence of such a third party probably reduces feelings of vulnerability on the part of the victim. She should be asked to state in her own words what happened; if she knew the attacker, and if not, to describe the attacker; and to describe the specific act(s) performed. A history of previous gynecologic conditions, particularly infections and pregnancy, use of contraception, and the date of last menstrual period, should be recorded. It is necessary to determine whether the patient may have a preexisting pregnancy or be at risk for pregnancy. It is also important to ascertain whether she has had a preexisting pelvic infection.

Experience derived at the Sexual Assault Center in Seattle, Washington, demonstrated that between 12% and 40% of victims who are sexually assaulted have injuries. Most of these, however, are minor and require simple reparative therapy. Only about 1% require hospitalization and major operative repair. Lack of genital injury does not rule out assault. Nonetheless, the victim will perceive the experience as having been life threatening, as in many cases it may have been. Many injuries occur when the victim is restrained or physically coerced into the sexual act. Thus the physician should seek bruises, abrasions, or lacerations about the neck, back, buttocks, or extremities. Where a knife was used as a coercive tactic, small cuts may also be found. Erythema, lacerations, and edema of the vulva or rectum may occur because of manipulation of these areas with the hand or the penis. These are particularly common in children or virginal victims but may occur in any woman and should be looked for. Superficial or extensive lacerations of the hymen, posterior

Box 9.14 Physician's Responsibilities in Caring for a Rape-Trauma Victim

Medical

- Treat injuries
- Diagnose and treat STDs
- Prevent pregnancy

Medicolegal

- Document history carefully
- Examine patient thoroughly and specifically note injuries
- Collect articles of clothing
- Collect vaginal (rectal and pharyngeal) samples for sperm
- Comb pubic hair for hair samples
- Collect fingernail scrapings where appropriate
- Collect saliva for secretion substance
- Turn specimens over to forensic authorities and receive receipts for chart

Emotional Support

- Discuss degree of injury, probability of infection, and possibility of pregnancy
- Discuss the general course that can be predicted
- Consult with a rape-trauma counselor
- Arrange a follow-up visit for a medical and emotional evaluation in 1 to 4 weeks
- Reassure as much as possible

fourchette, or vagina may occur in virginal victims or in the elderly. Lacerations may also be noted in the area of the urethra, the rectum, and at times through the vaginal vault into the abdominal cavity. In addition, bite marks may be noted in any of these regions. Occasionally, foreign objects are inserted into the vagina, the urethra, or the rectum and may be found in situ.

Most victims are concerned about possible infections incurred as a result of the rape. To determine actual risk, it is important to know the prevalence of existing STIs in the victim population. One study (Jenny, 1990) examined 204 girls and women within 72 hours of a rape and discovered that 88 (43%) were harboring at least one STI. These included *Neisseria gonorrhoeae* in 13 of 204 (6% of all tested), cytomegalovirus in 13 of 170 (8%), *Chlamydia trachomatis* in 20 of 198 (10.1%), *Trichomonas vaginalis* in 30 of 204 (14.7%), herpes simplex virus in 4 of 170 (2.4%), *Treponema pallidum* in 2 of 199 (1%), human immunodeficiency virus (HIV)-1 in 1 of 123 (0.8%), and bacterial vaginosis in 70 of 204 (34.3%). In 109 patients (53%) who returned for follow-up (excluding those who were found to be infected on the first visit or who were treated prophylactically), there were 3 of 71 (4%) cases of gonorrhea, 1 of 65 (0.02%) of chlamydia, 10 of 81 (12%) of trichomoniasis, and 15 of 77 (19%) of bacterial vaginosis. These authors concluded that women who are raped have a higher than average prevalence of preexisting STIs but are also at a substantial risk of acquiring such diseases as a result of the assault.

A review on the risk of infection in rape victims found it was difficult to separate new from existing infection but placed the prevalence of STIs as follows: *N. gonorrhoea* 0 to 26.3%, *C. trachomatis* 3.9% to 17%, *Treponema pallidum* 0 to 5.6%, *Trichomonas vaginalis* 0 to 19%, and HPV 0.6% to 2.3%. Few studies are available to predict the actual risk of acquiring an STI, but *Chlamydia trachomatis* may be the most commonly acquired infection incurred under these circumstances. Most victims fear acquiring HIV as a result of a sexual attack, but current risks are probably not high depending on the population involved and the sexual acts performed. Some studies place the risk for adult rape victims of acquiring syphilis as high as 3% to 10%. These authors did not believe the risk of acquiring STIs can be quantified, but they noted that the acquisition of viral sexually transmitted diseases (STDs), including HIV, has been reported both in adults and children. In consensual sex, the risk for HIV transmission from vaginal intercourse is 0.1% to 0.2% and for receptive anal intercourse it is 0.5% to 3%.

Commercial “evidence kits” are available. State crime lab testing may include urine or serum for “date rape” drugs when amnesia or sedation is present. A speculum exam is not always necessary, but if bleeding is reported or noted on external vulvar exam, it is appropriate. It must be remembered that infection may not be limited to the vagina but may also include the pharynx or the rectum. Specific history to raise a suspicion of this possibility should be sought. Urine or nonculture nuclear amplification tests (NAATs) for *Neisseria gonorrhoeae* and *Chlamydia trachomatis* are preferred according to the Centers for Disease Control 2015 guidelines. In addition, conventional cultures of the rectum and of the oral pharynx are indicated when the history suggests that this would be productive. A wet mount for *Trichomonas vaginalis* and bacterial vaginosis and a potassium hydroxide mount for *Candida albicans* are also useful

Box 9.15 Sexually Transmitted Diseases and Tests Available to Physicians Caring for a Rape-Trauma Victim

Should Perform

NAATs for *Neisseria gonorrhoeae*
NAATs for *Chlamydia trachomatis*

Could Perform

Herpes simplex—culture lesion or serology
Hepatitis B—screening serology
HIV—serology
Cytomegalovirus—serology
Condyloma virus—study lesion
Trichomonas—saline wet mount preparation and culture or point-of-care testing
Bacterial vaginosis—pH, saline wet mount preparation
Candida—potassium hydroxide wet mount preparation
Syphilis—rapid plasma regain (RPR)

Data from Centers for Disease Control website, www.cdc.gov/std/treatment/2010/STD-Treatment-2010-RR5912.pdf; Harborview Sexual Assault Center.

(Box 9.15). Investigation for syphilis (rapid plasma regain [RPR]) is not routinely recommended at the Sexual Assault Center in Seattle, Washington, but may be done in follow-up.

Because the victim is also at risk for infection by the herpesvirus, hepatitis B virus, cytomegalovirus, HIV, condyloma acuminatum, and a variety of other STIs, the physician may wish to screen for those that seem appropriate at the time the victim is seen in the acute stage. Hepatitis B and HPV vaccination may be appropriate if the victim is not previously vaccinated and of appropriate age. Tetanus prophylaxis is appropriate in some cases as well. At follow-up visits the patient should again be investigated for signs and symptoms of the STIs, and appropriate repeat cultures, NAATs, and serologies should be obtained. Be aware that compliance with follow-up visits is poor. Prophylactic antibiotics are useful in acute rape management when the patient is concerned about contracting an STI or knows the assailant to be high risk. The CDC recommends the woman can be given a single dose of ceftriaxone 250 mg intramuscularly, for gonorrhea prophylaxis plus single dose azithromycin, 1 g PO for chlamydia prophylaxis plus metronidazole 2 grams orally in a single dose or tinidazole 2 grams PO in a single dose for trichomonas. If the patient is pregnant, consider giving no medications, and follow-up screening should be done in 2 weeks. If prophylaxis is desired, these antibiotics are class B drugs in pregnancy (except doxycycline which should not be given and is class D). This should prevent gonorrhea and *Chlamydia* infection but will have no effect on herpes, condylomata, or many of the other problems mentioned. Postexposure therapy with combination therapy is controversial for HIV prevention, as the benefit is unknown and extrapolated from needle-stick injuries in health care workers. It should be discussed with individuals initiating care less than 72 hours after assault and particularly if the victim has genital or rectal trauma. It is recommended if the assailant is known to be HIV or AIDS positive.

Pregnancy

The patient's menstrual history, birth control regimen, and pregnancy status should be assessed. If the patient is at risk for pregnancy at the time of the assault, an appropriate emergency contraception or “morning after” prophylaxis can be offered as long as the pregnancy test was negative and if given within

120 hours after unprotected intercourse (1.5 mg levonorgestrel). This subject is discussed more fully in [Chapter 13](#). In the experience of most sexual assault centers, the chance of pregnancy occurring is quite low. Some have estimated that approximately 5% of victims having a single, unprotected coitus will become pregnant. However, if the patient has been exposed at midcycle, the risk will be higher.

Medicolegal

To be meaningful, medicolegal material must be collected shortly after the assault takes place and definitely within 96 hours. The woman can be reassured that laws in all 50 states strictly limit use of past STIs or past sexual history during a trial so as not to discredit her testimony. Commercially manufactured “evidence kits” are available and may help with preserving the “chain of evidence” for a legal case. Victims should be encouraged to come immediately to a center where they can be evaluated before bathing, urinating, defecating, washing out their mouths, changing clothes, or cleaning their fingernails. The United States Department of Justice, Office of Victims of Crime, supports Sexual Assault Nurse Evaluation (SANE) programs, which have models for acute care for sexual assault. Some institutions have Sexual Assault Response Teams (SARTs), so experts are available to do the appropriate psychological, medical, and legal evaluation. You should know the resources available in your community.

In general, evidence for coitus will be present in the vagina for as long as 48 hours after the attack, but in other orifices the evidence may last only up to 6 hours. Appropriate tests should document the patient’s physical and emotional condition as judged by her history and physical examination and should include data that document the use of force, evidence for sexual contact, and materials that may help identify the offender. To document that force was used, the physician should carefully describe each injury noted and illustrate with either drawings or photographs. Detail is important, because injuries suffered by sexual assault victims have common patterns. Because *rape* and *sexual assault* are legal terms, they should not be stated as diagnoses; rather the physician should report findings as “consistent with use of force.” Documentation of sexual contact must begin with a history of when the patient had intercourse before the attack. If sperm or semen is found in the vagina or cervix of a victim, it must not be confused with such substances deposited during the victim’s prior consenting sexual acts. Sexual contact will be verified by analysis of secretions from the vagina or rectum by identifying motile sperm. Nonmotile sperm may be present as well if the attack occurred 12 to 20 hours previously. In some instances, motile sperm will be noted for as long as 2 to 3 days in the endocervix. Vaginal wet mount is no longer recommended for identifying sperm as it lacks reproducibility. Manufactured evidence kits are available.

It is difficult to ascertain whether ejaculation occurred in the mouth, because residual seminal fluid is rapidly destroyed by bacteria and salivary enzymes, making documentation of such an event difficult after more than a few hours have passed. Seminal fluid may be found staining the skin or the clothing several hours after the attack, and this should be looked for. Because acid phosphatase is an enzyme found in high concentrations in seminal fluid, substances removed for analysis should be tested

Table 9.6 Survival Time of Sperm

Source	Motile Sperm	Sperm	Acid Phosphatase
Vagina	Up to 8 hr	Up to 7 to 9 days	Variable (up to 48 hr)
Pharynx	6 hr	Unknown	100 IU*
Rectum	Undetermined	20 to 24 hr	100 IU*
Cervix	Up to 5 days	Up to 17 days	Similar to vagina

From Anderson S. *Sexual assault—medical-legal aspects: an unpublished training packet for pediatric house staff*. Seattle, WA: Harborview Medical Center; 1980.

*Minimum detectable.

for this enzyme. [Table 9.6](#) demonstrates the survival time of sperm in the pharynx, rectum, and cervix.

In addition to documenting that intercourse has taken place, an attempt should be made to identify the perpetrator. In this regard, all clothing intimately associated with the area of assault should be collected, labeled, and submitted to legal authorities. In addition, smears of vaginal secretions or a Pap smear should be made to permanently document the presence of sperm. Vaginal secretions needed for DNA typing should be collected by wet or dry swab and refrigerated until a pathologist can process them. In the near future tests may also be available to identify prostate-specific antigen and seminal vesicle-specific antigen in vaginal secretions. Highly sensitive DNA fingerprinting is now readily available and is admissible in many jurisdictions. Pubic hair combings should be performed in an attempt to obtain pubic hair of the assailant. Saliva should be collected from the victim to ascertain whether she secretes an antigen that could differentiate her from substances obtained from the perpetrator. Finally, fingernail scrapings should be obtained for skin or blood if the victim scratched the perpetrator. Specific blood or DNA typing may be conducted to help identify the attacker. All materials collected should be labeled and turned over to the legal authority or pathologist, depending on the system used by the medical unit. A receipt should be obtained, and this should be documented in the patient’s chart.

Emotional Support of the Victim

After the physical needs of the patient have been met and after the physician has carefully documented the information concerning the sexual contact, he or she should discuss with the victim the degree of injury, probability of infection or pregnancy, general course that the victim might be expected to follow with respect to these, and how follow-up to aid prevention will be carried out. The physician must allow the victim to vent anxieties and correct misconceptions. The physician should reassure her, insofar as possible, that her well-being will be restored. In doing this, the physician may call on other health personnel, such as individuals trained to help rape-trauma victims, to facilitate counseling and follow-up. The patient should not be released until specific follow-up plans are made and the patient understands what they are. A follow-up visit should be planned within 1 to 4 weeks to reevaluate the patient’s medical, infectious disease, pregnancy, and psychological status. At this point, follow-up counseling should be encouraged. It is important at each visit to emphasize to the patient that she was a victim and holds no blame. At each step she must be allowed to vent her feelings and to discuss her current conceptions of the problem. It is important

that the physician realize that some patients will appear to have excellent emotional control when seen immediately after a rape. This is an acute expression of the patient's defense mechanisms and should not be misinterpreted to indicate that the patient is coping with the circumstances. All the recommendations just listed should be followed *regardless* of the patient's apparent condition. Specific plans for follow-up are equally important in such an individual, because it must be anticipated that she will follow the same post-rape emotional process as anyone else. Finally, it is important to emphasize and reemphasize that at no time during the management or follow-up care of the rape victim should any comments be made by health care professionals suggesting that the patient was anything other than a victim. These women are sensitive to any accusations and insinuations and may even believe that they may have in some way been responsible for the rape. Their future well-being may be severely affected by creating such an impression.

Female Circumcision

A form of sexual abuse only recently observed in the Western world is female circumcision or genital cutting. It is a practice growing out of cultural and traditional beliefs dating back several thousand years. The World Health Organization estimates that between 85 and 200 million women undergo these procedures each year. Although they are often performed in parts of Africa, the Middle East, and Southeast Asia, they are rarely performed in the United States or the rest of the Western world. About 168,000 women who have undergone such procedures currently live in the United States, and physicians may see the results of these procedures in patients who emigrate from countries where they are practiced.

The various forms of female genital mutilation include removal of the clitoral prepuce, excision of the clitoris, or removal of the clitoris and labia minora. Occasionally, the labia majora are also partially removed and the vagina partially sutured closed. The procedures are often performed between early childhood and age 14 and frequently without anesthesia under unsterile conditions by untrained practitioners. Therefore a variety of complications often occur, including infection, tetanus, shock, hemorrhage, and death. Long-term problems include chronic infection, scar formation, local abscesses, sterility, and incontinence. In addition, depression, anxiety, sexual dysfunction, dyspareunia, obstetric complications, and the psychosomatic conditions associated with sexual abuse may be seen. Physicians who care for women with this condition must develop an understanding of the cultural mores that lead to the performance of the procedure and the current implications on these cultural beliefs that remedial surgery may imply. Certainly the patient and her sexual partner should be involved in all decisions concerning intervention.

ABUSE

Intimate Partner Violence

Domestic violence, partner abuse, intimate partner violence (IPV), the battered woman, and spouse abuse are terms that refer to violence occurring between partners in an ongoing relationship even if they are not married. A battered woman is defined as any woman over the age of 16 with evidence of physical abuse on at least one occasion at the hands of an intimate male partner. The *battered wife syndrome* is defined as a symptom complex occurring

as a result of violence in which a woman has at any time received deliberate, severe, or repeated (more than three times) physical abuse from her husband or significant male partner in which the minimal injury is bruising. *Intimate partner violence (IPV)* is the CDC's currently preferred term because it allows for males or females to be the victim and intimate partners can be the same or opposite sex. Actual or threatened physical, sexual, or psychological abuse by a current or former spouse (including common-law spouses), dating partner, boyfriend, or girlfriend is considered intimate partner violence. The American Medical Association has treatment guidelines and defines IPV as a "pattern of coercive behaviors that may include repeated battering and injury, psychological or emotional abuse, sexual assault, progressive societal isolation, economic deprivation, intimidation and stalking." The actual physical abuse may vary from minimal activity, such as verbal abuse or threat of violence, to throwing an object, throwing an object at someone, pushing, slapping, kicking, hitting, beating, threatening with a weapon, or using a weapon. These acts may be spontaneous or intentionally planned. Most such violence is accompanied by mental abuse and intimidation. Partner abuse is often seen in conjunction with abuse of children and elderly persons in the same household. A 2008 study by Breiding and colleagues investigated risk factors for IPV in noninstitutionalized adults and found the victims to be female, of ethnic/racial minority, to have a lower income, to be less educated, and to be older. There remain significant societal, cultural, and economic barriers for victims to seek help.

It is difficult to ascertain the specific incidence of domestic violence, but it has been estimated that 4.5 million cases of IPV occur in the United States each year, and some authors have stated that at least 50% of family relationships are violent. In a 1984 U.S. Department of Justice study, 57% of 450,000 annual acts of family violence were committed by spouses or ex-spouses, and the wife was a victim in 93% of cases. In at least one fourth of these cases the violent acts had occurred at least three times in the previous 6 months. In 1990, statistics gathered by the Federal Bureau of Investigation (FBI) reported similar findings. A 2008 phone survey of noninstitutionalized adults provided some of the best IPV prevalence data to date. Nineteen percent of women reported threatened physical violence over their lifetime, 14.5% reported attempted physical violence, and 20.2% completed physical violence. The frequency of unwanted sex for an intimate partner was 10.2%. Within the previous 12 months, 1.4% of women reported completed physical or sexual violence.

In addition, it has been estimated that between one third and one half of female homicide victims are murdered by their male partners, whereas only 12% of male homicide victims are killed by their female partners. In 1992, the American Medical Association (AMA) published guidelines for the diagnosis and treatment of domestic violence. The association noted that 47% of husbands who beat their wives do so three or more times per year, that 14% of ever-married women reported being raped by their current or former husbands, and that rape is a significant or major form of abuse in 54% of violent marriages. The AMA guidelines also summarized various studies noting that battered women may account for 22% to 35% of women seeking care for any reason in emergency departments (the majority of whom are seen by medical or nontrauma services) and 19% to 30% of injured women seen in emergency departments. This was confirmed

in a 2005 study in which 17% of women seeking care in an emergency department reported current abuse. Nine percent to 14% of women seen in ambulatory care internal medicine clinics currently suffer IPV, and 26% to 28% of such women have been battered at some time. The study states that 25% of women who attempt suicide, 25% who are receiving psychiatric services, and 23% of pregnant women seeking prenatal care have been victims of domestic violence. In addition, 45% to 59% of mothers of abused children have been abused, and 58% of women older than 30 who have been raped have been abused. In a gynecologic clinic in England, John and colleagues surveyed a cohort of 825 women. Twenty-one percent reported physical abuse, and of those, 48% also had forced sexual activity. A 2005 report confirmed the prevalence rates in health care facilities with 35% of obstetrics and gynecology patients reporting IPV and 13% of women seeking care reporting current abuse. Therefore it can be seen that domestic violence and battered women are common in our society today.

The most common sites for injury are the head, neck, chest, abdomen, breast, and upper extremities. Minor injuries such as scratches, bruises, sore muscles, and welts are common. The upper extremities may be fractured as the woman attempts to defend herself. Broken teeth, burns, laceration, head injury, and strangulation are also frequently observed. In a study from Yale, 84% of the injuries were severe enough to require medical treatment, and in 81% of the cases patients stated that the assailant had beaten them with the fists. In an English study of 100 women brought to a hostel for battered women, 44% suffered from lacerations and 59% stated that they had been kicked repeatedly. All women stated that they had been hit with a clenched fist. Fractures occurred in 32, and 9 of the women had been beaten and taken to the hostel unconscious. A 2006 study also found significant injury among victims; of 519,031 cases, 41% of assaults caused observable injuries and 28% required medical treatment.

Murder and suicide are frequent components of the domestic violence problem. In a large study from Denver, Walker reported that three quarters of the battered patients felt that the batterer would kill them during the relationship, and almost half felt that they might kill the batterer. Of these victims, 11% stated that they had actually tried to kill the batterer, and 87% believed that they themselves would be the ones to die if someone were killed. This is not an exaggeration, as IPV resulted in 1544 deaths in 2004. One third of these women stated that they seriously considered committing suicide. Walker noted that victims and their attackers frequently are depressed and may move rapidly between suicidal and homicidal intent.

There is a strong relationship between spouse battering and child abuse. In Walker's study, 53% of men who abused their partners were noted also to abuse their children. Another one third had threatened to abuse their children. Interestingly, in the same relationship, 28% of the wives who themselves were abused stated that they had abused their children while living in the violent household, and an additional 6% thought that they might abuse their children at the time they were evaluated.

Physical abuse in pregnancy is common and may be referred to as *prenatal child abuse*. The incidence is somewhere between 1% and 20%, depending on the study population.

In one study, 81 of 742 (10.9%) patients visiting a prenatal clinic stated that they had been victims of abuse at some time in the past, and 29 of these women stated that the abuse had continued into the pregnancy. Violence may increase postpartum. One fifth of these noted an increase in abuse during pregnancy, and one third noted a decrease. In a study of a group of Medicaid-eligible postpartum women, a constellation of factors associated with violence during pregnancy was noted. Of the patients in this study, 7% suffered battering, and significant correlates including anxiety, depression, housing problems, inadequate prenatal care, and drug and alcohol abuse were identified. The women in the study who were battered during pregnancy suffered a more severe constellation of symptoms than did those who were battered only prior to pregnancy. In the case of pregnant patients, most studies note that battering is frequently directed to the breasts and abdomen.

It is important that physicians increase their ability to recognize the signs of domestic violence and spouse abuse. A study by Hilberman and Monson (1977) demonstrated that 25% of women treated for injuries in an emergency room were victims of wife battering. The physicians who were treating these patients made the correct diagnosis originally in only 3% of cases. Viken has listed a profile of the characteristics of the abused wife. These include a history of having been beaten as a child, raised in a single parent home, married as a teenager, and pregnant before marriage. Such women frequently visit clinics and emergency rooms with a variety of somatic complaints, including headaches, insomnia, choking sensation, hyperventilation, gastrointestinal symptoms, and chest, pelvic, and back pain. Noncompliance with the advice of physicians with respect to these complaints is frequent (Box 9.16).

In visits to the physician's office or emergency room, the patient often appears shy, frightened, embarrassed, evasive, anxious, or passive and often cries. The batterer may accompany the patient on such visits and stay close at hand to monitor what she says to the physician. Thus the woman may be hesitant to provide information about how she was injured, and the explanation given may not fit the injuries observed. Alcohol or other drug abuse is common in such individuals.

Box 9.16 Somatic Complaints in Abused Women

Headaches
Insomnia
Choking sensation
Hyperventilation
Chest, back, or pelvic pain

Other Signs and Symptoms

Shyness
Fright
Embarrassment
Evasiveness
Jumpiness
Passivity
Frequent crying
Often accompanied by male partner
Drug or alcohol abuse (often overdose)
Injuries

From ACOG Technical Bulletin Number 124: *The Battered Woman*. January 1989.

Physicians should become comfortable with asking the patient whether she has been physically abused. Every pregnant woman should be screened for intimate partner violence. Introductory questions such as “Has anyone hurt you or tried to injure you?” “Has an intimate partner ever threatened you with physical violence?” and “Have you ever been physically abused either recently or in the past?” are appropriate. The physician should follow up on any positive answers in a nonjudgmental manner in an attempt to learn what is happening. Physical examinations should be complete with particular attention to bruises, lacerations, burns, improbable injury, and other signs of injury. If the patient is wearing sunglasses, she should be asked to remove them so that the physician can determine whether there are eye injuries. If the patient is pregnant, bruises seen on the breasts or abdomen should always be discussed. Physicians should carefully note evidence for abuse in the patient’s record.

Battering acts tend to run in cycles consisting of three phases. The first phase is tension building, in which tension between the couple gradually escalates, manifested by discrete acts that cause family friction. Name-calling, intimidating remarks, meanness, and mild physical abuse such as pushing are common. The batterer often expresses dissatisfaction and hostility in a somewhat chronic form. The victim may attempt to placate the batterer in hopes of pleasing him or calming him. She may actually believe at this point that she has the power to avoid aggravating the situation. She may not respond to his hostile actions and may even be successful from time to time in apparently reducing tensions. This, of course, will reinforce her belief that she can control the situation. As the tension phase builds, the batterer’s anger is less controlled, and the victim may withdraw, fearing that she will inadvertently set off explosive behavior. Often this withdrawal is the signal for the batterer to become more aggressive. Anything may spark the hostile act, and the acute battering then takes place. This is the cycle’s second phase and is represented by an uncontrollable discharge of tension that has built up through the first phase. The attack may take the form of both verbal and physical abuse, and the victim is often left injured. In self-defense the victim may actually injure or kill the batterer. In approximately two thirds of cases reported by Walker, alcohol abuse was involved. However, the alcohol use may have been the excuse rather than the reason for the battering. After the abuse has taken place, the third phase generally follows. In this situation, the batterer apologizes, asks forgiveness, and frequently shows kindness and remorse, showering the victim with gifts and promises. This gives the victim hope that the relationship can be saved and that the violence will not recur. Batterers are often charming and manipulative, offering the victim justification for forgiveness. The cycles, however, do repeat themselves, with the first phase increasing in length and intensity, the battering becoming more severe, and the third phase tending to decrease in both duration and intensity. The batterer learns that he can control the victim without obtaining much forgiveness. The victim becomes more demoralized and loses her ability to leave the situation even if she has the means and opportunity to do so.

Batterers, too, tend to have a specific profile in most cases. They are men who refuse to take responsibility for their behavior, blaming their victims for their violent acts. They often have strong controlling personalities and do not tolerate autonomy in their partners. They have rigid expectations of marriage and sexual behavior and consider their wives or partners as chattel. They wish

to be cared for in their most basic needs, frequently make unrealistic demands on their wives, and show low tolerance for stress. Depression and suicide attempts are often a part of their behavior pattern, but in general they are aggressive and assaultive in most of their behavior, generally using violence to solve their problems. On the other hand, they are often charming and manipulative, especially in their relationships outside the marriage. They often exhibit low self-esteem, feelings of inadequacy, and a sense of helplessness, all of which are generally made worse by the prospects of losing their wives. It is typical behavior for male batterers to exhibit contempt for women in their usual activities. Therapy is usually ineffective and seems to work only when the man can be made to give up violence as his primary means of solving problems.

Once the physician discovers that a woman is living in an abusive relationship, it is important to acknowledge to the patient the seriousness of the situation. To do otherwise is to give the impression that the physician approves or at least accepts the violent condition. It is important to attend to the patient’s injuries and to assess the patient’s emotional status from the standpoint of a psychiatric condition such as a suicidal ideation, depression, anxiety, or signs of abuse of drugs, alcohol, or other medications. The physician should also attempt to estimate the woman’s ability to assess her own situation and her readiness to take appropriate action. If problems involving mental illness are present, a referral to an appropriate mental health worker who is sensitive to the issues of domestic violence should be made. Physicians should determine community resources available for handling family violence. The police department, crisis hotline, rape relief centers, domestic violence programs, and legal aid services for abused women can offer help in the acute situation. Hospital emergency rooms and shelters for battered women and children are also excellent resources. Health care workers in these organizations or private practitioners who specialize in the care of battered women, their spouses, and their children can offer counseling and follow-up care. Such individuals may be social workers, psychologists, psychiatrists, or other mental health workers trained specifically for this purpose. The physician’s job is to recognize the problem and either offer counseling or get counseling for the patient so that she understands her rights and alternatives and learns to protect herself and her children from future harm. The victim of abuse likely will not wish to leave her home because of economic concerns and a fear that the batterer may continue to pursue her. Although she may have the batterer arrested and served with restraining orders, she may be convinced that she and her children cannot be protected from the batterer. She may also believe that there is a possibility of reconciliation and of change in behavior on the part of the batterer. It is therefore reasonable to discuss an exit plan with the victim to be used should the violence recur. This exit plan should include the following:

1. Have a change of clothes packed for both her and her children including toilet articles, necessary medications, and an extra set of keys to the house and car. These can be placed in a suitcase and left with a friend or family member.
2. Keep some cash, a checkbook, and a savings account book with the friend or family member.
3. Other identification papers, such as birth certificates, social security cards, voter registration cards, utility bills, and

driver's license, should be kept available, because children will need to be enrolled in school and the woman may have to seek financial assistance.

4. Have something special, such as a toy or book, for each child.
5. Have financial records available, such as mortgage papers, rent receipts, and an automobile title.
6. Determine a plan on exactly where to go regardless of the time of day or night. This may be to a friend or relative's house or to a shelter for battered women and children.
7. Ask neighbors to call police if violence begins.
8. Remove weapons.
9. Teach children to call 9-1-1.

Rehearsing an exit plan as one would conduct a fire drill makes it possible for the battered woman to respond even under the stress of the battering. Long-term aid and referral of the patient, her children, and the batterer to the appropriate resources is an important aspect of the care of such patients. The American College of Obstetricians and Gynecologists has prepared a patient education brochure that physicians can keep in their offices and give to individuals who suffer from this problem. Making the brochures available in the office waiting room may encourage women with these needs to get help.

These women often suffer from severe psychiatric problems, such as anxiety, depression, posttraumatic stress disorder (PTSD), and other pathologic conditions that may require psychotherapy. Women who are both physically and sexually assaulted have significantly higher levels of PTSD compared with women who are physically abused only. However, women who suffer any abuse, including emotional abuse without physical or sexual abuse, have a higher rate of mental health problems, including postpartum depression. Group counseling or individual counseling may also help them to rebuild their lives as single individuals or single parents. It is frequently necessary to help them develop a skill that will enable them to be employable. Counseling programs take these things into consideration. Children of victims who may be victims as well also require counseling to avoid behavior patterns that will lead to aggressive behavior in their later lives.

Intimate partner violence is a common problem that affects the family unit in particular and society in general. It can occur in all segments of society and reflects the violence that is a part of life today and the behavior of many. Physicians should learn to detect its presence in their patients and offer ways the victim can seek help. The help may include counseling for the victim, batterer, and children or constructing a plan for the woman to exit the relationship and rebuild her life in safety. There are many possible barriers for physicians screening for IPV and acting on their suspicions (Box 9.17). Ferguson's 2010 presidential address about IPV gave multiple recommendations regarding clinical practice, education and training, and research needs in this area in hopes of "ending this blight against women."

If the male batterer has not undergone anger management therapy, family counseling or intervention can be extremely dangerous, as it often raises issues that exacerbate the violence and increase the risk of serious harm to the woman and her children. Therefore this should not be advised until such time as the male batterer has addressed and eliminated his violent behavior. In general, success in such attempts with respect to the male partner is usually minimal.

Although all states have requirements for reporting child abuse, not all states require the reporting of domestic violence.

However, many states have aggressive programs for intervening in domestic violence cases, and physicians should become aware of the programs in effect in their area. The patient should always be encouraged to leave a violent situation and may need community resources to help with economic and social adjustment, as well as protection for herself and her children from the violent partner. The American College of Obstetricians and Gynecologist's website has a page on resources for violence against women and lists each state's coalitions for sexual assault and domestic violence (www.acog.org/departments/dept_web.cfm?recno=17).

The Elderly

The Select Committee on Aging, in investigating domestic violence against the elderly, held hearings before the Subcommittee of Human Services of the House of Representatives in 1980. The committee noted that approximately 500,000 to 2.5 million cases involving abuse of the elderly occur per year in the United States. The committee documented that abuse of the elderly may be as large a nationwide problem as child abuse. Usually, the abused person is a woman older than age 75, often with a physical impairment. She is generally white, widowed, and living with relatives. The abuser is generally an adult child living within the family but may also be a spouse. Counseling issues involve the entire family but particularly the individual causing the abuse. Physicians who care for geriatric patients should be alert for signs and symptoms of this type of domestic abuse; when it is found, community resources should be activated. All 50 states have passed legislation protecting the elderly from domestic violence and neglect. Forty-two states have mandatory reporting laws.

GRIEF AND LOSS

The term *grief* is usually used to refer to the emotional, behavioral, and functional response to the death of a loved one. However, many people experience symptoms of grief in

Box 9.17 Possible Barriers to Physician Screening for Intimate Partner Violence (IPV)

Belief that "someone else will take care of it"
 Forgetfulness
 Not a physician's responsibility/role
 IPV "should be private"
 "Cannot offer much"
 Lack of scientific evidence that screening improves outcomes
 Cynicism: "nothing will happen"
 Legal entanglement
 Worry about offending/angering patients
 Screening will take too much time
 Insufficient training
 Uncertainty about training requirements
 Uncertainty about legal implications if screen is positive
 Uncomfortable discussing issues of IPV
 "Do not need to ask; the patient will volunteer the information"
 Beliefs about victims of spouse abuse
 Fear of retaliation against patient
 Frustration over lack of patient disclosure
 Not scientific, "sexy"

From Ferguson JE 2nd. Why doesn't SOMEBODY do something? *Am J Obstet Gynecol.* 2010;202(6):635-643.

response to losses other than death, such as losing a marriage, a job, one's health, or hope of having children, as in infertility. Gynecologists are likely to see women at times of uncomplicated grief, complicated grief, or grief-related major depression. Recognizing when a grief reaction is following an expectable course, as opposed to being complicated or involving major depression, is important in ensuring that the woman receives needed treatment.

Uncomplicated or "normal" grief has been postulated to follow defined stages, including initial numbness or shock, then sadness and depression, reorganization, and recovery. However, the literature suggests that grief experiences vary significantly among different cultures, people, and individual losses, often with intermingling of different "stages" of grief at the same time. Grief is currently thought to be a process with a wide spectrum of individual responses and a variable course, including not only painful feelings but also positive emotions and memories.

Shear (2015) has reviewed the nature of uncomplicated grief, complicated grief, and grief-related depression. Acute grief occurs early after the loss, is intensely painful, and includes sadness, longing, preoccupation with thoughts of the deceased or of the loss, disturbed sleep and appetite, trouble concentrating, and separation from and lack of interest in other people and usual activities. Bereavement may include benign hallucinations, such as hearing the voice, seeing, or sensing the presence of the deceased. Such experiences are normal and not of clinical concern. The loss of a loved one is associated with heightened risks of health problems such as myocardial infarction and Takotsubo (stress) cardiomyopathy, as well as depression, anxiety, and substance use disorders. Within a few months, acute grief gives way to integrated grief, a state in which the deceased or what has been lost is thought of often with sadness, but the woman is not preoccupied and can once more participate in pleasurable and meaningful activities and relationships. Triggers, including birthdays, anniversaries, or situations that remind her of the loss, may precipitate waves of grief, which gradually become less intense and less frequent over time. Uncomplicated grief does not require formal treatment, but instead gradually lessens with the support of family, friends, and community such as church and clergy; reassurance; information about the expected course of grief; and sometimes the help of support groups.

Complicated grief, or prolonged grief disorder, occurs in about 10% to 20% of people who lose a romantic partner and is more common than this with the death of a child. It is more likely when the death is sudden or violent (e.g., homicide or suicide). Symptoms include intense pain and longing, difficulty accepting the loss, anger, intrusive thoughts and ruminations, guilt, feelings of estrangement from other people, and suicidal thoughts. Risk factors include a history of mood and anxiety disorders, multiple losses, adverse life events, and other stressors reducing the woman's ability to cope. Complicated grief requires treatment to avoid becoming chronic and unremitting. Treatment should include psychotherapy and often also antidepressant medication.

Acute grief is commonly associated with symptoms that meet the criteria for major depression; 40% to 50% of bereaved people meet criteria at 1 month, about 20% to

25% at 2 months, and about 16% at 1 year (Zisook, 2009). There is considerable controversy about when to treat major depression occurring in the context of bereavement, especially because bereavement-related depression is similar in clinical characteristics, course, and treatment response to major depression occurring after a range of other stressors or without any identifiable trigger. Women with a past history of depression, or moderate to severe depressive symptoms as part of grief, should be treated aggressively, even in the first month or two after the loss, with antidepressant medication and psychotherapy, whereas those with milder depression can be monitored or referred for psychotherapy alone.

Obstetricians and gynecologists may need to counsel patients experiencing grief related to several areas of reproduction, including spontaneous abortion, perinatal loss, and infertility. About 15% of pregnancies end in miscarriage. Following a miscarriage, a woman may experience sadness, guilt, anger, posttraumatic stress disorder (PTSD) symptoms, and anxiety about future pregnancies. Men are also affected, although they tend to talk less about their feelings and may feel that they need to be strong to support their partner. In most cases, there is little discussion within the couple about the loss. A miscarriage most commonly represents the loss not of an established relationship but of hopes and expectations for the future, including pregnancy and motherhood. Despite this difference in the nature of the loss, the feelings of grief after miscarriage resemble those that may arise after losing a loved one, and the course of recovery is similar to that of other types of grief (Brier, 2008). Acute symptoms usually lessen significantly within about 6 months or sooner if the woman becomes pregnant again.

Several studies have examined psychological interventions after miscarriage. For example, Swanson and associates (2009) studied 341 couples, randomized to four different interventions at 1, 5, and 11 weeks after the miscarriage. Interventions were couples-focused counseling by a nurse in the couple's home for three sessions, a set of three video and workbook modules, a combination of one nurse counseling session with the three-video and workbook modules, and no intervention. All interventions used previously established models, Swanson's Caring Theory and the Meaning of Miscarriage Model, took a supportive approach, and focused on discussing the miscarriage, losses and gains resulting from the miscarriage, sharing the loss and rejoining public life, "getting through it," and trying again. The most effective intervention overall, for both depression and grief, was the three sessions of counseling by the nurse. In the absence of this resource, the obstetrician-gynecologist can help the patient and couple by normalizing feelings of depression and grief, giving the expectation that these will resolve, but also monitoring carefully for more severe or persistent symptoms of depression, PTSD, or suicidal thoughts indicating a need for referral for mental health treatment.

Perinatal loss, or stillbirth, occurs in 1% or less of pregnancies. In the weeks following a stillbirth, women commonly experience sadness, irritability, feelings of guilt, physical symptoms, depression, and anxiety, characteristic of grief; 20% continue to have symptoms a year later (Badenhorst, 2007). Women with poor social support or preexisting mental health problems are at higher risk for more intense and

prolonged grief. PTSD is reported in about 20% of women during the next pregnancy, and women who hold their dead baby are at higher risk. Fathers also experience similar symptoms of grief after a stillbirth, experience anxiety and PTSD with the next pregnancy, and are also reported to have a higher risk of subsequent PTSD if they hold the dead baby. Loss of a baby may cause relationship strain or breakup, especially if the intensity or timing of grief differs significantly between the two parents. In addition, siblings may, depending on their age, be confused about what has happened, feel that they are to blame, or feel loss. Parents preoccupied by their own grief may have difficulty recognizing or helping their other children with these feelings.

Recommendations for clinicians include giving the woman and her partner clear information about what is going wrong and what is being done, involving the parents in decision making as possible, ensuring that the woman has access to postpartum medical care (e.g., suppression of lactation, contraception, help with gynecologic and sexual problems), and holding a meeting 1 to 2 months later to review what is known about the cause of the baby's death and to answer questions regarding future pregnancies. Couples are commonly advised, at the time of the loss, to create memories of the child, including holding the dead baby, giving the baby a name, taking photographs, and having a funeral. Many parents may want this and find it very important. However, especially holding the dead baby has been associated with poorer psychological outcome, increased rates of PTSD in the next pregnancy, and poor attachment to the subsequent baby. Couples may benefit from support groups, and those women or their partners who experience more severe or persistent depression, grief, anxiety, PTSD, or suicidal thoughts should be referred for mental health treatment with psychotherapy and medication, as indicated.

A special counseling challenge involves the care of a woman with an unplanned pregnancy. Such individuals often suffer conflicting feelings, which may include shame and guilt, a genuine desire to have a child, fear of social and family consequences, and fear for their own future and physical well-being. In addition, they may suffer from guilt about the termination of pregnancy if abortion is considered. Although many such women have good social support (e.g., family, significant others, friends, and religious counselors), others will rely on the physician for advice and direction. The physician should discuss all possible options with the woman, including having and raising the child, offering the child for adoption, or terminating the pregnancy. Issues involving the role of the baby's father, the effect of any decision on the future life of the woman, and the risks of procedures should be considered. The woman should be aided in reaching the most appropriate decision for her circumstances and supported in carrying out her decision. When necessary, appropriate referrals to social agencies (e.g., adoption, abortion counseling, or welfare services) should be made. The woman may experience depression, anxiety, or grief in this situation, even when making what she thinks is the best decision possible.

The inability to have a child, or infertility, affects about 1 in 10 couples and can precipitate feelings of isolation, inadequacy, poor self-esteem, guilt, anger, loss of control over one's life, depression, difficulty being around pregnant women or couples with young children, changes in one's identity and sense of

meaning, and relationship strain. Infertility treatment involves significant cost, medical treatments and procedures, and psychological stress. Among women presenting for infertility treatment in one study, 40% met criteria for a psychiatric disorder, including 23% with an anxiety disorder and 17% with major depression (Burns, 2007). Failed infertility treatment engenders further stress and depression. Psychological distress has been reported to be the primary reason for dropout from infertility treatment, and pretreatment depression is predictive of dropout after one in vitro fertilization (IVF) cycle. There is some evidence that higher levels of psychological stress are associated with lower success rates of infertility treatment. Only about 50% of couples have a child as a result of infertility treatment, and those not succeeding commonly experience a grief reaction.

Many infertile women gain information and support from the Internet, although using this as one's sole source of support has been linked with higher levels of psychological distress. Women and their partners may benefit from support groups or individual or group psychotherapy. Interventions proved effective in reducing distress, and in some studies in improving conception rates, include cognitive behavioral therapy, ongoing counseling and education throughout the infertility treatment process, relaxation, stress management, coping skills, and group support. Cognitive behavioral therapy and fluoxetine have been shown to reduce both distress and depressive symptoms in mildly to moderately depressed infertile women (Faramarzi, 2013). Women with severe depression, grief, or suicidal thoughts should be referred for evaluation and antidepressant or other psychotropic medication treatment.

DEATH AND DYING

Gynecologists, especially gynecologic-oncologists, care for women who are dying. There are several challenges for physicians caring for dying patients. First, physicians have been shown to be optimistic and inaccurate in their prognoses for terminally ill patients and to overestimate their ability to combat disease. This makes it difficult to know when to shift the conversation with a patient from a focus on cure or fighting the disease to a focus on palliative care. Making this transition may be difficult for the physician, who does not wish to give up hope prematurely. On the other hand, most patients are very concerned about issues of quality of life in confronting dying and hope for a process in which they can retain dignity, feel like themselves as much as possible, have adequate time and opportunity to put their "house in order," and have maximal possible comfort and pain relief. It is important for physicians to help women by discussing with them issues of "do not resuscitate" (DNR) orders, treatment of pain, referral to hospice, and other end-of-life issues. In fact, introducing palliative care discussions earlier in treatment appears to be helpful. For example, in a study of 151 patients with metastatic non-small-cell lung cancer, patients randomized to early palliative care integrated with oncologic care had a better quality of life and mood, less aggressive care at the end of life, and longer survival (Temel, 2011).

Psychological issues for dying patients are highly variable, depending on the person's stage of life, sense of the meaning of her life and of the illness, coping style, relationships and family

support, spiritual beliefs, and economic circumstances. Feelings of grief, sadness, despair, fear, anxiety, and loneliness are present at some stage for nearly all dying patients, but some are able to achieve a high degree of equanimity and acceptance.

Developmentally, young adults with terminal illness commonly struggle with anger about the unfairness of the illness, grief and loss about life experiences they will not have, and issues related to being dependent on their parents for care. Parents of young children are concerned about the impact of their illness and death on their children, losing the opportunity to see their children grow up, and how to maintain a normal life and routine for their children and family in the face of their illness. For women in later stages of life, feelings about death depend on the degree of satisfaction and meaning that they feel with their life and what they have done, the kinds and quality of attachments they have, whether they feel robbed of retirement and later life, and whether they have lost their spouse or intimate partner already.

Block (2006) provided a comprehensive overview of psychological issues faced by dying patients and ways to explore with them issues related to the meaning of the illness, meaning of their life and achievements, spirituality, relationship issues, other life stressors, maintaining a sense of self, and fears and hopes that the patient has. Terminally ill patients benefit from the treatment of depression or anxiety states, in order to improve the quality of the remainder of their lives. Dying patients also benefit from psychological interventions, including listening, the opportunity to share feelings, and the chance to reflect on past experiences and future hopes. The gynecologist can help a dying woman by maintaining an engaged, genuine relationship with the woman as an individual throughout the dying process, helping the woman and family to anticipate and address practical issues such as enrolling in hospice and other palliative care services, and maximizing comfort and pain control.

KEY POINTS

- Depression, anxiety disorders, obsessive-compulsive disorder, and posttraumatic stress disorder are treatable with medications or psychotherapy.
- A history of manic or hypomanic symptoms increases the risk for a “switch” into mania with antidepressant treatment.
- Close follow-up, in 1 to 2 weeks, is recommended to monitor for increases in suicidal thoughts with antidepressants, especially in adolescents and young adults.
- Active suicidal thoughts and plans are a psychiatric emergency.
- Eating disorders are life-threatening conditions that are often unrecognized.
- Girls or women presenting with amenorrhea, menstrual dysfunction, low bone density, sexual dysfunction, infertility, anxiety, depression, or hyperemesis gravidarum should be screened for eating disorders.
- Women with anxiety disorders (especially panic disorder and posttraumatic stress disorder) are at increased risk for suicide and should be asked about suicidal thoughts or plans.
- Anxiety disorders respond well to reassurance, education, and treatment with psychotherapy and medications (especially SSRI antidepressants).
- Many substance use disorders, such as alcoholism, have a more rapidly progressive course in women than in men (“telescoping”).
- More than two drinks per day on average is considered heavy drinking for a woman.
- Motivational interviewing is a highly effective, brief intervention that increases women’s engagement in substance abuse treatment and other behavior change.
- In cases of misuse of potentially habit-forming medications, a formal treatment agreement may be necessary.
- Understanding attachment styles can help providers to work effectively with “difficult” patients.
- Nonpharmacologic treatments for hypoactive sexual desire disorder include lifestyle changes for reducing stress and fatigue, recognizing and treating depression, increasing quality time with the partner, improving body image, and bringing novelty into the sexual repertoire.
- Lesbian and bisexual women require routine gynecologic care, have a high rate of mental health and substance use problems, and prefer female, preferably lesbian, health care providers.
- Lesbian and bisexual women have an elevated rate of mental health problems, substance use disorders, and suicide attempts, especially during adolescence.
- Intimate partner violence crosses all ethnic, racial, educational, age, and socioeconomic lines and has a large burden of social, physical, mental, and public health implications.
- The physician has a responsibility to screen and acknowledge intimate partner violence and abuse, identify the community resources for immediate referrals, assess safety, assist with reporting if necessary or desired, document appropriately using medicolegal tools, and provide ongoing clinical care.
- Gynecologists are often called on to provide or refer women for counseling related to grief; losses such as miscarriage, perinatal loss, and infertility; and end-of-life issues.
- Women suffering losses as a result of miscarriage, perinatal loss, unplanned pregnancy, or infertility benefit from support, counseling, and screening for depression and posttraumatic stress disorder.
- Complicated grief and grief accompanied by symptoms of depression benefit from antidepressant medication treatment in addition to psychotherapy.
- Women with terminal illness benefit from an engaged, genuine relationship with physicians and other health care providers, treatment of depression and anxiety states, psychological interventions and psychotherapy, and early integration of palliative care into treatment.

Endoscopy: Hysteroscopy and Laparoscopy Indications, Contraindications, and Complications

Sarah M. Carlson, Jay Goldberg, Gretchen M. Lentz

This chapter presents an overview of frequently used endoscopic procedures in gynecology. Indications, contraindications, and complications are included for each procedure. For those unfamiliar with the procedures, the diagnostic uses are described. Therapeutic uses and pitfalls are introduced, but complex surgical procedures are better covered in focused gynecologic surgical textbooks.

Since the 1960s, there have been significant changes in the use of endoscopy in gynecologic practice. The fiberoptic bundle and more versatile light sources, as well as the incorporation of advances in technology, have dramatically increased the diagnostic and therapeutic capabilities of the hysteroscope and laparoscope.

The tremendous advances in technology have led to the emergence of more office-based procedures. Many gynecologic surgeries done by laparotomy in years past have been converted to ambulatory, outpatient procedures. Other cases traditionally completed only by laparotomy are now more likely to be performed laparoscopically with shorter hospital stays and recovery time. This chapter serves as an introductory overview of gynecologic endoscopy.

HYSTEROSCOPY

Hysteroscopy is the direct visualization of the endometrial cavity via the cervix using an endoscope and a light source. The earliest hysteroscope was nothing more than a hollow tube with an alcohol lamp and mirror for a light source. In 1869, Panteleoni reported the successful removal of an endometrial polyp through the scope. Modern hysteroscopes are modifications of cystoscopes with channels to introduce light via fiberoptics. Various infusion media are used for uterine cavity distention, which is necessary for inspection. Many surgical instruments and devices are available for diagnostic biopsy and pathology removal and therapeutic procedures. Office and operating room hysteroscopy requires knowledge of instrumentation, techniques, indications, contraindications, and complication management. If office hysteroscopy is used, proper office safety protocols are needed. Unfortunately, many physicians do not have the equipment and staffing available to perform hysteroscopy in the office.

Inserting a hysteroscope for diagnostic purposes only is a low-risk procedure. The key is predicting which diagnostic procedures may be challenging from severe cervical stenosis or which complex operative hysteroscopic procedures may be more safely accomplished in the operating room setting. Office hysteroscopy saves time for both the patient and physician, saves money, and is convenient. It makes sense when performing hysteroscopic procedures in the office to initially gain experience with simpler surgeries. Once expertise has been gained from sufficient operative hysteroscopic procedural volume, the more involved and challenging hysteroscopic procedures can be moved from the operating room to the office setting.

HYSTEROSCOPIC INDICATIONS AND CONTRAINDICATIONS

The popularity of hysteroscopy has grown because it is a simple technique that most gynecologists are trained to perform. It is most frequently used in the evaluation of abnormal uterine bleeding for both pre- and postmenopausal women. Women with recurrent abnormal uterine bleeding, particularly postmenopausal patients with persistent bleeding following a negative endometrial biopsy, are good candidates for hysteroscopy. Endometrial biopsy and dilation and curettage (D&C) procedures frequently miss focal lesions and pedunculated structures. One study (Feldman, 1994) evaluated 286 women with perimenopausal bleeding who had had a D&C or an endometrial biopsy. Nine of 86 (10.5%) who had negative findings initially, but continued to bleed, had carcinoma or complex hyperplasia on follow-up biopsy. Hysteroscopy with directed biopsy can be useful in this setting, although controversy exists regarding the spread of endometrial cancer with hysteroscopy. Hysteroscopy can also assist in directly visualizing and removing intrauterine foreign bodies like a partially perforated or broken intrauterine device (IUD) or retrieving an IUD with missing strings. Other indications include performing hysteroscopic sterilization, evaluation of recurrent miscarriage, uterine synechiae, abnormal hysterosalpingography (HSG) or sonohysterography, and infertility. More involved operative procedures include resection of submucous myomas, lysis of synechiae, incision of uterine septa, and removal of endometrial polyps or ablation of the endometrium. Box 10.1 lists common indications.

There are few contraindications to hysteroscopy. Absolute contraindications include acute pelvic or vaginal infections including genital herpes, because of the potential for disease spread by the distention media. One exception may be for the retrieval of an IUD if the pelvic infection is related to the device. Pregnancy is a contraindication, as is recent uterine perforation. Active bleeding is a relative contraindication. If the bleeding is brisk, the hysteroscopic view might be unsatisfactory. Other relative contraindications include extensive adhesions and leiomyomata that are largely (>50%) intramymometrial rather than submucous. Cervical and uterine cancers are cited as absolute contraindications. There continues to be debate over risking endometrial cancer dissemination into the peritoneal cavity by pushing endometrial cancer cells out the fallopian tubes with the distending media. A 2010 systematic review by Polyzos and colleagues found hysteroscopy resulted in a significantly higher rate of malignant peritoneal cytology (odds ratio 1.78) when done before surgery and therefore disease upstaging, although it is unclear if the outcome is adversely affected. Gynecologists are often doing hysteroscopy to discover the etiology of abnormal bleeding, and the diagnosis of endometrial cancer is sometimes made as a result.

Box 10.1 Possible Hysteroscopic Indications

Abnormal uterine bleeding
 Premenopausal
 Postmenopausal
 Persistent abnormal uterine bleeding after negative endometrial biopsy
 Postmenopausal endometrial thickening and negative endometrial biopsy
 Endometrial polyp
 Submucosal myoma or possibly <50% intramural
 Uterine septum
 Uterine synechiae
 Retained IUD
 Sterilization
 Endocervical lesions

HYSTEROSCOPIC EQUIPMENT AND TECHNIQUES

Rigid hysteroscopes vary in diameter. The smaller caliber scopes, 3 to 5 mm in diameter, are used for diagnostic purposes. Several are available that have views from 0 to 70 degrees, but those with views of 12 to 30 degrees are most commonly used. Similar to a cystoscope, the outer sleeve of a rigid hysteroscope contains several channels that extend the full length of the instrument. Figure 10.1 shows the anatomy of a hysteroscope and names of the various sections. For office hysteroscopy, often a 4-mm telescope with a 7-mm outer sheath is used, so there is a channel for seven French flexible or semirigid instruments such as scissors, or biopsy or grasping forceps. The outer sheath also allows for inflow of the distending media. Although a 5-mm hysteroscope often passes without cervical dilation, a 7-mm diameter scope usually does not. Large scopes, with diameters of 8 to 10 mm, may be used for high flow of distending media and have a second channel for outflow of blood and fluid. These are used for moderate to complex procedures. Flexible minihysteroscopic instruments and microendoscopes are convenient and well tolerated in the office for diagnostic and simple operative procedures such as directed biopsies. There is generally less pain with the small flexible hysteroscopes, but the visual quality is poorer. They do allow more ease when lysing intra-uterine adhesions in difficult locations (Fig. 10.2).

The cavity of the uterus is a potential space. The success of hysteroscopy depends on the media used to expand this space. Many distending media are available, including 32% dextran 70, which is highly viscous; 5% dextrose and water (D₅W), which has low viscosity; 1.5% glycine; Ringer's lactate; normal saline; and carbon dioxide gas. The surgeon must know which is ideal for the particular case and instrumentation and the potential risks (Table 10.1). High-molecular-weight dextran (average molecular weight, 70,000 Da in 10% glucose) is extremely viscous fluid and is biodegradable, nontoxic, nonconductive, and has good optical qualities. Most important, dextran is immiscible with blood, which helps to keep the field clear during intrauterine surgery, especially when there is active bleeding. Dextran has two drawbacks: it is antigenic, and anaphylaxis has been

Figure 10.1 Anatomy of a rigid endoscope. (From Beiber EJ, Sanfilippo JS, Horowitz IR. *Clinical Gynecology*. Philadelphia: Elsevier, 2006.)

reported. It also rapidly crystallizes; thus endoscopic instruments must be cleaned shortly after the procedure. It is sticky to work with and can lock the valves. Rare cases of pulmonary edema and coagulopathies from intravascular dextran have been reported. Dextran can osmotically draw fluid many times its own volume into the intravascular space if extravasation occurs. A different distention medium is recommended if one predicts that greater than 500 mL of dextran will be needed. Carbon dioxide must be infused with special equipment (not a laparoscopic insufflator) that carefully limits flow to less than 100 mL/min and maintains the pressure at approximately 60 to 70 mm Hg. Because no fluid is involved, there is no mess. If the patient has patent fallopian tubes, the CO₂ gas can cause diaphragmatic irritation and discomfort. The major precaution with D₅W is the monitoring of total fluid intake so as not to produce water intoxication. In contrast, office hysteroscopy with the smaller flexible scopes most commonly incorporates the use of saline or lactated Ringer's solution because either is easier to use, causes less pain, and avoids the risk of electrolyte and osmolar imbalances. For operative hysteroscopy, it is necessary to carefully and frequently

Figure 10.2 Flexible hysteroscopy. Uterine distention is maintained with normal saline or lactated Ringer's solution injected through intravenous extension tubing. (From Goldberg JM, Falcone T. *Atlas of Endoscopic Techniques in Gynecology*. London: WB Saunders; 2000:185.)

monitor the intake and outflow of distention media. Fluid management systems are available that calculate these values continuously. Guidelines exist for terminating a procedure when fluid deficits reach a set amount. For nonelectrolyte media, the recommended cutoff is 1000 to 1500 mL; for an electrolyte medium it is 2500 mL, but other factors should be considered such as age, comorbid conditions, cardiovascular disease, and patient body mass index. For operative procedures with electrocautery, saline or isotonic solutions cannot be used because they conduct electricity (except bipolar cautery).

Hysteroscopy techniques are fairly similar whether performed as an office procedure or in an operating room. A list of general equipment needed for office hysteroscopy is given in [Box 10.2](#). A complete history and physical exam is needed; in particular, a relevant allergies and medication list must be confirmed. Appropriate tests may include a Papanicolaou smear, pregnancy test, hemoglobin or hematocrit testing, and gonorrhea or chlamydia testing. Hysteroscopy can be performed at any time during the menstrual cycle, but it is best scheduled in the early to middle proliferative phase. Endometrial pretreatment with hormonal agents may be considered prior to hysteroscopic sterilization procedures, hysteroscopic myomectomies, resectoscopic ablations, and nonresectoscopic ablations. Thinning the endometrium facilitates visualization and may aid in tissue destruction during an ablation. A bimanual examination is performed to note the size of the uterus and direction of the uterine fundus. Knowing whether the uterus is anteverted or retroverted is important to avoid uterine perforation, and a rectovaginal exam can aid in determining position. It is helpful to explain to the patient that she will experience discomfort if cervical dilation is needed and uterine cramping during the short time that the hysteroscope is inside the uterus. A single-toothed tenaculum may be used to secure the anterior cervical lip. Gentle traction on the tenaculum straightens out the uterine axis to facilitate endocervical passage of the instruments. Techniques have been described for diagnostic hysteroscopy with a small scope diameter than do not utilize a tenaculum and thus avoid causing that pain. The exocervix is then cleaned of mucus and bacteria. Many physicians will cleanse the cervical os with an iodine solution prior to introducing the scope. The most frequent problem in performing hysteroscopy is cervical stenosis or spasm. When this is encountered, the optimal method to relieve pain and overcome resistance is a

Table 10.1 Comparison of Hysteroscopic Distention Media

Medium	Advantage	Disadvantage	Risk
CO ₂	Safe Ease of use Rapidly absorbed	Poor visibility in the presence of bleeding	
Normal saline	Isotonic	Not suitable for monopolar electrosurgery	Fluid overload
Lactated Ringer's	Electrolyte free	Hypotonic	Hypotonic fluid overload
Glycine 1.5%	Nonconductive		Hyponatremia
Sorbitol			Hypertonic fluid overload
Mannitol 5%			Anaphylactic reaction
Hyskon (32% dextran)	Nonconductive Immiscible with blood	Difficult to deliver

Box 10.2 Equipment for Office Hysteroscopy

- Procedure table that elevates to 46 to 48 inches
- Comfortable behind-the-knee padded stirrups
- Open-sided speculum
- Paracervical block equipment
- Tenaculum
- Hysteroscope with 4-mm diameter and fore-oblique 25- to 30-degree lens
- Diagnostic sheath of 5 mm
- Operative sheath of 7 mm
- Flexible or semirigid scissors and biopsy and grasping forceps
- Rigid scissors and biopsy and grasping forceps
- Ring forceps
- Myoma grasping forceps
- Emergency kit
- Foley catheter with 30-mL balloon

paracervical block with 1% lidocaine. Liberal use of paracervical block in difficult procedures allows the physician to be successful in obtaining endometrial biopsy tissue in more than 95% of cases, so this is likely true for hysteroscopy as well. Subsequently, the cervix can be dilated with tapered plastic or metal dilators, and the hysteroscopy can be completed. Unlike with larger rigid scopes, most patients will not require anesthesia for diagnostic procedures in the office. The infusion line should be flushed through the scope prior to insertion; otherwise bubbles will be introduced and obscure the view.

When inserting the hysteroscope, it is useful to wait a few seconds to let the distending media open the internal cervical os so that the uterine cavity can be entered more easily by following the fluid flow. Then angle of the telescope view is opposite the direction of the light post. This point must be remembered in the context of viewing an anteverted versus retroverted uterus. If the light post is pointing upward, the view is downward. If uterine cavity vision is obscured, it may be due to insufficient distention fluid, bleeding, or being up against the uterine wall or pathology. Withdraw the hysteroscope slowly while slightly increasing the distention fluid. Never advance the hysteroscope without good visualization because perforation can occur. The cavity should be inspected thoroughly and systematically. First, an overall view can be seen on entry looking for the general cavity shape, polyps, myomas, and foreign bodies. As the hysteroscope is advanced, it is rotated clockwise and counterclockwise to see the cornua and tubal ostia. On removal, endocervix is viewed. Overzealous cervical dilation can create a poor seal between the cervix and scope, allowing the fluid to run out of the cervix and poor uterine distention. Short-term complications are listed in [Table 10.2](#).

Vaginal and oral misoprostol (prostaglandin E₁) given the night before the procedure, in dosages of 200 to 800 mcg can aid in the transcervical passage of the hysteroscope. This can be useful for women at risk for cervical stenosis such as those with prior cervical surgery and nulliparous women. In postmenopausal women, pretreatment with vaginal estrogen for 2 weeks before

surgery may augment the cervical dilation caused by misoprostol. Women should be warned of the side effects of misoprostol, including diarrhea, cramping, uterine bleeding, and fever. Concomitant nonsteroidal anti-inflammatory drugs (NSAIDs) can reduce side effects and help with postoperative pain. Anxious patients may be pretreated with an anxiolytic such as alprazolam. For more involved procedures, intravenous analgesia and conscious sedation may be needed, and proper protocols are needed to ensure patient safety. If extensive resections are anticipated via hysteroscopy, then the procedure is better performed on an outpatient basis in the surgical suite.

For the severely stenotic cervix, having the right instruments available is critical. Lacrimal duct dilators (from ophthalmologic surgery) come in graduated sizes down to 1 mm in diameter. This can lead to cervical access when barely a dimple is seen in the external cervical os. Then, the usual tapered metal or plastic cervical dilators can facilitate complete dilation. Also, real-time ultrasonography can help the surgeon to visualize the tip of the dilator, direct the surgeon along the right track into the endometrial cavity, and prevent the surgeon from making a false cervical path or uterine perforation.

OPERATIVE HYSTEROSCOPY TECHNIQUES

The variety and extent of surgery performed transcervically with the hysteroscope has expanded significantly with technologic advances. Endoscopic procedures have progressed from snaring small polyps to hysteroscopic tubal sterilization, complex myomectomies, and ablating the entire endometrial lining. The ability to detect, biopsy, or remove focal lesions is extremely useful for abnormal bleeding workup over blind endometrial sampling. Approximately 50% of all Essure hysteroscopic tubal occlusions performed in the United States are done in an office setting, and the percentage is rising. Operative hysteroscopy may be performed with mechanical devices such as small operating scissors, electrocautery, and modified resectoscopes and lasers. Laser hysteroscopy with carbon dioxide or neodymium:yttrium-aluminum-garnet (Nd:YAG) or argon lasers requires more expensive equipment and expertise. With the development of the second-generation technology for uterine ablation and polyp and fibroid resection, the laser and resectoscope equipment is significantly less popular and less advantageous than simpler techniques.

Women with repetitive miscarriages should have a diagnostic hysteroscopic procedure, which often leads to an operative procedure. Congenital abnormalities that interfere with the success of early pregnancies, such as septa of the uterus, may be seen and removed ([Fig. 10.3](#)). Often endometrial polyps or submucous myomas are discovered and may be removed with a resectoscope wire ([Fig. 10.4](#)) or a newer morcellator type device ([Fig. 10.5](#)). The uterine synechiae of a woman with Asherman's syndrome can be cut with microscissors, reestablishing the endometrial cavity. Because adhesions interfere with the configuration of the cavity, it can be difficult for the surgeon to identify usual landmarks. Simultaneous laparoscopy guidance is often used to avoid perforation when cutting the intrauterine adhesions. Hysteroscopic metroplasty of intrauterine septa has replaced abdominal metroplasty, as it is safer and has fewer complications than laparotomy. Simultaneous laparoscopy is often used with this procedure as well to gauge the end point of cutting the septum.

Table 10.2 Short-Term Complications of Hysteroscopy

Complication	Rate (%)
Overall Complication Rate	
Diagnostic hysteroscopy	0.95
Operative hysteroscopy	2 to 3
Hysteroscopic myomectomy	1 to 5
Uterine Perforation	
Operative hysteroscopy	1
Endometrial ablation—resectoscope	2 to 2+
Endometrial ablation—nonresectoscope	1
Fluid overload	0.06 to 2
Bleeding	0.03 to 3
Pelvic infection	0.01
Death—fluid overload or septicemia	0.01
Embolism; gas, air	*
Cervical laceration	*
Creation of false cervical passage	*
Failure to complete the procedure	*
Electrocautery injury	*
Urinary tract or bowel injury	*
Pulmonary and cerebral edema	*
Dissemination of cervical or endometrial cancer	*

*Rare complication or exact rate of complication unknown.

Figure 10.3 The loop is placed at the center of the apex of the septum. As the current is activated, the loop is advanced toward the fundus in small increments, always staying in the center of the septum. The septum separates, as it is divided so that no tissue must be excised. (There are small endometrial fragments in the right cornua and a small clot adherent to the left aspect of the septum.) (From Goldberg JM, Falcone T. *Atlas of Endoscopic Techniques in Gynecology*. London: WB Saunders; 2000:194.)

Figure 10.4 A uterine polyp with the hysteroscopic resection tool behind the polyp. (From Goldberg JM, Falcone T. *Atlas of Endoscopic Techniques in Gynecology*. London: WB Saunders; 2000:187.)

Hysteroscopy is superior to hysterosalpingogram (HSG) in discovering intrauterine disease. In comparative studies, the use of hysteroscopy revealed synechiae, polyps, or myomas in 40% of patients with normal HSGs. These abnormalities were undetected and unsuspected using radiographic techniques. The false-positive rate of HSG is 33% compared with hysteroscopy. One in three women diagnosed as having an intrauterine filling defect by x-ray imaging will have a normal cavity directly visualized with the hysteroscope. Women with amenorrhea and a history of curettage who do not respond to a hormonal challenge should have an HSG or hysteroscopy. Uterine synechiae are identified by slowly injecting a water-soluble medium on HSG or by the inability to visualize the uterine cavity on hysteroscopy. If a woman has synechiae, tubal obstruction on HSG, and pelvic calcifications, a diagnosis of pelvic tuberculosis should be strongly suspected. In women with a history of recurrent abortions or infertility with a uterine abnormality seen on ultrasound, sonohysterography (SHG) is comparable to HSG and hysteroscopy in detecting uterine anomalies, especially septate and bicornuate uterus (Ludwin, 2011). SHG has the benefit of being noninvasive, cost effective, and does not expose the patient to radiation.

Submucous myomas were initially removed with a modified urologic resectoscope using a cutting 40-watt electric current and a 90-degree wire loop for shaving the myoma until it was flat with the surrounding endometrial lining. The electrocautery led to bubbles obscuring the view and the potential risk of gas or air emboli. If unsuspected perforation occurred, the risk of thermal injury was present. Greatly improved instrumentation is available with a hysteroscopic rotary or reciprocating morcellator blade for removing polyps and fibroids. It does not use electrocautery and simultaneously cuts and aspirates the pathology so that there are no bubbles and no pieces of shaved tissue floating in the cavity. Saline is used as the infusion medium as no cautery is used, which lessens the electrolyte imbalance risk. The drawback without electrocautery is that more bleeding can occur. Studies have shown successful removal of the submucous myoma at the initial hysteroscopy being 85% to 95%. The success rate of complete resection at the initial surgery is higher with myomas that are nearly completely submucous versus fibroids with a significant intramural portion. The pregnancy rate is as good as or better with hysteroscopic myomectomy than with transabdominal myomectomy.

In women with abnormal bleeding or menorrhagia who are poor surgical candidates, desire a minimally invasive procedure,

Figure 10.5 Intrauterine polyp before (A) and after (B) hysteroscopic morcellation. (Courtesy of Dr. Howard Topel and Smith & Nephew.)

or wish to preserve their uterus, the endometrial lining may be ablated or resected through the hysteroscope (Fig. 10.6). Performance of endometrial ablation or resection has decreased due to the increased usage of the levonorgestrel intrauterine device. Although endometrial ablation and levonorgestrel IUD both provide comparable reductions in menstrual blood loss, the IUD also provides contraception and protects the endometrium in women at risk for hyperplasia and carcinoma. Pregnancy following an endometrial ablation is contraindicated, but the procedure does not prevent pregnancy. Sterilization or contraception should be addressed prior to ablation. In patients with abnormal uterine bleeding following endometrial ablation, evaluation of the endometrial cavity can be hindered due to scarring. The U.S. Food and Drug Administration (FDA) has approved five global endometrial ablation devices: thermal balloon endometrial ablation (ThermaChoice, Ethicon Inc., Menlo Park, CA), radiofrequency endometrial ablation (NovaSure, Cytac Surgical Products, Palo Alto, CA), hydrothermal endometrial ablation (HydroTermAblator, Boston Scientific, Natick, MA), cryoablation (Her Option, CryoGen Inc., San Diego, CA), and microwave endometrial ablation (Microsulis, Hampshire, England). The 2013 Cochrane database review concluded that endometrial ablation techniques offer a less invasive alternative to hysterectomies (Fergusson, 2013). All of the currently available nonresectoscopic endometrial ablation devices have limitations on acceptable endometrial cavity size and endometrial surface irregularities such as myomas. No gold standard system exists yet, as comparative studies have shown similar treatment efficacy with the available ablative systems. The second-generation devices compare favorably with the earlier used roller ball and wire loop resectoscope techniques, but they are simpler to use. Similar rates of amenorrhea and patient satisfaction have been reported, but ablation via a resectoscope is associated with longer operative times, more frequent use of general anesthesia and higher rates of irrigation fluid overload and cervical laceration compared with non-resectoscope modes.

Selective salpingography is an extension of hysteroscopy to evaluate the lumen of the fallopian tubes. The tube can be

Figure 10.6 Endometrial cavity prior to ablation with a roller ball. (From Goldberg JM, Falcone T. *Atlas of Endoscopic Techniques in Gynecology*. London: WB Saunders; 2000:197.)

cannulized and contrast instilled for confirming proximal tubal obstruction observed on HSG.

Hysteroscopic sterilization may be accomplished with insertion of coils in the tubal ostia. This is desirable, as no incision is needed as for laparoscopic sterilization, and it can be performed in the office. The Essure device has been FDA approved in the United States since 2002. Under hysteroscopic viewing, the Essure coil is placed in the proximal portion of the fallopian tube. Over time, chronic inflammation around the coil leads to tubal blockage. A follow-up HSG is needed in 3 months to make sure the tubes are indeed blocked. This procedure is not reversible. Short-term efficacy studies suggest a rate equal to or greater than other tubal sterilization methods.

The risk of infection following hysteroscopy is low. Prophylactic antibiotics are not routinely administered.

COMPLICATIONS

Complications of hysteroscopy are rare and are noted in less than 2% of the procedures. One study used a large database of 136,000 hysteroscopies and noted the significant complication rate to be 0.28% (Jansen, 2000). Complications included uterine perforation (0.12%), pelvic infection (0.01%), bleeding (0.03%), fluid overload from absorption of distending media (0.06%), and bladder or bowel injury (0.02%). Diagnostic hysteroscopy has a significantly lower complication rate than operative hysteroscopy (0.95%). The major complication of diagnostic hysteroscopy is uterine perforation, and office hysteroscopy has an incidence of 1 or 2 cases per 1000. Uterine perforation can be midline or lateral. Midline perforation rarely results in significant complications unless electrocautery or laser energy is used. Lateral perforation into the broad ligament can cause bleeding complications. Suspect uterine perforation if the operative view suddenly disappears, the fluid deficit suddenly increases, or the hysteroscope suddenly inserts farther than the fundus. Thermal injury to surrounding organs may occur with deep resections or perforations with the electrocautery instrument. If perforation is suspected during operative hysteroscopy, then an intraperitoneal evaluation may be performed either by laparoscopy or by laparotomy. Unrecognized uterine perforation might result in postoperative abdominal or pelvic pain beyond what is normally expected; abdominal distention, heavy vaginal bleeding, hypotension, nausea or vomiting or hematuria, or bowel injury, particularly thermal injuries, may present with delayed onset of symptoms and often go unrecognized.

Infection and postprocedure hemorrhage are rare. If bleeding is excessive, electrocautery coagulation at the bleeding point may be sufficient. If not, others have reported injecting dilute vasopressin at the bleeding point with caution to avoid intraarterial injection, which can result in hypertension, bradycardia, cardiovascular collapse, and even death. An inflatable 30-cc Foley balloon can be inserted via the cervix, inflated, and left for 12 to 24 hours to tamponade the uterine cavity, facilitating hemostasis. Some women develop a severe vasovagal reflex from cervical dilation and instrumentation of the uterine cavity that can result in syncope. This reflex can be diminished by giving the patient IV fluids or by performing a paracervical block. Use of the Trendelenburg position or having the patient lie supine with the legs raised can be beneficial in recovery.

Table 10.2 summarizes the complications with diagnostic and operative hysteroscopy.

The potential complications of the distending media include anaphylaxis to dextran, circulatory overload with D₅W, pulmonary and cerebral edema, hyponatremia, seizure, coagulopathies, and the potential of air or gas embolism with carbon dioxide. Monitoring of the patient's fluid status is important because of problems with absorption of distending media, leading to volume overload and electrolyte imbalance. Cardiac arrest has been reported with uterine insufflation with carbon dioxide when unmonitored amounts of gas were used.

Some long-term complications exist after endometrial ablation, including recurrent or persistent abnormal bleeding. In a 2013 Cochrane review comparing endometrial destruction with hysterectomy, both procedures were successful at achieving a satisfactory reduction in menstrual bleeding (Fergusson, 2013). Hysterectomy was associated with longer operative and recovery times, and patients were more likely to experience postoperative complications. Women who underwent ablation were more likely to require a future definitive surgery than those who initially had a hysterectomy. Older women have a higher success rate, because menopause occurs before the recurrent bleeding problems or obstructive symptoms occur. The inability to evaluate the endometrium if bleeding recurs and the risk of a delay in diagnosis of endometrial cancer are added concerns. Pregnancy following an endometrial ablation can occur and is often complicated by the intra-uterine scarring and contracture. This can result in abnormal placentation including placenta accreta or percreta, uterine rupture, higher spontaneous abortion rates, preterm delivery, ectopic pregnancy, and fetal limb malformations. Pain from obstructed menses can occur with hematometra or postablation tubal sterilization syndrome (Sharp, 2012). Residual areas of endometrium that are not ablated or regrown can lead to trapped bleeding within the uterine cavity, leading to retrograde bleeding or cornual or uterine hematometra. (Additional risks are listed in Box 10.3.)

The American College of Obstetricians and Gynecologists (ACOG) published guidelines in 2010 that contain a section on free-standing surgical units where many operative hysteroscopy procedures are performed. Care must be taken to ensure adequate training of personnel, knowledge, uses, maintenance and cleaning of equipment, and safety protocols for sedation or anesthesia complications or surgical complications. Emergency care and hospital transfer protocols are required in writing in many states when more than minimal sedation or local anesthetic infiltration in peripheral nerves is required.

Box 10.3 Long-Term Complications of Endometrial Ablation Devices

- Persistent bleeding
- Central hematometra
- Cornual hematometra
- Postablation tubal sterilization syndrome (PATSS)
- Retrograde bleeding
- Inability to evaluate the endometrium if bleeding recurs
- Delay in diagnosis of endometrial cancer
- Pregnancy
- Postablation cornual endosalpingoblastosis

LAPAROSCOPY

Laparoscopy has radically changed the clinical practice of gynecology. As an often outpatient surgical technique, laparoscopy provides a window to directly visualize pelvic anatomy as well as a technique for performing many operations with less morbidity than laparotomy (Fig. 10.7).

The first human laparoscopy was first performed in 1910 in Sweden. By the mid-1970s, laparoscopy had been adopted as the method of choice for female sterilization. Once laparoscopic cholecystectomy was embraced and new instrumentation developed, the way was paved for laparoscopic hysterectomy. In 1989 the first laparoscopic hysterectomy was performed, and by 2009, 20% of hysterectomies were laparoscopic and an additional 5% were completed using a robotic approach.

The advantages of less postoperative pain, shorter recovery time, and shorter hospital stays are obvious when laparoscopy is compared with laparotomy. This is particularly true in the obese woman who has increased risk of wound infection, thromboembolic events, and other complications from laparotomy. These events are significantly less with a laparoscopic approach. Laparoscopic visualization is excellent because the video camera and endoscope magnify the image.

LAPAROSCOPIC INDICATIONS AND CONTRAINDICATIONS

The present indications for laparoscopy are almost identical to those for laparotomy, and the laparoscope is now utilized for more complicated surgery such as hysterectomy with pelvic and paraortic lymph node dissection for endometrial cancer. The most common indication used to be female sterilization but is now diagnostic laparoscopy, and this includes the evaluation of pelvic pain. Other indications include removal of ectopic pregnancies, resection or ablation of endometriosis, ovarian cystectomy or salpingo-oophorectomy, myomectomy, hysterectomy, lysis of adhesions, removal of intraperitoneal intrauterine device, lymph node dissections, and urogynecologic procedures.

Figure 10.7 Laparoscopic view of left pelvis viewing left lower quadrant port and right atraumatic grasper holding left fallopian tube with paratubal cyst and normal ovary. (Courtesy of Dr. Seine Chiang, University of Washington.)

Laparoscopic ovarian biopsy (for karyotyping in certain endocrine disorders) is possible. The limits and indications of surgical procedures via the laparoscope depend on the experience and judgment of the gynecologist.

Absolute contraindications to laparoscopy include intestinal obstruction, hemoperitoneum that produces hemodynamic instability, severe cardiovascular or pulmonary disease, and tuberculous peritonitis. Relative contraindications, in which each case must be individualized, include morbid obesity, large hiatal hernia, advanced malignancy, generalized peritonitis or peritonitis following previous surgery, inflammatory bowel disease, and extensive intraabdominal scarring. Even with these relative contraindications, the surgeon may attempt laparoscopy.

LAPAROSCOPIC EQUIPMENT AND TECHNIQUES

Laparoscopy may be performed under local, regional, or general anesthesia. For simple procedures, many prefer local anesthesia for its safety, with the addition of conscious sedation by intravenous medication. Regional anesthesia is possible, but the Trendelenburg position needed for gravity to keep the bowels in the upper abdomen can be bothersome to the patient and restrict respiration. The risks associated with general anesthesia are one of the major hazards of laparoscopy. However, when operative laparoscopy is contemplated, general anesthesia is recommended and ensures adequate muscle relaxation, patient comfort, and the ability to manipulate intraabdominal organs. The standard diagnostic laparoscope is 10 mm in diameter, but laparoscopes come in sizes varying from 2 to 10 mm. The microlaparoscopes are used primarily for diagnostic evaluation. The 5-mm and 10-mm forms are widely utilized. Laparoscopic telescopes come in 0-degree to 30-degree lens angles, but the 0-degree type is most commonly used. Most laparoscopes are 30 cm long and provide a field of vision of 60 to 75 degrees. The inferior margin of the umbilicus is the preferred site of entry, as this is the thinnest area of the abdominal wall. Alternative sites are detailed in Figure 10.8. The choice of gas to develop the pneumoperitoneum depends on the choice of anesthesia. Nitrous oxide is preferable with local anesthesia, but carbon dioxide is the choice with general anesthesia. Nitrous oxide is nonflammable but does support combustion. Carbon dioxide quickly forms carbonic acid on the moist parietal peritoneal surface, which results in considerable discomfort to a patient without regional or general anesthesia.

A Veress needle (Fig. 10.9; radially dilating trocar with Veress-type needle) has a retractable cutting point that is used for entry into the abdominal cavity for the purpose of insufflating the abdomen with gas for laparoscopy. A trocar is a blunt, bladed, or optical device for entering the abdominal cavity for laparoscopy and is the cannula for holding the laparoscope or laparoscopic instruments (Fig. 10.10). Secondary puncture trocars vary from 5 mm (bipolar forceps, 5-mm telescope, suction/irrigation device, vessel sealing, cutting or coagulation devices), 7 or 8 mm in width (Filshie clips for sterilization), to 10 to 12 mm for pouches to remove specimens, or a morcellating device for removing fibroids or a uterus.

There are three techniques to access the abdomen. First, Veress needle insertion is used to create a pneumoperitoneum followed by trocar placement. Second, direct trocar placement in a noninsufflated abdomen has been described. Third, an open or Hasson technique can be used when adhesions are expected, particularly under the umbilicus. When using the Veress technique,

Figure 10.8 Usual sites for insertion of insufflating needle in laparoscopy: (1) infraumbilical fold, (2) supraumbilical fold, (3) left costal margin, (4) midway between umbilicus and pubis, and (5) left McBurney's point. (From Corson SL. Operating room preparation and basic techniques. In: Phillips JM, ed. *Laparoscopy*. Baltimore: Williams & Wilkins; 1977. Copyright 1977 by the Williams & Wilkins Co., Baltimore.)

a skin incision is made large enough to hold the planned trocar, which is usually 10 mm if using the umbilical site. The angle of the Veress needle insertion should vary according to the body mass index of the woman from 45 degrees in a normal weight woman to 90 degrees in an obese woman. Veress intraperitoneal pressure of ≤ 10 mm Hg is a reliable indicator of correct intraperitoneal needle placement, and insufflation of the carbon dioxide gas can begin. Left upper quadrant (Palmer point) laparoscopic entry should be considered in patients with suspected or known periumbilical adhesions, presence of an umbilical hernia, or after three failed insufflation attempts at the umbilicus.

Once the abdomen is insufflated to 15 mm Hg, the primary trocar can be inserted. Because it has been recognized that primary trocar placement leads to the majority of vascular and bowel injuries, many surgical products are available to potentially lessen these injuries, but none has proved safer than another. A bladed, blunt, or radial dilating trocar can be passed. A bladed cutting trocar may come with automatic blade retraction or a shield for safety. These require significantly less force to insert through the abdominal wall compared with blunt trocars. The resulting fascial defects are larger for cutting trocars than radial dilating trocars. The port may not be as fixed in this case. It is recommended that bladed port sites ≥ 10 mm should have fascial closure at the conclusion of the surgery to avoid postoperative hernia formation. Blunt trocars require more force for passage into the abdomen but theoretically cause fewer vascular and bowel injuries. A systematic review of 8 randomized trials with 720 patients (Antoniou, 2013) reported that abdominal wall bleeding was threefold greater with bladed trocars (9% vs. 3% with an odds ratio of 0.42), as was the risk of complications when excluding abdominal wall bleeding (0.7% vs. 0.2%). This argues that blunt trocars have a lower risk of trocar site bleeding, but a larger study will be needed to estimate visceral injury rates. Radially dilating blunt trocars are available, and one of the touted advantages is that even 10-mm port sites do not need fascial closure because hernias are rare in nonbladed port sites.

Direct trocar entry has been proposed to alleviate the difficulties with preperitoneal or intestinal gas insufflation with the Veress needle and to reduce operative time. There are studies supporting this technique. Disposable optical trocars are available to use a cannula that allows the laparoscope to visualize passing through the abdominal wall. They do not seem to reduce vascular and visceral injury, however, but do save time.

Open laparoscopy, often called the *Hasson technique*, may be used as an alternative to the Veress needle option. Instead of blind entry into the peritoneal cavity, a small incision is made

in the fascia and parietal peritoneum. The cone is placed in the abdominal cavity under direct visual control. The fascia is secured to the sleeve of the cone to obtain an airtight seal. Open laparoscopy has not been proved to reduce the rate of bowel injury, but that is the theoretic benefit. Also, if the Veress needle technique fails to result in pneumoperitoneum, open laparoscopy is often an option. It is the procedure of choice if the patient has a history of multiple abdominal operations.

Once the primary trocar is in place, the telescope and camera can be attached and the pelvis visualized. Secondary trocars can be placed under direct visualization, which is why there are fewer vascular and bowel injuries with these trocars. Third and fourth puncture sites are often required for complex cases. Because each puncture site is a potential gas leak, high-flow insufflation equipment is necessary. In addition, several video monitoring screens are employed so that both the surgeon and assistant can work effectively. Unlike the short time needed for diagnostic laparoscopy, operative laparoscopy may require several hours.

Operative laparoscopy may be performed with mechanical instruments, including an extensive variety of scissors, scalpels, endoscopic syringes, myoma screws, suture devices, electrocautery instruments (both unipolar and bipolar), harmonic and vessel sealing devices for hemostasis and cutting, suction, irrigation, stapling devices, endoscopic clips, and laser instruments. During operative laparoscopy, stabilization of the pelvic organs is essential, such as traction and countertraction on the edges of an adhesion. Multiple trocar sites are needed so that the primary surgeon and assistant can use both hands. Uterine manipulators are particularly useful in laparoscopic hysterectomy. They are designed to aid in stabilizing and manipulating the uterus and identifying the cervicovaginal junction for cervix amputation.

The FDA approved robotic-assisted laparoscopy for use in gynecology in 2005. The only currently available system in the United States is the da Vinci Surgical System. The equipment is bulky and consists of a robot with three or four arms that hold the camera and surgical instruments, the camera and vision system, the console where the surgeon sits away from the patient bedside, and the wristed instruments that insert through the robotic arms and are controlled by the surgeon at the console. The camera is actually two cameras and allows for three-dimensional visualization via the computer image integrator. Other advantages include the added dexterity with the wristed instruments and ergonomic benefits for the surgeon. This can aid in surgeries that require a lot of suturing such as myomectomies or abdominal sacral colpopexy and complex gynecologic oncology or severe endometriosis procedures. Disadvantages include the high cost of the system and maintenance, lack of haptic feedback for the surgeon at the console, and increased operative time for docking the robot and the actual procedure.

LAPAROSCOPIC PROCEDURES

Laparoscopy has made outpatient sterilization available to women throughout the world. Cumulative 10-year pregnancy rates vary between 8/1000 and 37/1000. Sterilization is accomplished with electrocautery, titanium, or spring-loaded clips. Because of the serious complications with unipolar cautery, most cautery sterilization procedures are performed with bipolar coagulation of approximately 3 cm of the isthmus portion of the fallopian tube without division. Use of a current meter is recommended

Figure 10.11 Laparoscopic view of a woman with right lower quadrant pain and an adhesion stringing between the fallopian tube and the bowel near the cecum. Normal-appearing appendix inferiorly. (Courtesy of Dr. Seine Chiang, University of Washington.)

to indicate when complete coagulation has occurred, as visual inspection is not an accurate indication. Mechanical occlusion devices commonly used in the United States include the silicone rubber band (Falope ring), the spring-loaded clip (Hulka-Clemens clip), and the titanium clip lined with silicone rubber (Filshie clip). The ring or clip should be placed on the narrow isthmus so that the size of the appliance conforms to the diameter of the fallopian tube.

There are both diagnostic and therapeutic indications for laparoscopy in infertile women. Tubal patency and mobility can be directly observed via the laparoscope. Laparoscopy is a more sophisticated and accurate method of diagnosing tubal problems during an infertility investigation than HSG. Chromopertubation with an innocuous dye, such as indigo carmine, demonstrates tubal patency during laparoscopy. Comparative studies have documented that HSG discovers only 50% of the peritubal disease diagnosed by direct visualization via the laparoscope. Laparoscopy is able to confirm or rule out intrinsic pelvic disorders, such as endometriosis or chronic pelvic inflammatory disease with adhesions. It is possible not only to describe and stage the extent of endometriosis or pelvic adhesions but also to treat them. Adhesions can be lysed, endometrioma cysts can be removed, and areas of endometriosis can be ablated by electrocautery, laser, or completely excised, which is necessary for deep endometriotic implants (Fig. 10.11).

The management of pelvic pain has been dramatically changed by the laparoscope. The differential diagnosis of acute pain may be defined by direct visualization of the fallopian tubes, ovaries, and appendix. Laparoscopy may be used in the management of acute pelvic infection, taking direct bacterial cultures of purulent material from the tubes, draining a tubo-ovarian abscess, or removing a tubo-ovarian abscess complex with unilateral salpingo-oophorectomy. These direct transabdominal cultures have changed our opinions concerning the clinical management of polymicrobial pelvic infections. The classic violin string adhesions between the liver and the abdominal wall are sometimes noted by directing the laparoscope into the upper right quadrant in women with

Figure 10.12 Fitz-Hugh-Curtis syndrome in a patient with previous pelvic inflammatory disease. (From Goldberg JM, Falcone T. *Atlas of Endoscopic Techniques in Gynecology*. London: WB Saunders; 2000:71.)

Figure 10.13 Ectopic pregnancy in the right fallopian tube. (Courtesy of B. Beller, MD, Eugene, OR.)

prior pelvic inflammatory disease (Fig. 10.12). Sometimes the enigma of chronic pelvic pain may be solved by the findings at laparoscopy. Following the procedure, a plan for long-term management of the pain can be discussed with the patient.

Laparoscopic treatment of ectopic pregnancy most often involves salpingotomy but also may include salpingectomy (Fig. 10.13). HCG titers must be followed after conservative surgery (salpingotomy) until the titers fall to zero (usually 3 to 4 weeks) to ensure that all trophoblastic tissue has been removed. Tubal patency and subsequent pregnancy rates are comparable between laparoscopic techniques and laparotomy.

Laparoscopic hysterectomy is one area of considerable research. If vaginal hysterectomy cannot be done (which has lower complication rates, lower costs, and better outcomes), then laparoscopic hysterectomy should be considered over abdominal hysterectomy. Many considerations must go into this decision, such as the size of the uterus, adnexal disease with risk for ovarian cancer, severe endometriosis, or adhesions. The Cochrane Database of Systematic Reviews (Nieboer, 2009) considered 34 randomized trials of

hysterectomy route. Laparoscopic hysterectomy compared with abdominal hysterectomy was associated with faster return to normal activity, shorter hospital stay, lower intraoperative blood loss, fewer wound infections, longer operating time, and a higher rate of bladder and ureter injuries. [Figure 10.14](#) shows the beginning of a laparoscopic hysterectomy for uterine fibroids with creation of the bladder flap.

Laparoscopic myomectomy has been studied in two randomized controlled trials with comparison with myomectomy by minilaparotomy. This can be technically challenging laparoscopically because of the dissection and suturing required. The laparoscopic approach resulted in less blood loss, reduced length of postoperative ileus, shorter hospital stay, reduced use of pain medications, and more rapid return to normal activities, but a longer operative time. For unexplained infertility, both approaches improved reproductive outcomes similarly.

Operative laparoscopy has additionally been used for laparoscopic-assisted hysterectomy, salpingo-oophorectomy, salpingostomy and fimbrioplasty, tubal reanastomosis, appendectomy, uterosacral ligament transection, presacral neurectomy, retropubic bladder neck suspensions, and complex urogynecologic procedures. Laparoscopy may be used for major cancer staging, including paraaortic and pelvic lymphadenectomy.

Newer laparoscopic equipment using robotics has increased the ease at which minimally invasive major pelvic surgery can occur ([Fig. 10.15](#)). Cases that can be extremely challenging with traditional laparoscopy are being done with increasing frequency with robotics. Most of the published studies to date are nonrandomized and retrospective case series comparing robotic cases with historical controls. There are data showing safety and feasibility of robot-assisted surgery for numerous procedures, including tubal reanastomosis, myomectomy, hysterectomy, adnexectomy, pelvic, and paraaortic lymph node sampling and abdominal sacral colpopexy for pelvic organ prolapse. Compared with conventional laparoscopic surgery, robotic surgery achieved reduced blood

loss and fewer conversions to laparotomy during the staging of endometrial cancer.

There has been a rapid industry-driven increase in the performance of robotic-assisted hysterectomy. Although only 0.5% of all hysterectomies were performed robotically in 2007, the number increased to 9.5% in 2010 ([Wright, 2013](#)). Growth has continued to increase at an estimated 25% per year. This increased gynecologic utilization of the robot for primarily benign hysterectomies has occurred despite limited outcomes data demonstrating patient benefit compared to alternative surgical methods.

Robotic hysterectomy has been shown to have increased surgical complications, operating room time, and costs. A 2014 study by Dayaratna and Goldberg reported that mean total hospital costs for vaginal hysterectomy were \$7903, \$10,069 for laparoscopically assisted vaginal hysterectomy (LAVH), \$11,558 for laparoscopic, and \$13,429 for robotic hysterectomy ($P < .0001$). Net hospital income (insurer reimbursement – hospital cost) was \$1260 for vaginal hysterectomy. The hospital incurred losses of \$1306 for LAVH, \$4049 for laparoscopic hysterectomy, and \$4564 for robotic hysterectomy ($P = .03$).

Robotic hysterectomy has shown benefit over total abdominal hysterectomy (TAH) in regard to shorter hospitalization and a faster recovery. The same improvements over TAH, however, have been demonstrated with vaginal hysterectomy and laparoscopic hysterectomy, with more outcomes data. In appropriate candidates, the vaginal route of surgery is always preferable.

In 2013, ACOG recommended that robotic hysterectomy be limited for unusual and complex clinical conditions in which improved outcomes over standard minimally invasive approaches have been proved ([Breedon, 2013](#)).

LAPAROSCOPIC SURGERY IN PREGNANCY

Laparoscopic surgery can sometimes be safely performed on the pregnant patient. The benefits to this approach over an open procedure are the same as in the nonpregnant patient. In addition, laparoscopic surgery may provide better visualization and less manipulation of the gravid uterus.

Figure 10.14 The beginning of a laparoscopic hysterectomy for uterine fibroids showing the creation of the bladder flap with the left grasper elevating the bladder peritoneum and a bipolar/cutting device in the right hand. (Courtesy of Dr. Seine Chiang, University of Washington.)

Figure 10.15 Robotic surgery being performed. (Courtesy of Rosanne Kho, MD.)

Indications for laparoscopy in pregnancy include, but are not limited to, suspected appendicitis, ovarian torsion, and gallbladder disease. Laparoscopic surgery can be undertaken in all of pregnancy's trimesters; however, the optimal time to operate is early in the second trimester. In the third trimester, surgery may be technically difficult due to the enlarged uterus. Although currently used general anesthetic agents are not believed to have significant teratogenic effects, the data are limited.

To reduce compression of the vena cava and the subsequent effect on cardiac output and placental blood flow, pregnant patients are positioned in supine or lithotomy with a leftward tilt. Insufflation of the abdomen to pressures above 15 mm Hg may affect maternal and fetal physiology, including a reduction of maternal cardiac output, an increased risk for maternal respiratory acidosis, and a decrease in placental perfusion. Thus it is best for intraabdominal pressure to be maintained between 8 to 12 mm Hg.

In the second and third trimesters of pregnancy, initial abdominal entry has an increased risk of inadvertently injuring the enlarged uterus. To decrease this risk, an open entry technique or entry in the left-upper quadrant at the Palmer point should be considered. Subsequent trocars are inserted under direct visualization. Uterine manipulators that are placed through the cervix should not be used. Instead, a sponge stick in the vagina can be used to gently tilt the uterus.

The American College of Chest Physicians (ACCP) guidelines recommend thromboprophylaxis for all pregnant patients undergoing surgery. Mechanical compression devices are reasonable for shorter laparoscopic procedures. The addition of low-molecular-weight heparin is suggested for procedures lasting longer than 45 minutes. Early ambulation should be encouraged postoperatively. Prophylactic tocolytics are not routinely recommended. If the fetus is of a viable gestational age, fetal heart rate monitoring may be performed before and after the surgical procedure.

LAPAROSCOPIC COMPLICATIONS

The major categories of complications with laparoscopy are laceration of blood vessels, intestinal and urinary tract injuries, including trocar and thermal injuries, incisional hernias, and cardiorespiratory problems arising from the pneumoperitoneum (Box 10.4). One complication has remained unchanged for 25 years. At least 50% of the major laparoscopic complications arise before the

planned surgery starts and occur with accessing the abdomen. Most of these injuries are with the primary trocar placement at the umbilicus and involve major vascular injuries or the bowel. A Cochrane review (Ahmad, 2012) compared an open-entry technique with the Veress needle and did not find a difference in the incidence of visceral or vascular injury; however, an open-entry technique did reduce the rate of failed entry.

Several studies have evaluated the incidence of complications with operative laparoscopy. A large, multicenter French study of 29,966 laparoscopies showed a high frequency of trocar injuries with a total complication rate of 4.64 per thousand laparoscopies. Complications increase with the age of the patient and the complexity of the procedure. The overall rate of complications from large series of operative laparoscopy varies from 0.2% to 2%. Data were compiled from a series of injuries resulting from abdominal entry and laparoscopic access injuries reported to large insurance data banks (Chandler, 2001). The series included general surgery as well as gynecology from both the United States and other countries. Over a 20-year period, the data bank collected 594 reports of organ injury, 33% in gynecology patients. Importantly, 50% of bowel injuries were unrecognized for 24 hours or more. Sixty-five deaths were reported. Age older than 59 years and delayed diagnosis of injury were independently associated with mortality in this series. A systematic review of gynecology bowel injury from 90 studies found the overall incidence was 1 in 769 cases (Llarena, 2015). More complex surgeries resulted in higher injury rates. Hysterectomy led to the highest bowel injury incidence at 1 in 256. Most injuries occurred during abdominal access and insufflation using a Veress needle or trocar. A meta-analysis of 27 randomized controlled trials compared laparoscopy and laparotomy for benign gynecologic procedures. The overall risk of complication was 8.9% with laparoscopy compared with 15.2 with laparotomy (relative risk 0.6). The risk of major complications was the same at 1.4%, so the risk of minor complication was higher in the laparotomy group.

Laceration of the aorta, inferior vena cava, or iliac vessels is a surgical emergency. Because abdominal wall hematomas are usually subfascial in location, care must be taken to avoid the epigastric vessels. For safety, it has been recommended that lateral trocars be placed at least 5 cm above the symphysis and at least 8 cm from the midline (Hurd, 1994). The Veress needle or the trocar may produce intestinal injuries. Thermal injuries may be recognized at the time of surgery, but if they are not recognized intraoperatively, significant delays in recognition can lead to septicemia and death. The incidence of ureteral injuries varies from 1% to 4% with laparoscopic dissection of the cardinal ligaments.

The risk of incisional hernia is increased for port sites of 12 mm or greater and extraumbilical sites (0.17% to 0.23%). Many of these herniations occur despite fascial closure at the initial surgery. Clinical symptoms include a bulge at the incision site, which may be painful to a bowel obstruction or infarction.

Complications directly related to the pneumoperitoneum include pneumothorax, diminished venous return, gas embolism, and cardiac arrhythmias. It is important not to develop pressures greater than 20 mm Hg in establishing the pneumoperitoneum. High pressures impede venous return and limit excursion of the diaphragm. A rare but life-threatening complication of laparoscopy is gas embolism, which produces hypotension

Box 10.4 Intraoperative and Delayed Laparoscopic Surgery Risks

- Bleeding
Laceration of major blood vessels; epigastric, obturator, iliac, vena cava, aorta
Surgical site bleeding
- Trocar or Veress needle injury
- Intestinal injury; thermal or direct instrument
- Urinary tract injury; thermal or direct instrument
- Anesthetic complication
- Equipment malfunction
- Other endoscopic instrument injury
- Other thermal injury
- Subcutaneous emphysema

and the classical “mill wheel” murmur that can be heard over the entire precordium. The patient with this complication should be turned on her left side and the frothy blood aspirated by a central venous catheter directed into the right side of the heart. Other rare complications include incisional hernias at the site of the 10- to 12-mm trocar sites. This has been estimated to occur in 1 in 5000 procedures. Metastases from ovarian malignancies to the laparoscopic wound site are also a rare but real problem.

CONTROVERSY REGARDING POWER UTERINE OR FIBROID MORCELLATION

Power or electrical morcellators are composed of a rapidly rotating cylindrical sharp blade within a tube through which strips of cut tissue are then extracted. By enabling removal of pieces of uterine or fibroid tissue through small incisions, power morcellation has allowed the performance of laparoscopic or robotic supracervical hysterectomy and myomectomy. Primarily through industry driven efforts, the number of laparoscopic and robotic hysterectomy has significantly increased. Although the goal should be converting many procedures from a laparotomy to a laparoscopic approach, many hysterectomies that should be performed vaginally have similarly moved to laparoscopic or robotic routes due to physician preference.

The reported prevalence of uterine sarcoma, a type of malignancy that includes leiomyosarcoma, in women undergoing hysterectomy or myomectomy for suspected fibroids is approximately 1 in 350. During the morcellation process, small pieces of uterine tissue may be disseminated and left within the abdomen.

On November 24, 2014, the U.S. FDA issued a communication entitled *UPDATED Laparoscopic Uterine Power Morcellation in Hysterectomy and Myomectomy: FDA Safety Communication* (FDA, 2014). Due to the risk of spreading the sarcoma tissue within the abdomen, decreasing survival, “the FDA is warning against the use of laparoscopic power morcellators in the majority of women undergoing myomectomy or hysterectomy for the treatment of fibroids.” As a result of this communication, the majority of hospitals have banned the usage of power morcellation for gynecologic surgery. Many manufacturers have completely taken their power morcellators off the market. Thus laparoscopic and robotic supracervical hysterectomy and myomectomy can no longer be performed. Instead alternative routes for these procedures, such as vaginal or minilaparotomy, should be considered.

In summary, laparoscopy, more than any other advance, has changed the clinical practice of gynecology since the 1970s.

Today’s obstetric/gynecologic residents have a difficult time contemplating the practice of the specialty prior to the introduction of the “silver tube.” Laparoscopy provides a window for the diagnosis of infertility, pelvic pain, ectopic pregnancy, abdominal and pelvic trauma, staging the extent of pelvic disease, and the visual diagnosis of abnormal anatomy. Therapeutic uses of the laparoscope vary from female sterilization to hysterectomy and node sampling. The role of robotics is still being established, but benefits exist over laparotomy in nonrandomized but controlled trials, particularly in the gynecologic oncology population.

PATIENT SAFETY IN THE SURGICAL ENVIRONMENT

Many regulatory agencies, hospitals, medical societies and organizations, physicians, and staff have been striving for improvements in patient safety. Wrong-site surgery, wrong-patient surgery, wrong-side surgery, wrong-part surgery, and retained foreign objects have all been reported. Many factors have been associated with wrong-site surgery, including multiple surgical teams being involved in a case, multiple procedures being done during a single case, time pressures, and morbid obesity. In 2015, the Joint Commission for Hospital Accreditation published national patient safety goals for improving surgical safety. The protocol recommended a preprocedure verification process, marking the operative site and performing a “time out.” A time out promotes patient safety by checking items such as confirming correct patient in two ways, correct surgical site, and procedure(s). The commission further recommends labeling all medications in syringes, cups, and basins. The World Health Organization published a suggested surgical safety checklist to further improve care. Before induction of anesthesia, the first checklist set is done and might include items for team review like patient allergies, airway risks, and estimated blood loss. Before the skin incision, another team review occurs with introductions of all personnel and roles, antibiotic prophylaxis infused if indicated, deep vein thrombosis prophylaxis given or in place if indicated, any equipment issues or concerns voiced, and essential imaging displayed. Before the conclusion of the procedure, the third part of the checklist is completed and includes the name of the procedure, the correct instrument, and sponge and needle counts; the checklist also ensures that specimens are properly labeled and key concerns for the patient recovery are discussed. Good communication between team members appears to be another important factor in patient safety.

KEY POINTS

- The most frequent problem in performing endometrial sampling is cervical stenosis or spasm; it is also a problem for hysteroscopy, and this increases the risk of uterine perforation.
- Major indications for hysteroscopy include abnormal uterine bleeding, removal of endometrial polyps or submucous myomas, endometrial ablations, retained IUDs, desire of no incision sterilization, intrauterine adhesions diagnosis and treatment, infertility, resection of a uterine septum, and recurrent pregnancy loss.
- The endometrial lining may be ablated through the hysteroscope in women with abnormal bleeding or menorrhagia who have a normal uterine cavity and are poor surgical candidates, those who wish to retain their uterus, and those who do not desire further childbearing.
- Older resectoscopic and second-generation nonresectoscopic endometrial ablation devices appear to be equivalent with respect to successful reduction in menstrual flow and patient satisfaction at 1 year.

KEY POINTS—cont'd

- Vaginal misoprostol administration the night before the hysteroscopic procedure can aid in cervical softening.
- A paracervical block with local anesthetic is the best method of pain control for outpatient hysteroscopy compared with topical or intracervical anesthesia.
- Complications of hysteroscopy include uterine perforation with risk of injury to the surrounding vascular and visceral structures, pelvic infection, bleeding, and absorption of the distending media.
- The primary laparoscopic trocar placement leads to the >50% of vascular and bowel injuries in gynecologic laparoscopy.
- Absolute contraindications to laparoscopy include a hemoperitoneum that has produced hemodynamic instability, bowel obstruction, advanced malignancy, large abdominal masses, severe cardiovascular disease, and tuberculous peritonitis.
- The incidence of complications with operative laparoscopy varies from 0.2% to 2%. Thermal bowel injuries often go unrecognized intraoperatively, and diagnostic delays can be life threatening.

Congenital Abnormalities of the Female Reproductive Tract Anomalies of the Vagina, Cervix, Uterus, and Adnexa

Beth W. Rackow, Roger A. Lobo, Gretchen M. Lentz

Congenital abnormalities of the female reproductive tract are common and can affect the external genitalia and müllerian structures. They can be caused by genetic errors or by teratogenic events during embryonic development. Minor abnormalities may be of little consequence, but major abnormalities may lead to severe impairment of menstrual and reproductive functions and can be associated with anomalies of the urinary tract. This chapter reviews a number of such abnormalities and discusses diagnosis and treatment. Anomalies can present at varying times in a female's life—at birth, before puberty, with the onset of menses, and during a pregnancy with adverse pregnancy outcomes—but many women with congenital anomalies of the reproductive tract are asymptomatic. Based on large studies, the incidence of müllerian anomalies is considered to be 1% to 3% (Nahum, 1998). Because of the profound psychological effects such abnormalities can have, the gynecologist must approach the problems of genital and müllerian anomalies with sensitivity and an understanding of the effects on the female and her family. Most tertiary centers have a diverse multidisciplinary team available for the evaluation, treatment, and support of the patient with a serious disorder of sexual development.

AMBIGUOUS GENITALIA

After delivery of the neonate, the obstetrician is often the provider who identifies the gender of the neonate. Thereafter, a more detailed assessment of the neonate's genital anatomy is necessary. The physician should systematically observe the newborn's perineum, beginning with the mons pubis. The clitoris should be noted for any obvious enlargement, the opening of the urethra should be identified, and the labia should be gently separated to see if the introitus can be visualized. If it is possible to separate the labia, the hymen may be observed. Generally, the hymen is perforate, revealing the entrance into the vagina. At times the labia are joined by filmy adhesions; these adhesions generally separate during childhood or can be treated with the application of estrogen cream when medically indicated. Posteriorly the labia fuse in the midline at the posterior fourchette of the perineum. Posterior to the perineal body the rectum can be

visualized, and it should be tested to be sure that it is perforate. Meconium staining around the rectum is evidence for perforation. If there is doubt, the rectum may be penetrated with a moistened cotton-tipped swab. Palpation of the inguinal area and labia for any masses is also important.

In newborns with ambiguous genitalia, a range of abnormalities involving the clitoris, urethra, labia, and introitus can be identified, and immediate evaluation is necessary. The current terminology for individuals with abnormal external genitalia and associated issues is *disorder of sexual development (DSD)*, and these disorders can be related to in utero androgen exposure (too much or too little) that has affected development of the external genitalia. Females (individuals with XX karyotypes) with masculinized or virilized external genitalia are identified as 46,XX DSD, and males (with 46,XY karyotypes) with undervirilized external genitalia are identified as 46,XY DSD (Lee, 2006). For females, the timing of antenatal (embryonic) exposure to androgen influences the degree of masculinization (Fig. 11.1) (Grumbach, 2003). The vaginal plate separates from the urogenital sinus at about 12 weeks of fetal development. Androgen exposure before 12 weeks can result in labioscrotal fusion and retention of the urogenital sinus, which creates a single tract that the urethra and vagina empty into before reaching the perineum. Androgen exposure after 12 weeks presents primarily with clitoral hypertrophy (Low, 2003).

The finding of ambiguous genitalia occurs in a wide spectrum of possibilities, from labioscrotal fusion and an enlarged clitoris with a penile urethra to a urogenital sinus to clitoromegaly and a normal introitus. With labial fusion, the physician should palpate the groins and labial folds for evidence of gonads. Gonads palpable in the inguinal canal, labioinguinal region, or labioscrotal folds are almost always testes, and this finding is typically seen in a male with ambiguous genitalia rather than a virilized female. Conversely, an infant with ambiguous genitalia but without palpable testes in the scrotum is more likely to be a virilized female, most often the result of congenital adrenal hyperplasia. A rectal examination may allow palpation of a cervix and uterus, thus helping with gender assignment. If a bifid clitoris and labial fusion are noted, this anomaly is usually associated with extrophy of the bladder. As with any congenital anomaly, the neonate should be thoroughly evaluated for other congenital anomalies.

Figure 11.1 46,XX DSD induced by prenatal exposure to androgens. Exposure after 12th fetal week leads only to clitoral hypertrophy (left). Exposure at progressively earlier stages of differentiation (from left to right) leads to retention of the urogenital sinus and labioscrotal fusion. If exposure occurs sufficiently early, the labia fuse to form a penile urethra. (From Grumbach MM, Hughes IA, Conte FA. Disorders of sex differentiation. In Larsen RP, Kronenberg HM, Melmed S, Polonsky KS, eds. *Williams Textbook of Endocrinology*. 10th ed. Philadelphia: WB Saunders; 2003:916.)

The initial evaluation of ambiguous genitalia involves checking a karyotype, performing a transabdominal pelvic ultrasound to assess pelvic anatomy, and obtaining blood for serum electrolytes and steroid hormone levels. In a female neonate, an ultrasound can easily identify a uterus because the estrogenized tissue is easy to visualize. If further evaluation of neonatal pelvic anatomy is necessary, cystoscopy and vaginoscopy can be performed with a pediatric cystoscope to assess the pelvic structures, including the location of the urethra and vagina and the presence of a cervix. Possible causes of 46,XX DSD include congenital adrenal hyperplasia, other genetic mutations that affect the steroid pathway, maternal ingestion of androgens, or maternal production of excess androgens (Box 11.1) (Grumbach, 2003).

It is important to systematically evaluate the newborn's genitalia to make the appropriate gender assignment, when possible. In the past, gender was assigned primarily on the principle of "phallic adequacy," with neonates with an ambiguous phallus being assigned female gender. In contrast, the current approach is to initiate a thorough evaluation of the neonate and to defer gender assignment until the clinical picture is clear. For the evaluation and management of an individual with DSD, most tertiary centers utilize a multidisciplinary team including medical genetics, pediatric urology, pediatric endocrinology, gynecology, and psychiatry (Allen, 2009).

PERINEAL AND HYMENAL ANOMALIES

Clitoral Anomalies

In an adult female, the clitoris is generally 1 to 1.5 cm long and 0.5 cm wide in the nonerect state. The glans is partially covered by a hood of skin. The urethra opens near the base of the clitoris. Abnormalities of the clitoris are unusual, although it may be enlarged because of androgen stimulation. In such circumstances the shaft of the clitoris may be quite enlarged and partial development of a penile urethra may have occurred (Fig. 11.2) (Verkauf, 1970). Extreme cases of androgen stimulation are generally associated with fusion of the labia. These

Box 11.1 Classification of 46,XX DSD

I. Androgen-Induced

A. Fetal Source

1. Congenital adrenal hyperplasia
 - a. Virilism only, defective adrenal 21-hydroxylation (CYP21)
 - b. Virilism with salt-losing syndrome, defective adrenal 21-hydroxylation (CYP21)
 - c. Virilism with hypertension, defective adrenal 11 β -hydroxylation (CYP11B1)
 - d. Virilism with adrenal insufficiency, deficient 3 β -HSD 2 (HSD3B 2)
2. P450 aromatase (CYP19) deficiency
3. Glucocorticoid receptor gene mutation

B. Maternal Source

1. Iatrogenic
 - a. Testosterone and related steroids
 - b. Certain synthetic oral progestagens and rarely diethylstilbestrol
2. Virilizing ovarian or adrenal tumor
3. Virilizing luteoma of pregnancy
4. Congenital virilizing adrenal hyperplasia in mother*

C. Undetermined Source

1. Virilizing luteoma of pregnancy

II. Non—Androgen-Induced Disturbances in Differentiation of Urogenital Structures

From Grumbach MM, Hughes IA, Conte FA. Disorders of sex differentiation. In: Larsen RP, Kronenberg HM, Melmed S, Polonsky KS, eds. *Williams Textbook of Endocrinology*. 10th ed. Philadelphia: Saunders; 2003.

*In pregnant patient whose disease is poorly controlled or who is noncompliant, especially during the first trimester.

findings occur in infants with congenital adrenal hyperplasia and in those exposed in utero to exogenous or endogenous androgens (Fig. 11.3) (Black, 2003). Similar in appearance, males with partial androgen insensitivity syndrome have underdeveloped male external genitalia and a small phallus that appears as clitoral hypertrophy (Fig. 11.4) (Black, 2003).

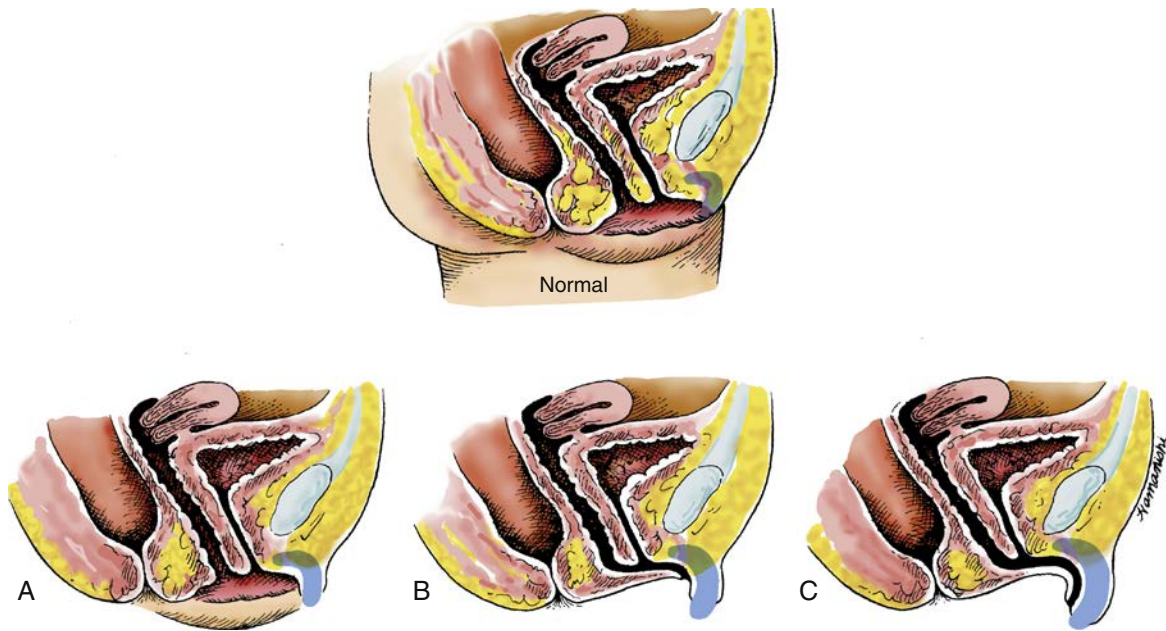

Figure 11.2 Sagittal views of genital deformities seen in female infants who are masculinized. **A**, Minimal masculinization with slight enlargement of the clitoris. **B**, Labial fusion and more marked enlargement of the clitoris. **C**, Complete labial fusion, enlargement of the clitoris, and formation of a partial penile urethra. Figure 11.5 An example of a bifid clitoris in an infant with extrophy of the bladder. (Courtesy of Richard Grady, MD.)

A bifid clitoris (Fig. 11.5) is usually seen in association with extrophy of the bladder. Extrophy of the bladder occurs rarely (1 per 30,000 births) and has a male predominance (3:1). However, when it occurs in females, it is often associated with a bifid clitoris. Approximately half of female patients with bladder extrophy may have associated reproductive tract anomalies such as vaginal anomalies and müllerian duct fusion disorders. In such cases, an anterior rotation and a shortening of the vagina with labial fusion are quite common.

Labial Fusion

Labial fusion may occur without clitoromegaly. The resultant ambiguous genitalia will imply a form of DSD. 46, XX DSD or 46, XY DSD applies to individuals with a pure XX or XY karyotype but with the external genitalia of the opposite sex of the karyotype or ambiguous genitalia. The term *hermaphrodite* is no longer used and was derived from the child of the Greek gods Hermes and Aphrodite, Hermaphroditus, who was part female and part male. A true hermaphrodite is now called *ovotesticular DSD* and has both ovarian (including follicular elements) and testicular tissue, either in the same or opposite gonads. Ovotesticular DSD is extremely rare in North and South America but more common (though still very rare) in Africa.

Ovotestes are present in individuals with ovaries that usually have an SRY antigen present and testicular tissue present. The degree to which müllerian and wolffian development occurs depends on the amounts of testicular tissue present in the ovotestes and the proximity to the developing duct system. When considerable amounts of testicular tissue are present within the organ, there is a tendency for descent toward the labial/scrotal area. Thus palpation of the gonad in the inguinal canal or within the labial scrotal area is fairly common. Ovulation and menstruation may occur if the müllerian system is appropriately developed. In a similar fashion, spermatogenesis may occur as well. Where testicular tissue is present, there is an increased risk for malignant degeneration, and these gonads should be removed after puberty. Germ cell tumors, such as gonadoblastomas and dysgerminomas, have been reported in the ovarian portion of ovotestes.

MINERALOCORTICOID GLUCOCORTICOID ANDROGENS

Figure 11.6 Steroid pathway in congenital adrenal hyperplasia with absence of 21 hydroxylase. ACTH, Adrenocorticotrophic hormone; 3β-HSDII, 3β-hydroxysteroid dehydrogenase; DHEA, dehydroepiandrosterone; DOC, deoxycorticosterone. (From Grumbach MM, Hughes IA, Conte FA. Disorders of sex differentiation. In: Larsen RP, Kronenberg HM, Melmed S, Polonsky KS, eds. *Williams Textbook of Endocrinology*. 10th ed. Philadelphia: WB Saunders; 2003:533.)

Congenital Adrenal Hyperplasia

Although labial fusion may result from exposure to exogenous androgens or be associated with defects of the anterior abdominal wall, by far the most common cause is congenital adrenal hyperplasia. The most common form of congenital adrenal hyperplasia is caused by an inborn error of metabolism involving deficiency of the 21-hydroxylase enzyme (Fig. 11.6). This condition is transmitted as an autosomal recessive gene coded on chromosome 6, and both severe and mild gene mutations have been identified. With the severe mutation, due to the absence of the 21-hydroxylase enzyme, the major biosynthetic pathway to cortisol is blocked; 17-OH-progesterone is produced instead, which is converted to the androgen androstenedione. The fetal hypothalamic-pituitary axis senses inadequate levels of cortisol and secretes excess adrenocorticotrophic hormone (ACTH), which leads to increasing levels of androstenedione from the female adrenal gland and subsequent masculinization of the external genitalia. Homozygous individuals occur with an incidence as high as 1 per 490, depending on the geographic location and population studied. Screening programs have noted the incidence to be approximately 1 in 14,500 births (Pang, 1988). Depending on the population, carriers of the gene (heterozygotes) are present in a frequency ranging from 1 per 20 to 1 per 250. Two other less common enzyme defects, also transmittable as autosomal recessive traits, may produce similar abnormal findings: the 11-hydroxylase deficiency and the 3β-hydroxysteroid dehydrogenase deficiency. These two enzyme defects as well as 21-hydroxylase deficiency may cause ambiguous genitalia with masculinized females.

Figure 11.7 Eleven-year-old girl with clitoromegaly and thick genital hair, who presented with facial hair and was found to have 21-hydroxylase deficiency. (From McKay M. Vulvar manifestations of skin disorders. In: Black M, McKay M, Braude P, et al, eds. *Obstetric and Gynecologic Dermatology*. 2nd ed. Edinburgh: Mosby; 2003:120.)

Congenital adrenal hyperplasia (CAH) may be demonstrated at birth by the presence of ambiguous genitalia in 46,XX individuals or present later in childhood. The majority of newborns (75%) who are homozygous for a CAH mutation are at risk for the development of a life-threatening neonatal adrenal crisis as a result of sodium loss because of lack of aldosterone production. In individuals with a milder disease presentation, delayed diagnosis may result in accelerated bone maturation due to high levels of androgens being aromatized to estradiol and thus leading to premature closure of the epiphyseal plates and short stature. The development of premature secondary sexual characteristics in males and further virilization in females may also occur (Fig. 11.7) (Black, 2003). Most states in the United States have mandatory neonatal screening for 17-OH progesterone levels to screen for CAH.

Treatment of congenital adrenal hyperplasia involves replacement of cortisol. This suppresses ACTH output and therefore decreases the stimulation of the cortisol-producing pathways of the adrenal cortex and subsequently decreases androgen production. For women known to be at risk, those diagnosed with CAH and those who have had children with CAH, antenatal therapy may be offered. After a positive pregnancy test, daily administration of dexamethasone will suppress the fetal adrenal glands until the fetal gender can be verified with prenatal diagnosis. Although this intervention remains an option, it should not be carried out routinely and is still considered experimental by the major societies (Endocrine and Pediatric Endocrine Societies). Many of the female infants exposed to high levels of androgens in utero may need corrective surgery. Children who have had initial corrective surgeries may need follow-up vaginoplasty as teenagers because of vaginal stenosis. Furthermore, because of the

Figure 11.8 Diagrammatic depiction of an imperforate hymen **A**, and a bulging hymen **B**, due to hematocolpos. (Modified from Dietrich JE, Miller DM, Quint EH. Obstructive reproductive tract anomalies. *J Pediatr Adolesc Gyn*. 2014;27[6]:396-402.)

profound gender identity issues related to ambiguous genitalia in females with CAH, and also for women with other DSDs, ongoing psychological support and counseling are important. When available, multidisciplinary team support is recommended for the gynecologic, urologic, endocrinologic, and psychological care of these individuals.

Hymenal Anomalies

The hymen represents the junction of the sinovaginal bulbs with the urogenital sinus and is composed of endoderm from the urogenital sinus epithelium. The hymen is initially a solid membrane of tissue, and the central cells of the membrane typically dissolve during late fetal development to establish a connection between the lumen of the vaginal canal and the vestibule. If this perforation does not take place, the hymen is imperforate (Dietrich, 2014) (Fig. 11.8). The incidence of an imperforate hymen is thought to be approximately 1 in 1000 live-born females (Usta, 1993). Occasionally, a hydrocolpos or mucocolpos may occur in neonates or infants when fluid or vaginal secretions build up behind an imperforate hymen. Although this fluid collection may spontaneously resolve, if it forms a mass that obstructs the urinary tract, then the hymen must be incised to release the obstructing fluid.

Menarche typically occurs within 2 to 3 years from the start of thelarche (breast development), and young women with an imperforate hymen may experience cyclic cramping but no menstrual flow. An imperforate hymen is commonly diagnosed after puberty in the setting of primary amenorrhea, hematocolpos, and possibly hematometra that can cause pelvic pain, urinary retention, and difficulty with bowel movements. In more advanced cases, due to retrograde menstruation, the menstrual blood may distend the fallopian tubes and form endometrial implants in the peritoneal cavity. Surprisingly, some females have minimal symptoms with this condition.

The diagnosis can be determined by history and physical examination; a bulging membrane with a bluish hue is appreciated at the introitus, and a vaginal mass is palpable on rectal exam. Surgical intervention is necessary to relieve the obstruction of the reproductive tract. Under anesthesia, a cruciate

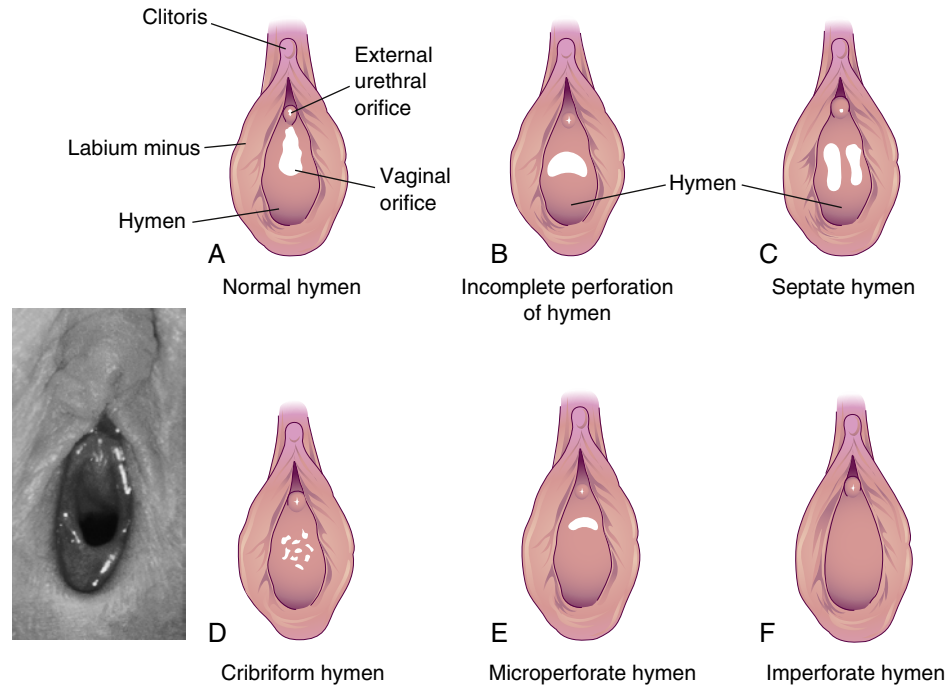

Figure 11.9 Congenital anomalies of the hymen. Panels **A-F** show different types of hymen abnormalities. The photograph shows a normal hymen as in **A**. (From Moore KL, Persaud TVN. *The Developing Human*. 7th ed. Philadelphia: WB Saunders; 2003:322.)

incision is made into the hymen extending from 10 to 4 o'clock and 2 to 8 o'clock. Once the imperforate hymen has been carefully incised and the hematocolpos drained, the excess hymenal tissue is trimmed and hemostasis is achieved with interrupted fine absorbable sutures. The tissue often heals quickly and well, leaving a patent hymen.

Several variations exist of partial hymenal perforation: microperforate, cribriform and septate hymen, and incomplete perforate hymen (Fig. 11.9) (Moore, 2003). Females with partial hymenal perforation commonly present with difficulty inserting a tampon or difficulty with sexual activity. Occasionally, a young female is able to insert a tampon past the hymen anomaly, but once the tampon expands with blood, it cannot be removed due to the partial hymenal obstruction. Surgical correction may be necessary to remove the excess hymenal tissue and restore normal hymenal anatomy.

Müllerian Anomalies

Müllerian anomalies, otherwise known as *congenital anomalies of the female reproductive tract*, occur due to defects in development of the müllerian ducts, which are the embryologic origin of the fallopian tubes, uterus, cervix, and a portion of the vagina. Before reviewing these disorders, it is important to understand the development of the female reproductive tract.

Embryology

Although genetic sex is determined when sperm fertilizes the oocyte, male or female phenotype is not defined until after the sixth week of development. Between the third and fifth weeks of embryologic development, both the wolffian (mesonephric) and müllerian (paramesonephric) ducts are present. The müllerian ducts form from clefts between the mesonephros and the developing gonad. The paired wolffian ducts connect the embryologic

kidney (mesonephros) to the cloaca between 5 and 10 weeks of gestation; development of the functional kidney (metanephros) is stimulated by an outgrowth of the wolffian duct, the ureteric bud. The fate of these various embryonic elements is closely entwined; an insult to or abnormal development of one embryonic element usually affects the others.

The subsequent steps of müllerian duct development are elongation, fusion, canalization, and septal resorption. The müllerian ducts elongate caudally and eventually fuse in the midline as they descend into the pelvis, reaching the urogenital sinus at an elevation known as the *müllerian tubercle*. At this point, the ducts are two solid tubes of tissue that are fused medially; this occurs by 10 weeks of gestation. Next, central absorption of the cells occurs, leading to two hollow tubes of tissue that remain fused medially. Lastly, the midline septum between the two tubes of tissue undergoes resorption, and this process commonly occurs in a caudal to cephalad direction, leading to a midline unified structure. The inferior portion of the müllerian ducts becomes the upper vagina, followed by the cervix and uterus, and the cephalad unfused portion of the ducts develops into the fallopian tubes. This process is completed by 20 weeks of embryologic development. Although this is the common theory of müllerian duct development, based on the variety of anomalies that arise from this process, many variations of this process can occur.

The vagina develops from both müllerian duct tissue and the urogenital sinus. Once the müllerian ducts reach the urogenital sinus at approximately 10 weeks of gestation, cells proliferate from the upper portion of the urogenital sinus to form solid aggregates known as the *sinovaginal bulbs*. These cell masses develop into a cord, the vaginal plate, which extends from the müllerian ducts to the urogenital sinus. This plate canalizes, starting at the hymen, which is where the sinovaginal bulb attaches to

the urogenital sinus, and proceeding cranially to the developing cervix, which has by this time already canalized. The process is completed by 20 weeks of gestation.

As previously mentioned, abnormalities in any or multiple parts of müllerian and urogenital sinus development can occur and lead to a constellation of structural defects of the female reproductive tract. Anomalies in müllerian duct elongation, fusion, canalization, and septal resorption have been identified, as have anomalies in vaginal plate resorption. Common müllerian anomalies are discussed in the next few sections.

Anomalies of Müllerian Duct Development

Müllerian anomalies are commonly classified into three categories of disordered duct development: agenesis and hypoplasia, lateral fusion defects, and vertical fusion defects. Reproductive tract abnormalities due to in utero exposure to diethylstilbestrol (DES), a synthetic estrogen that has not been used for several decades, constitute a fourth group of anomalies. Agenesis and hypoplasia can occur for a portion of or an entire müllerian duct, or for both ducts, affecting one or multiple müllerian-derived structures. Lateral fusion defects are the most common category of müllerian defects and originate due to failure of migration of one or both ducts, midline fusion of the ducts, or absorption of the midline septum between the ducts. A range of anomalies can occur, including symmetric or asymmetric and nonobstructed or obstructed müllerian structures. Vertical fusion defects occur due to disordered fusion of the müllerian ducts with the urogenital sinus or abnormal vaginal canalization, and they may present with menstrual flow obstruction. The next sections discuss specific abnormalities of müllerian duct development.

Vaginal Agenesis

Vaginal agenesis, also known as *müllerian agenesis* or *müllerian aplasia*, occurs due to failure of müllerian duct development or marked aberrations in the typical steps of müllerian development. This condition is also known as the *Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome*, named after the four physicians who discovered the syndrome (Fig. 11.10) (Baramki, 1984). This condition is characterized by congenital absence of the vagina and variable development of the uterus; 7% to 10% of women with vaginal agenesis have rudimentary uterine tissue present (Fedele, 2007). The syndrome occurs in approximately 1 in 5000 females. These individuals have normal pubertal development, normal ovarian function, and a 46,XX karyotype, and they commonly present with primary amenorrhea at 15 to 16 years of age. The cause of this disorder is currently unknown, but research into possible genetic disorders leading to MRKH is ongoing.

Complete vaginal agenesis is discovered in 75% of women with Mayer-Rokitansky-Küster-Hauser syndrome, and approximately 25% have a short vaginal pouch. Some women may have rudimentary uterine horns and can have myomas or adenomyosis in the rudimentary myometrium. If the uterine horns contain some endometrium with an epithelial lining, called *functional rudimentary horns*, menstruation into a blocked system can occur, which can lead to monthly cramping, pelvic pain, and endometriosis from retrograde menstruation. A study by Fedele and colleagues noted that 92 of 106 women with müllerian agenesis had small müllerian remnants.¹³ In women with müllerian

Figure 11.10 External genitalia of a female with congenital absence of the vagina. (From Baramki TA. Treatment of congenital anomalies in girls and women. *J Reprod Med*. 1984;29[6]:376-384.)

agenesis, the ovaries are normal and the fallopian tubes are usually present.

Other congenital anomalies are associated with the diagnosis of müllerian agenesis. Due to the concomitant development of the müllerian and urinary tracts, up to 50% of women with müllerian agenesis have concurrent urinary tract anomalies. Phelan and coworkers reported that of 72 patients with vaginal agenesis, 25% had urologic abnormalities noted on intravenous pyelography (Phelan, 1953). A later study by Baramki demonstrated that 40% of 92 patients with müllerian agenesis had urologic abnormalities (Baramki, 1984). These anomalies can include renal agenesis, pelvic kidney, multicystic dysplastic kidney, and ureteral duplication. One study described a 12% incidence of skeletal anomalies, usually involving congenital fusion or absence of vertebrae in these patients. Other anomalies associated with müllerian agenesis include cardiac defects and hearing loss. Hence, women with müllerian agenesis require dedicated imaging of the urinary tract as well as other evaluation as indicated.

Females with müllerian agenesis present with normal pubertal development and primary amenorrhea. Physical examination demonstrates the absence of a vaginal opening or the presence of a short vaginal pouch, and there is an inability to palpate a uterus on rectal examination. When evaluating a female with primary amenorrhea and a distal vaginal obstruction, the differential diagnosis includes vaginal agenesis, transverse vaginal septum, imperforate hymen, and androgen insensitivity syndrome. With müllerian agenesis, measurement of reproductive hormones reveals normal levels, and the karyotype is 46,XX. Although ultrasound examination may verify the presence of normal ovaries and the absence of the uterus, magnetic resonance imaging

(MRI) offers detailed evaluation of the soft tissues of the pelvis and can confirm the diagnosis of müllerian agenesis; it can also assess if any rudimentary uterine tissue is present. Surgical evaluation by laparoscopy is not necessary unless the evaluation of pelvic pain and possible removal of functional rudimentary horns is necessary. The ovaries of these females are normal and should not be removed.

Androgen Insensitivity

Although androgen insensitivity syndrome is not a müllerian anomaly, it presents in a similar manner to vaginal agenesis and therefore will be reviewed in this chapter. Androgen insensitivity occurs in individuals with a 46,XY karyotype who have certain genetic abnormalities that cause defective androgen receptors. The syndrome formerly was termed *testicular feminization syndrome*. Because the developing fetus cannot sense any testosterone, the external genitalia are feminized, and a short vaginal pouch can develop from the urogenital sinus. Due to testicular production of anti-müllerian hormone, the müllerian ducts resorb and the wolffian duct-derived tissue persists. Due to the lack of functional androgen receptors, the testes remain undescended. These individuals undergo normal pubertal development, and the testes make increasing amounts of testosterone, which is aromatized to estrogen, but without functional androgen receptors, there is no testosterone action (male muscle mass and hair production). These phenotypic females commonly present with primary amenorrhea, and they tend to be tall and have sparse to no pubic hair. After the estrogen-induced growth spurt, the undescended testes should be removed to prevent the development of a gonadoblastoma.

Treatment of Vaginal Agenesis

Once the diagnosis of vaginal agenesis is determined, it is recommended that this information is shared with the female and her support system during a face-to-face conversation. This diagnosis has significant emotional, physical, sexual, and reproductive consequences for the female, and psychological counseling should be encouraged to help her cope with this diagnosis and its implications. The treatment of vaginal agenesis involves creation of a neovagina for future sexual function. Additionally, the female should be aware that achieving motherhood is possible using her own eggs and a gestational carrier, or through adoption.

There are nonsurgical and surgical methods available to achieve creation of a neovagina. The purpose of a vagina is for sexual function, although some females may wish to pursue this intervention before they are ready to become sexually active. The first-line treatment to create a neovagina is the nonsurgical option that involves the use of vaginal dilators. This is a time-consuming process that requires the daily use of dilators for 15 to 20 minutes, and it can take 3 to 6 months or longer to create a functional vagina. Each set of dilators has several sizes that increase in width and length, and the dilator is pressed at the vaginal dimple to stretch the skin. Due to discomfort, lidocaine jelly can be applied to the vagina prior to each session. Appropriate instruction should be provided prior to initiating dilation and intermittently throughout the process to make sure that proper technique is being used. Once the neovagina is created, then maintenance dilation must be performed several times per week unless the female

is sexually active. These women must be counseled that they should still use condoms to protect against sexually transmitted infections.

There are multiple ways to reconstruct the vagina surgically. The goal of the operation is to develop the potential space between the bladder and the rectum and insert into this space a new tissue that will develop into a vagina. Common tissues utilized include a split-thickness skin graft, buccal mucosa, peritoneum, bowel (sigmoid or small bowel), or synthetic tissue grafts (Thomas, 2007). After the vaginal space is opened and the new tissue is inserted, the female must wear a mold for a number of months to maintain the vaginal shape as the surgical site heals. Thereafter, if she is not having intercourse regularly, she must use vaginal dilators several times per week to maintain the neovagina. Other surgical procedures to create a neovagina exist, but the discussion is beyond the scope of this chapter.

Transverse Vaginal Septum

A transverse vaginal septum occurs due to partial canalization of the vaginal plate, leaving a band of tissue across the vagina (Fig. 11.11). This septum may be partial (perforate) or complete, and it most commonly lies at the junction between the upper third and lower two thirds of the vagina (Fig. 11.12). Transverse vaginal septae occur less frequently in the midvagina and lower vagina, and the general incidence is approximately 1 per 75,000 females. Partial transverse vaginal septa have been reported in diethylstilbestrol (DES)-exposed females. In the prepubertal state, this diagnosis is rarely made unless there is the development of a mucocolpos or mucometrium behind the septum, and an unexplained abdominal mass may form. After menarche, the presence of a complete septum leads to hematocolpos and hematometrium, similar to that seen with an imperforate hymen, except that because the obstruction is higher in the vagina and the septum is made of thicker tissue than the hymen, there is no bulging tissue at the introitus. With this anomaly, the female presents with primary amenorrhea and reports cyclic cramping and worsening pelvic pain. In contrast, the female with an incomplete (perforate) transverse vaginal septum usually menstruates

Figure 11.11 Diagram of transverse vaginal septum.

but could develop hematocolpos over time along with foul-smelling vaginal discharge, or she could report normal menstrual function but the inability to insert a tampon or have intercourse. The transverse vaginal septum is often less than 1 cm thick; however, some septa can be more than 2 cm thick. With a thin transverse vaginal septum, the septal tissue is excised and the proximal and distal vaginal tissue are sutured together to create a normal vagina. A similar procedure is performed for a perforate transverse vaginal septum. The procedure to correct a thick vaginal septum is more difficult; once the septum is excised, a tissue graft may be needed to bridge the distance between the proximal and distal vaginal tissue edges. With all of these vaginal reconstructive procedures, the female may need to wear a stent or use dilators to prevent scarring and narrowing at the surgical site. Longitudinal septa of the vagina will be discussed with duplication of the uterus and cervix.

Vaginal Adenosis

In the female who was exposed to DES in utero, the junction between the müllerian ducts and the sinovaginal bulb may not be sharply demonstrated. If müllerian elements invade the sinovaginal bulb, remnants may remain as areas of adenosis in the adult vagina. Vaginal adenosis is generally palpated submucosally, although it may be observable at the surface.

ABNORMALITIES OF THE CERVIX

Cervical anomalies can occur along with uterine and vaginal anomalies or can occur in isolation. If one or both of the müllerian ducts do not fuse, do not develop, or develop incompletely, cervical duplication or agenesis can occur. Cervical duplication can result in two separate and distinct cervices or two cervices that are fused in the midline. Additionally, a septate cervix can occur when the midline septum within the cervix does not resorb. These anomalies do not typically obstruct menstrual flow. In contrast, cervical agenesis and hypoplasia occur due to incomplete or absent duct development and often present with obstructed menstrual flow with associated cyclic or chronic pain and hematometra. These rare anomalies require

ultrasound or MRI to clarify the anatomic disorder. Several management options are available, including long-term menstrual suppression with hormones, cervical reconstruction, or hysterectomy. Lastly, other cervical anomalies such as hoods, collars, and adenosis are possible in women who were exposed to DES in utero.

ABNORMALITIES OF THE UTERUS

Abnormalities of the uterus are categorized as lateral fusion defects and occur due to disordered duct fusion and septal resorption. There are several classification systems for müllerian anomalies; in 1988 the (American Fertility Society (Fig. 11.13) provided a straightforward classification system of uterine anomalies based on embryologic origin (American Fertility Society, 1988). A comparison of the American Fertility Society (now ASRM) system to that of the European Society of Human Reproduction and Embryology (ESHRE) found that the latter would lead to an overcalling of certain conditions that were not true anomalies (Ludwin, 2014). The hysteroscopic lysis of a uterine septum is usually straightforward and is illustrated in Video 11.1.

Hypoplasia/agenesis (category I) and unicornuate (category II) denote anomalies with developmental failure of one or both müllerian ducts; didelphys (category III) and bicornuate (category IV) describe anomalies involving a varying degree of failure of midline fusion; septate (category V) and arcuate (category VI) identify anomalies with some degree of failure of resorption of the midline septum. With this classification system, associated anomalies of the vagina, cervix, fallopian tubes, and urinary system must be documented separately. It should also be recognized that numerous anomalies exist that are exceptions to the standard theory of müllerian duct development.

Often, constellations of müllerian abnormalities occur together. A didelphys uterus is commonly seen with a duplicated vagina, and this presents similar to a longitudinal vaginal septum. In some cases, the vaginal septum obstructs one side of the duplicated system, causing a female to present with worsening pain during menstruation due to hematocolpos and hematometra on the obstructed side. A bicornuate uterus can present with a single cervix or a duplicated cervix, and a longitudinal vaginal septum can also be present. A septate uterus can present with a single, septate, or duplicated cervix and may also occur with a longitudinal vaginal septum. A unicornuate uterus may occur in isolation or be associated with a contralateral rudimentary uterine horn that may contain functional endometrial tissue. Another classification by Toaff (Toaff, 1984) depicts some of these variations (Fig. 11.14).

With uterus didelphys with an obstructed vagina and uterus or with a unicornuate uterus with a rudimentary horn, ipsilateral to the anomalous or obstructed side, urinary tract anomalies such as renal agenesis or pelvic kidney are common. Hence, in females with a müllerian anomaly, and especially in those with an obstruction of a duplicated system, imaging of the urinary tract is important to look for concomitant anomalies (Oppelt, 2007).

Imaging

MRI is the gold standard for the diagnosis of these abnormalities. However, three-dimensional (3D) ultrasound (US) is also beneficial and has been considered to be equivalent in most

Figure 11.12 Patient with complete transverse vaginal septum.

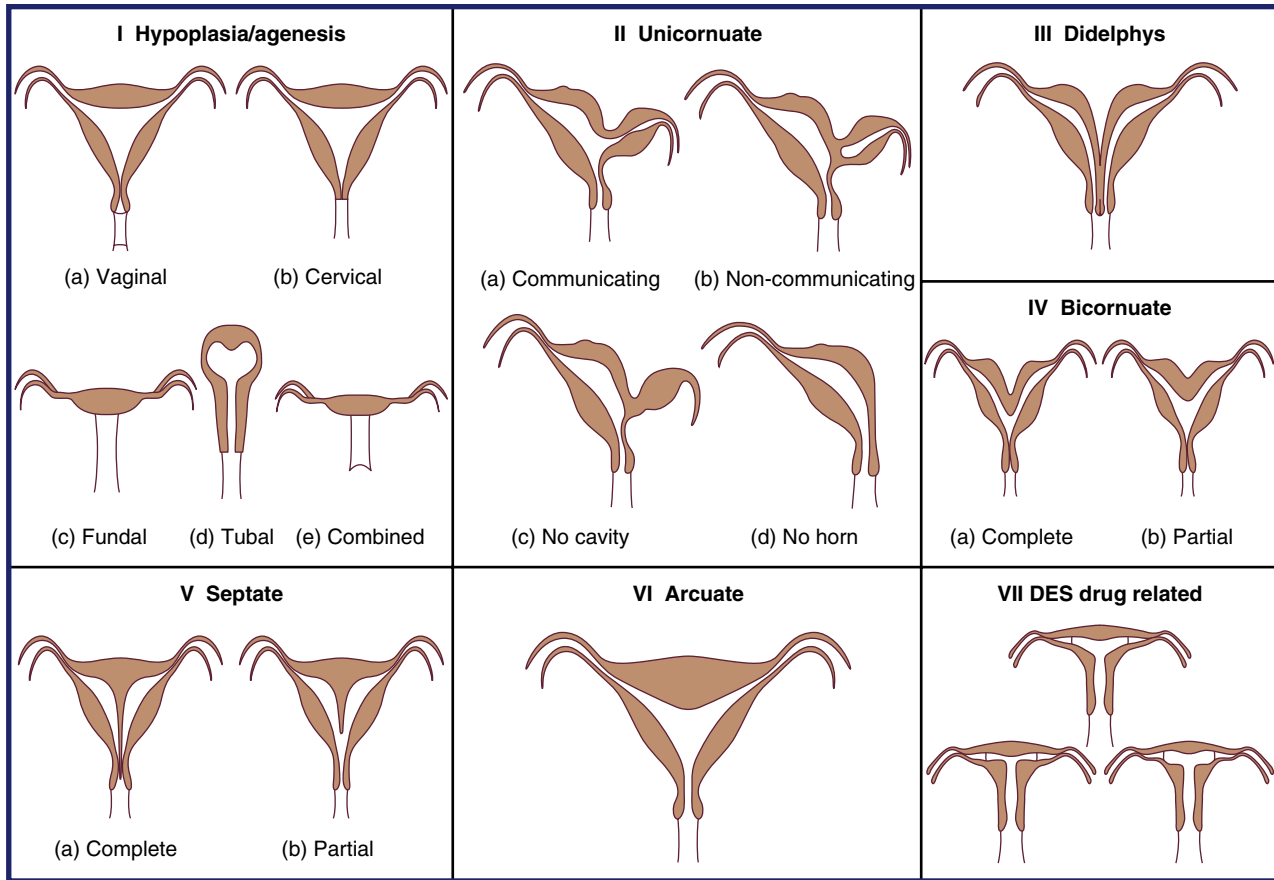

Figure 11.13 American Fertility Society classification. (From The American Fertility Society classification of adnexal adhesions, distal tubal occlusion, tubal occlusion secondary to tubal ligation, tubal pregnancies, müllerian anomalies and intrauterine adhesions. *Fertil Steril*. 1988;49[6]:944-955.)

circumstances (Bermejo, 2010; Benacerraf, 2015). Figure 11.15 compares MRI and 3D US images of some abnormalities using the American Fertility Society classification. Imaging with a hysterosalpingogram, which can show two uterine cavities (Fig. 11.16), could be either a bicornuate uterus or a septate uterus. Conventional two-dimensional (2D) US is not able to make this distinction because it is not able to determine the external contour of the uterus, which is accomplished either by 3D US or MRI (Troiano, 2004).

Symptoms and Signs

It is important to recognize several gynecologic and obstetric signs and symptoms that may indicate a uterine anomaly and to also remember that many females with congenital uterine anomalies are asymptomatic. Uterine agenesis presents with primary amenorrhea. Women with an obstructive anomaly may report cyclic or noncyclic pelvic pain and dysmenorrhea, and these symptoms can begin several months after menarche or into adulthood. Obstructive uterine anomalies are associated with hematometra, retrograde menstruation, and endometriosis. Endometriosis is a common finding in women with obstructive and nonobstructive müllerian anomalies. Abnormal bleeding can also occur with uterine anomalies and has been associated with septate uteri. Furthermore, vaginal anomalies may occur in conjunction with uterine anomalies, and abnormal bleeding

may be due to a partial or microperforate vaginal obstruction or a longitudinal vaginal septum. A longitudinal vaginal septum, which is associated with septate, didelphys, and bicornuate uteri, may be a woman's first presentation with a uterine anomaly; associated symptoms include difficulty with tampon insertion, bleeding around one tampon (two are required), and dyspareunia. Hence, if a vaginal anomaly is identified, then uterine imaging is warranted.

In obstetrics, congenital uterine anomalies are associated with a higher rate of poor obstetric outcomes: recurrent pregnancy loss (RPL), first- and second-trimester pregnancy loss, intrauterine growth restriction, preterm labor and delivery, placental abruption, malpresentation, and intrauterine fetal demise. Among women with RPL, the incidence of uterine anomalies is highly variable and ranges from 6% to 38%, but based on meta-analyses it is likely closer to 12% to 16% and is as high as 25% in women with second-trimester pregnancy loss (Chan, 2011; Saravelos, 2008). In one study, the odds ratio for preterm birth less than 34 weeks with a uterine anomaly was 7.4 (Hua 2011). However, many studies identify that in women with uterine anomalies, despite the high risk of miscarriage and midtrimester pregnancy loss, the chance of a live birth is greater than 50% (Grimbizis, 2001). Uterine dysfunction is thought to occur due to diminished cavity size, impaired ability to distend, abnormal myometrial and cervical function, inadequate vascularity, or abnormal endometrial development. Due to higher rates of fetal

Figure 11.14 Morphologic classification of communicating uteri. All have an isthmic communication except type 9, which has a low cervical communication. (Reprinted from Toaff ME, Lev-Toaff AS, Toaff R. Communicating uteri: review and classification with introduction of two previously unreported types. *Fertil Steril.* 1984;41[5]:661-679. Copyright 1984, with permission from The American Society for Reproductive Medicine.)

Figure 11.15 Comparison of müllerian anomalies as viewed by 3D ultrasound and MRI. The comparisons of 3D ultrasound (top row) and MRI (bottom row) are very similar. **A**, unicornuate uterus; **B**, bicornuate bicollis uterus; **C**, complete septate uterus with two cervices; **D**, partial septate uterus; **E**, uterus with diethylstilbestrol-related malformation. (From Bermejo C, Martinez Ten P, Cantarero R, et al. Three-dimensional ultrasound in the diagnosis of müllerian duct anomalies and concordance with magnetic resonance imaging. *Ultrasound Obstet Gynecol.* 2010;35[5]:593-601.)

Figure 11.16 Hysterosalpingogram (HSG) of a bicornuate uterus seen in a woman with repetitive abortions; a partial uterine septum would also look similarly on HSG. When an anomaly is appreciated on HSG, further testing is indicated to assess the myometrial contour of the uterus, which helps to make the correct diagnosis.

malpresentation, an increased rate of cesarean delivery can be seen with uterine anomalies. Additional obstetric complications, such as cervical incompetence, pregnancy-induced hypertension (due to renal anomalies), and antepartum and postpartum bleeding, are also associated with uterine anomalies. Last, pregnancy may occur in an obstructed or rudimentary uterine horn or in the fallopian tube associated with a rudimentary horn. Uterine horn pregnancies are surgical emergencies due to an 89% rate of rupture and the related morbidity and mortality (Jaysinghe, 2005).

Diagnosis

Diagnosis of a uterine anomaly may be indicated by an individual's history, suggested by physical examination, and confirmed with pelvic imaging. Depending on the population studied and the quality of the imaging, either the arcuate uterus or the septate uterus is the most common uterine anomaly. Several imaging modalities are possible as discussed previously. In general, MRI is able to assess more complex müllerian anomalies that may involve the uterus, cervix, and vagina, and simultaneous assessment of the urinary tract is possible. It is rarely necessary to perform surgery to diagnose a uterine anomaly. It must be emphasized that with müllerian anomalies, the evaluation of the urinary tract is commonly indicated to identify any concomitant abnormalities.

Management

Surgical intervention is indicated for women with obstructive anomalies with associated pelvic pain, endometriosis, and poor obstetric outcomes such as RPL, second-trimester loss, or preterm delivery. The goals of surgery include restoration of pelvic anatomy, preservation of fertility, and treatment of pelvic pain and endometriosis. Prior to attempting surgery for women with uterine anomalies and RPL or preterm delivery, it is important to rule out extrauterine causes of these obstetric issues. Of the uterine anomalies, the septate uterus is amenable to surgical correction (see Video 11.1). In contrast, the unicornuate uterus is never considered operable, but excision of a functional rudimentary uterine horn and the attached fallopian tube is recommended to prevent a horn or tubal gestation and to treat hematometra and pelvic pain. The bicornuate and didelphys uteri are considered operable in select circumstances; abdominal

metroplasty can be performed to unify a bicornuate or didelphys uterus, but it is only performed in certain patients with poor obstetric outcomes. Furthermore, when indicated, a cervical cerclage can be utilized to attempt to improve pregnancy outcomes in women with uterine anomalies and a history of poor reproductive outcomes.

Hysteroscopic metroplasty to correct a partial or complete septate uterus can improve reproductive outcomes and is indicated in women with recurrent pregnancy loss or second-trimester pregnancy loss (Homer, 2000). During the procedure, the septum is visualized and incised with a cutting device such as scissors, an electrode, or a laser, and the cavity achieves a normal contour. After the hysteroscopic procedure, the risk of pregnancy loss or other adverse perinatal outcomes decreases dramatically; live birth rates improve from 50% to approximately 80%, and miscarriage rates decrease from 45% to approximately 15% (Grimbizis, 2001; Homer, 2000). Due to its safety, simplicity, and excellent postoperative results, the hysteroscopic approach is preferred for surgical treatment of a uterine septum, and laparoscopy can be utilized to assess the fundal contour and guide the extent of septum resection but is not mandatory. The surgical treatment of uterine septa in

asymptomatic women is controversial, but some women elect to undergo surgery due to concerns regarding the obstetric risks associated with a uterine septum.

OVARIAN ABNORMALITIES

Accessory Ovary and Supernumerary Ovary

In 1959, Wharton defined *accessory ovary* and *supernumerary ovary*. The former term is used when excess ovarian tissue is noted near a normally placed ovary and connected to it. Supernumerary ovary occurs when a third ovary is separated from the normally situated ovaries. Printz and associates pointed out that such ovaries may be found in the omentum or retroperitoneally (Printz, 1973), and a dermoid cyst has been reported in a supernumerary ovary that occurred in the greater omentum. Wharton estimated that the occurrence of either accessory ovary or supernumerary ovary is rare, finding approximately 1 case of accessory ovary per 93,000 patients and 1 case of supernumerary ovary in 29,000 autopsies. In Wharton's review, three of four patients with supernumerary ovary and 5 of 19 patients with accessory ovary had additional congenital defects, most frequently abnormalities of the genitourinary tract (Wharton, 1959).

KEY POINTS

- Gender identification in a newborn infant has emotional and psychological implications and should be performed as accurately as possible. However, in the setting of ambiguous genitalia, gender assignment should not be made without definitive testing and multidisciplinary participation.
- Congenital adrenal hyperplasia is an autosomal recessive condition, most commonly the result of an inborn error of metabolism involving the enzyme 21-hydroxylase. Homozygous individuals occur in 1 of every 490 to 67,000 births, averaging 1 in 14,000, and are at risk of moderate-to-severe manifestations. Heterozygotes (carriers) are present in 1 in 20 to 1 in 250 individuals and can have a more mild presentation. Differences in incidence depend on ethnic background of the population tested.
- Up to 75% of female neonates with ambiguous genitalia may develop a sodium-wasting adrenal crisis.
- The hymen develops at the junction of the sinovaginal bulb with the urogenital sinuses and is derived from endoderm, and multiple variants of hymenal anatomy exist.
- Vaginal agenesis is most often associated with Mayer-Rokitansky-Küster-Hauser syndrome or müllerian agenesis. Up to 50% of these women will have urologic abnormalities, and approximately one in eight will have skeletal abnormalities as well.
- Anomalies of the uterus and cervix demonstrate a polygenic or multifactorial pattern of inheritance and occur in approximately 2% to 3% of the female population.
- Approximately 15% of women with a history of first-trimester recurrent miscarriage and 25% of those with a second-trimester miscarriage may have a uterine anomaly.
- The uterine septum is the only uterine anomaly that can be easily corrected with a surgical procedure. In women with poor reproductive outcomes, surgery can normalize their chances of miscarriage and live birth.

Pediatric and Adolescent Gynecology Gynecologic Examination, Infections, Trauma, Pelvic Mass, Precocious Puberty

Eduardo Lara-Torre, Fidel A. Valea

Gynecologic diseases are uncommon in children, especially compared with the incidence and prevalence of diseases in women of reproductive age. This chapter considers gynecologic diseases of children from infancy through adolescence. Congenital anomalies, precocious development, and amenorrhea are covered in more detail in other chapters.

The evaluation of children's gynecologic problems involves considerations of physiology, psychology, and developmental issues that are different from those of adult gynecology. The evaluation of young females is age dependent. For example, the physical presence of the mother often may facilitate examining a 4-year-old girl but may inhibit the cooperation of a 14-year-old adolescent. Thus the office visit and the gynecologic physical examination are performed differently in a prepubertal child compared with an adolescent girl or a mature reproductive-age woman.

GYNECOLOGIC VISIT AND EXAMINATION OF A CHILD

GENERAL APPROACH

Considerable effort should be devoted to gaining the child's confidence and establishing rapport. Young girls should feel that they are participating in their examination, not that they are being coerced or forced to have a gynecologic exam. If the interaction is poor during the first visit, the negative experience will detract from future physician-patient interactions ([Lara-Torre, 2008](#)).

The pediatric gynecologic visit may be unique to both the child and the parent. Most pediatric visits are preventive in nature. However, the pediatric gynecologic visit is usually problem oriented. This may create considerable and understandable anxiety in the child and parent. The majority of children's gynecologic problems are treated by medical, rather than surgical, means.

The most common gynecologic condition of children is vulvovaginitis. Other commonly seen diagnoses at a pediatric gynecology visit include labial adhesions, vulvar lesions, suspicion of sexual abuse, and genital trauma. Many, if not most, of these conditions will eventually require an examination to determine

the etiology of the problem. An organized stepwise approach in a nonthreatening environment is more likely to result in a successful evaluation of the genitalia.

A successful gynecologic examination of a child demands that the physician adapt an exam pace that conveys both gentleness and patience with the time spent and not seem to be hurried or rushed. One excellent technique is for the physician to sit, not stand, during the initial encounter. This conveys an unhurried approach. The ambiance of the examining room may decrease the anxiety of the child if familiar and friendly objects such as children's posters are present. Interruptions should be avoided. Speculums and instruments that might frighten a child or parent should be within drawers or cabinets and out of sight during the evaluation. If a child is scheduled to be seen in the middle of a busy clinic, the staff needs to be alerted that the pace and general routine will be different during her visit.

PERFORMANCE OF THE GYNECOLOGIC EXAM IN A CHILD

The components of a complete pediatric examination include a history; inspection with visualization of the external genitalia, non-invasive visualization of the vagina, and cervix; and, if necessary, a rectal examination ([Jacobs, 2014](#)).

Obtaining a history from a child is not an easy process. Children are not skilled historians and will often ramble, introducing many unrelated facts. Much of the history must be obtained from the parents. However, young children can help define their exact symptomatology on direct questioning. While obtaining a history, an opportunity exists to educate the child on vocabulary to describe the genital area. One way to describe genital area and breasts is to call them "private areas" and define this term as meaning areas that are covered by a bathing suit. The exam also allows a period of opportunity to counsel children, in an age-appropriate manner, about potential sexual abuse.

After the history has been obtained, the parents and the child should be reassured that the examination will not hurt. It is important to give the child a sense that she will be in control of the examination process. A helpful technique is to place the child's hand on top of the physician's hand as the abdominal

examination is being performed and to give her some choices, such as having a doll or toy with her. This will give the child a sense of control as well as divert the child's attention if she is ticklish or is squirming. Emphasize that the most important part of the examination is just "looking" and there will be conversation during the entire process. To successfully examine a child, one needs the cooperation of the patient and a medical assistant.

A child's reaction will depend on her age, emotional maturity, and previous experience with health care providers. She should be allowed to visualize and handle any instruments that will be used. Many young children's primary contact with providers involves immunizations; children should be counseled and assured that this visit does not involve any "shots." It is also helpful to assure the adult that has accompanied the child that speculums are not part of the examination.

Occasionally it is best to defer the genital examination until a second visit. This is a difficult decision and is based on the extent of the child's anxiety in relation to the severity of the clinical symptoms. Physicians may elect to treat the primary symptoms of vulvovaginitis for 2 to 3 weeks, realizing that on rare occasions they could be missing something more serious. It is recommended that the examination start with the nongenital areas, such as listening to the heart and lungs; an abdominal exam and inspection of the skin should be performed. This allows one to establish a rapport and mimics the traditional visits the child has with the pediatrician. A child should never be restrained for a gynecologic examination. Often reassurance and sometimes delay until another day are the best approaches. In rare circumstances, it may be necessary to use continuous intravenous conscious sedation or general anesthesia to complete an essential examination. The most important technique to ensure cooperation is to involve the child as a partner. Children should ideally feel they are part of the exam rather than having an "exam done to them."

Draping for the gynecologic examination may produce more anxiety than it relieves and is unnecessary in the preadolescent child. A handheld mirror may help in some instances when discussing specifics of genital anatomy. It is critical to have all tools, culture tubes, and equipment within easy reach during a pediatric genital examination. Children often cannot hold still for long intervals while instruments are being located.

The first aspect of the pelvic examination is evaluation of the external genitalia (Fig. 12.1, A through D). An infant may be examined on her mother's lap. Pads should be placed in the mother's lap, as examination often is associated with urination. Young children may be examined in the frog leg position, and children as young as 2 to 3 years of age may be examined in lithotomy with use of stirrups. Lithotomy is generally used for girls 4 to 5 years of age and older.

Once the child is positioned, the vulvar area and introitus should be inspected. Many gynecologic conditions in children may be diagnosed by inspection. The introitus will gape open with gentle pressure downward and outward on the lower thigh or undeveloped thigh or labia majora area (traction) (Fig. 12.2). Asking the child to pretend to blow out candles on a birthday cake may facilitate the process. Visualization of the introitus is better achieved using the above described traction and Valsalva than separation, as it gives a deeper view of the structures and partial visualization of the vagina.

The second phase of the examination involves evaluation of the vagina. This can be accomplished without the use of any insertion of instruments. One method is to utilize the knee chest position (see Fig. 12.1, B). The child lies prone and places her buttocks in the air with legs wide apart. The vagina will then fill with air, aiding the evaluation. The child is told to have her abdomen sag into the table. An assistant pulls upward and outward on the labia majora on one side while the examiner does the same with the nondominant hand on the contralateral labia. Then an oto/ophthalmoscope is used as a magnifying instrument and light source but *is not* inserted into the vagina.

While the light from the oto/ophthalmoscope is shone into the vagina, the examiner can evaluate the vaginal walls and visualize the cervix as a transverse ridge, or flat button, that is redder than the vagina. This technique is generally successful in cooperative children unless there is a very high crescent-shaped hymen, in which case it is too difficult to shine the light into the small aperture of the vaginal introitus. A foreign object and the cervix may be visualized using this technique. Following inspection of the vagina and cervix, vaginal secretions may be obtained for microscopic examination and culture (the technique is described later).

NORMAL FINDINGS: HYMEN AND VAGINA OF A PREPUBERTAL CHILD

The hymen of a prepubertal child exhibits a diverse range of normal variations and configurations (Fig. 12.3, A through G). Hymens are often crescent-shaped but may be annular or ring-like in configuration. They may have septums, microperforations, finger-like extensions, or be completely imperforate. There are no reported cases of congenital absence of the hymen. A mounding of hymeneal tissue is often called a *bump*. Bumps are usually a normal variant and are often attached to longitudinal ridges within the vagina. Hymens in newborns are estrogenized, resulting in a pink thick elastic redundancy. Older unestrogenized girls will have thin nonelastic hymens with significant signs of vascularity. Not every variant of hymen is normal and transections between 3 and 9 o'clock should raise a suspicion for abuse, as these are likely acquired (discussed further in Chapter 9).

The vaginal epithelium of the prepubertal child appears redder and thinner than the vagina of a woman in her reproductive years. The vagina is 4 to 6 cm long, and the secretions in a prepubertal child have a neutral or slightly alkaline pH. Recurrent vulvovaginitis, persistent bleeding, suspicion of a foreign body or neoplasm, and congenital anomalies may be indications to perform vaginoscopy and examine the inside of the vagina.

Vaginoscopy in a prepubertal child most often requires sedation with a brief inhalation or intravenous anesthetic, but it can also be performed in the office with older, cooperative children in select circumstances. The introduction of any instrument into the vagina of a young child takes skillful patience. The prepubertal vagina is narrower, thinner, and lacks the distensibility of the vagina of a woman in her reproductive years. There are many narrow-diameter endoscopes that will suffice, including the Kelly air cystoscope, contact hysteroscopes, pediatric cystoscopes, small-diameter laparoscopes, plastic vaginoscopes, and special virginal speculums designed by Huffman and Pederson. The ideal pediatric endoscope is a cystoscope or hysteroscope because the accessory channel facilitates the retrieval of foreign bodies as well as vaginal lavage. A nasal speculum or otoscope can also be used, but

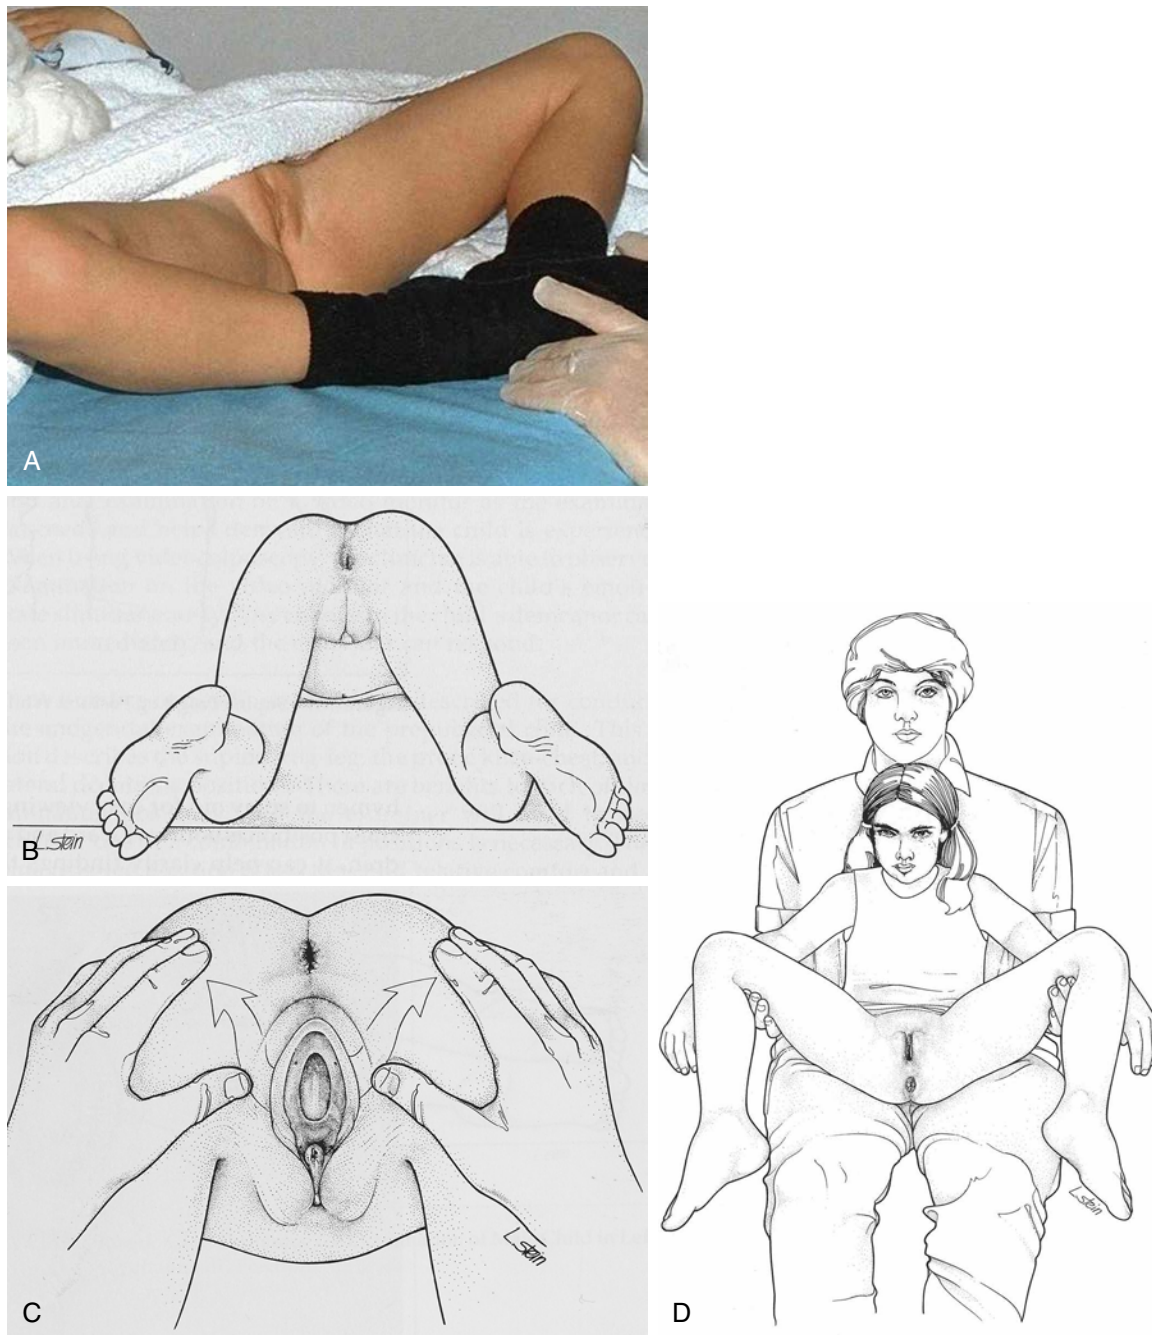

Figure 12.1 Different exam positions for performing a gynecologic exam on a child. **A**, Frog leg position. **B**, Knee chest position. **C**, Prone position. **D**, Sitting on mom's lap. (**A**, from McCann JJ, Kerns DL. *The Anatomy of Child and Adolescent Sexual Abuse: A CD-ROM Atlas/Reference*. they are usually too short for older girls and less optimal. Local anesthesia of the vestibule may be obtained with 2% topical viscous lidocaine (Xylocaine) or longer-acting products such as lidocaine/prilocaine. **A complete vaginal evaluation should never be performed under duress or by force**, frequently the reason to use sedation when performing this examination on children.

The last step in the pelvic examination may be a rectal examination. This is often the most distressing aspect of the

examination and may be omitted, depending on the child's symptoms. Common reasons to perform a rectal examination include genital tract bleeding, pelvic pain, and suspicion of a foreign body or pelvic mass. The child should be warned that the rectal examination will feel similar to the pressure of a bowel movement. The normal prepubertal uterus and ovaries are non-palpable on rectal examination. The relative size ratio of cervix to uterus is 2 to 1 in a child, in contrast to the opposite ratio in an

Figure 12.2 Examination of the vulva, hymen, and anterior vagina by gentle lateral retraction (**A**) and gentle gripping of the labia and pulling anteriorly (**B**). (From Emans SJ. Office evaluation of the child and adolescent. In: Emans SJ, Laufer MR, Goldstein DP, eds. *Pediatric and Adolescent Gynecology*. 4th ed. Philadelphia: Lippincott-Raven; 1998.)

adult. Except for the cervix, any mass discovered on rectal examination in a prepubertal exam should be considered abnormal. In this age of reliable access to ultrasonography, the internal genital exam to evaluate for the uterus and ovaries can be performed with the assistance of sonography, sparing the child from a rectopelvic or pelvic examination.

THE OFFICE VISIT AND EXAMINATION OF THE ADOLESCENT FEMALE

Adolescence is the period of life during which an individual matures physically and begins to transition psychologically from a child into an adult. This period of transition involves important physical and emotional changes. Before puberty, the girl's reproductive organs are in a resting, dormant state. Puberty produces dramatic alterations in the external and the internal female genitalia, as well as the adolescent's hormonal milieu. Because the pubertal changes are frequently a cause of concern for adolescent females and their parents, the gynecologist must offer the adolescent female an empathetic, kind, knowledgeable, and gentle approach. These interactions between the physician and the adolescent female will

allow the physician an opportunity to gain her trust and educate the pubertal teenager about pelvic anatomy and reproduction.

The critical factors surrounding the pelvic examination of a female adolescent are different from those of examinations of children 2 to 8 years old. Many female adolescents do not want their mother, guardian, or other observers in the examining room. In many adolescent gynecology visits, a full pelvic exam is unnecessary (Lara-Torre, 2008). Frequent indications for a pelvic exam in an adolescent are listed in Box 12.1.

Each adolescent is at a different stage of development, and the approach to the exam may require variations that fit her developmental stage. A patient in early adolescence (12 to 14 years of age) may behave and need similar support as those in the prepubertal stages. They may ask for their mothers to be there, be fearful of the examination concept, and need more than one visit to achieve the goals of the visit. Those in middle or late adolescence (15 to 19 years of age) may be more acceptable to the idea of an exam and more likely to cooperate with the proper counseling and in the appropriate setting (ACOG, 2011).

Adolescents often come for examinations with preconceived ideas that it will be very painful. Slang terminology for speculums among teens includes the threatening label "the clamp." Teens should be assured that although the exam may include mild discomfort, it is not painful. Providers can counsel patients that they will inform them of each step in the process and then ask the teen if she is ready before performing each step. This places the teen in control of the tempo and allows her to anticipate the next element of the examination. Allowing them to see and touch the instruments also may assist in demystifying the exam and allow for it to flow more smoothly. Use of the "extinction phenomenon" may be helpful in this setting. The examiner provides pressure lateral to the introitus on the perineum prior to insertion of the speculum.

PROBLEMS IN PREPUBERTAL CHILDREN

Vulvovaginitis

Vulvovaginitis is the most common gynecologic problem in the prepubertal female. It is estimated that 80% to 90% of outpatient visits of children to gynecologists involve the classic symptoms of vulvovaginitis: introital irritation (discomfort/pruritus) or discharge (Table 12.1) (Farrington, 1997).

The prepubertal vagina is neutral or slightly alkaline. With puberty the prepubertal vagina becomes acidic under the influence of bacilli dependent on a glycogenated estrogen-dependent vagina. Breast budding is a reliable sign that the vaginal pH is shifting to an acidic environment.

The severity of vulvovaginitis symptoms varies widely from child to child. The pathophysiology of the majority of instances of vulvovaginitis in children involves a primary irritation of the vulva, which may be accompanied by secondary involvement of the lower one third of the vagina. Most cases involve an irritation of the vulvar epithelium by normal rectal flora or chemical irritants. This is referred to as *nonspecific vulvovaginitis*. There often are predisposing factors that lead to vulvar irritations such as the use of perfumed soaps, the pressure from tight seams of jeans or tights, and the like, which create denudation, allowing the rectal flora to easily infect the irritated epithelium. Cultures from the vagina return as normal rectal flora or *Escherichia coli*.

Figure 12.3 Types of hymens. **A**, Crescentic. **B**, Annular. **C**, Redundant. **D**, Microperforate. **E**, Septated. **F**, Imperforate. **G**, Hymeneal tags. (**A** through **F**, From Perlman SE, Nakajima ST, Hertweck SP. *Clinical Protocols in Pediatric and Adolescent Gynecology*. London: Parthenon Publishing Group; 2004; **G**, From McCann JJ, Kerns DL. *The Anatomy of Child and Adolescent Sexual Abuse: A CD-ROM Atlas/Reference*. St. Louis: InterCorp; 1999.)

In a primary care setting, nonspecific vulvovaginitis accounts for the majority of vulvovaginitis cases.

There are both physiologic and behavioral reasons why a child is susceptible to vulvar infection. Physiologically, the child's vulva and vagina are exposed to bacterial contamination from the rectum more frequently than are the adult's. Because the child lacks the labial fat pads and pubic hair of the adult, when a child squats, the lower one third of the vagina is unprotected

and open. There is no significant geographic barrier between the vagina and anus. The vulvar and vaginal epithelium lack the protective effects of estrogen and thus are sensitive to irritation or infection. The labia minora are thin and the vulvar skin is red because the abundant capillary network is easily visualized in the thin skin. The vaginal epithelium of a prepubertal child has a neutral or slightly alkaline pH, which provides an excellent medium for bacterial growth. The vagina of a child lacks

glycogen, lactobacilli, and a sufficient level of antibodies to help resist infection. The normal vagina of a prepubertal child is colonized by an average of nine different species of bacteria: four aerobic and facultative anaerobic species and five obligatory anaerobic species.

A major factor in childhood vulvovaginitis is poor perineal hygiene (Box 12.2). This results from the anatomic proximity of the rectum and vagina coupled with the fact that following toilet training, most youngsters are unsupervised when they defecate. Many youngsters wipe their anus from posterior to anterior and thus inoculate the vulvar skin with intestinal flora. A minor vulvar irritation may result in a scratch-itch cycle, with the possibility of secondary seeding because children wash their hands infrequently. Children's clothing is often tight fitting and nonabsorbent, which keeps the vulvar skin irritated, warm, moist, and prone to vulvovaginitis.

In some cases, nonspecific vulvovaginitis may be caused by carrying viral infections from coughing into the hands directly to the abraded vulvar epithelium. Similarly, a child with an upper respiratory tract infection may autoinoculate her vulva, especially with specific organisms (see Box 12.2). Vulvovaginitis in children may also be caused by a variety of specific pathogens such as group A or group B β -hemolytic streptococci, *Haemophilus influenzae*, and *Shigella boydii*; *Neisseria gonorrhoeae*, *Trichomonas vaginalis*, and *Chlamydia trachomatis* may also be responsible in cases associated with abuse but are significantly less common.

Pinworms are another cause of vulvovaginitis in prepubertal children. Approximately 20% of female children infected with pinworms (*Enterobius vermicularis*) develop vulvovaginitis. The classic symptom of pinworms is nocturnal vulvar and perianal itching. At night the milk-white, pin-sized adult worms migrate from the rectum to the skin of the vulva to deposit eggs. They

may be discovered by means of a flashlight or by dabbing of the vulvar skin with clear cellophane adhesive tape ideally before the child has arisen in the morning. The tape is subsequently examined under the microscope.

Despite common belief, mycotic (yeast) vaginal infections are not common in prepubertal children, as the alkaline pH of the vagina does not support fungal growth. Mycotic vaginal infections may be seen in immunosuppressed prepubertal girls such as HIV patients, diabetic children, or patients on chronic steroid therapy. It can also present in patients using diapers as a chronic colonization

Figure 12.4 Assembled catheter within a catheter, as used to obtain samples of vaginal secretions from prepubertal patients. (Modified from Pokorny SF, Stormer J. Atraumatic removal of secretions from the prepubertal vagina. *Am J Obstet Gynecol.* 1987;156[3]:581-582.)

(diaper rash). Other specific causes of vulvovaginitis may include systemic diseases, chicken pox, and herpes simplex infection.

There is nothing specific about the symptoms or signs of childhood vulvovaginitis. Often the first awareness comes when the mother notices staining of the child's underwear or the child complains of itching or burning. There is a wide range in the quantity of discharge, from minimal to copious. The color ranges from white or gray to yellow or green. A discharge that is both bloody and purulent is likely not from vulvovaginitis but from a foreign body (see "Vaginoscopy for Prepubertal Bleeding without Signs of Puberty," presented later in this chapter), although patients infected with some pathogens, particularly *Shigella boydii*, often present with a bloody or blood-tinged discharge. The signs of vulvovaginitis are variable and not diagnostic, but they include vulvar erythema, edema, and excoriation.

The differential diagnosis of persistent or recurrent vulvovaginitis not responsive to treatment should include considerations of a foreign body, primary vulvar skin disease (allergic or contact dermatitis), ectopic ureter, and child abuse. If the predominant symptom is pruritus, then pinworms or an irritant/nonspecific vulvitis is the most likely diagnosis.

The vulvar skin of children may also be affected by systemic skin diseases, including lichen sclerosus, seborrheic dermatitis, psoriasis, and atopic dermatitis. The classic perianal "figure-8" or "hourglass" rash is indicative of lichen sclerosus with white patches and in some cases local trauma. An ectopic ureter emptying into the vagina may only intermittently release a small amount of urine; thus this rare congenital anomaly should be considered in the differential diagnosis in young children.

Treatment of Vulvovaginitis

The foundation of treating childhood vulvovaginitis is the improvement of local perineal hygiene. Both parent and child should be instructed that the vulvar skin should be kept clean, dry, and cool, and irritants should be avoided. The child should be instructed to void with her knees spread wide apart (even while facing the toilet to improve urine draining) and taught to wipe from front to back after defecation. Loose-fitting cotton undergarments should be worn. Chemicals that may be allergens or irritants, such as bubble bath, must be discontinued. Harsh soaps and chemicals should be avoided. Instructing patients to use nonmedicated, nonscented wipes rather than toilet paper may prevent the self-inoculation of the vagina with small pieces that can initiate a chronic discharge.

Most episodes of childhood vulvovaginitis are cured solely by improved local hygiene. The majority of symptoms improve

with hygienic changes and sitz baths (warm water, no soaps or chemicals). Utilizing this approach for a 2-week period should resolve most symptoms in patients with nonspecific vulvovaginitis. When this intervention fails, the suspicion for bacterial colonization is greater and a reasonable approach is the use of broad-spectrum oral antibiotics such as amoxicillin or trimethoprim sulfamethoxazole given for 10 to 14 days. Without continuation of the hygiene measures, then broad-spectrum antibiotics will only offer temporary relief, and the problem is likely to recur (Bercaw-Pratt, 2014).

If patients are going to be treated with antibiotics, one should attempt to collect a culture of the vulvovaginal discharge prior to initiation of the antibiotics. In noncooperative children, treatment should not be withheld if unable to collect a specimen and empiric treatment may be started. For attempting to collect a specimen, many techniques have been described including the use of a very slim urethral Dacron swab moistened with nonbacteriostatic saline (used for collection of male urethral cultures). Pokorny has described another method for collecting fluid from a child's vagina using a catheter within a catheter (Pokorny, 1987). This easily assembled adaptation uses a No. 12 red rubber bladder catheter for the outer catheter and the hub end of an intravenous butterfly catheter for the inner catheter (Fig. 12.4). The outer catheter serves as an insulator, and the inner catheter is used to instill a small amount of saline and aspirate into the vaginal fluid. The results of the vaginal culture may demonstrate a single organism that is a respiratory, intestinal, or sexually transmitted disease pathogen. The presence of sexually transmitted organisms in a child is usually a strong indication that sexual abuse may have taken place and appropriate referral and follow-up is necessary (see Chapter 9).

OTHER PREPUBERTAL GYNECOLOGIC PROBLEMS

Labial Adhesions

Labial adhesions literally mean the labia minora have adhered or agglutinated together at the midline. Another term sometimes used to describe this condition is *adhesive vulvitis*. Denuded epithelium of adjacent labia minora agglutinates and fuses the two labia together, creating a "flat appearance" of the vulvar surface. A telltale somewhat translucent vertical midline line is visible on physical exam at the site agglutination. This thin, narrow line in a vertical direction is pathognomonic for labial adhesions (Fig. 12.5). Labial adhesions are often partial and only involve the upper or lower aspects of the labia. Small adhesions are common

Figure 12.5 Labial adhesions before and after treatment. (From Acker A, Jamieson MA. Use of intranasal midazolam for manual separation of labial adhesions in the office. *J Pediatr Adolesc Gynecol.* 2013;26[3]:196-198.)

in preschool children, and perhaps as many as 20% will have some degree of labial adhesions on routine examination (Bacon, 2015).

Inexperienced examiners may confuse labial adhesions for an imperforate hymen or vaginal agenesis. Although the physical exam findings are significantly different, all of these conditions may occlude the visualization of the vaginal introitus. In the patient with an imperforate hymen, the labia minora normally appear like an upside down V, and no hymeneal fringe is visible at the introitus. In vaginal agenesis, the hymeneal fringe is typically normal, but the vaginal canal ends blindly behind the hymeneal fringe.

Labial adhesions are most common in girls between 2 and 6 years of age, with up to 90% of cases occurring before age 6. Estrogen reaches a nadir during this time, predisposing the non-estrogenized labia to denudation.

There is considerable variation in the length of agglutination of the two labia minora. In the most advanced cases, there is fusion over both the urethral and the vaginal orifices. It is extremely rare for this fusion to be complete, and most children urinate through openings at the top of the adhesions, even when the urethra cannot be visualized (pinpoint opening). However,

the partially fused labia may form a pouch in which urine is caught and later dribbled, presenting as incontinence. Associated urinary infections have also been reported and may be the presenting symptom leading to the diagnosis. Most patients will be asymptomatic or present with intermittent dysuria.

The recommended treatment in asymptomatic patients is observation (Bacon, 2015). Most of the time treatment requests are driven by the parental concern of a closed vagina and their interpretation that this may lead to an inability to have children in the future or engage in intercourse. Although they do not explicitly say this, upon further questioning, many parents disclose this kind of concern. With appropriate counseling and reassurance of the benign and common nature of this condition, as well as the likely resolution during puberty, most parents are reassured and follow advice. The majority of the patients will fall into this category and can be reassured and followed over time to spontaneous resolution when they produce their own endogenous estrogen. If spontaneous separation does not occur at puberty, and manual separation is required, the presence of a better estrogenized skin will decrease the chances of recurrence which in children can range from 25% to 65%.

Some children will present with symptoms and may include voiding difficulties, dysuria, frequent urinary infections, urine dribbling after voiding, recurrent vulvovaginitis, discomfort from the labia pulling at the line of adhesions, and in rare cases bleeding from the line of adhesion pulling apart.

Attempts to separate the adhesions apart in the office by pulling briskly on the labia minora should not be done. It is very painful, and the raw edges are likely to adhere again as the child will be reticent to allow application of medication after being subjected to this degree of pain. Even with local anesthesia, such as lidocaine ointments or creams, the potential pain and traumatic experience for the child should deter from this intervention, except in the well-motivated, mature child.

The most commonly utilized treatment of this condition is topical estrogen cream applied onto the labia two times per day at the site of fusion. This will usually result in spontaneous separation, usually in approximately 2 to 8 weeks. In cases when resolution takes longer than several weeks, the clinician can reexamine the patient. If increased pigmentation is noted lateral to the midline line of agglutination, the caregiver should be instructed to apply the cream to the line, as the lateral pigmentation indicates the estrogen is being applied lateral to the actual adhesion. The action of estrogen as well as the application over the adhesion line itself makes the treatment more effective. Care should be taken to not prolong the topical use of estrogen for more than 6 to 8 weeks. Prolonged use of topical estrogen has been associated with breast budding and in some less common cases vaginal bleeding from the peripheral effects of the absorption of estrogen. Failure of separation within the normal time frame should trigger alternate treatment.

When patients fail estrogen therapy, and symptoms persist, the use of topical corticosteroids twice a day for 6 to 8 weeks has also shown adequate results and can be considered as a first or secondary line of treatment.

Once the condition has been resolved, recurrence can often be prevented by applying a bland ointment (such as zinc oxide cream or petroleum jelly) to the raw epithelial edges for at least 1 month or even longer. As previously mentioned, recurrences are common.

McCann and colleagues reported the association between injuries of the posterior fourchette and labial adhesions in sexually abused children (McCann, 1988). Labial agglutination alone is so common that immediate suspicion of child abuse based solely on this finding in 2- to 6-year-olds is unwarranted. However, the combination of labial adhesions and scarring of the posterior fourchette, especially in children with new-onset labial adhesions after age 6, should prompt the clinician to consider sexual abuse in the differential diagnosis.

Physiologic Discharge of Puberty

In the early stages of puberty, children often develop a physiologic vaginal discharge. This discharge is typically described as having a gray-white coloration, although it may appear slightly yellow but is not purulent. The physiologic discharge represents desquamation of the vaginal epithelium. The estrogenic environment allows acid-producing bacilli to become part of the normal vaginal ecosystem. The acids the bacilli produce cause a desquamation of the prepubertal vaginal epithelium. When the physiologic discharge is examined with the microscope, sheets of vaginal epithelial cells are identified.

Clinically, there is usually very little symptomatology associated with this discharge. Occasionally the thickness of the discharge causes the vulva to be “pasted” to undergarments and causes some symptoms of irritation and erythema. Usually the only treatment necessary is reassurance of both mother and child that this is a normal physiologic process that will subside with time. Symptomatic children may be treated with sitz baths and frequent changing of underwear.

Urethral Prolapse

Prolapse of the urethral mucosa is not a rare event in children. The most common presentation is not urinary symptomatology but prepubertal bleeding. Often a sharp increase in abdominal pressure, such as coughing, precedes the urethral prolapse. On examination, the distal aspect of urethral mucosa may be prolapsed along the entire 360 degrees of the urethra (Fig. 12.6). This forms a red donut-like structure. The prolapse may be partial or incomplete, presenting as a ridge of erythematous tissue. It is critical to distinguish this from grapelike masses of sarcoma botryoides that originate from the vagina. Occasionally the prolapse becomes necrotic and blue-black in color.

The most common treatment is conservative and nonsurgical. Topical estrogen has been found effective in the management of this condition in many case reports and series. Although no randomized control trials exist, the short duration of treatment and shown benefits on these series supports treatment to prevent necrosis. Surgery is seldom necessary, except in rare cases where necrosis is obviously present.

Lichen Sclerosus

Lichen sclerosus (LS), or lichen sclerosus atrophicus, is a skin dystrophy most commonly seen in postmenopausal women and prepubertal children. The cause is unclear, although there is some evidence that it may be associated with autoimmune phenomena. This has not been confirmed by prospective studies. Histologically, there is thinning of the vulvar epithelium with loss of the rete pegs. The most common symptoms are pruritus and vulvar discomfort. Other presentations may include prepubertal bleeding from trauma, constipation, and dysuria (Bercau-Pratt, 2014).

Figure 12.6 Prepubertal urethral prolapse with high crescent-shaped hymen.

The appearance of LS varies, but lesions are always limited by the labia majora. If lesions go beyond the labia majora, the condition is unlikely to be LS. The lesion often appears in an hour-glass or figure-8 formation involving the genital and perianal area (Fig. 12.7). The skin may be lichenified with a hypopigmented parchment-like appearance. Parents may note that the genital area appears whitened. Pruritus is typical presenting symptom. Secondary changes may occur subsequent to the patient excoriating the area. When this occurs, there are often signs of trauma and breaks in the integument, which in turn can become colonized with skin bacteria and create a superimposed bacterial dermatitis.

Given the abnormal appearance of LS with secondary changes, clinicians unfamiliar with this skin dystrophy often arrive at the misdiagnosis of sexual abuse. However, clinicians experienced in pediatric or postmenopausal gynecology will usually have no difficulty arriving at the correct diagnosis. Given the classic appearance in children, and the lack of association at this age with cancer, a biopsy is not necessary or indicated before treatment. In cases in which the diagnosis is unclear, or recalcitrant to therapy, a small punch biopsy may confirm the diagnosis. Performing a biopsy in prepubertal children is often difficult. Many children will not tolerate a local injection, and holding down children to perform a biopsy is clearly not acceptable. Sedation anesthesia is preferable in this situation. Rarely, children will tolerate a biopsy using local anesthesia.

The treatment of LS in children should always start with avoiding irritation or trauma to the genital epithelium. Children should be encouraged to avoid straddle activities such as bicycle or tricycle riding when symptomatic. Patients should clean the labia by soaking in sitz baths. Parents sometimes may assume lack of cleanliness is contributing to the disorder and scrub the area with soap, which may actually exacerbate the disease. Tight clothing such as jeans or tights may also abrade and irritate the vulva.

Figure 12.7 Typical appearance of lichen sclerosus in a 9-year-old with 1-year history of vulvar pruritus. (From Bercaw-Pratt JL, Boardman LA, Simms-Cendan JS, North American Society for Pediatric and Adolescent Gynecology. Clinical recommendation: pediatric lichen sclerosus. *J Pediatr Adolesc Gynecol.* 2014;27[2]:111-116.)

The North American Society of Pediatric and Adolescent Gynecology (NASPAG) recommends the use of high-potency steroids such as clobetasol as the initial step in treatment of this condition. Tapering the steroid level should be considered as soon as a response is seen or within a 4- to 6-week interval. The tapering can be achieved by following the initial treatment with a 2- to 3-week of midpotency steroid such as betamethasone and conclude with 1% hydrocortisone for another 2 weeks (Fig. 12.8). The use of ointments is preferred over creams given there is less irritation compared with creams and the petroleum base of ointments appear to help it stay in place longer. The parents should apply the drug sparingly but consistently, avoiding application to nonaffected areas to prevent systemic effects of the drug such as adrenal suppression.

Recurrence or “flares” of the condition are common and continue for a significant period of time in most patients. Previously, many authors have asserted that LS improves with puberty. Though improvement and resolution occur sometimes, many patients will continue to have symptoms or physical findings.

PREPUBERTAL BLEEDING WITHOUT SECONDARY SIGNS OF PUBERTY

Puberty in the female is the process of biologic change and physical development after which sexual reproduction becomes possible. This is a time of accelerated linear skeletal growth and development of secondary sexual characteristics, such as breast development and the appearance of axillary and pubic hair. The usual sequence of the physiologic events of

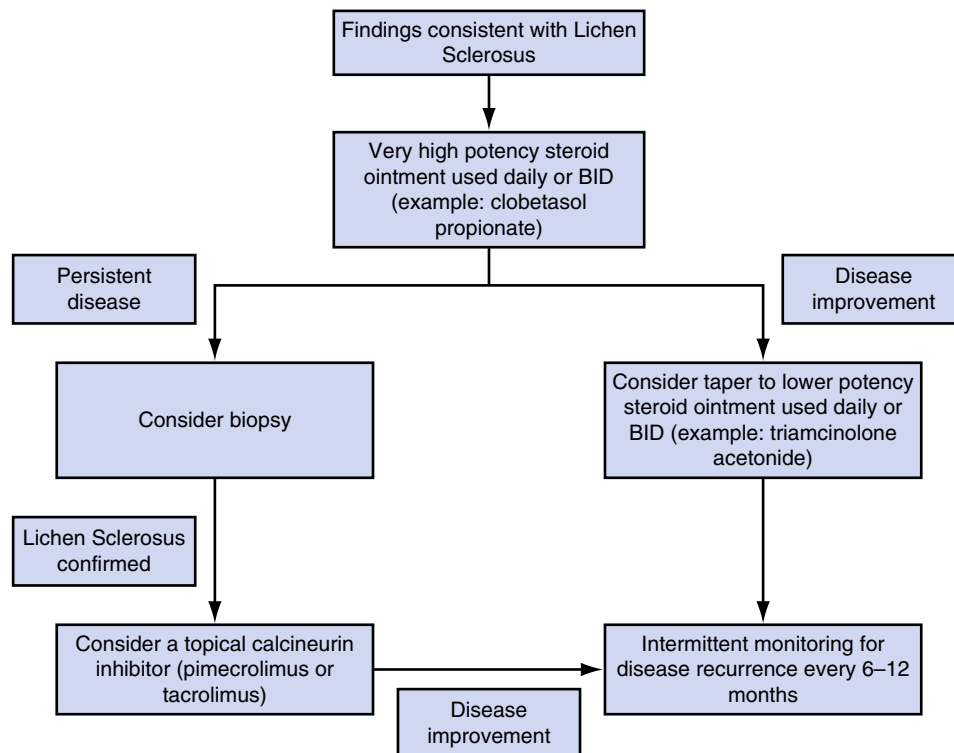

Figure 12.8 Algorithm for treatment of lichen sclerosus in children. (From Bercaw-Pratt JL, Boardman LA, Simms-Cendan JS, North American Society for Pediatric and Adolescent Gynecology. Clinical recommendation: pediatric lichen sclerosus. *J Pediatr Adolesc Gynecol.* 2014;27[2]:111-116.)

Box 12.3 Differential Diagnosis of Prepubertal Bleeding without Any Breast Development

Foreign object
Genital trauma
Sexual abuse
Lichen sclerosus
Infectious vaginitis (especially from *Shigella*)
Urethral prolapse
Breakdown of labial adhesions
Friable genital warts or vulvar lesions
Vaginal tumor
Rare presentation of McCune-Albright syndrome (typically have breast development)
Isolated menarche (controversial)
Dermatologic conditions with secondary excoriation
Nongenital bleeding; mistaken as genital: rectal and urinary

puberty begins with a somatic change: an increase in growth velocity followed by either breast development (thelarche) or the appearance of pubic hair (adrenarche), followed by the period of maximal growth velocity (approximately 9 cm/year), and, last, menarche. The onset of thelarche typically precedes adrenarche in white girls. In contrast, African-American girls often have adrenarche prior to thelarche (up to 15% of girls) (Appelbaum, 2012).

A cross-sectional study of more than 1700 American girls provided contemporary data on pubertal timing (the Pediatric Research in Office Settings [PROS] study) (Herman-Giddens, 1997). In this study approximately one third of the African-American girls had thelarche or adrenarche at age 7 and almost 50% by age 8. Approximately 15% of white girls had initiated puberty by age 8 and almost 40% by age 9. Mean ages for thelarche and adrenarche were 8.9 and 8.8 for African-American girls and 10 and 10.5 years for white girls, respectively. The mean age of menarche was almost 12.2 years for the African-American girls compared with 12.8 years in the white girls. It should be noted that these ages of pubertal onset were significantly earlier, and sequences somewhat different, than previous, much older, classic descriptions of British children published by Marshall and Tanner (Marshall, 1969).

Recommendations from the PROS have included a new guideline regarding the definition of precocious development. They propose that precocious puberty should be defined as thelarche or adrenarche prior to age 6 in African-American girls or 7 in white girls. These recommendations are controversial, as some serious pathologic causes (endocrine or central nervous system [CNS]) could be overlooked if these guidelines were strictly upheld. Certainly, in girls younger than 8 with CNS or behavioral issues, a pathologic etiology of development should be entertained. A common clinical problem that is sometimes mistaken for precocious puberty is prepubertal bleeding in children without any other signs of puberty such as breast development (Box 12.3).

Vaginal Bleeding

The normal sequence of puberty is that thelarche precedes menarche. In children with prepubertal bleeding without breast budding, there is almost never an endocrinologic cause, with the exception being a rare presentation of McCune-Albright

syndrome (polyostotic fibrous dysplasia) or the uncommon presentation of isolated premature menarche.

The differential diagnosis of vaginal bleeding without pubertal development includes foreign body, vulvar excoriation, lichen sclerosus, shigella vaginitis, separation of labial adhesions, trauma (abuse and accidental), urethral prolapse, and friable genital warts (see Box 12.2). Rare causes include malignant tumors (sarcoma botryoides and endodermal sinus tumors of the vagina) and an unusual presentation of McCune-Albright syndrome. Lists of the differential diagnosis of prepubertal bleeding often also include accidental estrogen exposure (for example, from ingestion of a mother's birth control pills or prolonged use of estrogen topical therapy). However, in reality such exposure would rarely provide enough endometrial stimulation to produce a withdrawal bleed without breast budding. Neonates may develop a white mucoid vaginal discharge or a small amount of vaginal spotting because of the withdrawal of maternal estrogens. The discharge and vaginal spotting are self-limited.

It should be remembered that although the differential diagnosis of prepubertal bleeding includes sexual abuse, most sexually abused children do not have prepubertal bleeding. In some settings, such as emergency departments, it is more likely that prepubertal bleeding is due to sexual abuse than in primary pediatric office or a tertiary referral practice.

Foreign Bodies

Symptoms secondary to a vaginal foreign body are responsible for approximately 4% of pediatric gynecologic outpatient visits. The majority of foreign bodies are found in girls between 3 and 9 years of age. The history is usually not helpful because an adult has not witnessed, nor does the child remember, putting a foreign object into the vagina. Many types of foreign bodies have been discovered; however, the most common are small wads of toilet paper. Other common foreign objects include small, hard objects such as hairpins, parts of a toy, tips of plastic markers, crayons, and sand or gravel. Some of these objects are not radiopaque. When small swabs are used to perform vaginal cultures, the examiner may note an odd sensation of touching something other than vaginal mucosa. Objects such as coins and plastic toys are often easily visible on vaginal examination, especially in the knee-chest position. Children may insert foreign bodies because the genital area is pruritic or when naturally curious children are exploring their bodies.

The classic symptom is a foul, bloody vaginal discharge. However, the discharge is often purulent and without blood. The natural history probably reflects the object initially causing irritation, creating a purulent discharge, and then as the object imbeds itself into the vaginal epithelium, bleeding and spotting may occur. There is often a lag between insertion of the object and the vaginal bleeding. Over time, the foreign body may become partially "buried" or imbedded within the vaginal wall. These imbedded objects are often difficult to remove without discomfort and may require sedation.

The presence of unexplained vaginal bleeding is an indication for a vaginoscopy. Especially in children younger than 6 years of age, without signs of an endocrinopathy (breast budding, estrogenization of the hymen), this should be done expeditiously to rule out malignant vaginal tumors. If an object is seen on exam, the clinician may be able, in a cooperative child, to either grasp the object with a forceps or wash the object out

by irrigation. The catheter technique described previously may be utilized. The use of a pediatric feeding tube with room temperature or warmed saline can also be used to “flush” the vagina. With either technique, care should be taken to minimize contact with the hymen, as it is a sensitive area at this age and the sensation can be enough for the child to stop cooperating with the procedure. In many instances this is not possible because the child cannot cooperate or because a solid object is imbedded into the vaginal wall. In these cases the object can be removed at vaginoscopy.

Children who insert foreign objects often have recurrences. This may be secondary to persistent pain or pruritus in the genital area that was not addressed at the initial encounter, and the child uses the object (solid or toilet paper) to rub or scratch the genital area. If the foreign object is toilet paper, then having the child use wipes instead of toilet paper may reduce recurrences.

Shigella Vaginitis

Approximately half of all cases of *Shigella* vaginitis present with prepubertal bleeding. There is generally no concurrent gastrointestinal symptomatology. Cultures for *Shigella* should be strongly considered in any child with no obvious cause for prepubertal bleeding. Rarely, vaginitis caused by other organisms can also present with prepubertal bleeding.

Rare Causes: Vaginal Tumors and McCune-Albright Syndrome

McCune-Albright syndrome is a rare somatic mutation that occurs during embryogenesis in neural crest cells. Because the mutation does not occur in the germline, it is not inherited. The mutation affects G protein receptors and has a variable expression, depending on how many early cells are affected (an example of mosaicism). The *GNAS1* gene is the affected area. Patients with the syndrome may manifest the classic triad of café-au-lait spots, abnormal bone lesions, and precocious puberty. Most McCune-Albright patients present with prepubertal bleeding along with thelarche. Rarely a child may present with bleeding and no breast budding. Examination of the child with prepubertal bleeding should include examination of the skin for café-au-lait spots, and the historical intake should include queries about frequent bone fractures. In cases of unexplained prepubertal bleeding, the possibility of McCune-Albright should be considered, and serial breast examinations may reveal breast budding.

Sarcoma Botryoides and Endodermal Sinus Tumors of the Vagina

Almost all cases of sarcoma botryoides of the vagina in prepubertal children occur prior to age 6 (although cases up until age 8 have been reported), and endodermal sinus tumors occur prior to age 2. Although these tumors are extremely rare causes of prepubertal bleeding, they must be considered in every young child. Both are aggressive malignancies, and prompt diagnosis is critical. In young children with no evident cause of prepubertal bleeding, a vaginoscopy should be done to rule out these malignancies.

Vaginoscopy for Prepubertal Bleeding without Signs of Puberty

Many times, no clear cause of prepubertal bleeding is defined at vaginoscopy. In these cases there likely was a small foreign object that has been expelled from the vagina or disintegrated. Even

though many vaginoscopies are negative, it is especially important for clinicians to perform them promptly in young prepubertal bleeders to exclude rare but aggressive vaginal malignancies.

ACCIDENTAL GENITAL TRAUMA

The usual cause of accidental genital trauma during childhood is a fall. Seventy-five percent of accidental trauma to the vulva and vagina involves straddle injuries. Obviously, sexual abuse is an important consideration in the differential diagnosis (Bond, 1995). Sexual abuse in a child is discussed later in this chapter.

VULVAR TRAUMA: LACERATIONS AND STRADDLE INJURY

One of the most common causes of genital trauma in a child is a straddle injury. This problem occurs when a child stands, or hovers, with her legs apart over a hard object and then falls with the perineum against the object. Common straddle injuries in children occur on playground climbing structures, such as a monkey bar, or fence rails and around the edges of pools. A straddle injury generally results in unilateral and superficial injury and rarely involves the hymen. In two separate series involving more than 130 children with straddle injuries, only 3 had hymeneal transection (Dowd, 1994).

In cases of hymeneal transection with a history of straddle injury, sexual abuse should be strongly considered. In the rare cases in which the hymen is transected from accidental trauma, there is usually a history of a penetrating injury such as falling onto a stick horse or broom. If hymeneal transection has occurred, the examiner must confirm that the object has not penetrated into the vaginal wall, which could result in a dangerous hematoma, perforation into the cul-de-sac, or perforation of the abdominal cavity with potential visceral damage. A vaginoscopy or laparoscopy (or both) is generally required to rule out these possibilities. Perforations into the abdomen may not result in significant vaginal bleeding.

In children presenting with trauma and genital bleeding, the examiner must first ascertain the site, extent, and amount of bleeding. Viscous lidocaine or a longer-acting topical agent such as lidocaine/prilocaine can be applied and allowed appropriate time to provide anesthesia. Then the area can be gently washed by irrigating with sterile warmed water onto the labial area. Typical lacerations may involve denudation around the urethra or labia. The posterior fourchette is less commonly involved. In children with vulvar trauma, considerations should be given to giving a booster injection of tetanus toxoid if the last immunization was more than 5 years before the trauma.

Lacerations that are superficial (equivalent to first-degree obstetric lacerations) generally do not require repair in contrast to deeper lacerations. Often, superficial lacerations can be adequately treated by applying oxidized cellulose or similar products to stop the bleeding. Slightly deeper lacerations can be repaired with small Steri-Strips. In some deeper lacerations, one well-placed suture will stop substantial bleeding. This scenario is typical of lacerations on the inferior aspect of the labia minora. Placement of the suture may be aided by injection of lidocaine in cooperative children or by conscious sedation in the emergency department.

General anesthesia is usually required for diagnosis and treatment of extensive lacerations and deep lacerations or in children who are unable to tolerate repair in the office or emergency department. In patients in whom the extent of the laceration cannot be visualized an exam under anesthesia should be performed to prevent missing deeper lacerations than what is visualized in the emergency room. While anesthetized, the laceration should be irrigated and débrided, the vessels ligated, and the injuries repaired. Occasionally it is necessary to perform laparoscopy or an exploratory laparotomy for a suspected retroperitoneal hematoma or intraabdominal injury. Appropriate consultation with urology or pediatric surgery is recommended when the extent of the laceration is beyond the vulvar-vaginal areas.

Vulvar Hematomas

If the vulva strikes a blunt object, a hematoma usually results. The lack of the mature reproductive woman's fat pad in the vulvar area predisposes a young child to bleeding from trauma. If the object is sharp, such as a fence post or skating blade, the injury may be a laceration with the potential for penetration of the perineum and injury to internal pelvic organs. Other common causes of vulvar and vaginal trauma include sexual abuse, automobile and bicycle accidents, kicks sustained in a fight, and self-inflicted wounds (Fig. 12.9).

The size of vulvar and vaginal hematomas varies widely. Initially there is bleeding into the loose connective tissue. When the pressure from the expanding hematoma exceeds the venous pressure, in most cases the hematoma will stop growing. In the majority of cases, surgical exploration should be avoided. It is rare to find a specific vessel to ligate except in cases in which the

hematoma is quickly expanding over 1 to 2 minutes of observation, which likely represents a rare arterial laceration. The extent of the hematoma should be determined by both visualization and palpation. The treatment of nonexpanding vulvar hematomas is observation by serial examinations and the use of an ice pack or cool sitz bath and pain medications. Patients may have difficulty voiding secondary to urethral injury or because they are anxious to void onto abraded vulvar surfaces or secondary to urinary obstruction or a urinary injury.

SEXUAL ABUSE

Sexual abuse in reproductive women is covered in [Chapter 9](#). This chapter contains information specifically related to sexual abuse in the prepubertal child. For a detailed and complete description of evaluation and treatment of the potentially sexually abused child, practitioners should refer to the American Academy of Pediatrics guidelines, initially published in 2009 and reaffirmed in 2013 (Kellogg, 2009), as well as the Sexually Transmitted Diseases Treatment Guidelines from the Centers for Disease Control and Prevention (CDC, 2015). These documents also contain a detailed table that describes the implications of commonly encountered sexually transmitted or sexually associated infections in the diagnosis and reporting of sexual abuse in children (Jenny, 2013).

Scope of the Problem

Unfortunately, the sexual abuse of children is extremely common in the United States. Estimates indicate that approximately 20% of girls are involved in some type of sexual activity during childhood. Globally this number is even higher, with approximately one fourth of all girls victimized sexually during childhood. Although abduction cases with subsequent sexual abuse by a person unknown to the family attract national media coverage, this scenario is rare. Most perpetrators are male acquaintances known and trusted by the families. Fathers are responsible approximately 21% of the time and other male relatives 19% of the time. It is often not appreciated that mothers are involved 4% to 8% of the time. Babysitting is a common modus operandi for abusers to gain access to children.

History in Sexual Abuse

There are two situations in which health care providers need to garner information regarding potential sexual abuse. One is the child or family that presents with potential sexual abuse as the chief complaint. The other situation is when the child is seen for another complaint, such as a purulent discharge, but the provider considers the possibility of sexual abuse based on historical information or physical examination.

Telephone calls regarding potential sexual abuse are a challenge for practitioners. Urgent evaluation is necessary if the abuse has occurred within 72 hours (for forensic evidence), if the child is currently in a danger of repeated abuse or self-harm, or for obvious injuries such as lacerations require treatment. If none of these criteria are encountered, the child and her family can be evaluated on a nonurgent basis. This is important, because specially trained personnel should become involved as soon as possible in these situations (pediatric forensic nurse examiners). In many settings these children can be referred to a sexual abuse team on a nonemergency basis. In settings where teams are not

Figure 12.9 Vulvar hematoma in an adolescent female as a result of a straddle injury. (From Mok-Lin EY, Laufer MR: Management of vulvar hematomas: use of a Word catheter. *J Pediatr Adolesc Gynecol.* 2009;22[5]:e156-e158.)

available, it is critical that practitioners are aware of other community resources. If at all possible, it is usually better if the child and family are interviewed separately by a qualified mental health provider (such as a social worker or psychologist) who is experienced in evaluating sexual abuse. Guidelines have been published on appropriate methods of interviewing children who may be victims of sexual abuse. Often state departments of children's services or the social work department of the community hospital can refer providers to appropriate mental health providers.

Unless there are compelling medical reasons, this interview should be performed prior to a genital examination. There are several reasons for this recommendation. First, latency age children may not be able to separate the exam from touching involved in abuse, making the history more difficult to obtain. Second, in the majority of abused children the exam is completely normal. It is important that families not rely on an exam to decide whether to seek counseling or intervention that would keep their child safe. Although providers should ask relevant questions, the more complete interview by an experienced mental health provider minimizes repetitive questioning of the child. The interview may also allow rapport to begin between the mental health professional doing the interview and the family so that the relationship can transit into therapy if indicated.

Practitioners may also consider sexual abuse based on historical complaints or physical examination findings. In this situation it is critical for the provider to query the guardian or parent in a nonthreatening manner. The approach should be "we are all on the same team and we both want to ensure the safety of your child." Queries directed to the child should be open ended and nonjudgmental. Leading questions should be avoided.

Legal Issues in Reporting Possible Sexual Abuse

Providers must be aware of their state's laws and how to file a report alleging sexual abuse. Every state requires that suspected and known child abuse be reported. The word *suspected*, however, deserves definition. *Isolated* complaints that may be associated with sexual abuse (e.g., nightmares or genital bleeding) often do not require a report. Clinicians may suspect sexual abuse based on a variety of historical complaints and physical exam findings. Consideration to other causes of these complaints and findings is also critical. For example, in children who present with genital bleeding, the differential diagnosis may also include urethral prolapse, foreign bodies, and lichen sclerosus, vaginal tumors, or nonabusive trauma.

If a provider is unsure if a report is required, he or she should discuss the situation with local child protective services or a social worker. These professionals can help providers avoid filing vague unnecessary reports, which clog the services of overburdened state agencies. They can also aid in filing reports in borderline cases that justify exploration to obtain safety of children. In addition, discussion with agencies may help protect providers from prosecution for failure to report. It is important to document discussions in patient charts. Guidelines have been developed by the American Academy of Pediatrics regarding appropriate filing of abuse reports (Kellogg, 2009). Providers should not be hesitant to file because of fear of liability for an alleged false report. Although suits have been filed against physicians, states generally ensure immunity. It should, however, be noted that there have been successful malpractice actions against providers who have failed to diagnose or report sexual abuse.

Physical Examination and Evaluation for Sexually Transmitted Infections

The exam of a potentially sexually abused child should include a general exam. Attention should be directed at evaluating skin for bruising, lacerations, or trauma. Parents or concerned adults should be counseled that a genital exam in children who have been abused is usually normal. Physical evidence is present in less than 5% of children. The genital exam should be carried out as described earlier in this chapter. In addition, a thorough physical exam looking for signs of physical abuse must be documented in the chart (Christian, 2000).

In situations in which abuse has occurred within 72 hours, careful collection of forensic evidence is important. Collection of all clothing and undergarments is critical. Approximately two thirds of forensic evidence is obtained from linens and clothing. Motile sperm will be present in the prepubertal vagina for approximately 8 hours, and nonmotile sperm for approximately 24 hours. Because prepubertal children do not have cervical mucous, sperm do not exist for the longer durations seen in reproductive females within the cervical canal. "Rape" kits will also often include testing for a protein specific to the prostate. Vaginal specimens may be obtained by using small swabs within the vagina, similar to the method described for obtaining vaginal cultures.

Given that only approximately 5% of abused children acquire a sexually transmitted infection (STI), providers must decide when STI testing is indicated. Both gonorrhea and chlamydia cause a vaginitis, not a cervicitis, in prepubertal children, so a vaginal culture should be done. In the United States, a vaginal culture for gonorrhea and chlamydia, not DNA testing, should be performed as recommended by the Centers for Disease Control and Prevention (CDC, 2015). There are several issues with the nucleic-acid amplification tests that are commonly used in reproductive females. Because nonculture methods are not labeled for use in children, positive testing may not be admissible in court. The prevalence of gonorrhea and chlamydia in children is usually lower than in appropriately screened adolescents and adults; therefore the actual positive predictive values of a positive test are lower.

Testing in prepubertal children is also influenced by typical incubation intervals of STIs. If a child was abused in an isolated incident, an STI may not be found on testing immediately after the abuse. However, a purulent discharge would prompt testing and be a red flag for possible ongoing abuse rather than an isolated incident.

When a child presents in a nonacute setting, the provider must decide whether to perform testing for STIs. It is rare for a child to have gonorrhea or chlamydia without a vaginal discharge (Bell, 1992). Standards of care regarding this issue may differ in various locations, and consultation with the local sexual assault team is warranted.

Hymen in the Evaluation of Sexual Abuse

There is a general misunderstanding regarding the significance of hymeneal changes. The transverse diameter of the hymen was previously used as a marker of abuse. However, it is now clear that there is significant variation in children, and the state of the hymen it is not a reliable marker of abuse. Complete transections of the hymen, and clefts that extend to the junction of the hymen between 3 o'clock and 9 o'clock, are not congenital, but

Figure 12.10 Hymenal bump alongside of an incomplete transection of the hymen at approximately 7 to 8 o'clock.

if present they could be from abuse or a child inserting an object. Controversies exist as to the significance of incomplete transections (Fig. 12.10).

Genital Warts

Human papillomavirus (HPV), the causative agent of genital warts, may be transmitted to children from the maternal genital tract at delivery or by sexual or nonsexual transmission after birth. The incubation interval from transmission to the presence of visible genital warts has not been defined in children; however, it appears likely that most warts appearing prior to 3 years of age are from maternal-child transmission (Fig. 12.11). If the child is 3 years of age or older, serious consideration should be given to the possibility of sexual transmission. However, genital warts “discovered” in a 4-year-old may have been present for some time prior to being noticed. This is particularly a problem in the perianal area, which may not be examined carefully even in children undergoing a cursory genital exam as part of well-child annual care (Handley, 1993).

Approximately half of lesions will regress over 5 years. Expectant management is reasonable, but parents may prefer treatment. Treatment in children is difficult. Caustic treatments such as trichloroacetic acid are painful even if children are pretreated with local anesthesia. Topical imiquimod cream is labeled for use in children 12 years and older and can cause significant vulvar irritation, but has been used successfully in younger children. If the child accidentally carries imiquimod cream to the cornea, it could cause damage to the eye. Laser and/or ultrasonic treatment is an option for significant wart tissue but must be performed under anesthesia and can be associated with significant postoperative pain.

THE OVARY AND ADNEXA IN PEDIATRIC AND ADOLESCENT GYNECOLOGY: CYSTS, TUMORS, AND TORSION

Most ovarian masses in this age group are functional ovarian cysts, and if a tumor is present it most often is a benign teratoma (dermoid). However, malignancies can occur and are most often of germ cell origin, but they can also be sex-cord/stromal in origin such as a granulosa cell tumor (Amies, 2014; Lara-Torre, 2002).

Figure 12.11 A 3-year-old with genital warts. (From Leclair E, Black A, Fleming N. Imiquimod 5% cream treatment for rapidly progressive genital condyloma in a 3-year-old girl. *J Pediatr Adolesc Gynecol.* 2012;25[6]:e119-e121.)

Physiologic and functional cysts of the ovaries arise from gonadotropin stimulation of the follicles. They may present in the fetus, newborn, infant, at puberty, and in adolescence. The appropriate management may depend on the age and on the appearance of the cyst on ultrasound. Cysts of follicular development will be clear without significant solid components and almost always are less than 7 to 10 cm in size in reproductive adolescents. Management of adolescent functional cysts is essentially the same as the management in reproductive females. Cysts in neonates can generally be observed until resolution. Neonates and children can be observed for any signs of torsion and advised to seek immediate medical attention, unless they have exceptionally large cysts. Torsion can certainly occur and is not rare. Many neonatal cysts were initially identified on antenatal ultrasound. There are few studies, all with small numbers, regarding the natural history of antenatal or neonatal ovarian cysts. Cysts during the preschool and early grade school years are unusual, reflecting that gonadotrophins are low.

Corpus luteum cysts are often more complex than other follicular cysts. Management is similar to that in mature reproductive women, and observation is warranted unless signs of malignancy are present. Consideration should be given to dermoids and the possibility of germ cell tumors if a mass has both solid and cystic components. In rare cases of intersex, such as mixed gonadal dysgenesis, suspicion of malignancy should be high. A rare presentation of hypothyroidism is pediatric ovarian cysts.

Prenatal Ovarian Cysts

Obstetric ultrasound of a female fetus frequently demonstrates a simple ovarian cyst (up to 80% of fetuses). Before a diagnosis of an ovarian cyst is made, it is critical to exclude urinary or gastrointestinal anomalies. Fetal malignancy is rare.

There is controversy regarding the management of large antenatal cysts. Antenatal aspiration for the large antenatal cyst (4 cm or more) has been proposed by some to avoid potential antenatal torsion. The obvious disadvantage is the risk of the antenatal surgery and the fact that resolution is a typical clinical course. Size and appearance enter heavily into management

decisions; for example, if the cyst seems to be wandering about the abdomen on repetitive ultrasounds, it may be of greater risk of torsion. Also, large cysts (probably greater than 9 cm) may require a cesarean section.

The natural history of both antenatal and neonatal cysts is difficult to define. Data generated from a few small series may be misleading, as the outcome may be dependent on size, mobility, and how the cyst first presented. Presence of what appears to be torsion may not result in the loss of an ovary. The relative rarity of congenital absence of one ovary makes it likely that untwisting occurs. The incidence of congenital unilateral ovarian agenesis is quite rare, perhaps as rare as 1 in approximately 10,000 females. Ovarian malignancy is extremely rare in this age group and is not a consideration in the therapeutic approach. For these reasons observation is reasonable in these cases (Bryant, 2004).

Neonatal Ovarian Cysts

Simple cystic ovarian masses in newborns and neonates are common and can be followed expectantly. Parents should be given ovarian torsion warnings, and if the infant presents with acute vomiting or abdominal pain, she should be immediately evaluated for ovarian torsion. Repeat serial ultrasonography should be performed every 4-6 weeks until the cyst resolves. Almost all will resolve if they do not undergo torsion. Malignancy is not a consideration in newborns when deciding therapy. Aspiration is an option for large cysts.

Ovarian Cysts in Children and Adolescents

The management of cystic ovarian structures in children and adolescents should also be expectant unless they are extremely large (>10 cm), in which case the possibility of functional cysts becomes less likely. Many times, physiologic and functional cysts are discovered on an abdominal ultrasound performed for complaints such as abdominal pain. Often the presence of a cyst is incidental and unrelated to the complaint. However, in patients with pain, the possibility of ovarian torsion should be entertained. Pain from ovarian cysts generally stems from three sources: (1) expansion of the ovarian cortex (which is typical during the growth phase of follicles and lasts less than 72 hours), (2) peritoneal bleeding from rupture (particularly common in bleeding disorders and patients on anticoagulation), and (3) ovarian torsion. These causes of pain do not typically present as chronic pelvic/abdominal pain. Recurrent functional ovarian cysts may be prevented by the use of anovulatory agents, such as combined oral contraceptives in adolescents, but these agents do not assist in the resolution of cysts that are actively present.

Ovarian Tumors in Children and Adolescents

A variety of tumors, both benign and malignant, can be seen in the childhood and adolescent years. One should always consider the possibility of a malignancy, particularly in patients with solid ovarian masses or cystic and solid components on ultrasound. A malignant diagnosis should also be considered in patients with presumed functional ovarian cysts that do not resolve during serial monitoring.

Germ cell tumors are the most common gynecologic neoplasm in this age group, and fortunately, most are benign ovarian teratomas. The most common malignant germ cell tumor is a dysgerminoma followed by endodermal sinus tumors and immature teratomas. These tumors are covered in detail in Chapter 33, but several issues are especially pertinent to children and adolescents.

Bilateral tumors are seen in 10% to 15% of dysgerminomas, but this condition is rare in all of the other germ cell tumors of the ovary except for immature teratomas. Sex cord tumors, such as granulosa and thecal cell tumors, can also be seen in this age group and often produce steroids (estrogen and testosterone respectively). Rare tumors such as gonadoblastomas, a germ cell and sex cord tumor, are seen in patients with intersex disorders such as mixed gonadal dysgenesis.

Recurrent abdominal pain is a frequent complaint of school-age children, and this common symptom is often a presenting symptom in patients with ovarian neoplasms. A young child may not be able to differentiate lower abdominal pain from pelvic pain because of the small size of the preadolescent female pelvis, making the ovaries essentially abdominal organs. One can understand why increasing abdominal girth is a frequent finding associated with ovarian enlargement.

The most common clinical manifestation of an ovarian tumor is lower abdominal pain or the presence of a mass. Some ovarian tumors in children produce only vague discomfort, such as abdominal fullness or bloating. However, adnexal masses in children are more frequently associated with acute complications—such as torsion, hemorrhage, and rupture—than are similar tumors in adults.

Ovarian tumors constitute approximately 1% of all neoplasms in premenarcheal children. Ultrasound, magnetic resonance imaging (MRI), or abdominal computed tomography (CT) may be utilized in the evaluation of a suspected pelvic mass or abdominal pain of uncertain origin in children. Abdominal ultrasonography may be used to establish that the origin of the mass is in the pelvis, whether the mass is cystic or solid, and the presence of ascites (Anthony, 2012) and should be considered as the initial imaging modality. Calcifications in an ovarian mass may appear toothlike, indicating a likely diagnosis of an ovarian teratoma.

As part of the preoperative workup, the child may be screened for elevated serum levels of tumor markers such as α -fetoprotein, both alpha and beta human chorionic gonadotropin (HCG), inhibin (A and B), lactate dehydrogenase, estradiol, and testosterone; even tumor markers that are associated with other neoplasms can be detected in girls. HCG may be positive for either the α or the β subunit, so a pregnancy test that only tests for the β subunit is inadequate.

Ovarian tumors in preadolescent females, both benign and malignant, are usually unilateral. Thus it is imperative to be as conservative as possible in managing the opposite ovary in order to protect potential future fertility. During surgery the opposite ovary should be carefully inspected and palpated if possible. It is generally unnecessary and potentially harmful to perform a biopsy on a normal-appearing contralateral ovary in a preadolescent female. This is especially true in patients with dermoids. Careful inspection of the contralateral ovary in patients with a dysgerminoma or an immature teratoma—malignancies in which bilateral tumors are not as rare—is also appropriate, reserving biopsy only for when an abnormality is detected by clinical inspection. It was common practice to perform a “wedge biopsy” of the contralateral ovary, but that practice was not evidence based and was abandoned as it clearly increased the possibility of scarring and infertility.

Children with suspected ovarian cancer should be referred to specialists who are up to date on the most current data from research groups such as the Pediatrics Oncology Group and

the Gynecologic Oncology Group, now part of NRG Oncology (Cushing, 1999). Providers should be skilled in providing their patients proper staging procedures, including lymph node assessment and evidence-based adjuvant therapy as indicated by standard national guidelines such as the guidelines of the National Comprehensive Cancer Network (NCCN) (Morgan, 2013). The role of adjuvant therapy should be individualized for each patient. The use of tumor markers to help differentiate patients with benign teratoma from malignancies is helpful in triaging appropriate referrals. However, regardless of what the makers show, referral is prudent.

Approximately 75% to 85% of ovarian neoplasms that necessitate surgery in premenarcheal females are benign, and approximately 15% to 25% are malignant neoplasms. The risk is less in young children. In a review of ovarian masses in children, Brown and coworkers reported that the risk of malignancy was only 3% up to age 8.

In summary, even though ovarian neoplasms are rare in children, this diagnosis should be considered in a young girl with abdominal pain and a palpable mass. The surgical therapy should have two goals: first, and most important, the appropriate surgical procedure including selective evaluation of lymph nodes and appropriate staging procedures; second, the preservation of future fertility, as hysterectomy is usually not necessary, even in rare cases of bilateral childhood or adolescent ovarian malignancy. The uterus should be retained to keep the patient's options for future fertility intact. Even in the absence of ovaries, fertility may be possible with artificial reproductive technology and the use of donor eggs.

Ovarian Torsion

Ovarian torsion is covered in more detail in Chapter 18. Issues unique to children and adolescents are covered in this discussion. Torsion in prepubertal females may be secondary to a pelvic mass or due to mechanical factors that occur in the prepubertal interval. In early puberty, the ovaries drop from their

prepubertal position at the pelvic brim into the pelvis. This drop occurs under the influence of gonadotropins that surge at puberty. Some young women may have longer supportive ligaments, predisposing them to twisting. Approximately two thirds of the time, ovarian torsion occurs on the right side, increasing the likelihood of the process being confused with appendicitis. The sigmoid colon in the left lower quadrant helps prevent the left ovary from twisting.

Although both appendicitis and torsion can present with acute pain and rebound, the gradual progression of appendicitis is quite different from the acute severe pain of torsion. Nausea and emesis often ensue immediately with torsion, owing to the severity of the pain. Appendicitis tends to present with anorexia, which gradually worsens. The young girl with an acute onset of pain and simultaneous emesis likely has ovarian torsion rather than appendicitis.

Approximately one third of ovarian torsion cases in children and adolescents are not associated with a predisposing ovarian mass such as a dermoid, large functional cyst, or malignancy. Nevertheless, even in children without an ovarian mass, after torsion the ovary will become swollen and enlarged as the lymphatic flow is blocked. In children and adolescents, the differentiation between torsion and appendicitis is a common dilemma. Radiologic evaluation to rule out appendicitis may reveal a pelvic mass. Unfortunately, the presence of vascular flow in the ovary does not rule out torsion. In fact, many cases of surgically proven torsion had normal vascular flow on ultrasound evaluation. Once a torsion is identified at the time of surgery, it is important to consider the patient's future fertility. There are numerous reports in the literature demonstrating the benefit of untwisting the gonad, regardless of its appearance, as most will regain function after the edema resolves. Risk of embolus from a thrombosed ovarian vein has not been reported in the literature. In institutions where pediatric surgeons manage these patients, consultation and co-management with gynecology will likely result in better outcomes and fewer adnexectomies.

KEY POINTS

- It is important to give the child a sense that she will be in control of the examination process. Emphasize that the most important part of the examination is just “looking” and that there will be conversation during the entire process.
- Many gynecologic conditions in children can be diagnosed by inspection alone.
- The vaginal epithelium of the prepubertal child appears redder and thinner than the vaginal epithelium of a woman in her reproductive years.
- The prepubertal vagina is also narrower, thinner, and lacks the ability to distend like that of the vagina of a reproductively mature woman.
- The vagina of a child is 4 to 5 cm long and has a neutral pH.
- During the physical examination and rectal examination of the prepubertal child, no pelvic masses except the cervix should be palpable. The normal prepubertal uterus and ovaries are nonpalpable. The relative size ratio of cervix to uterus is 2 to 1 in a child.
- Many female adolescents do not want other observers, such as mothers, in the examining room.
- It is estimated that 80% to 90% of outpatient visits of children to gynecologists involve the classic symptoms of vulvovaginitis: introital irritation and discharge.
- Positive identification of gonorrhea, or chlamydia in a child with premenarcheal vulvovaginitis, is considered diagnostic of sexual abuse. However, many infants are infected with *Chlamydia trachomatis* during birth and remain infected for up to 2 to 3 years in the absence of specific antibiotic therapy.
- The major factor in childhood vulvovaginitis is poor perineal hygiene.
- A vaginal discharge that is both bloody and foul smelling strongly suggests the presence of a foreign body.
- In the period surrounding the time of puberty, children often develop a physiologic discharge secondary to the increase in circulating estrogen levels.

Continued

KEY POINTS—cont'd

- The foundation of treating childhood vulvovaginitis is the improvement of local perineal hygiene.
- The majority of cases of persistent or recurrent nonspecific vulvovaginitis respond to improved hygiene and treatment of irritation resulting from trauma or irritating substances.
- The classic symptom of pinworms (*Enterobius vermicularis*) is nocturnal vulvar and perianal itching, the treatment for which is the antihelminthic agent, mebendazole.
- The most common vaginal foreign body in preadolescent females is a wad of toilet tissue.
- Persistent vaginal bleeding is an extremely rare symptom in a preadolescent female. However, it is important to do a thorough workup because of the serious sequelae of some of the causes of vaginal bleeding.
- Labial adhesions do not require treatment unless they are symptomatic or voiding is compromised. If necessary, small amounts of daily topical estrogen to the labia may be used for treatment.
- The usual cause of genital trauma during childhood is an accidental fall. Most such traumas involve straddle injuries.
- Accidental genital trauma often produces extreme pain and overwhelming anxiety for the child and her parents. Because of compassion and empathy, the gynecologist may underestimate the extent of the anatomic injuries.
- Small follicular cysts in preadolescent females are usually self-limiting.
- Ovarian tumors constitute approximately 1% of all neoplasms in premenarcheal children. In preadolescent females, both benign and malignant ovarian tumors are usually unilateral. Routine biopsy of the normal-appearing contralateral ovary should be avoided.
- Approximately 75% to 85% of ovarian neoplasms necessitating surgery are benign, with cystic teratomas being the most common.
- The most common malignancy in preadolescent females is a germ cell tumor.
- Even though ovarian neoplasms are rare in children, this diagnosis must be considered in a young girl with abdominal pain and a palpable mass.
- The surgical therapy of an ovarian neoplasm in a child should have two goals: the appropriate surgical removal of the neoplasm and the preservation of future fertility.
- Ovarian torsion should be managed conservatively with untwisting and preservation of the adnexa, regardless of the appearance.
- Presence or absence of Doppler flow on the ovary on ultrasound is not diagnostic of ovarian torsion, and the decision for surgical intervention should be based on the level of clinical suspicion.

Family Planning

Katherine Rivlin, Carolyn Westhoff

CONTRACEPTION OVERVIEW

Seventy percent of the 64 million U.S. women aged 15 to 44 are at risk of unintended pregnancy. In other words, these women are sexually active, capable of becoming pregnant, not currently pregnant or postpartum, and are not trying for pregnancy. Half of pregnancies in the United States are unintended, and among women who experience unintended pregnancy, more than half are not using contraception (Mosher, 2010). According to the 2011-2013 National Survey of Family Growth, 61.7% of women aged 15 to 44 in the United States, or about 90% of those at risk, are using some method of contraception (Table 13.1). The most common methods are the oral contraceptive pill (16%), female

sterilization (15.5%), condoms (9.4%), long-active reversible contraception (LARC) (7.2%), or intrauterine devices (IUDs) and implants (Table 13.2) (Daniels, 2014). Thus, most women at risk of unintended pregnancy are using a method.

Because each of the currently available methods of contraception has distinct advantages and disadvantages, clinicians should be able to explain the unique features of each method. The clinician must also evaluate whether medical contraindications to a particular method exist for a woman and offer her safe and effective alternatives. The health risks associated with unintended pregnancy must always be considered in the medically challenging patient, as these risks are generally greater than those of a birth control method. In general, the best method for an individual is one that is relatively safer than pregnancy and that will be used correctly and consistently.

CONTRACEPTIVE EFFECTIVENESS

All contraceptive methods have a **typical use** effectiveness (pregnancy rate given actual use, including occasional inconsistent or

From Trussell J. Contraceptive efficacy. In: Hatcher RA, Trussell J, Nelson AL, et al. *Contraceptive Technology*. 20th rev. ed. New York: Ardent Media; 2012.

incorrect use) and **perfect use** effectiveness (pregnancy rate given correct and consistent use of a method with every act of intercourse). Pregnancy rates can vary widely between typical and perfect use depending on how complicated it is to use a method perfectly (Table 13.3). In general, coitus-related methods and more user-dependent methods are less effective than “forgettable methods” such as LARC. Use of two methods, or “dual method use,” provides added contraceptive protection. Combining a hormonal method with a condom provides the additional health benefit of reducing sexually transmitted infection. Other multi-purpose technologies are in development to concurrently prevent unintended pregnancy and reduce the risk of sexually transmitted infection, particularly HIV (Lusti-Narasimhan, 2014).

In this chapter, contraceptive methods are presented using a “tiered approach,” with the most effective methods presented first followed by the less effective methods. This concept is based on the contraceptive method effectiveness communication tool offered by the World Health Organization (WHO) (Fig. 13.1).

TIER 1 METHODS: HIGHLY EFFECTIVE (FEWER THAN 1 PREGNANCY PER 100 WOMEN IN 1 YEAR): INTRAUTERINE DEVICES (IUDs), IMPLANTS, MALE AND FEMALE STERILIZATION

LARC METHODS

The top-tier contraceptive methods include all LARC methods. These methods require only one act of motivation to enable long-term use, which virtually eliminates user error once

placement has occurred. LARC methods are highly effective and immediately reversible with a rapid return to fertility after removal. Very few medical contraindications to LARC exist. These methods do not require frequent visits for resupply or incur costs after placement (though upfront costs can be high). When used in the postpartum and postabortion period, LARC and permanent sterilization reduce the risk of short interval pregnancy significantly when compared to other hormonal methods (White, 2015). All of this contributes to high continuation rates and user satisfaction. As a result, the American Congress of Obstetricians and Gynecologists (ACOG) recommends that LARC methods be offered as first-line contraception to most women (ACOG, 2009).

The LARC methods currently available in the United States include a single-rod etonogestrel subdermal implant (Nexplanon), the Copper T380A intrauterine device, and several levonorgestrel intrauterine systems (LNG-IUS).

INTRAUTERINE DEVICES

A safe and highly effective method of birth control with similar rates of failure for typical or perfect use, the IUD is the most commonly used reversible method of contraception worldwide. In the United States, IUD use has increased among contraceptive users from 2% in 2002 to 6.4% in 2011 to 2013 (Branum, 2015). First-year failure rates with the copper T 380A IUD and the levonorgestrel-releasing IUD are less than 1%. Pregnancy rates are somewhat related to the skill of the clinician inserting the device because correct high-fundal insertion lowers the incidence of partial or complete expulsion. Furthermore, the

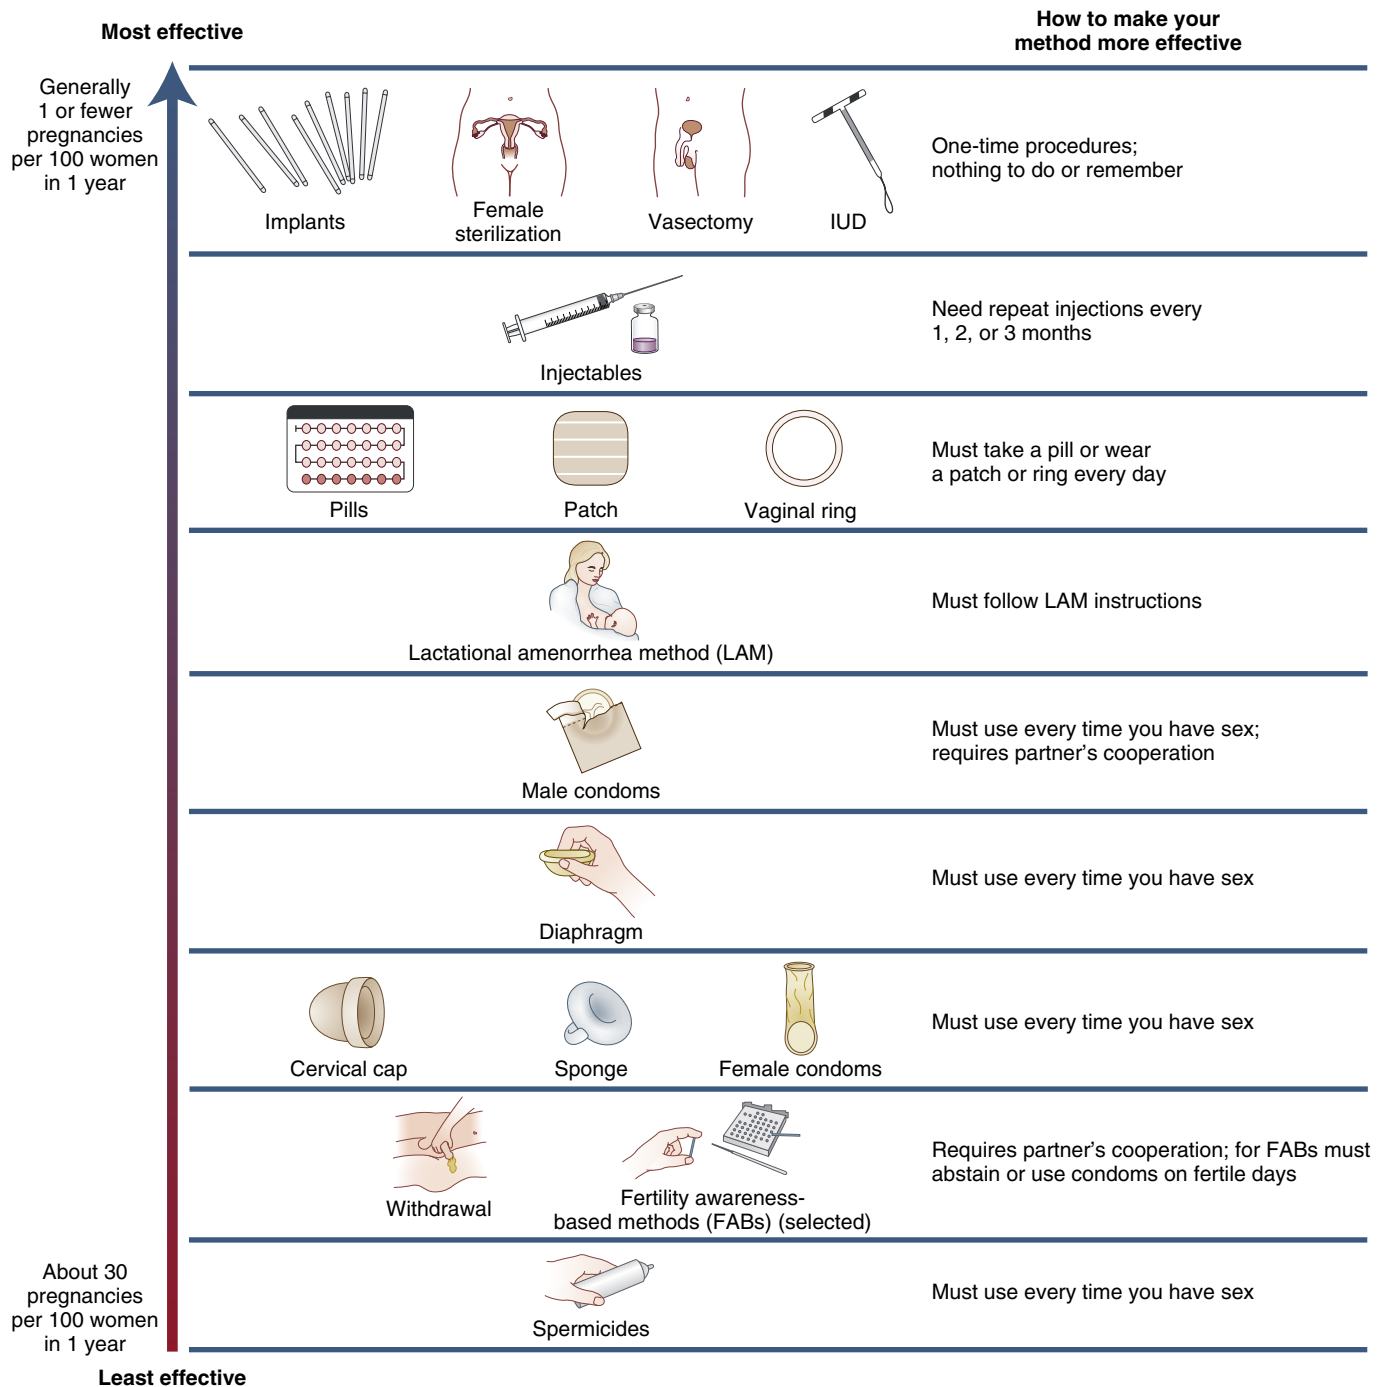

Figure 13.1 WHO's tiered approach contraception counseling tool comparing typical effectiveness of contraceptive methods. (Redrawn from Association of Reproductive Health Professionals [ARHP]: You decide tool kit: contraceptive efficacy tools. Adapted from World Health Organization. *Comparing typical effectiveness of contraceptive methods*. [Job Aid]. Geneva, Switzerland, WHO, 2006.)

annual incidence of accidental pregnancy decreases steadily after the first year of IUD use. The cumulative pregnancy rate after 12 years of use of the copper T 380A IUD is only 1.7%, and after 5 years of use of the LNG-IUS the pregnancy rate is about 1.1%. The failure rates associated with IUDs are comparable to those achieved with surgical sterilization.

Types of IUDs

The copper T 380A IUD (Paragard) (Fig. 13.2) is the only copper-bearing IUD currently marketed in the United States, although a new copper IUD (Veracept) is undergoing clinical trials. Because of the constant dissolution of copper (which on a daily basis amounts to less than that ingested in the normal

Figure 13.2 **A**, Copper T intrauterine device. **B**, Levonorgestrel intrauterine system (LNG-IUS) Mirena. (**A**, From Yu J, Li H, Li J, et al. Comparative study on contraceptive efficacy and clinical performance of the copper/low-density polyethylene nanocomposite IUD and the copper T220C IUD. *Contraception*. 2008;78(4):319-323; **B**, From Searle ES. The intrauterine device and the intrauterine system. *Best Pract Res Clin Obstet Gynaecol*. 2014;28[6]:807-824.)

diet), the copper IUDs require periodic replacement. The copper T 380A is currently approved for use in the United States for 10 years and maintains its effectiveness for at least 12 years. At the scheduled time of removal, for women desiring continued contraceptive protection, the device can be removed and another inserted during the same office visit.

Adding a reservoir of a progestin to the vertical arm also increases the effectiveness of the T-shaped devices. With the LNG-IUS (Mirena) (see Fig. 13.2), about 20 µg of levonorgestrel (LNG) is released into the endometrial cavity each day. The LNG-IUS has a high level of effectiveness for at least 5 years. This IUD also reduces menstrual blood loss and has been used therapeutically to treat excessive uterine bleeding. In 2015, a new 20-µg LNG IUS device (Liletta) was approved by the Food and Drug Administration (FDA) for up to 3 years of use, though clinical trials will continue for up to 7 years, opening up the possibility for extended use.

In addition, a 13.5-µg LNG-releasing IUD device with a slightly smaller body than the Mirena has been approved for up to 3 years of use (Skyla). For the purposes of this chapter, we will be referring to the Mirena IUD when discussing the LNG-IUS.

Mechanisms of Action

All IUDs induce a local inflammatory reaction of the endometrium, creating an environment that is hostile to sperm so that fertilization of the ovum does not occur. Although this sterile inflammatory reaction is the only mechanism of inert IUDs, medicated IUDs containing either copper or levonorgestrel produce additional local effects that increase their efficacy in preventing pregnancy.

Copper IUD

Copper markedly increases the extent of the inflammatory reaction, allowing it to accumulate throughout the uterine lumen and penetrate the cervix and probably the fallopian tubes. This affects the function and viability of gametes at

many levels, preventing fertilization and lowering the chances of development of any zygote that may be formed before it reaches the uterus. In addition, copper impedes sperm transport and viability in the cervical mucus. Because of these actions of IUDs, very few, if any, sperm reach the oviducts, and the ovum usually does not become fertilized. The small numbers of fertilizations that do occur underlie the failure rate of these devices.

LNG-IUS

The primary effect of the progestin in the LNG-IUS is to thicken cervical mucus. This impedes sperm penetration and access to the upper genital tract. Additionally, the LNG-IUS decreases tubal motility and also produces a thin, inactive endometrium. The low levels of circulating steroid sometimes inhibit ovulation. Systemic LNG levels are lower than those of the progestin implant and progestin-only pills.

Insertion

Timing

The IUD can be safely inserted in any of the following scenarios: (1) on any day of the cycle provided the woman is not pregnant, (2) immediately postabortion, and (3) immediately postpartum following either vaginal or cesarean section delivery. Immediate postpartum insertion carries a higher risk of IUD expulsion, particularly in the case of an LNG-IUS following vaginal delivery, with expulsion rates up to 24% (Chen, 2010). In addition, the copper IUD can be used as emergency contraception for up to 5 days following unprotected intercourse. (See the [Emergency Contraception](#), presented later in the chapter, for details.)

Pain

Most insertions are easy and accomplished on the first attempt. Cervical preparation with misoprostol does not increase the success of insertion and increases pain. Ibuprofen administered

prior to insertion does not reduce insertion pain but may be helpful for the cramping that occurs in the hours immediately following insertion. Multiple trials show that topical anesthesia does not affect pain, although a paracervical block may decrease it. Clinicians should receive training in correct insertion technique as detailed in the product labeling (Video 13.1). If a narrow cervix prevents the passage of a uterine sound, a paracervical block should be placed and dilation performed. Difficult insertions should be referred to clinicians with expertise in family planning procedures.

Adverse Effects

Uterine Bleeding

The majority of women discontinuing the copper IUD do so for heavy or prolonged menses or intermenstrual bleeding. The increased bleeding may be produced by an increased rate of prostaglandin release in the presence of the intrauterine foreign body. Stimulation of uterine contractions by prostaglandins may prolong menses, which is about 1 day longer in women with copper IUDs. The copper T 380A IUD is associated with as much as a 50% increase in menstrual blood loss (MBL); however, most women with a copper IUD will experience slightly increased or no change in bleeding. This heavy bleeding rarely leads to anemia.

In contrast, there is a 60% reduction of MBL during the use of the LNG-IUS. This reduction is seen as early as 3 months after insertion and persists for the duration of use of the device. After 24 months of use, 50% of users have amenorrhea and 25% have oligomenorrhea. The LNG-IUS is thus useful in the prevention and the treatment of iron deficiency anemia.

Excessive bleeding in the first few months following IUD insertion should be treated with reassurance and supplemental oral iron. The bleeding usually diminishes with time, as the uterus adjusts to the presence of the foreign body.

Perforation

Although rare (1 in 1000 insertions), one of the potentially serious complications associated with IUD use is perforation of the uterus, usually at the fundus. Perforation always begins at the time of insertion. IUDs correctly inserted entirely within the endometrial cavity do not migrate or wander through the uterine muscle into the peritoneal cavity. With experienced providers, the risk of perforation is less. Perforation of the uterus is best prevented by straightening the uterine axis with a tenaculum and then measuring the cavity with a uterine sound before IUD insertion.

The clinician should always suspect a perforation if the user cannot feel the threads and did not observe that the device was expelled. Sometimes the IUD is still in its correct position in the uterine cavity, but the threads have been withdrawn into the cavity as the position of the IUD has changed. To assess this situation, after pelvic examination has been performed and pregnancy excluded, a transvaginal ultrasound may be performed to locate the device. If the device is not visualized with pelvic ultrasonography, a radiograph visualizing the abdominal cavity should be performed to visualize the entire pelvis and abdomen. IUDs found to be outside the uterus usually can be removed by means of laparoscopy. In a study of 61,448 women with IUD insertions conducted with a year or more of follow-up, no IUD

perforations led to serious clinical outcomes beyond the need for laparoscopic retrieval (Heinemann, 2015).

The widespread use of transvaginal ultrasound has led to the discovery that many IUDs sit in the lower uterine segment. Faúndes and colleagues found no relationship between the IUD position evaluated by ultrasound and complaints of bleeding and pain.⁹ In asymptomatic individuals, the device should be left in place regardless of location within the uterine cavity. However, if the stem of the device is visible at the external cervical os, the IUD should be removed (Faúndes, 1997).

Complications Related to Pregnancy

A pregnancy with an IUD in place is rare. Among the few IUD users who do become pregnant, an extrauterine location is more likely than among pregnant women without an IUD. Therefore, in the case of a pregnancy, a pelvic ultrasound must be carried out to locate the pregnancy. In the event of an intrauterine pregnancy, the device should be removed regardless of whether the pregnancy is desired or undesired. As the uterus grows with the pregnancy, the threads will eventually be drawn inside the cervix and become inaccessible. If a pregnancy occurs and the IUD is not subsequently removed, the incidence of spontaneous abortion is approximately three times greater than would occur in pregnancies without an intrauterine device. Once the IUD is removed, the complication rate becomes similar to that of a pregnancy without an IUD. In the case of an undesired pregnancy, a manual vacuum aspiration can be performed with the IUD in place for removal of both the pregnancy and the device.

Infection in the Nonpregnant IUD User

Despite great concern among clinicians in the 1970s and 1980s that use of the IUD would markedly increase the incidence of pelvic inflammatory disease (PID), well-conducted studies provided little evidence of such an increase. A WHO combined analysis of clinical trial data including 22,908 women with IUDs showed that the PID rate was six times higher in the first 3 weeks after insertion compared with later times. Following these 3 initial weeks, the risk remained low and constant for as long as 8 years thereafter, at 0.5 cases per 1000 woman-years (Farley, 1992). The placement process, not the device itself or its thread, creates a transient risk of infection, as does any transcervical procedure.

In a meta-analysis of randomized controlled trials (RCTs), Grimes and colleagues showed that the routine use of prophylactic antibiotics preceding IUD insertion did not change outcomes, including the risk of pelvic infection (Grimes, 1999). An IUD may be placed in the absence of cervical screening for infection; however, if a provider has clinical suspicion of infectious endocervicitis, or the patient has two out of three of the following: (1) purulent vaginal discharge, (2) adnexal tenderness, or (3) cervical motion tenderness, testing for gonorrhea and chlamydia should be performed and the IUD insertion delayed.

Positive gonorrhea or chlamydia screening tests that occur with an IUD already in place (i.e., more than 3 weeks after insertion) can usually be successfully treated without removing the IUD. For a symptomatic patient continuing an IUD, an antibiotics regimen for PID approved by the Centers for Disease Control and Prevention (CDC) should be used until the woman becomes symptom free. If the infection does not improve or if there is evidence of tubo-ovarian abscess, the device should be removed

after a therapeutic serum level of appropriate parenteral antibiotics has been reached, preferably after a clinical response has been observed (CDC Guidelines, 2015). An alternative method of contraception should be substituted if the IUD is removed.

Actinomyces organisms are often identified in routine cytology in women with IUDs in place. If the woman is asymptomatic, she may be followed without therapy at usual intervals. The IUD should not be removed from an asymptomatic colonized woman. In the rare event that a significant pelvic infection is present, the woman should be treated with long-term antibiotics (usually penicillin) and the IUD removed.

Contraindications

It is good medical practice that IUDs not be inserted into women with any of the following six conditions: (1) pregnancy or suspicion of pregnancy, (2) acute PID, (3) postpartum endometritis or infected abortion, (4) known or suspected uterine or cervical malignancy, (5) genital bleeding of unknown origin, and (6) a previously inserted IUD that has not been removed. Few data are available to indicate whether the complications of Wilson disease or an allergy to copper are true contraindications for insertion of copper-bearing IUDs. Because of the infrequency of these conditions, it is unlikely that data will ever become available.

The high rate of complications specifically associated with the Dalkon Shield in the early 1970s reduced the confidence and enthusiasm of clinicians and women for all IUDs. It has taken 40 years, considerable research, and excellent modern medicated IUDs to reverse this trend, and IUDs are once again a mainstream method. The method was initially conservatively marketed to only parous women. However, both copper and levonorgestrel IUDs can and should be offered to young or nulliparous women.

Overall Safety

Several long-term studies have indicated that the IUD is not associated with an increased incidence of endometrial or cervical carcinoma; rather, IUD use is associated with a reduction in risk of developing these neoplasms. Data are promising for the use of the LNG-IUS as a fertility-sparing treatment of early stage endometrial cancer (Laurelli, 2011). To date, few studies have evaluated whether hormonal IUD use changes the risk of breast cancer; however, it is an active research question.

The IUD is a particularly useful method of contraception for women who have completed their families and have contraindications to sterilization. Women in the United States who use an IUD have a higher level of satisfaction with their method of contraception than women using any of the other methods of reversible contraception.

Subdermal Implants

Subdermal implants are among the most effective methods of contraception available, with an effectiveness equal or superior to that of sterilization and IUDs. Subdermal implants consist of one or more thin rods containing a progestin hormone. Insertion is performed in the outpatient setting, and the entire procedure takes less than 5 minutes. After skin infiltration with local anesthesia, the implant is inserted superficially into the subcutaneous tissue of the upper arm using a trocar. The insertion site is closed with adhesive, without the need for suture (Fig. 13.3).

When the implant is inserted in any area of subcutaneous tissue, the steroid diffuses into the circulation at a relatively constant rate. The implant must be removed at the end of its duration of use through a small 2-mm incision, which also can be performed in the outpatient setting under local anesthesia, and closed with adhesive. Superficial insertion enhances the ease of removal; deeply implanted implants are more difficult to remove. The implant can be inserted on any day during a woman's cycle provided she is not pregnant.

The most commonly used implant in the United States is the Nexplanon, which contains 68 mg of etonogestrel (ENG). This implant is approved for use up to 3 years, is extremely effective, and is easy to insert and remove. Preliminary studies also indicate continued effectiveness for a longer duration (McNicholas, 2015). Ovulation inhibition is the main mechanism of action of this implant and thickening of the cervical mucus also occurs. Ovulation is completely inhibited for at least 30 months after insertion, and no pregnancies were reported in clinical trials of nearly 2000 women with 7500 cycles of use. Following removal of the implant, serum etonogestrel levels decline rapidly and are undetectable within 1 week after removal. Ovulation resumes rapidly, and 90% of women ovulate within 1 month after removal.

The Nexplanon implant does not result in a decrease of bone mineral density, even in women with amenorrhea. In clinical trials, continuation rates are high, with 50% to 80% of women continuing use until 2 years. Bleeding irregularities are the most common reason for discontinuation, accounting for about 60% of early removals. As with other progestin-only methods, nearly all women experience changes in their regular bleeding pattern. Amenorrhea is common, occurring in about 20% of women, and 27% have infrequent bleeding. About 12% of women have prolonged bleeding, and 6% have frequent bleeding. Unlike depo-medroxyprogesterone acetate (DMPA) or the LNG-IUS, the bleeding patterns of individual women will be unpredictable.

Figure 13.3 Insertion of a contraceptive implant. (Modified and used with permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

Three other implants are used worldwide but are not currently available in the United States. Jadelle is a two-rod system containing 75 mg levonorgestrel approved for up to 5 years of use. Sino-implant is also a two-rod system containing 75 mg levonorgestrel. Norplant, once widely used, is a six-rod system containing 216 mg levonorgestrel approved for 7 years of use. Insertion and particularly removal of six rods can pose challenges to providers, and the Norplant has been largely supplanted by other implants.

PERMANENT CONTRACEPTION: STERILIZATION

Male and female sterilization are safe and highly effective methods of contraception. In contrast to the other methods of contraception, which are reversible or temporary, sterilization should be considered permanent. If women who have tubal sterilization wish to conceive, in vitro fertilization is now being performed more frequently than tubal reconstructive surgery.

Voluntary sterilization is legal in all 50 states, and the decision to be sterilized should be made solely by the individual in consultation with a provider. When a woman younger than age 30 requests sterilization, there is up to a 20% risk of regret following sterilization (Hillis, 1999).

Male Sterilization

Male sterilization, or vasectomy, is a safe and highly effective outpatient procedure that takes about 20 minutes and requires only local anesthesia. More than 300,000 vasectomies are performed annually in the United States. The vas deferens is isolated and cut. The ends of the vas are closed, either by ligation or by fulguration, and then replaced in the scrotal sac. This occlusion of the vas prohibits sperm from passing into the ejaculate. The ejaculate is therefore sperm free, but otherwise unchanged.

Vasectomy offers several important advantages over tubal sterilization of women. The procedure is low cost (it is the most cost-effective of all contraceptive methods) and can be performed in the office with only local anesthesia. It does not involve entry into the peritoneal cavity, and efficacy is easily verified. About 13 to 20 ejaculations must occur after the operation before the ejaculate will be sterile. The absence of sperm is confirmed with a semen sample. Until that time, another method of birth control must be used. Although in the United States reversal requests range from 5% to 7% among men who have had a vasectomy, vas reanastomosis is a difficult and meticulous procedure that has a success rate of approximately 50% (ASRM, 2004).

Female Sterilization

Approaches to female sterilization in the United States include interval sterilization using laparoscopy or hysteroscopy and postpartum sterilization at the time of cesarean section or with an infraumbilical minilaparotomy incision after vaginal delivery. Sterilization for women blocks fertilization by cutting or occluding the fallopian tubes and preventing the union of the sperm and egg. U.S. women have undergone more than 600,000 sterilization procedures annually. About half of these are performed in the postpartum period. This is the most prevalent method of contraception used by U.S. women over the age of 30 (Chan, 2010).

Female sterilization is highly effective, in the same tier of contraception effectiveness as LARC methods. The Collaborative

Review of Sterilization (CREST) was a large prospective multicenter observational study of more than 10,000 women who underwent transabdominal sterilization and that included 14 years of follow-up. The CREST study found a 5-year cumulative failure probability of 13 per 1000 procedures, with failures sometimes occurring years after the sterilization procedure. Risk factors for failure included age and method of sterilization; the younger the woman, the higher the risk of failure. Postpartum partial salpingectomy carried the lowest 10-year cumulative risk of failure (7.5 per 1000 procedures), and Hulka clips (which are no longer available) carried the highest risk (36.5 per 1000 procedures) (Peterson, 1996).

The CREST study occurred prior to the introduction of Filshie clips and transcervical sterilization techniques. Some data show a 10-year cumulative failure rate of 2 to 3 per 1000 procedures for the Filshie clip (Shaw, 1999). Data are less clear for transcervical sterilization as most studies excluded women who do not return for confirmatory testing or for whom the procedure is not successfully completed at the time of insertion. Using a model to predict pregnancy probability that includes all women seeking transcervical sterilization, Garipey and colleagues calculated a failure rate of 57 in 1000 in the first year after the initial attempt of hysteroscopic sterilization (Garipey, 2014).

Transabdominal Approach

Tubal occlusion can occur at the time of cesarean section, immediately postpartum through an infraumbilical minilaparotomy while the uterus is still enlarged, or, as commonly used outside of the United States, during an interval minilaparotomy. In these cases, ligation and resection of a portion of both fallopian tubes using a technique such as the modified Pomeroy method is common (Fig. 13.4). These methods typically

Figure 13.4 Modified Pomeroy technique of female sterilization. (From Sciarra JJ. Surgical procedures for tubal sterilization. In: Sciarra JJ, Zatuchni GI, Daly MJ. *Gynecology and Obstetrics*. vol 6. Philadelphia: Harper & Row; 1984.)

involve general or regional anesthesia, though local anesthesia is possible.

Laparoscopic Approach

General anesthesia is usually used for laparoscopic sterilization. Although unipolar electrosurgical techniques were popular in the early days of laparoscopic sterilization, this method was abandoned due to an increased risk of surgical complications. The most common techniques used today include bipolar cautery, the Filshie clip, and the Silastic band (Falope ring). Neither material is reactive, and the titanium does not create artifact or otherwise interfere with magnetic resonance imaging (MRI) scans.

Transcervical Approach

Sterilization using the Essure device involves the introduction of a microinsert device transcervically through a hysteroscope (Fig. 13.5). The device is placed in the proximal portion of the fallopian tube. Over time, the device causes tissue ingrowth and permanent tubal occlusion. As with vasectomy, another method of birth control must be used to prevent pregnancy until occlusion is confirmed. A hysterosalpingogram is performed 3 months after insertion to document tubal occlusion (Fig. 13.6). Testing is under way using modified inserts that may prove to be effective much sooner. Anesthesia options include local anesthesia, intravenous sedation or general anesthesia. In a meta-analysis of 20 RCTs, the use of local anesthesia

Figure 13.5 Microinsert for transcervical sterilization in women.

Figure 13.6 HSG after successful Essure. (From Ogburn T, Espey E: Transcervical sterilization: past, present, and future. *Obstet Gynecol Clin North Am* 34(1):57-72, 2007.)

at the time of laparoscopic tubal ligation reduced postoperative pain for up to 8 hours after surgery (Harrison, 2014).

Cancer Prevention

Multiple studies indicate a reduced risk of ovarian cancer following tubal ligation. Current investigations are under way to assess an improvement in risk reduction when using bilateral salpingectomy rather than simple tubal ligation (McAlpine, 2014).

TIER 2 METHODS: VERY EFFECTIVE (6 TO 12 PREGNANCIES PER 100 WOMEN IN 1 YEAR): INJECTABLES, PILLS, PATCH, RING

INJECTABLE SUSPENSIONS

Depo-Provera, or depo-medroxyprogesterone acetate (DMPA), given in a dose of 150 mg intramuscularly (IM) or 104 mg subcutaneously (SC) every 3 months, is the only injectable contraceptive available in the United States. Worldwide, other short-term injectables composed of progestin alone or a combination of progestins and estrogens are also available but will not be discussed in this chapter.

Depot Formulation of MPA

Medroxyprogesterone acetate (MPA) is a 17-acetoxy-6-methyl derivative of progesterone that has increased progestogenic potency and is longer acting (Fig. 13.7). DMPA, the long-acting injectable formulation of MPA, consists of a crystalline suspension of MPA. DMPA is an extremely effective contraceptive and involves three mechanisms of action: (1) inhibition of ovulation by suppressing levels of FSH and LH and eliminating the LH surge; (2) thickening of cervical mucus inhibiting sperm from reaching the oviduct; and (3) altering the endometrium, which causes atrophy. When used correctly and consistently, the chance of pregnancy is 0.2%. Typical failure rates are around 6%. These effectiveness rates apply to women of all body weights.

The contraceptive dosage with the IM formulation is 150 mg DMPA, given by injection deep into the gluteal or deltoid muscle, after which the progestin releases slowly into the systemic circulation. The SC formulation contains 104 mg of DMPA in 0.65 mL of diluent and is injected into the subcutaneous tissue of the anterior thigh or abdominal wall. For both formulations, the total volume injected is 1 mL.

MPA can be detected in the systemic circulation within 30 minutes after its IM injection. Although serum MPA levels vary among individuals, levels rise steadily to effective contraceptive

Figure 13.7 Comparative structures of progesterone and MPA.

blood levels (>0.2 ng/mL) within 24 hours after both IM and SC injections. One RCT showed that self-administration of subcutaneous DMPA is not only feasible for women, but that continuation rates and DMPA levels were similar in women randomized to self versus clinical administration (Beasley, 2014).

Return of Fertility

Because of the lag time in clearing DMPA from the circulation after both IM-DMPA and SC-DMPA, resumption of ovulation is

delayed on average for 6 months and as long as 1 year after a single injection. The median delay to conception is 9 to 10 months after the last injection, with a wide range in resumption of ovulation, from 15 to 49 weeks from the last injection (Paulen, 2009).

Women who wish to become pregnant after discontinuing DMPA should know that they might experience a delay in the resumption of fertility until the drug has cleared from their circulation. After this initial delay, fecundity is similar to that found after discontinuing a barrier contraceptive (Fig. 13.8). Thus use of DMPA delays but does not prevent return of fertility.

Figure 13.8 Cumulative conception rates of women who discontinued a contraceptive method to become pregnant. *IUCD*, Intrauterine contraceptive device. (From Schwallie PC, Assenzo JR. The effect of depo-medroxyprogesterone acetate on pituitary and ovarian function, and the return of fertility following its discontinuation: a review. *Contraception*. 1974;10[2]:181-202.)

Clinical Side Effects

Bleeding Patterns

The major side effect of DMPA is a change of the menstrual cycle. In the first 3 months after the first injection, about 30% of women experience amenorrhea and another 30% to 40% have irregular bleeding and spotting occurring more than 11 days per month. Usually light, the bleeding does not cause anemia. As the duration of therapy increases, the incidence of frequent bleeding steadily declines and the incidence of amenorrhea increases. At the end of 1 year, about 55% of women experience amenorrhea. After 2 years, about 70% of women experience amenorrhea (Fig. 13.9). Women who use this method should receive counseling that with time irregular bleeding will diminish and amenorrhea will most likely occur.

After discontinuation of DMPA, about half of women resume a regular cyclic menstrual pattern within 6 months and about three fourths have regular menses within 1 year.

Weight Changes

About one fourth of women using DMPA gain weight, usually in the first 6 months of use. Several longitudinal studies indicate that DMPA users gain between 1.5 and 4 kg in their first year of use and continue to gain weight thereafter. While we do not have a clear understanding of how this weight gain differs from women not on DMPA, some suggest that the injection should

Figure 13.9 Percentage of patients with bleeding or spotting on days 0, 1-7, 8-10, or 11-30 per 30-day cycle while receiving injectable DMPA, 150 mg, every 3 months. (From Schwallie PC, Assenzo JR. Contraceptive use: efficacy study utilizing medroxyprogesterone acetate administered as an intramuscular injection once every 90 days. *Fertil Steril*. 1973;24:331-339, from The American Society for Reproductive Medicine.)

be used with caution in patients who are already overweight or obese (Le, 2009).

Mood Changes

The product labeling lists depression and mood changes as side effects of DMPA. Several studies, however, indicate that the incidence of depression and mood change in women using this method of contraception is less than 5%, and thus no greater than the overall incidence of depression. No clinical trials have been performed to assess whether a causal relation between DMPA and the development of depression exists.

Headache

The development of headaches is the most frequent medical event reported by DMPA users and a common reason for discontinuation of its use. No comparative studies indicate that DMPA increases the incidence or severity of tension or migraine headaches and the presence of migraine headaches does not contraindicate DMPA use.

Bone Loss

Because DMPA suppresses production of estradiol, bone remodeling is increased and may resemble menopause. Observational studies consistently indicate that DMPA is associated with a degree of decreased bone mineral density (BMD). Longer-term studies, however, indicate that bone loss is reversible after stopping DMPA use. Measurement of bone mineral density during DMPA use is unnecessary because bone density increases after stopping DMPA and bisphosphonate therapy should not be used in DMPA users with low BMD.

Noncontraceptive Health Benefits

DMPA reduces the risk of developing iron deficiency anemia and PID. The reduction in risk of endometrial cancer in women on DMPA is long lasting and substantial. DMPA also reduces the incidence of primary dysmenorrhea, symptoms of endometriosis, ovulation pain, and functional ovarian cysts because it inhibits ovulation. Many believe that DMPA also reduces seizure frequency in women with epilepsy. In some studies, DMPA seems to have beneficial effects on sickle cell pain crises.

Clinical Recommendations

DMPA can be started at any time during the menstrual cycle as long as the woman and her provider are reasonably certain that she is not pregnant. If given later than 7 days into the menstrual cycle, backup contraception should be used for 7 days. Women should be informed prior to receiving the first injection of the occurrence of irregular bleeding and the development of amenorrhea with DMPA with reassurance that these are normal changes. Pretreatment counseling may improve continuation rates. In addition, women need to know that the action may last as long as 1 year following the last injection if they decide to discontinue use of DMPA. If pregnancy occurs in a woman receiving DMPA, the hormone does not adversely impact the pregnancy.

ORAL CONTRACEPTIVES

Because of their effectiveness and ease of administration, oral contraceptives (OCs) became the most widely used method of

reversible contraception among both married and unmarried women within a few years of their introduction to the United States in 1960. The high doses of steroids in the original pill formulations caused minor side effects such as nausea, breast tenderness, and weight gain that frequently led to discontinuation of use. Since that time, other formulations have been developed and marketed with steadily decreasing dosages of both the estrogen and progestin components. Reduction in ethinyl estradiol (EE) dose has coincided with a lower incidence of severe adverse cardiovascular effects and minor adverse symptoms without increasing the failure rate. All the formulations marketed after 1975 contain less than 50 µg of EE and 3 mg or less of one of several progestins.

The most widely used methods combine EE with one of several synthetic progestins. The major effect of the progestin component is to inhibit ovulation, but progestins also contribute other contraceptive actions such as thickening of the cervical mucus and thinning of the endometrium. The major effects of the estrogen are to maintain the endometrium and thus prevent unscheduled bleeding as well as to inhibit follicular development through a synergistic effect with the progestin.

Pharmacology

Synthetic steroids have greater oral potency per unit of weight than do natural steroids. The modifications in chemical structure of different synthetic progestins and estrogens affect their biologic activity. One cannot define the pharmacologic activity of the progestin or estrogen in a particular contraceptive steroid formulation based only on the amount of steroid present. The biologic activity of each steroid also has to be considered.

The three major types of OC formulations include daily progestin-only pills (POPs), also known as minipills (see [Progestin-Only Pills](#), presented later in the chapter), fixed-dose (monophasic) combination pills, and multiphasic combination pills. The combination formulations are the most widely used. Monophasic products contain tablets with the same dose combination of an estrogen and progestin each day. In multiphasic formulations, pills containing several different dose combinations come in the same pack. A different tablet color corresponds to each dose. Depending on the number of different dose combinations, these formulations are further classified as biphasic, triphasic, or four phasic.

In the United States, most oral contraceptive regimens are packaged in a 28-day (4-week) cycle. Many combination OC formulations provide active pills continuously for 21 days (3 weeks) followed by a 7-day hormone-free interval (HFI). Most products are packaged with inactive spacer (placebo) pills during the HFI to improve compliance. Some formulations provide an iron supplement in the spacer pills. Uterine bleeding occurs secondary to hormone withdrawal during the HFI, typically 1 to 3 days after taking the last active pill. This withdrawal bleeding usually lasts 3 to 4 days and is generally lighter than during menses in an ovulatory cycle. Some formulations provide active tablets for 24 days, reducing the HFI to only 4 days, and these may be more effective than 21-day active pill formulations. Other formulations provide a small amount of EE (alone without progestin) during all parts of the 7-day HFI to reduce symptoms associated with estrogen withdrawal and the resurgence of follicle-stimulating hormone (FSH).

Newer dosing strategies include extended and continuous cycles. Extended cycle regimens contain 84 days of active pills followed by a 7-day HFI (or 7 days of EE only) that results in withdrawal bleeding only four times a year. A continuous daily LNG 90- μ g/EE 20- μ g regimen with 28 active pills in a treatment pack was introduced in 2007 to completely eliminate scheduled withdrawal bleeds. Some providers recommend extended use of generic, less expensive monophasic 20- μ g EE OCs, instructing patients to discard the placebo pills and begin a new cycle pack after 21 days.

Randomized studies comparing cyclic and continuous dosing regimens have documented a decrease in the total scheduled bleeding days but an increase in irregular bleeding and spotting with extended or continuous use of hormonal contraceptives. Bleeding patterns typically improve over time in most users of cyclic or continuous OCs, with rates of unscheduled bleeding highest in early cycles of use. Women who experience prolonged breakthrough bleeding while taking combined OCs continuously might benefit from discontinuing the active pills for 3 days and then restarting. Greater gaps could result in ovulation and unintended pregnancy.

OCs have a 1% failure rate with perfect use and an 8% failure rate with typical use. Accidental pregnancies occurring during OC use probably do not occur because of missing just one to two pills, but rather because initiation of the new cycle of medication is delayed for a few days or because a greater number of tablets are missed. It is particularly important that the pill-free interval is not extended more than 7 days. Women should be advised that the most important pill to remember to take is the first one of each cycle. In practice, clinicians should ensure that all patients are able to easily access refills of oral contraceptives. When a woman misses two or more pills in a pack, she should take emergency contraception and use backup contraception.

Physiology

Mechanism of Action

Combination oral contraceptives suppress gonadotropins. The estrogen component prevents a rise in follicle-stimulating hormone (FSH) and enhances the effect of the progestin component, which inhibits ovulation and, specifically, the luteinizing hormone (LH) surge. These dual actions lead to inhibition of follicle development and ovulation. The lowest amount of a progestin needed to suppress LH is the **ovulation inhibition dose**. Changes in the cervical mucus (which prevent sperm transport into the uterus), the fallopian tube (which interfere with gamete transport), and the endometrium (which reduce the likelihood of implantation) represent secondary contraceptive effects of the progestin component. Contraceptive steroids prevent ovulation mainly by interfering with release of gonadotropin-releasing hormone (GnRH) from the hypothalamus. Most studies also support that contraceptive steroids directly suppress the pituitary in addition.

With all OCs, neither gonadotropin production nor ovarian steroidogenesis is completely abolished. Levels of endogenous E_2 in the peripheral blood during ingestion of combination OCs are similar to those found in the early follicular phase of a physiologic cycle.

In a cohort study of U.S. women, 24-day oral contraceptive regimens containing a progestin with a long half-life had

higher contraceptive effectiveness compared to 21-day regimens (Dinger, 2011). No other difference in clinical effectiveness has been demonstrated among the various combination formulations currently available in the United States.

The balance between estrogen and progestin influences the bleeding profile of a combination OC. Estrogen induces endometrial proliferation. Progestins oppose the mitotic action of estrogen, leading to a stable decidualized endometrium. Even though women taking combined OCs are exposed to both hormones at the same time rather than sequentially, they typically undergo some endometrial proliferation. The bleeding that users of combined OCs experience during the hormone-free interval is called **withdrawal bleeding**, as it occurs upon cessation of the progestin component of the pill. Bleeding that occurs during the time that active pills are ingested is called **breakthrough bleeding**.

Unscheduled (breakthrough) bleeding and absence of withdrawal bleeding (amenorrhea) occur as a result of insufficient estrogen to support the endometrium. If the user considers this problematic, increasing the amount of estrogen in the pill formulation or changing progestins often provides a solution. Otherwise absence of withdrawal bleeding is not a reason to change pills if the patient is satisfied.

Metabolic Effects

The synthetic steroids in OC formulations have many metabolic effects in addition to their contraceptive actions. These metabolic effects can lead to side effects and rare potentially life-threatening complications. The magnitude of these effects may be related to the dosage and potency of the steroids in the formulations. Fortunately, the more common adverse effects are relatively mild. The most frequent symptoms produced by the estrogen component include nausea (12%), breast tenderness (9%), and headache (18%). However, in placebo-controlled trials, there is no difference in the incidence of these complaints between OC users and placebo users (Redmond 1999). Reduction in EE dose to below 50 μ g has greatly reduced the incidence of all of these estrogenic side effects.

OCs decrease androgen levels, which tends to reduce acne. The net effect of an OC on acne relates to three qualities: the androgenicity of the progestin component, the extent that endogenous androgens circulate freely or are bound to plasma proteins, and the activity of 5 α -reductase, the enzyme that converts testosterone to dihydrotestosterone. For most low-dose OCs, the net effect favors a reduction of acne. In two multicenter, double-blind, placebo-controlled studies, evaluating the effectiveness of triphasic norgestimate/ethinyl estradiol (Ortho Tri-Cyclen) for the treatment of acne, the OC group had a greater reduction of acne with no difference in adverse events between both groups (Redmond, 1999), a result confirmed in studies of several other OCs (O'Connell, 2008, Gallo, 2014).

Weight gain represents a common complaint of women using hormonal contraception. However, a 2013 study assessed weight gain following OC initiation in obese and normal weight women, weighing participants prior to and after 3 months of OCP use. Neither group experienced a substantial change in weight (Mayeda, 2014, Gallo, 2014).

Progestin-Only Pills (POPs)

The minipill formulations consist of tablets containing a low dose of progestin and no estrogen. They are taken every day without

a steroid-free interval. Because doses of a progestin are below the **ovulation inhibition dose** in the minipills that contain norethindrone or norgestrel, the other progestogenic effects become the primary mechanism of action. Clinicians should counsel their patients using the minipill that preparations should be consistently taken at the same time of day to ensure that blood levels do not fall below the effective contraceptive level. Newer POPs contain progestins that inhibit ovulation more effectively.

With minipill use, many women may still ovulate; therefore, estradiol and progesterone produced by the ovary will affect endometrial bleeding patterns. Women may experience irregular bleeding, spotting, or amenorrhea, depending on an individual woman's response.

Coagulation Parameters

Epidemiologic studies consistently demonstrate that the risk of both venous and arterial thrombosis increases among users of combined OCs compared with nonpregnant nonusers. However, although combined oral contraceptives increase the risk of VTE, they offer significant protection against pregnancy, a condition associated with a substantially higher risk of thrombosis roughly twofold higher than that observed with OCs.

The increased risk is related to the estrogen component of the pill and is dose dependent (Gerstmann, 1991). A woman's baseline risk of venous thromboembolism (VTE) increases by three times if she ingests estrogen-containing oral contraception. If a woman already has an increased baseline risk, such as having a personal history of idiopathic VTE, she should not take an estrogen-containing contraceptive. Screening for coagulation deficiencies should only be performed before starting OC use if the woman has a family history of thrombotic events. Although progestins alone do not affect coagulation parameters, whether recent progestins increase the coagulation risk of OC use remains controversial. It has been suggested that OCs with the newer progestins increase the risk over that of the older, early generation products.

Obesity is a modest risk factor for VTE (Fig. 13.10), and extreme obesity (e.g., a body mass index [BMI] >40) should be considered a relative contraindication to use of a combined hormonal method. Use of OCs by women older than age 35 who also smoke is contraindicated due to the risk of myocardial infarction.

Return to Fertility

After discontinuation of low-dose OCs, the suppressive effect on the hypothalamic-pituitary-ovarian axis disappears quickly. After the initial recovery, completely normal endocrine function occurs. There is little, if any, effect of duration of OC use on the length of delay of subsequent conception. There is no risk of congenital malformations or other adverse outcomes in pregnancies among women who conceive while taking OCs or shortly thereafter.

Neoplastic Risks and Benefits

Breast Cancer

Although OC use increases the risk of breast cancer by 25%, this risk disappears after cessation of use. The absolute risk of breast cancer is low given the young age of most OC users. Some evidence indicates that those breast cancers diagnosed during OC use are more likely to be localized. The risk of developing breast cancer with OC use is not changed even in women with a

*Adjusted for age and sex.
Figure 13.10 Relative risk (with 95% confidence intervals) of deep vein thrombosis by categories of body mass (BMI). Adjusted for age and sex. (From Pomp ER, le Cessie S, Rosendaal FR, Doggen CJ. Risk of venous thrombosis: obesity and its joint effect with oral contraceptive use and prothrombotic mutations. *Br J Haematol.* 2007;139: 289-296.)

high risk of developing breast cancer, including women with an immediate family history of breast cancer and those with *BRCA-1* and *BRCA-2* mutations (Milne, 2005).

Cervical Cancer

The epidemiologic data regarding the risk of invasive cervical cancer as well as cervical intraepithelial neoplasia and OC use are conflicting. Confounding factors could account for contrasting results in different studies. Studies indicate that the risk of cervical cancer, both invasive and in situ, for OC users compared with nonusers increases with increasing duration of OC use. These risks persist after adjusting for HPV infection, squamous cell or adenocarcinoma, number of sexual partners, cervical cytology screening, smoking, and use of barrier contraceptive (Smith, 2003, Appleby, 2007). However, some studies suggest that there may be an increased relationship between OC use and adenocarcinoma of the cervix compared with squamous cell.

There is no evidence that OC use alters the incidence or rate of the progression of cervical dysplasia to invasive cancer. Women with treated cervical dysplasia can use OCs, as can those with newly diagnosed dysplasia awaiting evaluation.

Endometrial Cancer

Studies have consistently demonstrated a strong protective effect between OCs and endometrial cancer. Compared with nonusers, women who use OCs for at least 1 year have an age-adjusted relative risk of 0.5 for development of endometrial cancer between ages 40 and 55. This protective effect is related to duration of use, increasing from a 20% reduction in risk with 1 year of use to a 40% reduction with 2 years of use to about a 60% reduction with 4 years of use. This protective effect persists for at least 15 years after stopping use of OCs.

Ovarian Cancer

Numerous epidemiologic studies have consistently demonstrated that OCs reduce the risk of developing ovarian cancer. The risk of ovarian cancer decreases by about 20% for every 5 years of use. For woman using OCs for 15 years or more, the risk is almost halved. One year of use may obtain a protective effect (Grimbizis, 2010). OCs reduce the risk of the four main histologic types of epithelial ovarian cancer: serous, mucinous, endometrioid, and clear-cell, and the risk of both invasive ovarian cancers and tumors of low malignant potential (borderline tumors). The protective effect continues for at least 30 years after the use of OCs ends. OC use also reduces the risk of ovarian cancer in women with *BRCA-1* and *BRCA-2* mutations and in those with a family history of ovarian cancer to the same extent as in women without these risk factors.

Liver Adenoma and Cancer

The development of a benign hepatocellular adenoma is an extremely rare occurrence. An increased risk of this tumor was reported in early OC studies of prolonged use of high-dose formulations but seems to be far lower for women taking lower OC doses. Women with active liver disease should not use hormonal contraception, as the liver is a major site for the metabolism of synthetic steroids.

Colorectal Cancer

A meta-analysis of published studies of the relationship between OCs and colorectal cancer showed that OC ever-use was associated with a 15% to 20% reduction in the risk of colorectal cancer in the eight case-control studies and four cohort studies analyzed. Thus OC use decreases the risk of developing both colon and rectal cancer (Fernandez, 2001).

Noncontraceptive Health Benefits

In addition to the long-term reduction in risk of ovarian and endometrial cancer, some of the immediate benefits of OC use include improvement of menorrhagia and dysmenorrhea and decreased acne (Maguire, 2011). As a result of the antiestrogenic action of the progestins in OCs, there is less proliferation of the endometrial glands. These changes reduce the amount of blood loss at the time of endometrial shedding. This decreased blood loss makes the development of iron deficiency anemia less likely for OC users than for nonusers. OC users are significantly less likely to have menorrhagia, irregular menstruation, or intermenstrual bleeding. As OCs inhibit ovulation, they can reduce such ovulatory disorders as dysmenorrhea and premenstrual syndrome.

Contraindications to Oral Contraceptive Use

The World Health Organization has published detailed guidelines listing the medical eligibility criteria for the use of contraceptive methods. These guidelines are regularly updated, and the revised fifth edition can be downloaded from the WHO website (www.who.int/reproductivehealth) (WHO, 2010).

The Centers for Disease Control and Prevention (CDC) Guidelines, specific to practice in the United States and also regularly updated, were published in 2010 and are available at the CDC website (www.cdc.gov/reproductivehealth) (CDC, 2010).

OCs can be prescribed for the majority of women of reproductive age, because these women are young and generally healthy. There are, however, certain absolute contraindications, including a history of vascular disease (thromboembolism, thrombophlebitis,

atherosclerosis, and stroke) and systemic disease that may affect the vascular system (e.g., active lupus erythematosus with vascular involvement or diabetes with retinopathy or nephropathy). Cigarette smoking by OC users older than age 35 and uncontrolled hypertension are also contraindications. As breast or endometrial cancer may involve hormone-sensitive tumors, avoiding OC use is prudent. Other contraindications include undiagnosed uterine bleeding and elevated triglyceride levels.

Pregnancy is an obvious contraindication. As mentioned, OCs are not teratogenic nor will they negatively affect pregnancies occurring during or after use. Women with active liver disease should not take OCs. Women who have recovered from liver disease, such as viral hepatitis, and whose liver function tests have returned to normal can safely take OCs.

Relative contraindications to OC use include heavy cigarette smoking younger than age 35, migraine headaches, and undiagnosed causes of amenorrhea or genital bleeding. The risk of stroke, albeit low, is significantly increased in women with migraine headaches with aura who use OCs. Women who have migraine headache with aura or peripheral neurologic symptoms should not use oral contraceptives. If headache occurs only during the hormone-free interval, continuous dosing might help to control the symptoms. Women with migraine headaches without aura under 35 years of age can use OCs.

OC use may mask the symptoms produced by a prolactin-secreting adenoma. Therefore women with either galactorrhea or amenorrhea should not receive OCs until a diagnosis is established. If galactorrhea develops during OC use, OCs should be discontinued, and after 2 weeks a serum prolactin level should be measured. If elevated, further diagnostic evaluations are indicated.

Women with diabetes without cardiovascular progression can take low-dose OC formulations, because these agents do not affect glucose tolerance or accelerate diabetes mellitus.

Beginning Oral Contraceptives

Adolescents

A pubertal girl who has demonstrated maturity of the hypothalamic-pituitary-ovarian axis with presumably ovulatory menstrual cycles can begin OCs without concern that their use will alter future reproductive endocrinologic function. It is also not necessary to be concerned about accelerating epiphyseal closure in the postmenarchal female. Endogenous estrogens have already initiated the process a few years before menarche, and use of contraceptive steroids will not hasten this process.

After Pregnancy

For women who deliver after 28 weeks and are not nursing, the combination pills should be initiated no sooner than 6 weeks after delivery as the increased risk of postpartum thromboembolism may be further enhanced by the hypercoagulable effects of combination OCs. Progestin-only methods can be initiated immediately.

Estrogen inhibits the action of prolactin in breast tissue receptors; therefore, the use of combination OCs (those containing both estrogen and progestin) diminishes the amount of milk produced by OC users who breast-feed their babies. The diminution of milk production is directly related to the amount of estrogen in the contraceptive formulation, and no significant health risks are associated with hormones in breast milk for the nursing infant. The major concern is that combined OCs will lower the success of initiation of lactation. Women at high risk for

unintended pregnancy following delivery should consider the relative advantages of a combination pill over other methods, as well as the effect of the contraceptive on nursing success. A number of authorities, including the CDC, are not enthusiastic about the use of combined OCs until breast-feeding has been established, with many preferring to wait until 6 months have passed.

Progestins do not diminish the amount of breast milk, and progestin-only OCs are highly effective in this group of women, though not recommended by some prior to 6 weeks postpartum with breast-feeding.

Cycling Women

Woman may find it convenient to start a pill pack on a particular day of the week. Sunday starts have been a popular recommendation; however, delaying the start of a pill pack can lead to unintended pregnancies. Starting a pill pack on the same day as a clinic visit instead of waiting until after menses allows for a quicker onset of contraception with no adverse effects on bleeding patterns and is highly acceptable to many women.³⁹

Type of Formulation

Estrogen dose, side effect profile, and cost should guide decisions regarding the type of formulation to prescribe. Doses with 35 µg or more of estrogen are rarely used because of the cardiovascular risks and estrogenic side effects. The U.S. Food and Drug Administration (FDA) has stated that the product prescribed should be one that contains the least amount of estrogen and progestin that is compatible with a low failure rate and the needs of the individual woman.

The progestin-only contraceptive formulations have a lower incidence of risks than do the combination formulations. Because the factors that predispose to thromboembolism are caused by the estrogen component, the incidence of thromboembolism in women taking the minipill is not increased compared to nonusers.

It is unfortunate that the infrequent adverse effects of OCs have received widespread publicity, but the more common non-contraceptive health benefits have attracted little attention.

CONTRACEPTIVE PATCH

The contraceptive skin patch Ortho Evra (Fig. 13.11) contains 75 µg ethinyl estradiol and 6 mg norelgestromin. A generic patch

Figure 13.11 The contraceptive skin patch releasing ethinyl estradiol and norelgestromin.

is now available, and new combination patches are in development. One patch is applied to the skin each week for 3 consecutive weeks and no patch for the following week of a 4-week cycle to allow withdrawal bleeding. The patch may be applied to one of four anatomic sites: buttocks, upper outer arm, lower abdomen, or upper torso excluding the breasts. Following skin application, both steroids appear in the circulation rapidly and reach a plateau within 48 hours. Like OCs, the primary mechanism of action is the inhibition of gonadotropin release and prevention of ovulation. Contraceptive effectiveness and metabolic and clinical effects, including irregular bleeding, are similar to combination oral contraceptives. Results from clinical trials suggest that patch efficacy may be slightly lower in women with body weight more than 90 kg. In a pooled analysis of three multicenter trials, 7 out of 15 pregnancies occurred in women >80 kg. Five of the 15 pregnancies were in women >90 kg. For this reason, the Ortho Evra label indicates a possible decrease in effectiveness among overweight or obese women (Zieman, 2002). However, even in the heaviest women the patch was 90% effective. Newer patch results do not support a possible decrease in effectiveness.

CONTRACEPTIVE VAGINAL RING

Steroids pass easily through the vaginal epithelium directly into the circulation. A flexible ring-shaped device containing 2.7 mg of ethinyl estradiol and 11.7 mg of etonogestrel (Fig. 13.12), the contraceptive ring (NuvaRing) is placed in the vagina for 21 days and then removed for up to 7 days to allow withdrawal bleeding. After this ring-free interval the woman inserts a new ring regardless of whether withdrawal bleeding has occurred. Because the steroids act systemically, the ring comes in only one size and does not have to be fitted or placed in a certain location. Like oral contraceptives, the main mechanism of action is inhibition of gonadotropins and prevention of ovulation. Because each ring delivers sufficient steroids to inhibit ovulation for 6 weeks, contraceptive action can be assumed

Figure 13.12 The contraceptive vaginal ring releasing ethinyl estradiol and etonogestrel.

even if the ring is left in place beyond 21 days. Continuous use has been studied, and results are similar to those observed with continuous OCs.

Despite the low dose of ethinyl estradiol, bleeding control is good, with irregular bleeding occurring less than with OCs. Contraceptive effectiveness as well as metabolic and clinical effects are similar to that for combination oral contraceptives. Ring expulsion is uncommon, and both partners typically report high acceptability with use.

Phase III clinical trials showed no difference in efficacy for women in the heaviest weight category (>166 lb/75 kg) (Westhoff, 2005), but few overweight or obese women had been enrolled. A pharmacokinetic study showed therapeutic progesterone and ethinyl estradiol levels in both normal-weight and obese women. Observed progesterone levels in obese vaginal ring users were high enough to inhibit ovulation and there was no increase in follicular activity (Dragoman, 2013).

TIER 3 METHODS: EFFECTIVE (18 OR MORE PREGNANCIES PER 100 WOMEN IN 1 YEAR): BARRIER METHODS, LACTATIONAL AMENORRHEA, PERIODIC ABSTINENCE, COITUS-RELATED METHODS

BARRIER METHODS

Diaphragm and Cervical Cap

When Margaret Sanger introduced the vaginal diaphragm to the United States in 1916, it became the most widely used female-controlled reversible contraceptive method for 4 decades prior to the introduction of oral contraceptive. The diaphragm is a thin, dome-shaped membrane of latex rubber or silicone with a flexible spring modeled into the rim. The spring allows the device to be collapsed for insertion and then allows for expansion within the vagina to seat the rim against the vaginal wall, creating a mechanical barrier between the vagina and the cervix. Traditionally, a diaphragm has been fitted by a health care provider to find the largest size that does not cause discomfort or undue pressure on the vaginal mucosa; however, no data have assessed whether a “good fit” correlates with improved effectiveness. The FDA has approved Caya, a single-size diaphragm that does not require fitting by a practitioner, intended for use over the counter (Fig. 13.13).

A cervical cap is a cup-shaped silicone or rubber device that fits around the cervix. It should be fitted to the cervix by a clinician. The only cap currently on the U.S. market is the FemCap. This product, made of soft, durable, hypoallergenic, silicone rubber, is designed to contact the vaginal walls as the dome of the device sits over the cervix (Fig. 13.14). Prescriptions of the diaphragm and cervical cap have become much less frequent.

The diaphragm and cervical cap should be used with a spermicide and be left in place for at least 8 hours after the last coital act. If repeated intercourse takes place, additional spermicide should be used vaginally. Failure rate during the first year of use for the diaphragm ranges from 13% to 17% among all users and may be as low as 4% to 8% with perfect use. The cervical cap failure rate is comparable to the diaphragm. The diaphragm and cervical cap may also reduce the risk of cervical dysplasia and cancer.

Male and Female Condom

The latex and polyurethane male condoms are the only method with FDA-approved labeling that supports use of the product to prevent both pregnancy and the transmission of sexually transmitted infections (STIs). Condoms should be encouraged as STI protection along with another more effective method for pregnancy prevention. Clinicians should review proper condom use with both men and women. The condom should be applied to the erect penis before any contact with the vagina or vulva. The tip should extend beyond the end of the penis by about half an inch to collect the ejaculate. After ejaculation, the penis must be removed from the vagina while still somewhat erect, and the base of the condom grasped to ensure the condom is removed without spillage of the ejaculate. Water-based lubrication may reduce condom breakage.

When used by strongly motivated couples, the male condom is effective. The typical use failure rate is around 15% (Hatcher, 2011).

The female condom consists of a soft, loose-fitting polyurethane sheath with two flexible rings. One ring lies at the

Figure 13.13 The Caya diaphragm. (Courtesy of Kessel Medintim GmbH, www.medintim.de.)

Figure 13.14 The female barrier method FemCap.

closed end of the sheath and serves as an insertion mechanism and internal anchor for the condom inside the vagina. The outer ring forms the external edge of the device and remains outside the vagina after insertion, thus providing protection to the introitus and the base of the penis during intercourse (Fig. 13.15). The female condom is prelubricated and intended for one-time use only. Like male condoms, the device is available over the counter and does not require fitting by a health professional. It also protects against sexually transmitted diseases. It can be inserted prior to the onset of sexual activity and left in place after ejaculation has occurred. The typical use failure rate at 1 year is estimated to be 21% (Hatcher, 2011). New female condoms are forthcoming.

LACTATIONAL AMENORRHEA METHOD (LAM)

Because prolactin inhibits gonadotropin pulsatility, nursing women typically remain amenorrheic for a variable length of time after giving birth. Higher frequency and longer duration of nursing contribute to menstrual suppression and night nursing is highly correlated with anovulation and amenorrhea.

The criteria for successful use of LAM are continuous amenorrhea and exclusive breast-feeding (no supplements) for up to 6 months after delivery. Night nursing is highly protective. When used correctly, the failure rate in the first 6 months postpartum is less than 2%.

Effective use of LAM improves with education regarding the efficacy of the method. Because breast-feeding may end sooner than anticipated, a provider should discuss in advance a reliable ongoing contraceptive plan for prompt initiation if the conditions required for success with LAM are no longer in place.

Figure 13.15 A female condom. (From Beksinska M, Smit J, Joanis C et al. Female condom technology: new products and regulatory issues. *Contraception*. 2011;83[4]:316-321.)

PERIODIC ABSTINENCE

Many motivated couples use abstinence from sexual intercourse or a barrier method during the days of the menstrual cycle when the ovum can be fertilized, or during the 5 days preceding ovulation or the day of ovulation. Because precisely identifying the timing of ovulation is difficult, several techniques of periodic abstinence have been utilized.

The oldest of these is the calendar rhythm method. With this method, the period of abstinence is determined by calculating the length of the individual woman's previous menstrual cycle and makes three assumptions: (1) the human ovum can be fertilized for only about 24 hours after ovulation, (2) sperm can fertilize for 3 to 5 days after coitus, and (3) ovulation usually occurs 12 to 16 days before the onset of menses. The woman therefore establishes her fertile period by subtracting 18 days from the length of her previous shortest cycle and 11 days from her previous longest cycle and abstains from coitus during this time.

Other periodic abstinence methods rely on cyclic physiologic changes. Increasing levels of progesterone occurring after ovulation cause a detectable rise in daily basal body temperature. The woman must abstain from intercourse from the cessation of menses until the third consecutive day of elevated basal temperature, or when she is postovulatory. The cervical mucus method requires that the woman recognize and interpret the presence and consistency of cervical mucus. Increasing estradiol levels increase the production of cervical mucus. Intercourse can occur after menses ends until the first day that copious, slippery mucus is observed to be present and again 4 days after the last day when the characteristic mucus was present.

The calendar, temperature, and cervical mucus methods can be used separately or in combination with one another, or the symptothermal method. Overall typical failure rates are around 24%. Women with irregular cycles should not use periodic abstinence methods, over the age of 35, or immediately following a pregnancy. Women using these methods should also have control over when intercourse occurs.

COITUS-RELATED METHODS

Spermicides

Spermicides consist of an active agent and a carrier. The carriers include gels, foams, creams, tablets, films, and suppositories. The active agent is a surfactant that immobilizes or kills sperm on contact by destroying the sperm cell membrane. Spermicides must be placed into the vagina before each coital act, often in combination with a barrier contraceptive to increase effectiveness. The contraceptive sponge, a cylindric piece of soft polyurethane impregnated with 1 mg of nonoxynol-9 spermicide, must be inserted into the vagina before intercourse and is effective for 24 hours. The failure rate ranges from 15% to 25%.

Coitus Interruptus (Withdrawal)

Removal of the penis from the vagina prior to ejaculation to prevent pregnancy is an ancient male-controlled method of contraception without contraindications, devices, or cost. Withdrawal can fail because of the small numbers of sperm present in some pre-ejaculate, the fluid produced by the penis during sexual excitement and before climax. More commonly, the method fails if withdrawal is not performed in a timely fashion. Correct and consistent use

with every act of intercourse should be stressed, not only during suspected fertile times. A major drawback of the method is the lack of any protection against sexually transmitted infections. Failure rates range from 4% with perfect use to 22% with typical use.

EMERGENCY CONTRACEPTION

Emergency contraception (EC) allows women to prevent pregnancy after an act of unprotected intercourse. Commonly misdescribed as

the morning-after pill, EC can actually be used up to 120 hours after intercourse, depending on the method. Effectiveness of EC is greater the closer it is taken to the time of intercourse. Developed in the 1970s, the Yuzpe method uses various forms and doses of combined OCs that prevent pregnancy after intercourse by inhibiting ovulation. The Yuzpe method involves one dose of one to six OC tablets, depending on the brand, with a second dose 12 hours later (Table 13.4). This method reduces the pregnancy risk by about 75%. Since the 1990s, this method is used infrequently in the United States as new methods seem to have greater effectiveness.

Table 13.4 Pills That Can Be Used for Emergency Contraception in the United States*

Brand	Company	Pills per Dose†	Ethinyl Estradiol per Dose (µg)	Levonorgestrel per Dose (mg)‡
Antiprogesterin Pills: Take One Pill				
Ella§	Actavis	1 white pill	0	0

From Trussell J, Raymond EG, Cleland K. Emergency contraception: a last chance to prevent unintended pregnancy. 2015. Available at <http://ec.princeton.edu/questions/ec-review.pdf>.

*Ella, Plan B One-Step, Next Choice One Dose, My Way and Levonorgestrel Tablets are the only dedicated products specifically marketed for emergency contraception. The oral contraceptive pills listed above have been declared safe and effective for use as emergency contraceptive pills (ECPs) by the United States Food and Drug Administration. Plan B One-Step is available without age restrictions to women and men; Next Choice One Dose, My Way, and Levonorgestrel Tablets are available over the counter to women and men aged 17 and older. Ella is prescription-only regardless of age. Outside the United States, more than 100 emergency contraceptive products are specifically packaged, labeled, and marketed. Levonorgestrel-only ECPs are available either over the counter or from a pharmacist without having to see a clinician in 60 countries. For a worldwide directory of pills that can be used for emergency contraception, see <http://ec.princeton.edu/worldwide/default.asp#country>.

†The labels for Plan B One-Step, Next Choice One Dose, and My Way say to take the pill within 72 hours after unprotected intercourse. Research has shown that they are effective when used within 96 hours after unprotected sex. The label for Levonorgestrel Tablets says to take one pill within 72 hours after unprotected intercourse and another pill 12 hours later. Research has shown that that both pills can be taken at the same time with no decrease in efficacy or increase in side effects and that they are effective when used within 96 hours after unprotected sex.

‡The progestin in Cryselle, Lo/Ovral, Low-Ogestrel, and Ogestrel is norgestrel, which contains two isomers, only one of which (levonorgestrel) is bioactive; the amount of norgestrel in each tablet is twice the amount of levonorgestrel.

§Ella contains 30 mg ulipristal acetate.

Currently, most dedicated EC medications contain the progestin levonorgestrel. The most well known and most commonly used progestin EC is Plan B One Step (with generic forms Take Action, Next Choice One Dose, and My Way also available), a 1.5-mg levonorgestrel single dose pill or two 0.75-mg pills given 12 hours apart, both to be given within 72 hours from the time of unprotected sex. This method of EC is currently available over the counter. Plan B works by delaying or inhibiting ovulation. Because this effect is preovulatory, it is efficacious when taken during the periovulatory phase of the menstrual cycle. Effectiveness depends on the time in the cycle that it is taken. When comparing methods directly, the risk of pregnancy among women receiving the levonorgestrel only method is about half of that for women using the Yuzpe method (Raymond, 2004).

A newer type of EC is a 30-mg single dose of the selective progesterone receptor modulator ulipristal acetate (Ella). Ovulation is delayed for 5 days in women who take ulipristal acetate. Women can take it closer to the time of ovulation than other methods and still successfully delay ovulation, even after the LH surge has occurred. Thus, Ella has been approved for use up to 120 hours from the time of unprotected intercourse, and it is 42% more effective at preventing pregnancy than the levonorgestrel-only method (Glasier, 2010).

The copper IUD is the most effective form of EC. Insertion up to 5 days after unprotected intercourse is 99% effective at preventing pregnancy. When appropriate, another benefit is the fulfillment of a woman's long-term contraceptive needs. Studies evaluating Mirena placement for use as EC are under way, but currently there is insufficient evidence to recommend its use for this purpose.

Current controversies include initiation of long-term contraception at the time of EC use and EC's effectiveness in heavier women. Some data indicate that EC may be less effective when used in conjunction with long-term hormonal contraceptive methods and that it may be less effective in heavier women (Glasier, 2011). These questions are active areas of research interest. Importantly for both questions, the copper IUD is highly effective as long-term contraception even when used as EC, and its effectiveness does not depend on weight.

INDUCED ABORTION

Induced abortion is one of the most common gynecologic operations performed in the United States and in many other countries. As determined by the landmark *Roe v. Wade* Supreme Court decision, the state may not interfere with the practice of abortion in the first trimester. In the second trimester, individual states may regulate abortion services in the interest of preserving the health of the woman.

From a public health perspective, safe and legal abortion services are a cornerstone of maternal health care. Worldwide, illegal abortion is one of the leading causes of maternal death. Despite impressive gains in contraceptive safety and use, unintended pregnancy remains a major health and social problem in the United States (see [Contraception Overview](#), presented earlier in the chapter). Although we can and should work to reduce the number of unintended pregnancies, contraceptive failures inevitably occur, and access to safe and legal abortion services remains a keystone of reproductive health. Some abortions are performed for pregnancies that are initially intended, but abortion becomes the only recourse for maternal indications or abnormal fetal screens.

In the United States, half of pregnancies are unintended, and about 4 in 10 of these end in elective abortion (Finer, 2014). U.S. abortion rates have declined gradually since 1980 but are higher than in Western European countries. In 2011, 1.06 million abortions occurred, a 13% decline since 2008 (Fig. 13.16). By the age of 45, at least half of U.S. women will experience an unintended pregnancy, and 1 in 10 women will have an abortion by age 20, 1 in 4 by age 30, and 3 in 10 by age 45 (Jones, 2011).

Ninety percent of abortions are performed within the first 12 weeks of pregnancy, and the distribution of abortions within the first 12 weeks is becoming earlier. In September 2000, the U.S. Food and Drug Administration approved the abortion drug mifepristone to be marketed in the United States as an alternative to surgical abortion. By 2011, medication abortion accounted for 23% of all nonhospital abortions and for 36% of abortions prior to 9 weeks' gestation (Jones, 2014).

Figure 13.16 Trends in abortion. (From Guttmacher Institute, Induced abortion in the United States, Fact Sheet, New York: Guttmacher Institute, 2014, http://www.guttmacher.org/pubs/fb_induced_abortion.html)

METHODS OF ABORTION

Curettage Methods

Curettage by vacuum aspiration is the predominant method of performing abortion in the first trimester. Early pregnancy aspiration can be performed with a small, flexible, plastic cannula connected to an aspiration syringe. This technique, called **manual vacuum aspiration (MVA)**, can be performed up to a gestational age of 10 weeks and sometimes later. Dilation of the cervix is often required as well as some type of anesthesia, either local or with IV sedation. After 10 weeks, the uterus may be more efficiently evacuated with an electric vacuum aspiration system (EVA). In earlier gestations, randomized trials have shown similar efficacy and patient satisfaction with MVA and EVA.

Following any vacuum aspiration, good practice is to examine the tissue to determine that the gestational sac, placenta, and any fetal parts have been removed. MVA produces less disruption of small gestational sacs and may facilitate their identification. If products of conception can't be visualized, a sonogram can identify retained tissue. In the case of very early pregnancy, it can be difficult to identify a gestational sac. Serial hCG evaluation or repeat ultrasound in 1 week can ensure that pregnancy termination has occurred. If inspection reveals no gestational sac, retained products or uterine perforation should also be ruled out. The MVA technique is also a low-cost and highly efficient technique to manage miscarriage in an office setting, including incomplete or missed abortion.

Dilation and evacuation (D&E) is the surgical technique used to perform abortion beyond the first trimester. Among mid-trimester abortions performed in the United States, more than 90% are D&Es. Because a greater amount of cervical dilation is usually needed, cervical preparation with osmotic dilators may be necessary for several hours or sometimes an additional day before the procedure. The most commonly used dilators are small tents of dried and sterilized seaweed, *Laminaria japonica*. By gently opening the cervix over several hours, the osmotic dilators substantially reduce the risk of uterine trauma, such as perforation and cervical injury. *Laminaria* can be used in concert with a single dose of mifepristone to reduce the number of *laminaria* placed without affecting dilation (Shaw, 2015). Another strategy for cervical preparation is the administration of misoprostol, a prostaglandin and E₁ analogue, in a dosage of 400 µg given vaginally, or buccally a few hours before vacuum aspiration or D&E. Misoprostol softens the cervix and can reduce the amount of dilation needed.

Medical Abortion

First-Trimester Medication Abortion

Mifepristone, or Mifeprex, once known as RU-486, has weak progestational activity but a marked affinity for progesterone receptors in the endometrium. A competitive inhibitor of the progesterone receptor, it prevents progesterone from binding to its receptors. When mifepristone is combined with a prostaglandin up to 72 hours later, more than 95% of early pregnancies terminate. When used alone, it is only effective for two out of three pregnancies. The favorable properties of misoprostol (low cost, orally active, highly effective) have led to its widespread adoption as the preferred prostaglandin for medical abortion at all gestational ages. The FDA approved a regimen of 600 mg

mifepristone followed 48 hours later by 400 µg oral misoprostol for elective termination of pregnancies of 49 days or less gestational age based on a the large multicenter trial of Spitz and associates which showed a 92% efficacy (Spitz, 1998).

Subsequent studies have evaluated lower doses of mifepristone, alternative routes of ingesting misoprostol, and alternative intervals between mifepristone and misoprostol. At this point in time, the Society of Family Planning has recommended a regimen of 200 mg of mifepristone taken by mouth, followed by 800 mg of misoprostol taken intravaginally or buccally 24 to 72 hours later at home and cite this as effective for up to 63 days gestational age (SFP, 2014). This "evidence-based" protocol reduces the cost of medical abortion, as only one 200-mg tablet of mifepristone is used and one office visit is avoided. Additional studies indicated that mifepristone remains effective to at least 70 days gestation (Winikoff, 2012).

Typical duration of bleeding after a medication abortion is 7 to 14 days. On rare occasions, prolonged bleeding can lead to the need for emergency curettage or even blood transfusion.

Second-Trimester Abortion

Nonsurgical midtrimester abortion through induction of uterine contractions is most commonly performed with the administration of prostaglandins vaginally, usually at a dose of 400 mg intravaginally every 6 hours. This regimen appears to be safe in women with a prior cesarean delivery, as uterine rupture is uncommon. Some advantages of a medical induction of labor over D&E include the avoidance of surgery and the chance to view or hold the fetus if desired. If no provider is available skilled in D&E, labor induction may be the only option available to a woman. Disadvantages include a longer inpatient hospitalization with a higher risk of retained products of conception and with a 30% chance of requiring further intervention for retained products, such as a D&C.

Ancillary Techniques

In the United States, many protocols for both medical and surgical abortion make use of ultrasound to verify gestational age and to confirm that the pregnancy is intrauterine and not ectopic. If a gestational sac is not identified, a serum quantitative β-hCG is helpful in correlation with ultrasound findings. In the first trimester, sonography is useful to determine gestational age when a substantial discrepancy occurs between the menstrual history and clinical examination; when uterine abnormalities, such as leiomyomata, are present; or when the presence of an ectopic gestation is suspected. Sonography can help to avoid inaccurate estimation of gestational age before initiating second-trimester abortions. Performing ultrasonography during a D&E may facilitate the procedure.

Complications

Elective abortion in the United States is a very safe operation. Complications are rare, and the overall mortality is less than 1 per 100,000 procedures. Two important determinants of complications are the gestational age and method of abortion chosen. Beyond 10 weeks, abortion complication rates increase progressively with gestational age. The earlier the abortion is performed, the safer the procedure is. Therefore, access to abortion is vital to maternal safety. Legislation that delays care such as mandated

waiting periods only increase the risk of complications. Induced abortion is substantially safer than the continuation of pregnancy to term. Suction curettage is the safest surgical method of abortion, followed by D&E, induction of labor, and major operations such as hysterotomy or hysterectomy.

KEY POINTS

- Half of all pregnancies in the United States are unintended, and among women who experience unintended pregnancy, more than half are not using contraception.
- By the age of 45, at least half of U.S. women will experience an unintended pregnancy, and one in three will have had an abortion.
- Failure rates in the first year of contraceptive use are highest for coitus-related methods (e.g., withdrawal, periodic abstinence, condoms, barrier methods) followed by combined contraceptives (pill, patch, ring) and the progestin injection. The IUD, implants, and sterilization have typical use failure rates of less than 1%, similar to that of sterilization.
- The copper IUD can increase bleeding with menses, whereas the LNG-IUS is likely to decrease bleeding with menses or lead to amenorrhea. The primary mechanism of action for the LNG-IUS is thickening of the cervical mucus.
- The contraceptive implant has an effectiveness that is equal to or superior to that of sterilization and IUDs. It inhibits ovulation and may cause irregular bleeding patterns.
- The DMPA injection completely inhibits ovulation and is likely to cause amenorrhea. Return to fertility after cessation of use can be delayed, and some DMPA users may experience weight gain.
- Combined hormonal contraceptives increase a woman's risk of VTE by about threefold to about 1/1000 per year. Women with multiple risk factors for VTE or cardiovascular disease (e.g., obesity, age >35, smoking, a personal or family history of clotting disorder) should use effective birth control methods without estrogen.
- The most effective method of emergency contraception is the copper IUD, followed by a single dose of oral ulipristal acetate (Ella). Plan B, or an oral dose of levonorgestrel, is somewhat less effective.
- First- and second-trimester medical and surgical abortion is safe and effective. Overall, abortions have a lower complication risk than carrying a pregnancy to term. Access to legal and safe abortion is a cornerstone of maternal health.

Menopause and Care of the Mature Woman Endocrinology, Consequences of Estrogen Deficiency, Effects of Hormone Therapy, and Other Treatment Options

Roger A. Lobo

Menopause is defined by the last menstrual period. Because cessation of menses is variable and many of the symptoms thought to be related to menopause may occur prior to cessation of menses, there is seldom a precise timing of this event. Other terms used are *perimenopause*, which refers to a variable time beginning a few years before and continuing after the event of menopause, and *climacteric*, which merely refers to the time after the cessation of reproductive function. Although the terms *menopausal* and *postmenopausal* are used interchangeably, the former term is less correct because *menopausal* should only relate to the time around the cessation of menses. As life expectancy increases beyond the eighth decade worldwide, particularly in developed countries, an increasing proportion of the female population is postmenopausal. With the average age of menopause being at 51 years, more than a third of a woman's life is now spent after menopause. Here, symptoms and signs of estrogen deficiency merge with issues encountered with natural aging. As the world population increases and a larger proportion of this population is made up of individuals older than 50, medical care specifically directed at postmenopausal women becomes an important aspect of modern medicine. In the United States, the number of women entering menopause is expected to double in the 30 years between 1990 and 2020, and the total number of postmenopausal women is expected to be in range of 60 million (Table 14.1).

Age of menopause, which is a genetically programmed event, is subject to some variability. The age of menopause in Western countries (between 51 and 52 years) is thought to correlate with

general health status; socioeconomic status is associated with an earlier age of menopause. Higher parity, on the other hand, has been found to be associated with a later menopause. Smoking has consistently been found to be associated with menopause onset taking place 1 to 2 years earlier. Hysterectomy has also been cited as resulting in an earlier menopause (Siddle, 1987), presumably because of a diminution in the blood supply to the ovary; however, the data have not been consistent. Although body mass has been thought to be related to age of menopause (greater body mass index [BMI] with later menopause), the data have not been consistent. However, physical or athletic activity has not been found to influence the age of menopause. There also appear to be ethnic differences in the onset of menopause. In the United States, black and Hispanic women have been found to have menopause approximately 2 years earlier than white women. Although parity is generally greater around the world than in the United States, the age of menopause appears to be somewhat earlier outside the United States. Malay women have menopause at approximately age 45, Thai women at age 49.5, and Filipina women between ages 47 and 48; menopause has also been reported to occur in the mid to late 40s among Indian women. Countries at higher altitude (Himalayas or Andes) have been shown to have menopause 1 to 1.5 years earlier. Because the average age of menopause in the United States is 51 to 53 years, menopause prior to age 40 is considered premature. Conversely, by age 58, 97% of women will have gone through menopause. The primary determinate of age of menopause is genetic. Based on family studies, de Bruin and colleagues² showed that heritability for age of menopause averaged 0.87, suggesting that genetics explains up to 87% of the variance in menopausal age. Although other estimates have not been this high, genetic programming remains extremely important.

Other than specific gene mutations that have been shown to cause **premature ovarian failure or insufficiency** (explained later in this chapter), no specific genes have been implicated to account for this genetic influence. However, several genes are likely to be involved in determining the age of menopause, and these involve immune function and DNA repair (Stolk, 2012) and may also include genes coding telomerase activity, which affects aging in general.

Table 14.1 U.S. Population Entering the Postmenopausal Years, Ages 55 through 64

Year	Population
1990	10.8 million
2000	12.1 million
2010	17.1 million
2020	19.3 million

PREMATURE OVARIAN FAILURE AND INSUFFICIENCY

Premature ovarian failure (POF) or premature ovarian insufficiency (POI), which is the more recently used term, is defined as hypergonadotropic ovarian failure occurring prior to age 40. POI occurs in 5% to 10% of women who are evaluated for amenorrhea, thus the incidence varies according to the prevalence of amenorrhea in various populations. Estimates of the overall prevalence of POI in the general population range between 0.3% and 0.9% of women. Throughout life, there is an ongoing rate of atresia of oocytes. Because this process is accelerated with various forms of gonadal dysgenesis because of defective X chromosomes, one possible cause of POI is an increased rate of atresia that has yet to be explained. A decreased germ cell endowment or an increased rate of germ cell destruction can also explain POI. Nevertheless, about 1000 (of the original 2 million), primarily follicles, may remain. Although most of these oocytes are likely to be functionally deficient, occasionally spontaneous pregnancies occur in young women in the first few years after the diagnosis of POI. There are several possible etiologies of POI (Box 14.1).

Defects in the X chromosome may result in various types of gonadal dysgenesis with varied times of expression of ovarian failure. Even patients with classical gonadal dysgenesis (e.g., 45,XO) may undergo a normal puberty, and occasionally a pregnancy may ensue as a result of genetic mosaicism. Very small defects in the X chromosome may be sufficient to cause POI. Familial forms of POI may be related to either autosomal-dominant or sex-linked modes of inheritance. Mutations in the gene encoding the follicle-stimulating hormone (FSH) receptor (e.g., mutation in exon 7 in the gene on chromosome 2p) have been described, but these are extremely rare outside of the Finnish population, in which these mutations were originally described. An expansion of a trinucleotide repeat sequence in the first exon on the FMR1 gene (Xq 27.3) leads to fragile X syndrome, a major cause of developmental disabilities in males.

The permutation in fragile X syndrome has been shown to be associated with POI. Type 1 blepharophimosis/ptosis/epicanthus inversus (BPES) syndrome, an autosomal dominant disorder caused by mutations in the forkhead transcription factor FOXL2, includes POI. Triple X syndrome has also been associated with POI. It has been suggested that functional mutations of antimüllerian hormone (AMH) may also be associated with POI (Alvaro, 2015).

Dystrophic myotonia has also been linked to POI, although the mechanism underlying this relationship is unclear. Under the category of enzymatic defects, galactosemia is a major cause of POI that is related to the toxic buildup of galactose in women who are unable to metabolize the sugar. Even in

women with fairly well-controlled galactose-free diets, POI tends to occur. Another enzymatic defect linked to POI is 17 α -hydroxylase deficiency. This rare condition manifests differently from the other causes discussed here because the defect in the production of sex steroids leads to sexual infantilism and hypertension.

The degree to which autoimmunity may be responsible for POI is unclear but has been suggested to be associated in 17.5% of cases. Virtually all autoimmune disorders have been found to be associated with POI, including autoimmune polyendocrinopathies such as autoimmune polyendocrinopathy/candidiasis/ectodermal dystrophy (APECED), which is caused by mutations in the autoimmune (AIRE) gene on band 21 q22. The presence of the thymus gland appears to be required for normal ovarian function as POI has been associated with hypoplasia of the thymus. In patients who have undergone ovarian biopsy as part of their evaluation, lymphocytic infiltration surrounding follicles has been described, as well as resumption of menses after immunosuppression. Immunoassays utilizing antibodies directed at ovarian antigens have been developed and have demonstrated positive findings in some patients with POI, although the relevance of these findings remains unsettled. Ovarian autoantibodies could also conceivably be a secondary phenomenon to a primary cell-mediated form of immunity. Specific enzymes such as 3 β -hydroxysteroid dehydrogenase (3 β HSD) may also be the target of ovarian autoimmunity. Approximately 2% to 4% of women with autoimmunity for POI will have antiadrenal antibodies as well (Chen, 1996). This can be screened for by an assay for 21-hydroxylase antibodies. Adrenal function can practically be assessed by measuring dehydroepiandrosterone sulfate (DHEA-S) levels as well, which are higher in younger women than in menopausal women, unless the adrenal gland is affected. It may also be helpful to assess ovarian volume and follicular presence by vaginal ultrasound in these women as well. The ovaries in younger women with POI are more normal in size and have follicles present as compared with the smaller atrophic ovary in menopause.

From a practical standpoint, screening for the common autoimmune disorders is appropriate in women found to have POI. More from a theoretic standpoint, however, are abnormalities in the structure of gonadotropins, in their receptors, or in receptor binding, which could be associated with POI; these measurements are difficult. Although abnormal urinary forms of gonadotropins have been reported in women with POI, these data have not been replicated. Abnormalities of FSH receptor binding, as mediated by a serum inhibitor, have been described. A genetic defect that may lead to alterations in FSH receptor structure was mentioned previously.

Under the category of ovarian insults, POI may be induced by ionizing radiation, chemotherapy, or overly aggressive ovarian surgery. Although not well documented, viral infections have been suggested to play a role, particularly mumps. A dose of 400 to 500 rads is known to cause ovarian failure 50% of the time, and older women are more vulnerable to experiencing permanent failure. A dose of approximately 800 rads is associated with failure in all women. Ovarian failure (transient or permanent) may be induced by chemotherapeutic agents, although younger women receiving this insult have a better prognosis. Alkalinizing agents, particularly cyclophosphamide, appear to be most toxic. By exclusion, the majority of women are considered to have idiopathic

Figure 14.1 Effect of type of “early” menopause on cardiovascular disease. Data taken from a meta-analysis. (From Atsma F, Bartelink ML, Grobbee DE, et al. Postmenopausal status and early menopause as independent risk factors for cardiovascular disease: a meta-analysis. *Menopause*. 2006;13[2]:265-279.)

POI because no demonstrable cause can be pinpointed. Among these women, small mutations in genes lying on the X chromosome or yet to be identified autosomal genes may be the cause.

MANAGEMENT OF PREMATURE OVARIAN INSUFFICIENCY

Evaluation of POI in women younger than 30 should include screening for autoimmune disorders and a karyotype; detailed recommendations for screening of such women are available (Rebar, 2000). In addition, vaginal ultrasound may be useful for assessing the size of the ovaries and the degree of follicular development, which, if present, may signify an immunologic defect. Cases of POI caused by immunologic defects must be screened carefully for thyroid, adrenal, and other autoimmune disorders.

Treatment of all cases usually consists of estrogen replacement. Although in menopausal therapy clinicians have steered away from the term *replacement* therapy, in this specific instance of POI, estrogen treatment is truly *replacement* therapy. If fertility is a concern, the most efficacious treatment is oocyte donation. Various attempts at ovarian stimulation are usually unsuccessful; sporadic pregnancies that may occur (~5%) are just as likely to occur spontaneously as with any intervention, and often while on physiologic E2 replacement. In this setting it has been our preference not to use oral contraceptive pills for replacement in women wishing to conceive. In a long-term follow-up of a large number of women diagnosed with POI, within a year, there was spontaneous ovarian function observed in 24% of the women and over time the rate of spontaneous pregnancies was 4.4% (Bidet, 2011).

Why estrogen replacement in these young women with POI is extremely important and is not analogous to hormone therapy (HT) after menopause, is that these young women are at substantial long-term risk for osteoporosis and cardiovascular disease (CVD). Coronary heart disease and death are specifically increased in approximately 70% of women with POI; but not stroke, according to one study (Roeters van Lennep, 2014). A more extreme example of this phenomenon is with premature oophorectomy, with which the risk of CVD is many-fold increased (Fig. 14.1) (Atsma, 2006). Women with POI should be offered estrogen replacement, with some form of progestogen in women with a uterus, at least up to the natural age of menopause.

MENOPAUSAL TRANSITION (PERIMENOPAUSE)

A workshop was convened in 2001 to build consensus on describing various stages of the menopausal transition. A more recent follow-up conference, the Study of Reproductive Aging Workshop (STRAW+10), had more streamlined bleeding criteria for the various stages and expanded the stages including the use of biochemical markers such as inhibin B and AMH in addition to FSH (Harlow, 2012) (Fig. 14.2). This scheme is important from a descriptive standpoint for the physiology behind the normal menopausal transition and is useful for characterization of women in various stages in research studies.

The ovary changes markedly from birth to the onset of menopause (Fig. 14.3). The greatest number of primordial follicles is

	Menarche				FMP (0)

Figure 14.2 The Stages of Reproductive Aging Workshop + 10 staging system for reproductive aging in women. (From Harlow SD, Gass M, Hall JE, et al. Executive summary of the stages of reproductive aging workshop + 10: addressing the unfinished agenda of staging reproductive aging. *J Clin Endocrinol Metab.* 2012;97[4]:1159-1168.)

Figure 14.3 Photomicrographs of the cortex of human ovaries from birth to 50 years of age. Small nongrowing primordial follicles (arrowheads) have a single layer of squamous granulosa cells. (Modified from Erickson GF. An analysis of follicle development and ovum maturation. *Semin Reprod Endocrinol.* 1986;3:233.)

Figure 14.4 The age-related decrease in the total number of primordial follicles (PFs) within both human ovaries from birth to menopause. As a result of recruitment (initiation of PF growth), the number of PFs decreases progressively from about 1 million at birth to 25,000 at 37 years. At 37 years, the rate of recruitment increases sharply, and the number of PFs declines to 1000 at menopause (about 51 years of age). (Modified from Faddy MJ, Gosden RJ, Gougeon A, et al. Accelerated disappearance of ovarian follicles in mid-life: Implications for forecasting menopause. *Hum Reprod.* 1992;7:1342.)

present in utero at 20 weeks' gestation and undergoes a regular rate of atresia until around the age of 37. After this time, the decline in primordial follicles appears to become more rapid between age 38 and menopause (Fig. 14.4), when no more than 1000 follicles remain. These remaining follicles are primarily atretic in nature.

These changes are reflected in circulating levels of AMH, which decline rapidly with ovarian aging (see Chapter 42). When levels of serum AMH become undetectable, menopause is likely to occur in 4 to 5 years.

TYPES OF OVARIAN CHANGES DURING PERIMENOPAUSE

Although perimenopausal changes are generally thought to be endocrine in nature and result in menstrual changes, a marked diminution of reproductive capacity precedes this period by several years. This decline may be referred to as *gametogenic ovarian failure* and is reflected by decreased anti-müllerian hormone (AMH), inhibin B levels, and antral follicle counts, and a rising FSH (Chapter 42). The concept of dissociation in ovarian function is appropriate. These changes may occur with normal menstrual function and no obvious endocrine deficiency; however, they may occur in some women as early as age 35 (10 or more years before endocrine deficiency ensues). Although subtle changes in endocrine and menstrual function can occur for up to 3 years before menopause, it has been shown that the major reduction in ovarian estrogen production does not occur until approximately a year before menopause (Fig. 14.5) (Randolph, 2011). There is also a slow decline in androgen status (i.e., androstenedione and testosterone), which cannot be adequately detected at the time of perimenopause. The decline in androgen is largely

Figure 14.5 Adjusted population means (95% CI) for segmented mean profiles for follicle-stimulating hormone and estradiol across the final menstrual period in the Study of Women's Health Across the Nation (N = 1215). (From Randolph JF Jr, Zheng H, Sowers MR, et al. Change in follicle-stimulating hormone and estradiol across the menopausal transition: effect of age at the final menstrual period. *J Clin Endocrinol Metab.* 2011;96[3]:746-754.)

a phenomenon of aging. Products of the granulosa cell are most important for the feedback control of FSH. As the functional capacity of the follicular units decreases, the secretion of substances that suppress FSH also decreases. A marker of this is inhibin B, in which levels are lower in the early follicular phase in women in their late 30s (Fig. 14.6). Inhibin B is seldom measured clinically; rather AMH (which also reflects granulosa cell function) is most frequently assessed as noted previously. Indeed, FSH levels are higher throughout the cycle in older ovulatory women than in younger women (Fig. 14.7). The functional capacity of the ovary is also diminished as women enter into perimenopause. With gonadotropin stimulation, although estradiol (E_2) levels are not very different between younger and older women, total inhibin production by granulosa cells is decreased in women older than 35. From a clinical perspective, subtle increases in FSH on day 3 of the cycle, or increases in the clomiphene challenge test, correlate with decreased ovarian responses to stimulation and decreased fecundability. Müllerian inhibiting substance (MIS) or AMH serves as the most practical marker of reproductive aging. Levels decrease throughout life, being undetectable at menopause, and show less variability during the menstrual cycle compared with other markers such as FSH. However, values are lower by up to 20% in women on oral contraceptives, and this should be taken into account when assessing levels in younger women. When values reach an undetectable range (<0.05 ng/mL), menopause has been found to occur within 5 years as stated previously (Fig. 14.8).

Although there is a general decline in oocyte number with age, an accelerated atresia occurs around age 37 or 38 (see Fig. 14.4). Although the reason for this acceleration is not clear, one possible theory relates to activin secretion. Because granulosa cell-derived activin is important for stimulating FSH receptor expression, the rise in FSH levels could result in more activin production, which in turn enhances FSH action.

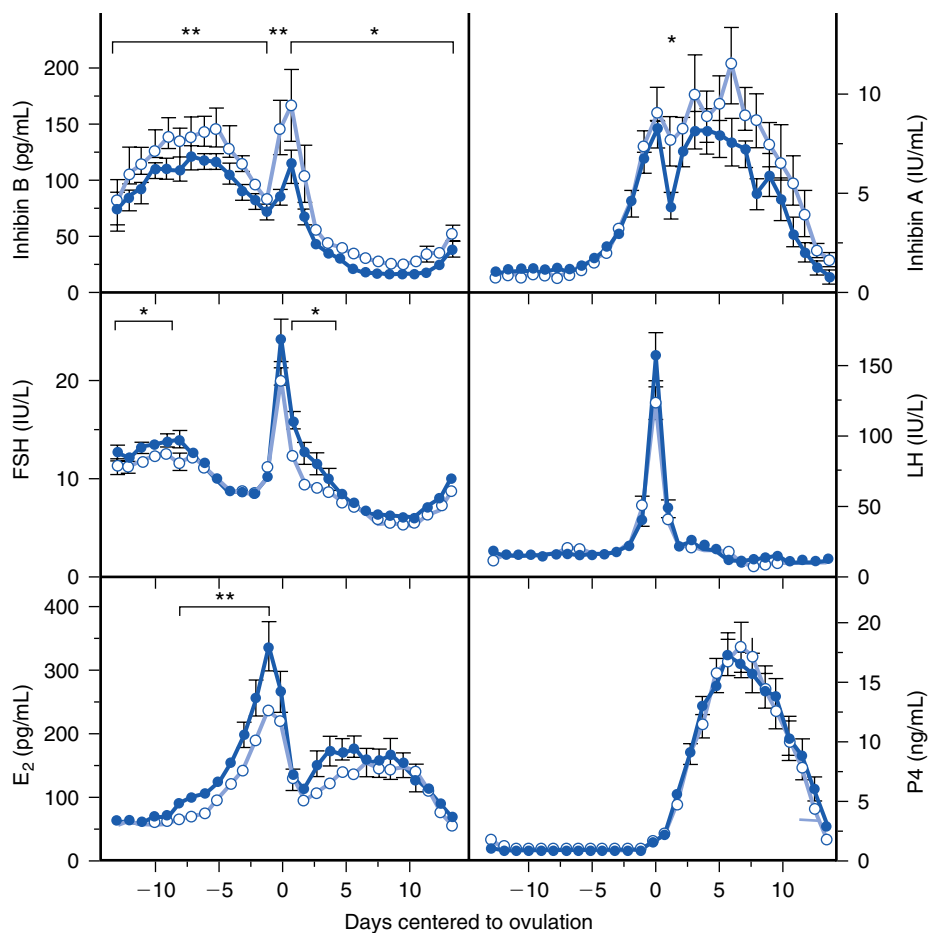

Figure 14.6 An inhibin B, follicle-stimulating hormone (FSH), estradiol (E_2), inhibin A, and progesterone (P_4) levels in cycling women 20 to 34 years old (\circ) and 35 to 46 years old (\bullet). Hormone levels are depicted as centered to the day of ovulation (*, $P < .04$; **, $P < .02$) when comparing the two age groups. (From Welt CK, McNicholl DJ, Taylor AE, et al. Female reproductive aging is marked by decreased secretion of dimeric inhibin. *J Clin Endocrinol Metab*. 1999;84[1]:105.)

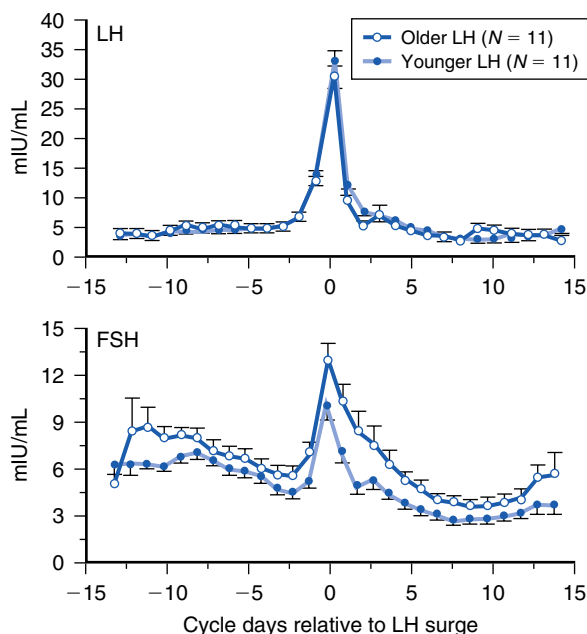

Figure 14.7 The daily serum follicle-stimulating hormone (FSH) and luteinizing hormone (LH) levels throughout the menstrual cycle of 11 women in each group (mean \pm SE). The gonadotropin secretion pattern in normal women of advanced reproductive age in relation to the monotropic FSH rise. (Modified from Klein NA, Battaglia DE, Clifton DK, et al. The gonadotropin secretion pattern in normal women of advanced reproductive age in relation to the monotropic FSH rise. *J Soc Gynecol Investig*. 1996;3:27.)

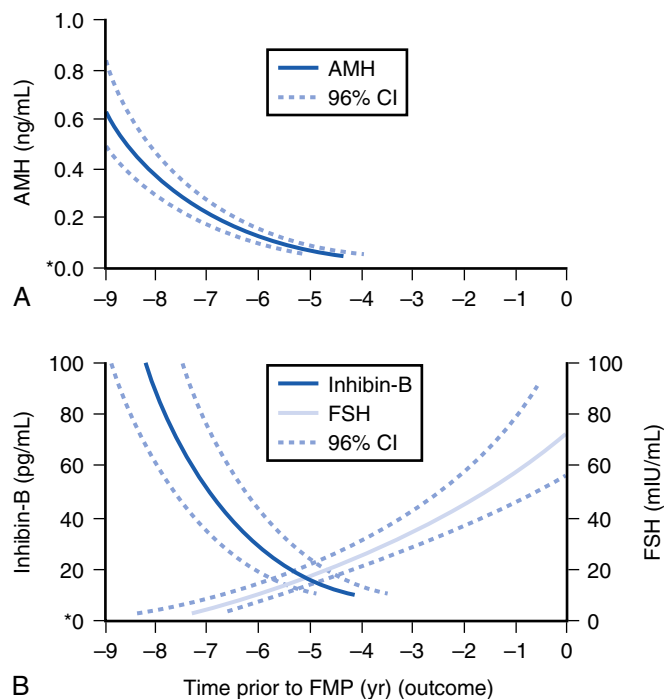

Figure 14.8 AMH decreases to undetectable levels (0.05 ng/mL) 5 years before the final menstrual period, **A**; and inhibin B (10 pg/mL) does so 4 years before the last menstrual period, **B**. (From Sowers MR, Eyvazzadeth AD, McConnell D, et al. Antimüllerian hormone and inhibin in the definition of ovarian aging and the menopause transition. *J Clin Endocrinol Metab*. 2008;93[9]:L34768-L34783, 2008.)

A profile of elevated activin with lower inhibin B has been found in older women (Fig. 14.9). This autocrine action of activin, involving enhanced FSH action, might be expected to lead to accelerated growth and differentiation of granulosa cells. Furthermore, activin has been shown to increase the size of the pool of preantral follicles in the rat. At the same time, these follicles become more atretic. Clinical treatment of perimenopausal women should address three general areas of concern: (1) irregular bleeding, (2) symptoms of early menopause, such as **hot flashes**, and (3) the inability to conceive. Treatment of irregular bleeding is complicated by the fluctuating hormonal status. Estrogen levels may be higher than normal in the early follicular phase and progesterone secretion may be normal, or slightly decreased, although not all cycles are ovulatory. For these reasons, short-term use of an oral contraceptive (usually 20 µg ethinyl estradiol) may be an option for otherwise healthy women who do not smoke to help them cope with irregular bleeding. Early symptoms of menopause, particularly vasomotor changes, may occur as the result of fluctuating hormonal levels. In this setting, an oral contraceptive again may be an option if symptoms warrant therapy. Alternatively, lower doses of estrogen used alone may be another option. Reproductive concerns often require more aggressive treatment because of decreased cycle fecundity.

Once day 3 FSH levels increase (>15 mIU/mL) and AMH levels decrease (≤ 0.4 ng/mL), the prognosis for pregnancy is markedly reduced.

Hormonal Changes with Established Menopause

Figure 14.10 depicts the typical hormonal levels of postmenopausal women compared with those of ovulatory women in the early follicular phase. The most significant findings are the marked reductions in E_2 and estrone (E_1). Serum E_2 is reduced to a greater extent than E_1 . Serum E_1 , on the other hand, is produced primarily by peripheral aromatization from androgens, which decline principally as a function of age. Levels of E_2 average 15 pg/mL and range from 10 to 25 pg/mL but are closer to 10 pg/mL or less in women who have undergone oophorectomy. Serum E_1 values average 30 pg/mL but may be higher in obese women because aromatization increases as a function of the mass of adipose tissue. Estrone sulfate ($E_1 S$) is an estrogen conjugate that serves as a stable circulating reservoir of estrogen, and levels of $E_1 S$ are the highest among estrogens in postmenopausal women. In premenopausal women, values are usually above 1000 pg/mL; in postmenopausal women, levels average 350 pg/mL. Apart from elevations in FSH and luteinizing hormone (LH), other pituitary hormones are not affected. The rise in FSH, beginning in stage -2 as early as age

Figure 14.9 Mean concentrations of gonadal proteins from the same subjects. Total inhibin is a derived number from the sum of inhibin A and inhibin B. *Group differences; $P < .05$. Net increase in stimulatory input resulting from a decrease in inhibin B and an increase in activin A may contribute in part to the rise in follicular phase follicle-stimulating hormone of aging cyclic women. (Modified from Reame NE, Wyman TL, Phillips DJ, et al. Net increase in stimulatory input resulting from a decrease in inhibin B and an increase in activin A may contribute in part to the rise in follicular phase follicle-stimulating hormone of aging cyclic women. *J Clin Endocrinol Metab.* 1998;83:3302.)

38 (see Fig. 14.2), fluctuates considerably until approximately 4 years after menopause (stage + 1c), when values are consistently greater than 20 mIU/mL. Specifically, growth hormone (GH), thyroid-stimulating hormone (TSH), and adrenocorticotrophic hormone (ACTH) levels are normal. Serum prolactin levels may be slightly decreased because prolactin levels are influenced by estrogen status. Both the postmenopausal ovary and the adrenal gland continue to produce androgen. The ovary continues to produce androstenedione and testosterone but not E_2 , and this production has been shown to be at least partially dependent on LH. Androstenedione and testosterone levels are lower in women who have experienced bilateral oophorectomy, with values averaging 0.8 ng/mL and 0.1 ng/mL, respectively. The adrenal gland also continues to produce androstenedione, dehydroepiandrosterone (DHEA), and dehydroepiandrosterone sulfate (DHEA-S); primarily as a function of aging, these values decrease somewhat (adrenopause), although cortisol secretion remains unaffected. Most “ovarian” testosterone production may actually arise from the adrenal by way of precursors (Couzinet, 2001). Most likely, the adrenal supplies precursor substrate (DHEA and androstenedione) for ovarian testosterone production. Although DHEA-S levels decrease with age (approximately 2% per year), data have suggested that levels transiently rise in perimenopause before the continuous

decline thereafter (Fig. 14.11). This interesting finding from the Study of Women Across the Nation (SWAN) also suggested that DHEA-S levels are highest in Chinese women and lowest in African-American women.

Testosterone levels also decline as a function of age, which is best demonstrated by the reduction in 24-hour means levels (Fig. 14.12). Because of the role of the adrenal in determining levels of testosterone after menopause, adrenalectomy or dexamethasone treatment results in undetectable levels of serum testosterone. Compared with total testosterone, the measurement of bioavailable, or “free,” testosterone is more useful in postmenopausal women. After menopause, sex hormone-binding globulin (SHBG) levels decrease, resulting in relatively higher levels of bioavailable testosterone or a higher free androgen index (Fig. 14.13). In women receiving oral estrogen, bioavailable testosterone levels are extremely low because SHBG levels are increased. How this relates to the decision to consider androgen therapy in postmenopausal women will be discussed later in this chapter.

Elevated gonadotropin (FSH/LH) levels arise from reduced secretion of E_2 and inhibin as described earlier. Although some aging effects of the brain are likely to exist, there is abundant human evidence for menopause in women to be an ovarian-induced event.

Figure 14.10 Circulating levels of pituitary and steroid hormones in postmenopausal women compared with levels in premenopausal women studied during the first week (days 2 to 4 [D₂₋₄]) of the menstrual cycle. Figure 14.11 Mean (\pm SE) circulating dehydroepiandrosterone sulfate (DHEA-S) at each year of age of the entire study population before and after adjustment for age, current smoking, menopausal status, log body mass index (BMI), ethnicity, site, and the interaction between ethnicity and log BMI. (Modified from Lasley BL, Santoro N, Randolph JF, et al. The relationship of circulating dehydroepiandrosterone, testosterone, and estradiol to stages of the menopausal transition and ethnicity. *J Clin Endocrinol Metab.* 2002;87: 3760-3767.)

Figure 14.12 The 24-hour mean plasma total testosterone (T) level compared with age in normal women. The regression equation was $T \text{ (nmol/L)} = 37.8 \times \text{age (years)} - 1.12$ ($r = -0.54$; $P < .003$). (Modified from Zumoff B, Strain GW, Miller LK, et al. Twenty-four hour mean plasma testosterone concentration declines with age in normal premenopausal women. *J Clin Endocrinol Metab.* 1995;80:1429.)

EFFECTS OF MENOPAUSE ON VARIOUS ORGAN SYSTEMS

CENTRAL NERVOUS SYSTEM

The brain is an active site for estrogen action as well as estrogen formation. Estrogen activity in the brain is mediated via estrogen receptor (ER) α and ER β . Whether or not a novel membrane receptor (non-ER α /ER β) exists is still being debated. However, both genomic and nongenomic mechanisms of estrogen action clearly exist in the brain. Figure 14.14 illustrates the

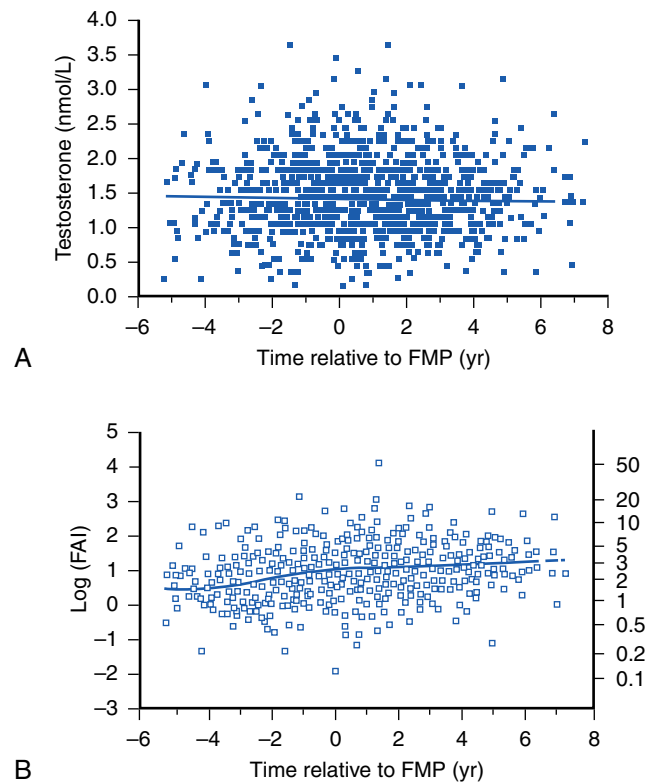

Figure 14.13 **A**, Linear regression model: observed testosterone (T) and fitted levels of mean T across the menopausal transition. **B**, Double logistic model: observed free androgen index (FAI) and fitted levels of mean FAI across the menopausal transition. The left and right axes show FAI levels on the log and antilog scales, respectively. The horizontal axis represents time (years) with respect to first menstrual period (FMP); negative (positive) numbers indicate time before (after) FMP. (From Burger HG, Dudley EC, Cui J, et al. A prospective longitudinal study of serum testosterone, dehydroepiandrosterone sulfate, and sex hormone-binding globulin levels through the menopause transition. *J Clin Endocrinol Metab.* 2000;85:2832.)

predominance of ER β in the cortex (frontal and parietal) and the cerebellum, based on work in the rat. Although $17\beta E_2$ is a specific ligand for both receptors, certain synthetic estrogens (e.g., diethylstilbestrol) have greater affinity for ER α , whereas phytoestrogens have a greater affinity for ER β .

There are multiple actions of estrogen on the brain as reviewed by Henderson (Box 14.2), thus some important functions linked to estrogen contribute to well-being in general and, more specifically, to cognition and mood. The hallmark feature of declining estrogen status in the brain is the hot flush, which is more generically referred to as a *vasomotor episode*. The hot flash usually refers to the acute sensation of heat, and the flush or vasomotor episode includes changes in the early perception of this event and other skin changes (including diaphoresis).

Hot flushes usually occur for 2 years after the onset of estrogen deficiency but can persist for 10 or more years. Prospective data suggest that the average time for persistence of bothersome hot flushes is 7.4 years, (Avis, 2014) and up to 42% of women aged 60 to 65 years have bothersome symptoms. In 10% to 15% of women, these symptoms are severe and disabling. In the United States the incidence of these episodes varies in different ethnic groups.

Figure 14.14 **A**, Each region of the brain has an important role in specific brain functions. Optimal brain activity is maintained by means of the integration of different areas by neural tracts. ARC, Arcuate nucleus; POA, preoptic area; PVN, paraventricular nucleus; SO, supraoptic nucleus; VMN, ventromedial nucleus. **B**, Distribution of estrogen receptors ER α and ER β mRNA in the rat brain. Philadelphia: Lippincott Williams & Wilkins; 1999:247-262.)

Symptoms are greatest in Hispanic and black women, intermediate in white women, and lowest among Asian women (Fig. 14.15). The severity and persistence of hot flushes for 10 or more years may cause a series of “irregular” symptoms, such as irritability, which may affect quality of life (Oldervave, 1993) (Fig. 14.16). The fall in estrogen levels precipitate the vasomotor symptoms. It has been found that some women who experience hot flushes have a thermoregulatory disruption with a much narrower temperature range between sweating and shivering. Freedman has shown that the difference in temperature at

which shivering occurs, and when sweating occurs, termed the *thermoneutral zone*, is wide in asymptomatic women (Freedman, 2007). This zone is substantially more narrowed in symptomatic women, explaining their vulnerability to vasomotor symptoms (Fig. 14.17).

Although the proximate cause of the flush remains elusive, the episodes result from a hypothalamic response (probably mediated by catecholamines) to the change in estrogen status. The flush has been well characterized physiologically. It results in heat dissipation as witnessed by an increase in peripheral temperature (fingers, toes); a decrease in skin resistance, associated with diaphoresis; and a reduction in core body temperature (Fig. 14.18). There are hormonal correlates of flush activity, such as an increase in serum LH and in plasma levels of pro-opiomelanocortin peptides (ACTH, β -endorphin) at the time of the flush, but these occurrences are thought to be epiphenomena that result as a consequence of the flush and are not related to its cause. One of the primary complaints of women with hot flushes is sleep disruption. They may awaken several times during the night and require a change of bedding and clothes because of diaphoresis. Nocturnal sleep disruption in postmenopausal women with hot flushes has been well documented by electroencephalographic (EEG) recordings. Sleep efficiency is lower, and the latency to rapid eye movement (REM) sleep is longer in women with hot flushes compared with asymptomatic women. This disturbed sleep often

Figure 14.15 A Study of Women's Health Across the Nation (SWAN). Symptom severity. (Modified from Gold EB, Sternfeld B, Kelsey JL, et al. Relation of demographic and lifestyle factors to symptoms in a multi-racial/ethnic population of women 40 to 55 years of age. *Am J Epidemiol.* 2000;152:463.)

Figure 14.16 Impact of menopause on well-being. (Modified from Oldenhave A, Jaszmann LJ, Haspels AA, et al. Impact of climacteric on well-being: a study based on 5213 women 39 to 60 years old. *Am J Obstet Gynecol.* 1993;168:772.)

leads to fatigue and irritability during the day. The frequency of awakenings and hot flushes is reduced appreciably with estrogen treatment (Fig. 14.19). Sleep may be disrupted even if the woman is not conscious of being awakened from sleep. In this setting, EEG monitoring has indicated sleep disruption in concert with physiologic measures of vasomotor episodes.

In postmenopausal women, estrogen has been found to improve depressed mood regardless of whether or not this is a specific complaint (critics of some of this work point out that mood is affected by the symptomatology and by sleep deprivation). Blinded studies carried out in asymptomatic women have also shown benefit. In an estrogen-deficient state such as occurs after menopause, a higher incidence of depression (clinical or

Figure 14.17 Narrowing of the thermoregulatory zone in symptomatic women. HF, Hot flush. (Data from Freedman RR: Menopausal hot flashes. In: Lobo RA, ed. *Treatment of the Postmenopausal Woman*. 4th ed. New York: Academic Press; 2007:187-198.)

subclinical) is often manifest. However, menopause per se does not cause depression, and although estrogen does generally improve depressive mood, it should not be used for psychiatric disorders. Nevertheless, very high pharmacologic doses of estrogen have been used to treat certain types of psychiatric depression in the past. Progestogens as a class generally attenuate the beneficial effects of estrogen on mood, although this effect is highly variable.

Cognitive decline in postmenopausal women is related to aging as well as to estrogen deficiency. The literature is somewhat mixed about whether there are benefits of estrogen in terms of cognition. In more recent studies, verbal memory appears to be enhanced with estrogen and has been found to correlate with acute changes in brain imaging, signifying brain activation. Dementia increases as women age, and the most common form of dementia is Alzheimer disease (AD). Box 14.2 lists several neurotropic and neuroprotective factors related to how estrogen deficiency may be expected to result in the loss of protection against the development of AD. In addition, estrogen has a positive role in enhancing neurotransmitter function, which is deficient in women with AD. This function of estrogen has particular importance and relevance for the cholinergic system that is affected in AD. Estrogen use after menopause appears to

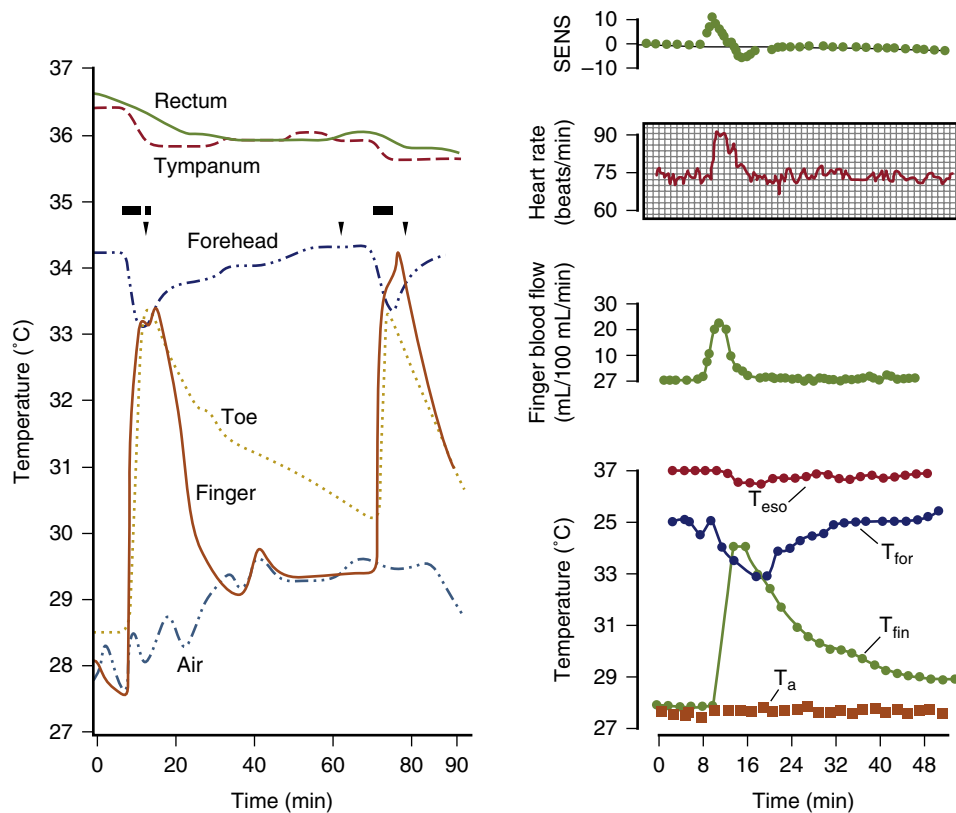

Figure 14.18 Temperature responses to two spontaneous flashes and evoked flash. Down arrow indicates finger stab for blood sample. Black bars indicate time of flush. (Data from Molnar GW: Body temperature during menopausal hot flashes. *J Appl Physiol.* 1975;38[3]:499-303.)

decrease the likelihood of developing or delaying the onset of AD according to several observational studies and meta-analyses. However, once a woman is affected by AD, estrogen is unlikely to provide any benefit. Data from the Women's Health Initiative (WHI), however, suggested a lack of benefit of estrogen or estrogen/progestogen, or even a worsening of cognition in women initiating hormonal therapy after age 65. This suggests that timing of initiation of hormone therapy is critical, and this has also been supported by basic science studies. Here the early exposure to estrogen decreased the possibility of brain damage from free radicals and also promoted maintenance of neuronal and synaptic activity. However, prospective trials in younger women still have not been able to confirm the older observational data, suggesting a cognitive benefit of estrogen. Therefore, this area remains somewhat inconclusive. In summary, while early treatment with estrogen in younger women at the onset of menopause *may* be beneficial for cognition as it is with certain types of mood (although not proved yet), later treatment (e.g., after age 65) has no benefit and may even be detrimental, depending on the regimen of hormones used.

COLLAGEN AND OTHER TISSUES

Estrogen has a positive effect on collagen, which is an important component of bone and skin and serves as a major support tissue for the structures of the pelvis and urinary system. Both estrogen and androgen receptors have been identified in skin fibroblasts.

Nearly 30% of skin collagen is lost within the first 5 years after menopause, and collagen decreases approximately 2% per year for the first 10 years after menopause. This statistic, which is similar to that of bone loss after menopause, strongly suggests a link between skin thickness, bone loss, and the risk of **osteoporosis**. Although the literature is not entirely consistent, estrogen therapy generally improves collagen content after menopause and improves skin thickness substantially after about 2 years of treatment (Dunn, 1997). There is a possible bimodal effect with high doses of estrogen causing a reduction in skin thickness. The supportive effect of estrogen on collagen has important implications for bone homeostasis and for the pelvis after menopause. Here, reductions in collagen support and atrophy of the vaginal and urethral mucosa have been implicated in a variety of symptoms, including prolapse and urinary symptoms (Falconer, 1996). Vaginal estrogen has also been shown to reduce recurrent urinary tract infections. Symptoms of urinary incontinence and irritative bladder symptoms occur in 20% to 40% of perimenopausal and postmenopausal women. Uterine prolapse and other gynecologic symptoms related to poor collagen support, as well as urinary complaints, may improve with estrogen therapy. Although estrogen generally improves symptoms, urodynamic changes have not been shown to be altered. Estrogen has also been shown to decrease the incidence of recurrence of urinary tract infections. Restoration of bladder control in older women with estrogen has been shown to decrease the need for admission to nursing homes in Sweden. Estrogen may also have an

important role in normal wound healing. In this setting, estrogen enhances the effects of growth factors such as transforming growth factor- β (TGF- β) (Ashcroft, 1997).

Although still not completely settled, it appears that oral estrogen does not improve stress urinary incontinence in postmenopausal women and may even cause such symptoms in previously asymptomatic older women. Estrogen may, however, improve urge and other irritative urinary symptoms.

VULVOVAGINAL ATROPHY

Vulvovaginal complaints are often associated with estrogen deficiency. During perimenopause, symptoms of dryness and atrophic changes occur in 21% and 15% of women, respectively. However, these findings increase with time, and by 4 years these incidences are 47% and 55%, respectively. With this change, an increase in sexual complaints also occurs, with an incidence of dyspareunia of 41% in sexually active 60-year-old women. Estrogen deficiency results in a thin, paler vaginal mucosa. The moisture content is low, the pH increases

(usually greater than 5), and the mucosa may exhibit inflammation and small petechiae.

With estrogen treatment, particularly when used locally, vaginal cytology changes have been documented, transforming from a cellular pattern of predominantly parabasal cells to one with an increased number of superficial cells. Along with this change, the vaginal pH decreases, vaginal blood flow increases, and the electropotential difference across the vaginal mucosa increases to that found in premenopausal women. Vaginal DHEA (0.25% to 1.0%) has been used with some suggested efficacy; the mechanism is presumed to be the local conversion of DHEA into estrogen, with possibly some other modulating effects as well (Labrie, 2011).

Ospenifene 60 mg, a selective estrogen receptor agonist (SERM), has been approved as an oral treatment for vulvovaginal atrophy. This SERM has particular properties of acting as an agonist in the vagina and as an antagonist in other tissues such as the breast. Information on these and other treatment options, including the use of lubricants and moisturizers, has been provided by the North American Menopause Society (Position Statement, 2013).

BONE HEALTH

Estrogen deficiency has been well established as a cause of bone loss. This loss can be noted for the first time when menstrual cycles become irregular in perimenopause from 1.5 years before menopause to 1.5 years after menopause, spine bone mineral density has been shown to decrease by 2.5% per year, compared with a premenopausal loss rate of 0.13% per year. Loss of **trabecular bone** (spine) is greater with estrogen deficiency than is loss of **cortical bone**.

Postmenopausal bone loss leading to osteoporosis is a substantial health care problem. In Caucasian women, 35% of all postmenopausal women have been estimated to have osteoporosis based on bone mineral density. Furthermore, the lifetime fracture risk for these women is 40%. The morbidity and economic burden of osteoporosis is well documented. Interestingly, some data suggest that up to 19% of Caucasian men also have osteoporosis. Bone mass is substantially affected by sex steroids through classic mechanisms to be described later in this chapter. Attainment of peak bone mass in the late second decade (Fig. 14.20) is key to ensuring that the subsequent loss of bone mass with aging and estrogen deficiency does not lead to early osteoporosis. E_2 together with GH

Figure 14.20 Bone mass by age and sex. (Modified from Finkelstein JS: Osteoporosis. In: Goldman L, Bennet JC, eds. *Cecil Textbook of Medicine*. 21st ed. Philadelphia: Saunders; 1999:1366-1373; Riggs BL, Melton LJ III. Involutional osteoporosis. *N Engl J Med*. 1986;314:1676.)

and insulin-like growth factor-1 act to double bone mass at the time of puberty, beginning the process of attaining peak bone mass. Postpubertal estrogen deficiency (amenorrhea from various causes) substantially jeopardizes peak bone mass. Adequate nutrition and calcium intake are also key determinants. Although estrogen is of predominant importance for bone mass in both women and men, testosterone is important in stimulating periosteal apposition; as a result, cortical bone in men is larger and thicker.

However, even in men estrogen appears to be important for bone health in that in male individuals with aromatase deficiency (inability to convert androgen to estrogen) osteoporosis ensues (Carani, 1997).

Estrogen receptors are present in osteoblasts, osteoclasts, and osteocytes. Both ER α and ER β are present in cortical bone, whereas ER β predominates in cancellous or trabecular bone (Bord, 2001). However, the more important actions of estradiol are believed to be mediated via ER α . Estrogens suppress bone turnover and maintain a certain rate of bone formation. Bone is remodeled in functional units, called *bone multicenter units* (BMUs), where resorption and formation should be in balance. Multiple sites of bone go through this turnover process over time. Estrogen decreases osteoclasts by increasing apoptosis thus reducing their life span. The effect on the osteoblast is less consistent, but E_2 antagonizes glucocorticoid-induced osteoblast apoptosis. Estrogen deficiency increases the activities of remodeling units, prolongs resorption, and shortens the phase of bone formation. It also increases osteoclast recruitment in BMUs, thus resorption outstrips formation. The molecular mechanisms

of estrogen action on bone involve the inhibition of production of proinflammatory cytokines, which increase with a decrease in estrogen at menopause, leading to increased bone resorption (Pacifci, 1996). These cytokines include interleukin-1, interleukin-6, tumor necrosis factor- α , colony-stimulating factor-1, macrophage colony-stimulating factor, and prostaglandin E_2 , all which may contribute to increased resorption. Estradiol also upregulates TGF- β in bone, which inhibits bone resorption. Receptor activation of nuclear factor kappa (NF κ B) ligand (RANKL) is responsible for osteoclast differentiation and action. A scheme for how all these factors interact has been proposed (Fig. 14.21) (Riggs, 2000). In women, Riggs has suggested that bone loss occurs in two phases. With estrogen levels declining at the onset of menopause, an accelerated phase of bone loss occurs, which is predominantly of cancellous bone. Here 20% to 30% of cancellous bone and 5% to 10% of cortical bone can be lost in a span of 4 to 8 years. Thereafter, a slower phase of loss (1% to 2% per year) ensues, during which more cortical bone is lost. This phase is thought to be induced primarily by secondary hyperparathyroidism. The first phase is also accentuated by the decreased influence of stretching or mechanical factors, which generally promotes bone homeostasis, as a result of estrogen deficiency. Genetic influences on bone mass are more important for the attainment of peak bone mass (heritable component, 50% to 70%) than for bone loss. Polymorphisms of the vitamin D receptor gene, TGF- β gene, and the Spl-binding site in the collagen type 1 A1 gene have all been implicated as being important for bone mass (Nguyen, 2000).

Figure 14.21 Model for mediation of effects of estrogen (E) on osteoclast formation and function by cytokines in bone marrow microenvironment. Stimulatory factors are shown in orange and inhibitory factors are shown in blue. Positive (+) or negative (-) effects of E on these regulatory factors are shown in red. The model assumes that regulation is accomplished by multiple cytokines working together in concert. NA, Not applicable.

Bone mass can be detected by a variety of radiographic methods (Table 14.2). Dual-energy x-ray absorptiometry (DEXA) scans have become the standard of care for detection of **osteopenia** and osteoporosis. By convention, the **T score** is used to reflect the number of standard deviations of bone loss from the peak bone mass of a young adult. Osteopenia is defined by a T score of -1 to -2.5 standard deviations; osteoporosis is defined as greater than 2.5 standard deviations.

Various biochemical assays are also available to assess bone resorption and formation in both blood and urine (Table 14.3). At present, serum markers appear to be most useful for assessing changes, with antiresorptive therapy having less variability compared with the urinary assessments. Although these biochemical measurements cannot reliably predict bone mass, they may be useful as markers of the effectiveness of treatment. For example, an increased resorption marker may decrease within months into the normal range with an antiresorptive therapy, whereas it takes 1 to 2 years to see a change in BMD with DEXA.

Fracture risk is not only determined by bone mass but by many factors, the most important of which is bone strength. This in turn is determined by bone mass as well as bone turnover for which biochemical assessments may be helpful. A research method employs a high-resolution quantitative computed tomography of bone, which is intended to provide a "virtual" bone biopsy. This may be available in the future. The World Health Organization (WHO) has made available an algorithm to predict the 10-year fracture risk of men and women living around the world. This model, called *FRAX*, can be accessed at www.shef.ac.uk/FRAX and is calculated based on individual patient history data and the results from DEXA.

Many agents are now available for preventing osteoporosis. It is important to make a distinction about using various agents for the *prevention* of osteoporosis (e.g., in a woman who has risk factors and is osteopenic: T score above -2.5) as opposed to using drugs to *treat* established osteoporosis (T scores greater than -2.5.)

The use of estrogen will depend on whether there are other indications for estrogen treatment and whether there are any possible contraindications. Estrogen has been shown to reduce the risk of osteoporosis as well as to reduce osteoporotic fractures. A dose equivalent of 0.625 mg of conjugated equine estrogens (CEE) was once thought to be necessary for the prevention of

Table 14.3 Bone Turnover Markers

Marker	Specimen
Bone Resorption Markers	
Cross-linked N-telopeptide of type I collagen (NTX)	Urine, serum
Cross-linked C-telopeptide of type I collagen (CTX)	Urine ($\alpha\alpha$ and $\beta\beta$ forms) Serum ($\beta\beta$ form)
MMP-generated telopeptide of type I collagen (ICTP or CTX-MMP)	Serum
Deoxypyridinoline, free and peptide bound (fDPD, DPD)	Urine, serum
Pyridinoline, free and peptide bound (fPYD, PYD)	Urine serum
Hydroxyproline (OHP)	Urine
Glycosyl hydroxylysine (GylHyl)	Urine, serum
Helical peptide (Hep)	Urine
Tartrate resistant acid phosphatase 5b isoform specific for osteoclasts (TRACP 5b)	Serum, plasma
Cathepsin K (Cath K)	Urine, serum
Osteocalcin fragments (uOC)	Urine
Bone Formation Markers	
Osteocalcin (OC)	Serum
Procollagen type I C-terminal propeptide (PICP)	Serum
Procollagen type I N-terminal propeptide (PINP)	Serum
Bone-specific alkaline phosphatase (bone ALP)	Serum

osteoporosis, but we now know that lower doses (0.3 mg of CEE or its equivalent) in combination with progestogens, or even with adequate calcium alone, can prevent bone loss, although there are no long-term fracture data with lower-dose therapy (Fig. 14.22). Whether the addition of progestogens by stimulating bone formation increases bone mass beyond that produced by estrogen alone is unclear. The androgenic activity of certain progestogens such as norethindrone acetate (NET) also has been suggested to play a role, by stimulating bone formation. Figures 14.23 and 14.24 provide data on changes in bone mineral density (BMD) at the spine and hip using various agents.

Figure 14.22 Changes in spine bone mineral density (BMD) with hormone therapy (HT). Intent-to-treat population only. The Women's HOPE Study. CEE, Conjugated equine estrogens; HOPE, Heart, Osteoporosis, Progestin, Estrogen; MPA, medroxyprogesterone. (From Lindsay R, Gallagher JC, Kleerekoper M, et al. Effect of lower doses of conjugated equine estrogens with and without medroxyprogesterone acetate on bone in early postmenopausal women. *JAMA*. 2002;287:2668.)

*Doses ranged from 250 to 2800 IU per week; predominantly nasal delivery.

Figure 14.23 Meta-analysis of osteoporosis therapies: spine bone mineral density (BMD). CI, Confidence interval; HT, hormone therapy. (From Cranney A, Guyatt G, Griffith L, et al. Meta-analyses of therapies for postmenopausal osteoporosis. Meta-analyses of therapies for postmenopausal osteoporosis. I. Systematic reviews of randomized trials in osteoporosis: introduction and methodology. *Endocrine Rev*. 2002;23:496.)

Selective estrogen receptor modulators (SERMs) such as **raloxifene**, droloxifene, and tamoxifen have all been shown to decrease bone resorption. Raloxifene has been shown to decrease vertebral fractures in a large prospective trial (Ertinger, 1999). All of these agents are used for *prevention*. In younger women, one complicating factor is that agents such as raloxifene may induce hot flashes; however, they do afford some protection for breast cancer risk, as they act as estrogen antagonists at the level of the breast. SERMs such as raloxifene act as a low-dose estrogen and can prevent vertebral fractures but not hip fractures (Fig. 14.25).

Tibolone (structurally related to 19-not progestins) has also been shown to be an effective treatment for the prevention of osteoporosis. Tibolone (not marketed in the United States) has

SERM-like properties, but it is not specifically a SERM because it has mixed estrogenic, antiestrogenic, androgenic, and progestogenic properties, due to its metabolites. The drug does not seem to cause uterine or breast cell proliferation and also is beneficial for vasomotor symptoms. It prevents osteoporosis and has been shown to be beneficial in treatment of osteoporosis as well at a dose of 2.5 mg daily.

Bisphosphonates have been shown to have a significant effect on the *prevention and treatment* of osteoporosis, using similar doses for both indications. With this class of agents (etidronate, alendronate, risedronate, ibandronate, and zoledronic acid), incorporation of the bisphosphonate with hydroxyapatite in bone increases bone mass. The skeletal half-life of bisphosphonates in bone can be as long as 10 years, and their effects on the

Meta-analyses of therapies for postmenopausal osteoporosis. I. Systematic reviews of randomized trials in osteoporosis: introduction and methodology. *Endocrine Rev*. 2002;23:496; Rosen C. Presentation for ASBMR at NIH Scientific Workshop: Menopausal hormone therapy, October 23–24, 2002.)

skeleton are sustained for a few years after discontinuation, which does not occur with other agents. These agents reduce both spine and hip fractures (see Fig. 14.25). Most data have been derived with alendronate, which, at a dosage of 5 mg daily (35 mg weekly), prevents bone loss; at 10 mg daily (70 mg weekly), alendronate is an effective treatment for osteoporosis, with evidence available that this treatment reduces vertebral and hip fractures (Cummings, 1998). Similar data are available for risedronate (35 mg weekly). Ibandronate has been approved as a once-a-month treatment (150 mg), and some data to date support the reduction in vertebral fractures. It can also be injected (3 mg) every 3 months. Zoledronic acid 5 mg is available as an intravenous infusion (over 15 minutes) once a year for the treatment of osteoporosis and every 2 years for prevention. This class of medications has the property of causing esophageal irritation, and care must be taken in administering the oral doses in an upright position with a full glass of water.

Some concern has been raised about bisphosphonates and osteonecrosis of the jaw, fractures of long bones such as the femur with long-term use, and atrial fibrillation. Jaw problems only occur with high doses when poor dentition is present. Femur fractures with long-term use are extremely rare and atrial fibrillation, although statistically increased with bisphosphonate use, is also rare. Nevertheless, we do not have long-term data (>10 years), and these drugs should not be used for more than 10 years and not with another antiresorptive agent. Its use in younger postmenopausal women (<60 years) should be limited unless there is significant osteoporosis present.

RANKL secreted by osteoblasts causes bone resorption (see Fig. 14.21). Denosumab is a monoclonal antibody that binds up RANKL, thus preventing bone resorption. It is an effective treatment for osteoporosis, and although it can also be used for prevention, it is largely viewed as a secondary agent, particularly for women intolerant to other treatments. Denosumab 60 mg is administered subcutaneously every 6 months, and it is effective both at the vertebrae and at the

hip, (Cummings, 2009), with an efficacy that is similar to or greater than that of the bisphosphonates. Unlike the bisphosphonates, however, the effects wear off immediately after discontinuation of treatment. Although denosumab does not carry the small risks of jaw osteonecrosis and long bone fractures, as an immune therapy, long-term effects of immune modulation are not known.

Calcitonin (50 IU subcutaneous injections daily, or 200 IU intranasally) has been shown to inhibit bone resorption. Vertebral fractures have been shown to decrease with calcitonin therapy. Long-term effects, however, have not been established, and this is not a first-line therapy today.

Fluoride has been used for women with osteoporosis because it increases bone density. Currently, a lower dose (50 µg daily) of slow-release sodium fluoride does not seem to cause adverse effects (gastritis) and has efficacy in preventing vertebral fractures.

Intermittent parathyroid hormone (PTH) is an effective agent to increase bone mass in women with significant osteoporosis. In a randomized trial lasting 3 years, average bone density increased in the hip and spine with fewer fractures observed. This therapy, now available in the United States, is a second-tier therapy reserved for severe cases of osteoporosis. Teriparatide at 20 µg needs to be injected subcutaneously on a daily basis for no longer than 18 months (Murad, 2012).

Adjunctive measures for prevention of osteoporosis are calcium, vitamin D, and exercise. Calcium with vitamin D treatment has been shown to increase bone only in older individuals. It will not prevent bone loss in younger women at the onset of menopause. These modalities alone are not thought to be effective for the treatment of osteoporosis. A woman's total intake of elemental calcium should be 1500 mg daily if no agents are being used to inhibit resorption, and 400 to 800 IU of vitamin D should also be ingested. Caution should be exercised in prescribing excessive calcium, particularly in older individuals, as this has been linked to coronary events. Exercise has been shown to be beneficial for building muscle and bone mass and for reducing falls.

There has been the realization that many women in the United States are vitamin D deficient, particularly those in the northern parts of the country, because of less sunlight exposure. Vitamin D may also be important as an antimetastatic agent that may prevent certain types of cancer. Although there is some controversy about what a normal vitamin D level should be, a blood level of 25 OH vitamin D <30 ng/mL usually warrants supplemental treatment with 25 hydroxy vitamin D.

Although it is clear that women with established osteoporosis (fractures or a T score of -2.5 or greater) should receive an antiresorptive agent (usually a bisphosphonate), there is more controversy with initiating preventive strategies with T scores in the osteopenia range (-1.0 to -2.5). Many women, however, may sustain fractures in this range of T scores. Age and risk factors (thinness, immobilization, nutritional deficiencies, family history, etc.) largely help determine the need to treat those with osteopenia. In this setting, depending on the age of the woman, her family history, and whether she has vasomotor symptoms, she may be offered hormone therapy, a SERM, or a bisphosphonate. The FRAX algorithm may also be useful as a guide to therapy.

DEGENERATIVE ARTHRITIS

Degeneration of intervertebral discs is a process that occurs rapidly after menopause. This is consistent with changes in collagen as noted previously. There is evidence that this is benefited by estrogen after menopause.

Osteoarthritis is a source of significant distress. There is a powerful effect of estrogen in inhibiting damage to chondrocytes (Tanko, 2007). In WHI, estrogen alone (but not combination hormone therapy) significantly decreased osteoarthritis. However, much more work is needed in this area.

CARDIOVASCULAR EFFECTS

Women have a very low incidence of cardiovascular disease (CVD) prior to menopause, but after menopause, the risk increases significantly. Data from the Framingham study have shown that the incidence is three times lower in women before menopause than in men (3.1 per 1000 per year in women ages 45 to 49). The incidence is approximately equal in men and women ages 75 to 79 (53 and 50.4 per 1000 per year, respectively). This trend also pertains to gender differences in mortality resulting from cardiovascular disease. Coronary artery disease is the leading cause of death in women, and the lifetime risk of death is 31% in postmenopausal women versus a 3% risk of dying of breast cancer.

Although CVD becomes more prevalent only in the later years following a natural menopause, premature cessation of ovarian function (before the average age of menopause) constitutes a significant risk. Premature menopause, occurring before age 35, has been shown to increase the risk of myocardial infarction two- to threefold, and oophorectomy before age 35 increases the risk sevenfold (Lobo, 2007).

When the possible reasons for the increase in CVD are examined, the most prevalent finding is an accelerated rise in total cholesterol in postmenopausal women. The changes of weight, blood pressure, and blood glucose with aging, although important, are not thought to be as important as the rate of rise in total cholesterol, which is substantially different in women after menopause versus men. This increase in total cholesterol is explained by increases in levels of low-density lipoprotein cholesterol (LDL-C). The oxidation of LDL-C is also enhanced, as are levels of very low density lipoproteins and lipoprotein (a). High-density lipoprotein cholesterol (HDL-C) levels trend downward with time, but these changes are small and inconsistent relative to the increases in LDL-C.

Coagulation balance is not substantially altered as a counterbalance of changes occurs. Some procoagulation factors increase (factor VII, fibrinogen), but so do counterbalancing factors such as antithrombin III, plasminogen, protein C, and protein S. Blood flow in all vascular beds decreases after menopause; prostacyclin production decreases, endothelin levels increase, and vasomotor responses to acetylcholine are constrictive, reflecting reduced nitric oxide synthetase activity. Most of these latter changes are due primarily to the fairly rapid reduction in estrogen levels in that with estrogen, all these parameters (generally) improve, and coronary arterial responses to acetylcholine are dilatory with a commensurate increase in blood flow.

Circulating plasma nitrites and nitrates have also been shown to increase with estrogen, and angiotensin-converting enzyme levels tend to decrease. Estrogen and progesterone receptors have been found in vascular tissues, including coronary arteries (predominantly ER β). In addition, some membrane effects are mediated by estrogen, which may or may not relate to either ER α or ER β .

Overall, the direct vascular effects of estrogen are viewed to be as important, or more important, than the changes in lipid and lipoproteins after menopause. Although replacing estrogen has been thought to be beneficial for the mechanisms previously cited, these beneficial arterial effects may only be seen in younger (stage + 1(a-c) postmenopausal women (Fig. 14.26). (Mendelsohn, 2005) Women with significant atherosclerosis or risk factors such as those studied in secondary prevention trials, who have established atherosclerosis and prior coronary disease, do not respond well to this treatment because of coronary plaque burden (see Fig. 14.26), which prevents estrogen action. Some of this lack of effect may be accounted for by increased methylation of the promoter region of ER α , which occurs with atherosclerosis and aging. Another mechanism is the significant conversion of cholesterol to 27-OH cholesterol, which also impedes estrogen's production of nitric oxide (Fig. 14.27).

In normal, nonobese postmenopausal women, carbohydrate tolerance also decreases as a result of an increase in insulin resistance. This, too, may be partially reversed by estrogen, although the data are mixed, and high doses of estrogen with or without progestogen cause a deterioration in insulin sensitivity. Biophysical and neurohormonal responses to stress (stress reactivity) are exaggerated in postmenopausal women compared with premenopausal women, and this heightened reactivity is blunted by estrogen. Whether these changes influence cardiovascular risk with estrogen deficiency is not known, but clearly estrogen treatment returns many parameters into the range of premenopausal women in early postmenopausal women. Several trials including data from both hormonal trials of the WHI have shown a reduction in the development of diabetes with hormone therapy (Bonds, 2006; Lobo, 2014).

These consistently strong basic science and clinical data for the protective effects of estrogen on the cardiovascular system together with strong epidemiologic evidence for a protective effect of estrogen (Fig. 14.28) led to the belief that estrogen should be prescribed to prevent CVD in women. Clinical trial data, however, have refuted this notion in women with established disease, as noted previously. Results from several randomized trials in women have failed to show a protective effect in women with established coronary disease. Furthermore, a trend toward increased cardiovascular events (early harm) has been observed in this setting in some women within the first 1 to 2 years. The Women's Health Initiative (WHI) trial, which compared CEE/medroxyprogesterone acetate (MPA) with placebo, came to similar conclusions. Though considered to be a primary prevention trial, it studied subjects in a large range of ages (mean age 63). These women did not have vasomotor symptoms and had more risk factors than the healthy women studied in observational cohorts as shown in Figure 14.28.

The protective effect of estrogen demonstrated in the observational trials such as the Nurse's Health Study (NHS) (see Fig. 14.28) occurred predominantly in young, healthy,

Figure 14.26 Mechanisms of benefit of hormonal therapy with estrogen in early menopause (relatively clean coronary vessels) and the lack of effect in older women and those with significant atherosclerotic plaque burden. symptomatic women. Table 14.4 compares the demographics of the participants of WHI and the NHS. Trials carried out in the monkey model have shown a 50% to 70% protective effect against coronary atherosclerosis when estrogen is begun at the time of oophorectomy, with or without an atherogenic diet; delaying the initiation of hormonal therapy for even 2 years (in

the monkey) prevents this protective effect (Fig. 14.29). This has been called the “timing” hypothesis, in which early intervention shows benefit and late intervention with hormonal therapy is possibly harmful for the cardiovascular (CV) system. Nevertheless the 13-year follow-up data from both hormonal trials of WHI do not show overall CV harm (there were no statistical changes in

any age group when the combined data were analyzed); and benefit was demonstrated in younger women using estrogen alone (Manson, 2013). This will be reviewed in more detail later.

The perception of coronary harm and other risks in older women receiving combined CEE/MPA in WHI led to widespread confusion and concern about HT in general and led to

most women stopping HT and not starting it even when there were significant symptoms. As will be discussed later, more recent data now have confirmed that HT is safe for young, healthy women, and it is particularly indicated in women with symptoms. It appears we have come full circle as many of the original concepts of cardioprotection and reduction in all-cause

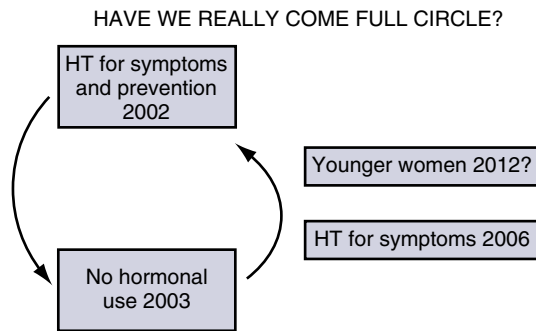

Figure 14.30 Depiction of use of hormone therapy (HT) over time, including the current status, which is still in flux. (From Lobo RA. Where are we 10 years after the Women's Health Initiative? *J Clin Endocrinol Metab.* 2013;98[5]:1771-1780.)

mortality with estrogen have been once again confirmed from the randomized trials, when one examines the effects in younger women, close to menopause (Lobo, 2013) (Fig. 14.30). However, what we have learned from WHI is that while younger women benefit, older women do not (the timing hypothesis) and may endure harm as several secondary prevention trials (in women with established coronary disease) have shown. No clear explanation exists for what may cause the observed “early harm,” but these effects were not observed in those women receiving statins concurrently. This finding suggests that HT (in the doses used) may lead to plaque destabilization and thrombosis in some women with established (although possibly silent) coronary disease. The molecular mechanisms for this effect may be due to estrogen upregulating matrix metalloproteinase-9 and inhibiting its natural inhibitor within the mural area of the plaque; the resultant disruption of the gelatinous covering then leads to thrombosis. The anti-inflammatory effects of statins inhibit this process. Additional lessons learned from WHI and more recent data are findings that **estrogen** is what is protective, and **progestogens**, depending on the type and dose, are likely to attenuate or eliminate any protective effect and may be implicated as well in the risk of breast cancer.

WHAT ARE THE CURRENT DATA ON THE EFFECTS OF ESTROGEN AND ESTROGEN/PROGESTOGEN ON THE CARDIOVASCULAR SYSTEM?

Data from WHI first reported that the younger women, ages 50 to 59, receiving CEE alone had a significantly reduced coronary score. In 2007, WHI reported that women ages 50 to 59 receiving CEE and CEE/MPA (combined analysis) had a significant 30% reduction in all-cause mortality (Rossouw, 2007). Subsequently pooled analyses of prospective studies, including data from WHI, showed a statistical benefit in the reduction of coronary disease with estrogen in women less than 10 years from menopause or <60 years of age. A Bayesian meta-analysis (looking at retrospective and prospective studies) showed consistent data for a reduction in all cause mortality of about 30% in younger women receiving hormonal treatment (Salpeter, 2009) (Fig. 14.31).

As discussed previously, the 13-year follow-up data from WHI including the intervention and follow-up phases of the trial showed a significant benefit in younger women receiving CEE

alone (Manson, 2013) (Fig. 14.32). The data with CEE/MPA were in the same direction for mortality but were less robust.

Several prospective trials in younger women deserve some discussion. The Kronos Estrogen Early Prevention Study (KEEPS) studied women within 3 years of menopause and compared the effects of CEE 0.45 mg or transdermal E₂ 0.05 mg, with micronized progesterone 200 mg for 12 days a month, compared with placebo, for 4 years. Carotid intima-media thickness (which reflects atherosclerosis progression) and coronary calcium were assessed as end points. The data were not able to show a benefit of estrogen compared with placebo, although estrogen provided the well-known benefits in terms of menopausal symptom relief (see Fig. 14.32). (Harman, 2014) There were very small changes in each group, and it has been suggested that the size of the trial (720 women) and the short 4 years of intervention was insufficient to show significant changes in a healthy population of women. A prospective trial in Denmark of 1000 recently postmenopausal women who received estradiol alone or estradiol and norethindrone (in women with a uterus) or no treatment for up to 10 years, with follow-up for up to 16 years, showed significant coronary benefit (Schierbeck, 2012). Cardiovascular death, myocardial infarction, and hospitalizations for congestive heart failure were significantly reduced in users of HT (Fig. 14.33). ELITE tested the “timing” hypothesis by treating women who were within 6 years of menopause and another group of women who were more than 10 years after menopause. Oral E₂ 1 mg or placebo was used in both groups, with vaginal progesterone for endometrial protection. The primary end point was carotid intima-media thickness, which showed a significant reduction in recently menopausal women but not in the older women, which confirmed the hypothesis (Hodis, 2014).

WORLD CONGRESS ON MENOPAUSE OF THE INTERNATIONAL MENOPAUSE SOCIETY, MAY 1-4, 2014, CANCUN, MEXICO

A Cochrane analysis reviewed CV and overall mortality with HT and found no change in mortality when all ages and both primary and secondary prevention trials were combined (Boardman, 2015). However, in women <10 years from menopause the data were consistent with findings noted previously, with significant protective effects of 30% in all-cause mortality and 40% to 50% protection from CV mortality. It was noted, however, that there was a significant increase in venous thromboembolism (VTE), which is well known to occur with oral therapy (as also occurs with oral contraceptives) but does not affect mortality. Stroke was not affected in this younger population. The complications of VTE and potentially of ischemic stroke will be discussed later.

The two risk areas for CVD, even in younger women, at least potentially, are VTE and ischemic stroke. It is now accepted that there is a two- to threefold increase in venous thrombosis risk with oral hormonal therapy. However, the prevalence of this risk is low, particularly in young, healthy women. This two- to threefold risk is similar to that with the use of oral contraceptives. For pulmonary embolism risk, in women ages 50 to 60 years, the background risk is approximately 10 to 20 events/100,000 woman-years. Thus, with HT, the twofold increase may result in 40 events/100,000 woman-years, which is less than the rate in normal pregnancy (approximately 60/100,000 women). This risk is related to

Figure 14.31 Bayesian meta-analysis of reduction in mortality with HT in younger women. (Modified from Salpeter SR, Cheng J, Thabane L, et al. Bayesian meta-analysis of hormone therapy and mortality in younger postmenopausal women. *Am J Med.* 2009;122[11]:1016-1022.)

age, weight, dose, and route of administration of estrogen. It has also been suggested that some progestogens increase this risk further, although this has not been established. Most events (deep vein thrombosis or pulmonary emboli) occur early (within the first year) and decrease thereafter, suggesting

an aberrant thrombophilic interaction with oral estrogen. The risk has been found not to be increased with transdermal estrogen (Canonico, 2008) (Fig. 14.34), which warrants consideration of the use of transdermal therapy in more high-risk women (e.g., obesity, hypertension).

Figure 14.32 Cumulative 13-year follow-up data, intervention and follow-up phases with CEE and CEE/MPA arms of the WHI in different age groups (CEE, light blue; CEE/MPA, dark blue). (Modified from Manson JE, Chlebowski RT, Stefanick ML, et al: Menopausal hormone therapy and health outcomes during the intervention and extended poststopping phases of the Women’s Health Initiative randomized trials. *JAMA* 310[13]:1353-1368, 2013.)

Figure 14.33 Sixteen-year follow-up of women randomized to hormone therapy (HT) showing a reduction in death, heart failure, and myocardial infarction (MI). (Modified from Schierbeck IL, Renmark L, Tofteng CL, et al. Effect of hormone replacement therapy on cardiovascular events in recently postmenopausal women: randomized trial. *BMJ*. 2012;345:e6409.)

Stroke (ischemic, not hemorrhagic) was found to be increased in the WHI trials (both HT and Estrogen Therapy [ET]). There was an approximately 30% increase over the 5 to 6 years of the trial, but this outcome was confined primarily to older women in the trial. These data are similar to data from the NHS trial where even younger women had a very small but statistically increased risk of ischemic stroke with standard doses of oral estrogen. The increase in younger women is extremely small and may not be statistically significant. In the 13-year follow-up data from WHI (Manson, 2013) and in the Cochrane review, (Boardman, 2015),

stroke was not significantly increased in the younger age groups. Thus, although a rare event, ischemic stroke risk may be increased in women taking standard doses of oral estrogen (women using CEE at 0.625 mg or more) but not with lower doses (e.g., CEE 0.3 mg). Similarly, transdermal therapy has not been associated with an increased risk. These and other data point to a thrombotic risk with oral estrogen (in susceptible women). The mechanism of ischemic stroke risk in younger women is not likely to be due to atherosclerosis as it is in coronary disease in older women but is due to acute thrombosis (Lobo, 2011) (Fig. 14.35). The thrombosis risk in younger women, much like the risk of venous thrombosis, is likely due to an aberrant interaction of estrogen with thrombotic factors, at times due to an underlying thrombophilia.

In summary, there should be no concern regarding increased cardiovascular risk for young, healthy women at the onset of menopause who are contemplating HT for treatment of symptoms. In this setting there is no evidence of increased risk, and, indeed, these women may be found to benefit from a cardiovascular standpoint.

CANCER RISKS IN POSTMENOPAUSAL WOMEN

Just as CVD is a concern for women after menopause, the risk of cancer also increases with time after menopause, but this is a function of aging and not as a consequence of menopause per se. *Prevention* requires healthy lifestyle measures and screening for early detection, which will be emphasized again later in the chapter.

Although breast cancer is generally believed to be the leading cause of death in postmenopausal women, in fact it is lung cancer. Indeed, mortality from breast cancer tends to decrease after menopause, on an age-specific basis, but cardiovascular mortality increases, and these lines transect around the time of menopause (Fig. 14.36). The gynecologist should be well versed in the epidemiology and preventive strategies for breast, lung, cervical, endometrial, ovarian, and colorectal cancer. Further discussions of these cancers may be found in Part IV (Gynecologic Oncology) of this text. What follows is the potential effects of ET and HT on endometrial, breast, ovarian, and colorectal cancer.

Endometrial cancer is a common cancer in postmenopausal women and is increased in women using **unopposed estrogen therapy**. Although a woman’s risk for endometrial cancer with unopposed estrogen use is two to eightfold higher than that for the general population, precursor lesions (primarily endometrial hyperplasia) signal the presence of an abnormality in most patients, and the cancer is usually well differentiated and hormonally responsive, as are hyperplasias.

One study showed that the risk of endometrial hyperplasia was 20% after 1 year of using 0.625 mg of oral CEE. In another study, the 3-year postmenopausal Estrogen/Progestin Interventions Trial, this risk of hyperplasia was approximately 40% at the end of 3 years. No cancers were reported in either of these two studies, and the addition of a progestogen essentially eliminated the hyperplasia risk. Use of CEE alone at 0.3 mg/day for 2 to 3 years results in a hyperplasia risk of 5% to 10%. With the same dose of esterified estrogens (which is less potent), no hyperplasia was found after 2 years.

Figure 14.34 Meta-analysis of various studies showing no increased risk of thrombosis with transdermal therapy. (Modified from Canonico M, Plu-Bureau G, Lowe GD, et al. Hormone replacement therapy and risk of venous thromboembolism in postmenopausal women: systematic review and meta-analysis. *BMJ*. 2008;336[7655]:1227-1231.)

The risk for endometrial cancer in women taking estrogen and progestogen is similar to that of women in the general population because combination therapy merely eliminates the excess risk attributed to estrogen; a few studies, however, have suggested a lower risk of endometrial cancer with **continuous combined hormone treatment**. It is important to remember that some endometrial cancers occurring in postmenopausal women are not hormonally related; thus some women may develop a serous type of cancer (poorly differentiated) while on HT, making continuous surveillance important. It could be argued that these serous cancers, which are usually receptor negative, may have arisen independently of HT use.

Although the risk for endometrial cancer is increased substantially in estrogen users, the risk of death from this type of

endometrial cancer does not increase proportionately. Endometrial cancers associated with estrogen use are thought to be less aggressive than spontaneously occurring cancers, in part because tumors in women taking estrogen are more likely to be discovered and treated at an earlier stage, thus improving survival rates.

RISK OF BREAST CANCER WITH ESTROGEN USE

Several studies and meta-analyses have shown a borderline or small statistical increase in the risk of breast cancer (relative risk [RR] 1.2 to 1.4) after approximately 5 years of estrogen use. This risk is related to the dose of estrogen, as well as duration of use. Data have pointed to the addition of progestogen as a major contributor to this increased risk of breast

Figure 14.35 Mechanisms of ischemic stroke risk with estrogen in older women due to atherosclerosis with complicated lesions (*left*) and due to thrombosis in younger women (*right*).

Figure 14.36 Risks of breast cancer and lung cancer versus cardiovascular disease in various age categories. (Modified from Phillips KA, Glendon G, Knight JA. Putting the risk of breast cancer in perspective. *N Engl J Med.* 1999;340:141. Copyright 1999 Massachusetts Medical Society.)

cancer. There is some biologic plausibility to this notion in that progesterone in the normal luteal phase increases breast mitotic activity and HT increases mammographic tissue density relative to ET alone. Several small case-control studies found no increase with ET alone, but the same studies showed a statistically significant increase with progestogen use (in the range of 1.3 or 1.4 RR). In the WHI trial, the increase in breast cancer risk was of borderline significance with CEE/MPA (hazard ratio [HR] 1.24, 1.01 to 1.54). A reanalysis by Anderson and coworkers found that when correcting for variables known to affect breast cancer risk, the average risk was

no longer statistically significant: 1.20 (0.94 to 1.53) (Anderson, 2006). It is important to note that the total duration of therapy is very important for the risk with estrogen/progestogen therapy. In WHI the significant increase over 5 years was only found in prior users of HT, suggesting a longer cumulative effect. *There was no statistical increase over 5 years with CEE/MPA in women in WHI who had not used HT in the past* (Anderson, 2006). A large collaborative case-control study also has shown that continuous combined estrogen-progestogen therapy is associated with increased breast cancer risk over time.

The effect of estrogen/progestogen therapy and breast cancer risk is thought to be one of promotion, rather than carcinogenesis per se. Occult breast tumors are extremely common in breast tissue and take up to 10 years of slow growth to be clinically detectable. It has been suggested that certain doses of estrogen, and particularly with estrogen/progestogen therapy, stimulate the growth of these occult receptor positive tumors, which shortens the time to clinical detection, thus allowing them to be recognized as a consequence of HT. Modeling of growth kinetics by Santen and applying these numbers to findings in WHI lend credence to this notion (Santen, 2012).

In the estrogen-only arm of WHI, after 6½ years there was a decrease in breast cancer risk of borderline significance HR = 0.77 (0.59 to 1.01). In a more complete analysis of these findings, Stefanick and associates found the risk to be significantly decreased for ductal cancer (0.71 [0.52 to 0.99]), and in a sensitivity analysis among adherent women, the decrease was statistically significant (0.67 [0.47 to 0.9]) (Stefanick, 2006) (Fig. 14.37). Thus, although it is unclear why there should be a decrease in breast cancer risk, we may conclude that standard dose ET (0.625 mg CEE) is not associated with a risk of breast cancer except for very long-term users. In an analysis from the NHS, Chen and colleagues found that this risk only increases significantly after 20 years (Table 14.5). This risk is predominantly seen in lean women because overweight/obese women already have an increased risk of breast cancer, which is not further increased. A theory proposed by Jordan has suggested

that the decrease in risk is confined to women who did not receive hormones immediately after menopause, but some time later. The theory suggests that this lag allowed the occult breast cancers to undergo apoptosis when later exposed to estrogen, thus decreasing the risk of breast cancer (Jordan, 2015).

Putting these risks into perspective is important for patient counseling. The background risk for breast cancer in a woman between the ages of 50 and 60 is 2.8/100 women. According to data from the WHI, the overall risk for women taking

No. at Risk						
CEE	5310	3399	2448	1718	469	161
Placebo	5429	3638	2540	1760	422	168

Figure 14.37 Cumulative hazard for invasive breast cancer: sensitivity analysis. CEE, Conjugated equine estrogen; CI, confidence interval; HR, hazard ratio. (From Stefanick ML, Anderson GL, Margolis KL, et al. Effects of conjugated equine estrogens on breast cancer and mammography screening in postmenopausal women with hysterectomy. *JAMA*. 2006;295:1647.)

CEE/MPA for 5 years was approximately a relative risk of 1.24. Note that this applies to women who had also used hormones in the past, as noted earlier. This 24% increase translates into an overall risk of 3.47/100 women, less than 1% above the background risk. This risk is expected to be even lower with different regimens including lower dose therapy, and potentially with different progestogens, such as natural progesterone, which has been shown in observational studies not to increase the risk. A relative risk of 1.24 for breast cancer is less than that for obesity alone (3.3) or for being a flight attendant (1.87) because of the increase in cosmic radiation. Furthermore, for estrogen alone, there is probably no increased risk at moderate to low doses for up to 20 years of exposure, as noted by Chen and colleagues. The risk of breast cancer is much higher with certain endogenous risk factors such as obesity and increased breast density than it is with any type of HT (Fig. 14.38).

With some exceptions in the literature, most reports have shown that the mortality rate in users of ET/HT is improved compared with those women not receiving hormones who are diagnosed with breast cancer. Figure 14.39 depicts the 10-year follow-up data from WHI with women receiving CEE alone; both breast cancer mortality and total mortality were reduced in users of estrogen (Anderson, 2012). It should be appreciated that women receiving HT are likely to have (and should have) closer surveillance (exams and mammography); accordingly, most tumors, if they occur, will be detected at an early stage.

Family history and genetic mutations (*BRCA* 1 and 2, etc.) substantially increase the risk of a woman developing breast cancer. However, the literature suggests that the use of HT does not increase this risk further. Nevertheless, for many women it is unacceptable to consider a potentially promotional effect of using HT, and they may opt for risk reduction strategies such as the use of tamoxifen or other SERMs.

Figure 14.38 Risks of breast cancer with various exposures and endogenous traits, particularly increased breast density. (Modified from Gompel A, Santen RJ: Hormone therapy and breast cancer risk 10 years after the WHI. *Climacteric*. 2012;15[3]:241-249.)

Figure 14.39 In women with breast cancer, women taking E₂ had significantly reduced mortality; breast cancer (A) and total (B). (Modified from Anderson GL, Chlebowski RT, Aragaki AK, et al. Conjugated equine oestrogen and breast cancer incidence and mortality in postmenopausal women with hysterectomy: extended follow-up of the Women's Health Initiative randomized placebo-controlled trial. *Lancet Oncol*. 2012;13[5]:476-486.)

If there is a concern regarding hormones and breast cancer, it is with larger doses, a longer duration, and specifically the use of a progestogen. Accordingly, for longer-term therapy, if warranted (>5 years) lower doses of estrogen should be used, and progestogen exposure should be minimized.

OVARIAN CANCER

Several studies have suggested an increased risk of ovarian cancer with long-duration use of ET/HT. However, the data are inconsistent, and the purported risk is less than a twofold relative risk. Prospective randomized trials such as WHI have found no statistical increase in risk. The most recent meta-analysis suggested a modest risk of 30% to 40% (Collaborative Group, 2015). In this analysis it is unclear if adequate attention was paid to confounders, and there was no association with length of exposure regarding risk, which does not make sense physiologically. Further, estrogen and estrogen/progestogens both carried some risk, whereas use of oral contraceptives are known to decrease ovarian cancer risk. According to this meta-analysis, the risk was calculated to be approximately 1 extra case of ovarian cancer per 1000 women over 5 years, which suggests if this association is real, it is extremely rare.

COLORECTAL CANCER

The third most frequent cancer in women, colorectal cancer, is often preventable by the detection and treatment of polyps. Women older than 50 should have a colorectal evaluation by some means (detection of occult blood, sigmoidoscopy, or a colonoscopy). Data have been fairly consistent for a reduction in risk with the use of HT/ET. Several meta-analyses have shown an approximate 33% decrease in risk, as did the observational data from the NHS and the prospective randomized trial data of the CEE/MPA arm of WHI. It is unclear why in the ET arm of WHI, a decrease was not observed. No definitive mechanism for this protective effect has been found, although several theories have been advanced (changes in the composition of bile acids, anti-inflammatory effects, etc.).

OTHER CANCERS

There has been more attention paid to lung cancer recently, in part because it is the leading cause of cancer mortality in women. The data on HT, however, has not been consistent and is without convincing evidence of any risk of lung cancer with HT use.

CONCEPT OF DISEASE PREVENTION AFTER MENOPAUSE

Since all major diseases such as CVD, obesity, and metabolic diseases, particularly diabetes, cancer, cognitive decline and Alzheimer's increase after menopause, menopause itself heralds an important opportunity to screen for, and prevent many of these problems (Lobo, Prevention of disease after menopause, 2014).

Details of this approach may be found in the review cited, but in essence stresses the introduction of screening procedures for these disorders and then beginning prevention strategies such as prescribing diet and exercise regimens and the consideration of hormone therapy. Primary strategies for the prevention of CVD in men,

such as statins and aspirin, have not been shown to be of benefit in women (Hodis, 2013). Thus, apart from lifestyle measures, there are no good prevention strategies for women, with the possible exception of HT. As discussed previously, in a young healthy population of women close to menopause, estrogen-based therapy has been shown to significantly decrease coronary disease and mortality, with minimal to rare risks of adverse outcomes. As Figure 14.30 shows, the use of HT was considered for prevention until the time of the various secondary prevention trials (such as the Heart and Estrogen/Progestin Replacement Study [HERS]) and then WHI, and this concept is now being reconsidered but remains controversial. Table 14.6 lists a compilation of several studies and meta-analyses that are remarkably consistent in showing a reduction in mortality in younger women receiving estrogen after menopause, which strengthens the argument of using estrogen for prevention.

Using a conservative approach fostered by the early reports of "early harm" in older women taking standard doses of CEE/MPA in secondary prevention trials or the older women in WHI, it has been suggested that women have a cardiovascular risk assessment prior to initiating HT. The American Heart Association (www.heart.org) offers an easy-to-use, rapid risk assessment calculator, which defines women at low risk if they have a <7.5% chance of sustaining a myocardial infarction in 10 years. Although some investigators have questioned the validity of this approach, risk assessment is not an unreasonable course in general, along the lines of stressing the need for *prevention* after menopause. Because most of the CV-related risks of HT relate to oral therapy, "higher" risk women may benefit more by being placed on transdermal estrogen.

In summary, apart from the need to screen carefully for all diseases at the onset of menopause, and stressing healthy lifestyle measures, the decision to initiate HT should be straightforward in symptomatic women who will benefit more in terms of absolute

Table 14.6 Consistency in the Reduction in All-Cause Mortality in Younger Women Receiving Estrogen at the Onset of Menopause

Figure 14.41 Putting risks and benefits in perspective for the 50- to 59-year-old. (Modified from Santen R. Endocrine Society position paper. *J Clin Endocrinol Metab.* 2010;95[7 Suppl 1]:s1-s66.)

numbers of women affected by treatment (see Figure 14.41). Figure 14.40, generated from newer data and data from WHI in the 50- to 59-year-old age group, shows the absolute benefits and risks associated with the use of estrogen, strongly emphasizing benefits. However, when these absolute numbers are compared with the benefit of the reduction in hot flashes in women receiving estrogen, the latter appears to be the predominant effect (Fig. 14.41). The decision to use HT at the onset of menopause probably applies for women who are at greater risk for osteoporosis as well, based on family history and their physical characteristics. Otherwise, it is not unreasonable to consider HT in otherwise healthy women with adequate counseling and discussion of the risks and benefits. This should be an individual decision. For some women, the fear of breast cancer, particularly in those with

some family history of the disease, will overshadow any potential benefits, and this view has to be respected. Women who decide to initiate HT should be made aware that this need not be a long commitment, and therapy should be reassessed annually based on needs and symptoms. Finally, the data to date regarding protection are strongest for the use of estrogen; certain progestogens may eliminate or attenuate the benefit, and some progestogens increase the promotional risk of breast cancer. Philosophically, therefore, HT should be about using the lowest amount of a progestogen necessary to prevent endometrial disease.

HORMONE REGIMENS

The various hormonal preparations available for treatment are listed in Box 14.3. A more complete list may be found in the Consumer section of the North American Menopause Society website at www.menopause.org. Also included are the SERMs raloxifene, bazedoxifene, and other compounds like bisphosphonates, tibolone, and human parathyroid hormone. For the clinician and patient, as noted earlier, the decision to start estrogen therapy need not involve a long-term commitment. For short-term treatment of symptoms, estrogen should be used at the lowest dose that can control hot flushes or can be administered via the vaginal route for symptoms of dryness or dyspareunia. There are no definitive data on what doses are necessary for CV protection, but whereas low doses of estrogen may be sufficient to prevent bone loss (discussed earlier) the doses necessary to afford CV protection may have to be a bit higher, although there are no data to this point in women. Therefore, lower doses are still recommended, which are sufficient for symptom control.

Oral estrogen results in higher levels of estrone (E₁) than estradiol (E₂); this is true for oral micronized E₂ as well as E₁ products. CEE is a mixture of at least 10 conjugated estrogens derived from equine pregnant urine. Estrone sulfate is the major component, but the biologic activities of equilin, 17 α -dihydroequilin, and several other B-ring unsaturated estrogens, including δ 5 dehydroestrone, have been documented. Table 14.7 compares the standard doses of the most frequently prescribed oral estrogens and the levels of E₁ and E₂ achieved. Much of the following clinical information may be found in systematic reviews.

Synthetic estrogens, given orally, are more potent than natural E₂. Ethinyl estradiol is used in oral contraceptives, with a dose of 5 μ g being equivalent to the standard ET doses used (0.625 mg CEE or 1 mg micronized E₂). Standard ET doses are five or six times less than the amount of estrogen used in oral contraceptives. Although there are incomplete data available to compare the equivalencies of CEE and micronized estradiol (because of different end organ effects and the mixture of estrogens in CEE, which are difficult to measure), 0.625 mg CEE is probably equivalent to 1.5 mg of micronized E₂. Oral estrogens have a potent hepatic “first-pass” effect that results in the loss of approximately 30% of their activity with a single passage after oral administration. However, this results in stimulation of hepatic proteins and enzymes. Some of these changes are not particularly beneficial (e.g., an increase in procoagulation factors and an increase in C-reactive protein), whereas other changes are beneficial (an increase in HDL-C and a decrease in fibrinogen and plasminogen activator inhibitor-1).

E₂ can be administered in patches, gels, lotions, sprays, and subcutaneously. These routes of administration are not subject to

Box 14.3 Hormonal and Osteoporosis Treatments: Available and Approved for Use in Postmenopausal Women**Estrogens****Oral**

CEE, 0.3, 0.45, 0.625, 0.9, 1.25, and 2.5 mg
 Piperazine estrone sulfate, equivalent of 0.625, 1.25, and 2.5 mg
 Esterified, 0.3, 0.625, 0.9, 1.25, and 2.5 mg
 Micronized estradiol, 0.5, 1, and 2 mg

Transdermal

Estradiol patches, 0.014, 0.025, 0.0375, 0.05, 0.75, and 0.10 mg/d
 Estradiol gels, 0.25 to 1.5 mg/day various brands
 Estradiol spray, 1.53 mg/day

Vaginal

Cream, CEE (0.0625%), estradiol (0.01%)
 Estradiol ring, 2 mg; vaginal tablets, 10 µg
 Estradiol acetate ring for vasomotor symptoms: 50–100 µg/day for 3 months

Parenteral

Intramuscular injections should be avoided

Progestins**Oral**

Medroxyprogesterone acetate, 2.5, 5, and 10 mg
 Norethindrone acetate, 5 mg
 Micronized progesterone, 100 and 200 mg

Vaginal

Micronized progesterone, 100 mg
 Progesterone gel, 4% and 8%

Combinations**Oral**

CEE + MPA (0.625 mg) + MPA (2.5 or 5 mg)
 CEE + MPA (0.3 mg + MPA, 1.5 mg)
 Micronized estradiol (1 mg) + norethindrone, acetate (0.5 mg)

Micronized estradiol (1 mg) + 0.5 mg drospirenone
 Ethinyl estradiol 5 µg, norethindrone, 1 mg
 CEE+ Bazedoxifene (SERM), 0.45 + 20 mg/day

Transdermal

Patch, 0.05 mg estradiol with 140 µg or 250 µg norethindrone acetate
 Patch, 0.045 mg estradiol with levonorgestrel 0.05 mg

Androgens**Oral**

Esterified estrogen and methyl testosterone (0.625/1.25 mg and 1.25/2.5 mg)

Transdermal

Patch, 150 µg/300 µg approved outside of US

Other Nonhormonal Products

Ospemifene (SERM), 60 mg/day for vulvovaginal atrophy
 Paroxetine (SSRI), 7.5 mg/day for vasomotor symptoms

Medications for Osteoporosis**Bisphosphonates**

Alendronate, 5 and 10 mg daily; 35 and 70 mg weekly
 Risedronate, 5 mg; 35 mg weekly
 Ibandronate, 150 mg monthly and 31 mg IV every 3 months
 Zoledronic acid 5 mg once/yr
 Etidronate, 200 mg (intermittent)

Selective Estrogen Receptor Modulators (SERMs)

Raloxifene, 60 mg

Others for Osteoporosis

Tibolone, 2.5 mg (not approved in the United States)
 Denosumab, 60 mg subcutaneously every 6 months
 Human parathyroid hormone 1–34; 20 µg subcutaneously daily

CEE, Conjugated equine estrogens; MPA, medroxyprogesterone acetate.

major hepatic effects as with oral therapy. Accordingly, there is no increase in C-reaction protein and minimal if any change in coagulation factors, but there is also only a minimal increase in HDL-C. Doses of patches are available from 0.014 mg to 0.1 mg, available for administration once or twice weekly. The ultralow-dose patch of 0.014 mg/day has been marketed for osteoporosis prevention in older women and not for treating hot flashes. Matrix patches are preferable to the older alcohol-based preparations because there is less skin reaction and estrogen delivery is more reliable. Whereas levels of E₂ with oral therapy may vary widely among women and within the day (peaks and valleys), levels with transdermal therapy are more constant within each woman, yet values achieved may vary from woman to woman based on absorption and metabolic characteristics. With the 0.05-mg patch, E₂ levels should be in the 40- to 50-pg/mL range, but an occasional woman can have values as high as 200 pg/mL or levels that are <20 pg/mL. Note also that many commercial assays for E₂ are not reliable and do not accurately reflect estradiol status; this is particularly the case after oral estrogen therapy, because of the increase in estrogen conjugates, which interfere with many commercial assays.

In women with vulvovaginal or urinary complaints, vaginal therapy is most appropriate. Creams of E₂ or CEE are available, as well as tablets and an estrogen ring. With creams, systemic absorption occurs but with levels that are one fourth of that achieved after similar doses administered orally. Absorption decreases as the mucosa becomes more estrogenized. For CEE,

Table 14.7 Mean Serum Estradiol (E₂) and Estrone (E₁)

	Level (pg/mL)	Level (pg/mL)
Estrogen dose (mg)	E ₂	E ₁
CEE (0.3)*	18	76
CEE (0.625)	39	153
CEE (1.25)	60	220
Micronized E ₂ (1)	35	190
Micronized E ₂ (2)	63	300
E ₁ sulfate (0.625)	34	125
E ₁ sulfate (1.25)	42	220

*Conjugated equine estrogen (CEE) contains biologically active estrogens other than E₂ and E₁.

only 0.5 g (0.3 mg) or less is necessary; for micronized E₂, doses as low as 0.25 mg are sufficient. Other products (tablets and rings) are available that have been designed to limit systemic absorption. A Silastic ring is available that delivers E₂ to the vagina for 3 months with only minimal systemic absorption.

Estrogen may be administered continuously (daily) or for 21 to 26 days each month. If the woman has a uterus, a progestogen should be added to the regimen (see Table 14.7). For women who are totally intolerant of progestogens (regardless of the dose and route of administration) and take unopposed estrogen, even at lower doses, periodic endometrial sampling is necessary. In this setting, endometrial thickness by ultrasound may be a guide.

DEALING WITH SIDE EFFECTS

Apart from the thrombotic risks of larger doses of oral estrogen (discussed previously) there may be an “idiosyncratic” blood pressure response to oral estrogen. This has been described primarily with the use of CEE and occurs about 5% of the time. Estrogen typically causes no change in blood pressure and often can lower blood pressure, even in hypertensive women. A hypertensive response is often dealt with by changing the dose, preparation, or route of administration. The important clinical point is that blood pressure should be checked after initiation of therapy.

Other “somatic” effects of estrogen include potential breast tenderness, fluid retention, and bloating (more common with progestogens). All these symptoms are easily dealt with by changing the dose, preparation, and potentially by changing the route of administration as well. There should be a great deal of flexibility in the prescribing of estrogen, because there is no ideal product for all women.

USE OF A PROGESTOGEN

There are many ways to administer progestogens. The most commonly used oral progestins are MPA in doses of 2.5 and 5 to 10 mg, NET in doses of 0.3 to 1 mg, and micronized progesterone in doses of 100 to 300 mg. Equivalent doses to prevent hyperplasia when administered for at least 10 days in a woman receiving ET (equivalent to 0.625 mg CEE) are as follows: MPA, 5 mg; NET, 0.35 mg; and micronized progesterone, 200 mg. Larger doses of estrogen may require larger doses and particularly more prolonged regimens. In the sequential administration of progestogens, the number of days (length of exposure) is more important than the dose. Thus, if a woman is receiving oral ET continuously, a regimen of at least 10 to 12 days exposure is preferable to a 7-day regimen.

When progestogens are administered sequentially (10 to 14 days each month), withdrawal bleeding occurs in about 80% of women. Continuous administration of both estrogen and progestogen (continuous combined therapy) was developed to achieve amenorrhea. In the first 3 to 6 months, breakthrough bleeding and spotting are common. In some women on this regimen, amenorrhea is never completely achieved. The most common combinations in the United States are single tablets containing 0.45 or 0.625 mg CEE with 1.5 and 2.5 mg of MPA, respectively, and 5 µg of E₂ with 1 mg NET and 1 mg micronized E₂ with 0.5 mg NET. A patch with E₂ and NET or E₂ and levonorgestrel is also available.

Progesterone administered vaginally (in low doses) avoids systemic effects and results in high concentrations of progesterone in the uterus. This can be accomplished with capsules, suppositories, or a 4% gel. Intrauterine delivery of progestogens is ideal for targeting the uterus and minimizing systemic effects. However, the only marketed product, the Mirena intrauterine system, delivers too high a dose of levonorgestrel (52 mg in the system) for lower doses of estrogen therapy; a 13.5 mg system (Skylar) has been made available. Progestogens, particularly when taken orally, may lead to problems of continuance or compliance because of adverse effects, including mood alterations and bleeding. This requires flexibility in prescribing habits. Most short-term clinical trials have demonstrated an attenuating effect of progestogens on cardiovascular end points that are improved with estrogen; these effects include lipoprotein changes (an attenuation of the rise in HDL-C) and arterial and metabolic effects, and potentially

a further increase in thrombotic risk. The cardiovascular effects in WHI with CEE alone and CEE with MPA, which showed a more favorable effect without MPA, also suggest some detrimental effects of added progestogen. However, two different populations of women were studied in the two WHI trials, which limits any direct comparison. The most inert progestogens, such as micronized progesterone, or vaginal delivery of progesterone should have the fewest attenuating effects. As noted earlier, it is most likely that progestogen exposure is what increases the risk of breast cancer with HT. Natural micronized progesterone was found not to increase the risk of breast cancer in several French observational studies (Fournier, 2008). Progestogens should not be used in women who have had a hysterectomy.

ANDROGEN THERAPY

In a subtle way, some women are relatively androgen deficient. Clinicians have proposed adding androgen to ET or HT for complaints or problems relating to libido and energy, which are not relieved by adequate estrogen. Although well-controlled trials using parenteral testosterone have shown benefit in younger oophorectomized women, there have been few data showing a benefit to using more physiologic therapy. Recently, however, data using a testosterone patch or pellet (with near physiologic levels) have shown improvement in several scales of well-being and sexual function (Simon, 2005). An oral preparation (esterified estrogens 0.625 mg with 1.25 mg of methyl testosterone) was shown to improve sexual motivation and enjoyment in women with hypoactive sexual desire who were unresponsive to estrogen alone. The latter findings correlated with an increase in circulating unbound testosterone levels. As newer forms and doses of androgen become available, perhaps more women may benefit from this approach. At present, androgen therapy should be individualized and considered for those women who have symptoms that are not adequately relieved with traditional hormonal therapies. It is important to note that there are no approved products for androgen therapy in the United States.

At lower doses, androgenizing side effects are infrequent. At present, small doses of methyltestosterone (1.25 and 2.5 mg) added to esterified estrogens are available in tablets, which only have the indication of relief of vasomotor symptoms. As testosterone patches are only available for men, as are gels and creams, considerable dose titration must be considered in administering testosterone to women. The low-dose testosterone patch that showed benefit for hypoactive sexual desire in hysterectomized women receiving estrogen has been approved for use in Europe but not in the United States. The U.S. Food and Drug Administration (FDA) has been concerned about long-term cardiovascular and cancer effects, although there are no data in either direction. Administration of dehydroepiandrosterone at 25 to 50 mg/day may also be an option for raising endogenous testosterone, but data have not shown it to be beneficial for symptoms such as hypoactive sexual desire.

An Endocrine Society practice guideline, supported by other major societies as well, advised against making a diagnosis of androgen insufficiency in women and suggested against its routine use in women after menopause. However, the society did suggest limited efficacy of testosterone therapy for women with hypoactive sexual desire disorder (Wierman, 2014).

Another SERM-like compound that is used worldwide but is not approved in the United States is tibolone. This progestogen-like compound exhibits estrogenic, antiestrogenic, and androgenic effects by virtue of its structure and metabolites. At 2.5 mg, tibolone

suppresses hot flashes, prevents osteoporosis, and has a positive effect on mood and sexual function. There is also limited (or no) uterine stimulation. However, there is suppression of HDL-C, but at the same time a decrease in triglycerides. In the monkey, there is no deleterious effect of tibolone on coronary arteries.

“BIOIDENTICAL” THERAPY

It has become popular to have compounding pharmacies dispense a mixture of “bioidentical” hormones in a cream or suspension for topical administration. These preparations usually contain one or more estrogens, progesterone, testosterone, and often other precursors such as pregnenolone. As an unregulated industry, without approval by the FDA, there is inadequate quality control for these products, with batch-to-batch variation and the inclusion of some steroid hormones that may not be necessary. Claims that these compounded products are safer than pharmaceutical grade hormones is completely unsubstantiated. Also “titrating” preparations to salivary hormone levels is not accurate and has never been validated. Indeed micronized estradiol, orally or estradiol as a transdermal product, and micronized progesterone, are bioidentical products approved by the FDA, and should be first-line therapy. Several major societies have come out with strong statements against the use of compounded bioidentical preparations, and there is a combined statement from the American Society for Reproductive Medicine (ASRM) and the American College of Obstetricians and Gynecologists (ACOG) ([Practice Committee, 2012](#)).

TSEC CONCEPT

The Tissue Selective Estrogen Complex (TSEC) concept is a newer therapy for menopause. It pairs together an estrogen and a SERM, which when complexed together have specific and different tissue properties than either one would exert independently. A specific SERM, bazedoxifene (BZA)—which has agonistic effects (acting like an estrogen) on bone, antagonistic effects on the uterus and breast, and minimal effects on the CNS—when paired with CEE maintains the effects of CEE on reducing hot flashes, yet prevents endometrial hyperplasia. Accordingly, a progestogen is not needed, and this continuous regimen results in a low rate of vaginal bleeding. It is beneficial for osteoporosis protection and at least theoretically should be safer for the breast as well ([Kagan, 2012](#)). It is available as a combination product of CEE 0.45 mg and 20 mg of BZA.

ALTERNATIVE THERAPIES FOR MENOPAUSE

There are several nonhormonal alternatives for symptoms of menopause, which are listed in [Box 14.4](#), although none of these is as effective as estrogen. Nevertheless, for women who cannot or choose not to take a hormonal preparation, some of these are viable substitutes. Because there is a fairly significant placebo effect in the reduction in hot flashes (up to 40% reduction), at least in the short term, randomized trials against placebo are necessary to establish efficacy.

Not listed here, because this list includes non-hormonal preparations, other than estrogen or estrogen/progestogen regimens, there is an established efficacy of using progestogens alone. MPA 10 to 20 mg, and NET 5 to 10 mg (as well as other progestogen regimens) used alone, have shown some benefit in women with hot flashes, but this is less beneficial than the use of estrogen, and

has more side effects, particularly with more long-term therapy (>3 months). Also if a woman cannot or will not take estrogen, it is unlikely that she would take a progestogen alone. Therefore this is often an impractical choice for dealing with symptoms.

ANTIDEPRESSANTS (SSRIs/SNRIs) (SELECTIVE SEROTONIN REUPTAKE INHIBITORS [SSRIs]/SEROTONIN NOREPINEPHRINE REUPTAKE INHIBITORS (SNRIs))

Several well-controlled clinical studies have shown the efficacy for several drugs in this class for hot flashes, which were initially used in women with breast cancer. These include fluoxetine (20 mg), venlafaxine (75 mg), paroxetine (12.5, 25 mg), and escitalopram (10, 20 mg) ([Nelson, 2006](#)). Apart from some side effects, such as nausea, dry mouth, and sexual dysfunction, all these agents are superior to placebo in reducing hot flashes. However, only one product, paroxetine, is approved currently by the FDA, at a lower dose of 7.5 mg. This has a moderate effect, and in breast cancer patients it may interfere with tamoxifen therapy.

GABAPENTIN

Gabapentin has been shown to be superior to placebo in doses ranging from 300 to 900 mg. Side effects include somnolence, dizziness, fatigue, and ataxia, which are dose related. If doses are titrated up to 2400 mg (a very large dose), the efficacy has been shown to be similar to that of CEE at 0.625 mg ([Reddy, 2006](#)).

ANTIHYPERTENSIVES

Clonidine has been the most studied, but methyldopa also has efficacy over placebo in reducing hot flashes. Typically a 0.1-mg patch is used daily. There is an obvious hypotensive response, and the efficacy is not very large, precluding its routine use unless the patient is also hypertensive.

PHYTOESTROGENS

It has been suggested that 30% to 60% of women with symptoms at menopause seek “natural” therapies, and the majority are botanicals such as phytoestrogens. The Dietary Supplement Health and Education Act of 1994 classifies most botanical medicines as food supplements and removes them from regulatory oversight and scrutiny by the FDA. Adulteration, contamination, and poor quality control in their harvesting, manufacture, and formulation yield products of questionable efficacy and safety.

The FDA has determined that more than 25% of Chinese patent medicines are adulterated with hidden pharmaceutical drugs. These kinds of deficiencies make it difficult for consumers and practitioners to employ botanicals with confidence and

security. Furthermore, clinical trial data obtained using one brand of herbal product cannot necessarily be extrapolated to other brands using the same plant.

Phytoestrogens are a class of plant-derived estrogen-like compounds conjugated to glycoside moieties. Phytoestrogens are not biologically active in their native forms unless taken orally. After oral ingestion, colonic bacteria cleave the glycosides, producing active compounds that are subject to the enterohepatic circulation. These compounds can produce estrogen-agonistic effects in some tissues, whereas in other tissues they produce antagonistic effects.

Few randomized trials have examined the efficacy of phytoestrogens. For large daily doses (60 mg isoflavone), there appears to be some limited efficacy in relieving hot flashes, although the literature on this issue is mixed. In placebo-controlled trials, red clover and black cohosh have been found to have similar effects as placebo (Fig. 14.42) (Geller, 2009).

With doses of 30 to 40 mg of soy isoflavone, cholesterol levels may be reduced, but this is not a consistent finding. Phytoestrogens do not appear to have much of an effect on bone loss or on vaginal atrophy.

Figure 14.42 **A** depicts the number of vasomotor symptoms per week; **B** depicts the number of hot flashes per week; and **C** depicts the intensity of the hot flashes. Black cohosh and red clover are not different from placebo. (Modified from Geller SE, Shulman LP, van Breemen RB, et al. Safety and efficacy of black cohosh and red clover for the management of vasomotor symptoms: a randomized controlled trial. *Menopause*. 2009;16[6]:1156-1166.)

COGNITIVE BEHAVIOR THERAPY

It has been shown that “talk therapy,” which teaches coping skills that may change one’s cognitive appraisal of the symptoms, may be beneficial (Norton, 2013). It is not clear if this treatment will be sustained over time.

ACUPUNCTURE

Acupuncture has been used in several trials to assess the treatment of hot flushes and other menopausal symptoms. A meta-analysis

confirmed that acupuncture may be effective in alleviating the frequency and severity of hot flushes (Chiu, 2015).

STELLATE GANGLION BLOCKADE

While somewhat invasive, needle injection of the stellate ganglion has been shown to be effective in some women, such as those being treated for breast cancer. In one study, image-guided stellate ganglion blockade with 5 mL of 0.5% bupivacaine was shown to be beneficial, compared with sham injection with saline for vasomotor symptoms (Walega, 2014).

KEY POINTS

- The average age of menopause in the United States is 51.3 years, and it is younger in certain ethnic groups.
- Age at menopause is genetically predetermined and is not related to the number of ovulations, race, socioeconomic conditions, education, height, weight, age at menarche, or age at last pregnancy.
- Stages of menopause have been established, and the earliest clinical sign is menstrual alterations.
- The initial endocrinologic change signaling the onset of menopause is decreased AMH and ovarian inhibin-B production accompanied by an increase in FSH.
- Estradiol does not begin to significantly diminish until approximately 1 year before menopause. The rise in FSH occurs before this and stabilizes about 2 years after menopause.
- Because most diseases in women occur after menopause, the onset of menopause heralds an important opportunity to institute prevention strategies for prolonging and improving the quality of life for women.
- Botherome vasomotor symptoms or hot flushes may persist for 10 or more years, with the mean duration of 4.5 years.
- Estrogen is the best therapy for the hot flush; other effective therapies are progestogens, selective serotonin reuptake inhibitors (SSRIs), gabapentin, clonidine, some phytoestrogens, acupuncture, and stellate ganglion blockade.
- About 1% to 1.5% of bone mass is lost each year after menopause in nonobese white and Asian women. Fractures begin to occur about age 60 to 65 in trabecular bone, such as the vertebral spine, and by age 60, 25% of these women develop spinal compression fractures. Hip fractures begin to increase after age 70.
- Dual-energy x-ray absorptiometry (DEXA) is the most accurate method to measure bone density. The bone mineral density is usually expressed as T scores and Z scores.
- Bone density does not completely reflect bone strength, which is what determines risk of fracture.
- In addition to estrogen (with and without progestogen), alendronate, risedronate, ibandronate, zoledronic acid, raloxifene, calcitonin, denosumab, and teriparatide will reduce postmenopausal bone loss, and some agents will stimulate bone formation as well.
- The primary indication for estrogen therapy is symptoms of menopause (hot flushes as well as quality-of-life issues); bone health may also be an indication in some women.
- In younger postmenopausal women who are receiving hormonal therapy for symptoms, the benefits outweigh risks with standard doses; lowering doses further decreases risks.
- There is no risk of coronary disease and possibly some benefit with early treatment; there are small risks of venous thrombosis and possibly of ischemic stroke, which can be minimized or eliminated with lower doses or transdermal therapy.
- There are consistent data for a reduction in all-cause mortality of 20% to 30% in younger women who initiate estrogen therapy at the onset of menopause. These data are mostly with the use of estrogen. Estrogen/progestogen therapy shows the same trend, but the data are less robust.
- These findings suggest a potential role of estrogen as a prevention therapy after menopause, although the primary indication is for symptom control and osteoporosis prevention.
- Breast cancer risk is related to dose, duration of use, and progestogen exposure. Estrogen alone and possibly the use of natural progestogen do not substantially increase the risk.
- There is no proved cognitive benefit (although this has been shown in observational studies), but there is also no evidence for harm if initiated in symptomatic women at the onset of menopause.

Breast Diseases

Detection, Management, and Surveillance of Breast Disease

Samith Sandadi, David T. Rock, James W. Orr, Jr., Fidel A. Valea

The gynecologist's role in managing breast problems is broad and extensive, as he or she will frequently serve as a woman's primary health care advocate. Historically, gynecologists have assumed a leadership role in women's breast cancer care, having been directly involved in the organization of the American Cancer Society (formerly known as the American Society for the Control of Cancer) in 1913 and taking a major role in the initial organization of the American Society of Breast Disease in 1976. A comprehensive plan for the diagnosis and management of breast disease is a critical component of high-quality women's health care because of the prevalence and immense psychological impact of breast disease. In the United States, 7.8% of office visits by women (>51 million/year) are for breast disease. Additionally, breast cancer is the second most common cause of cancer-related death in women, and it is the leading cause of premature mortality from cancer in women as measured by total years of life lost in the United States.

Despite the high incidence and prevalence of breast disease, and the enormous personal, psychosocial, and psychosexual aspects attached to conditions of the breast, there is surprisingly little didactic and clinical teaching time devoted to the evaluation and management of breast disease during medical school and postgraduate training. Regardless, the role of the gynecologist in the management of breast disease has been addressed in a number of published clinical opinions and practice bulletins from the American College of Obstetrics and Gynecology. The role of the gynecologist includes but is not limited to the following:

- Identifying risk factors during the medical and family history
- Performing clinical breast examinations
- Offering instructions for breast self-evaluation
- Evaluating all palpable breast masses
- Encouraging women to have a routine screening mammography
- Performing diagnostic procedures or referral to those who specialize in breast disease when clinically indicated

Guidelines have questioned the benefit of breast self-examination, despite the fact that many women identify their own breast cancer. Thus the term *breast self-awareness* has been coined to imply the potential benefit of women being aware of their breasts and

looking for changes, without mention of frequency or proper technique. Additionally, these guidelines indicate that there is insufficient current evidence to assess the additional benefit of clinical breast examination (CBE) beyond screening mammography in women aged 40 years or older (Siu, 2016).

Cultural and societal norms place great importance on breasts. A change or abnormality frequently ignites a fear of breast cancer and strong psychological concerns. The goal of this chapter is to present a clinically oriented approach that allows the practitioner to better understand breast anatomy, the important diagnostic and clinical aspects of benign breast disease, and the epidemiology, detection, and management of breast cancer.

ANATOMY/EMBRYOLOGY

Breast development begins in utero during the sixth gestational week from the integument along the epithelial mammary ridges. Ducts and acini are derived from ectoderm, whereas supporting tissue arises from mesenchyme. Ductal tissue and secretory lobule development occurs under the influence of the hormonal changes that occur during puberty (see [Chapter 38](#)). Actual milk production is initiated by hormonal changes that occur during and after pregnancy.

The breasts are large, modified apocrine/sweat glands located in the superficial fascia anterior to the deep pectoralis major fascia of the chest wall. Posteriorly, the retro mammary space, a loose connective tissue plane, allows free movement over the chest wall (i.e., the breast is not firmly attached to the deep fascia). The breast tissue is suspended from the clavicle and deep clavipectoral fascia by the suspensory ligaments of Cooper that weave through the breast tissue and attach to the dermis of the skin ([Fig. 15.1](#)). These fibrous septa maintain the natural shape of the breast. Clinically, malignant involvement of these ligaments often produces skin retraction, suggesting the presence of advanced breast carcinoma.

Breast size and shape depend on genetic, racial, and dietary factors as well as age, parity, and menopausal status. On average, during the reproductive ages the adult breast weighs approximately 250 grams. Typically, a superolateral projection

Figure 15.1 Lactating breast. (From Shah P, ed. Breast. In: Standing S, ed. *Gray's Anatomy*. London: Churchill Livingstone; 2005: 969.)

of glandular tissue (axillary tail of Spence) pierces the deep fascia and extends toward the axilla. Glandular tissue composes approximately 20% of the mature breast with the remainder being adipose and connective tissue. Adipose tissue volume is the major determinant of breast size. Breast density refers to the proportion of fibrous/glandular tissue to adipose tissue. The periphery of the breast is predominantly adipose, and the central area contains a higher proportion of glandular tissue (Fig. 15.2). Typically, glandular tissue regresses and is replaced by adipose tissue after menopause.

A breast is composed of 12 to 20 varying-sized, triangular-shaped lobes distributed radially from the nipple. Each lobe contains its own duct system draining the 10 to 100 lobules with alveoli (acini). These functional lobules have epithelial (ductal) and stromal components and are affected by hormonal changes (estrogen, progesterone, and prolactin) resulting in development, maturation, and differentiation (Fig. 15.3). The organization of the ductal system is stimulated at puberty. Secretory cells drain into alveoli, which drain into “terminal” ducts that then coalesce into larger collecting ducts, and join with ducts from other lobules to end in lactiferous ducts, terminating at the excretory ducts of the nipple.

5 to 20 areolar (Montgomery) glands produce an oily secretion designed to keep the nipple supple and protected, particularly important during breast-feeding. They also produce a volatile compound that has been implicated in stimulating the infants' appetite through olfactory pathways (Doucet, 2009). The glands are located in the areola and even on the nipple. They are generally sensitive. Blockages or irritation result in significant problems.

The principal blood supply of the breast is derived from the perforating branches of the internal mammary arteries that originate from the internal thoracic artery. Additional sources include the lateral thoracic and thoracoacromial arteries, which originate from the axillary artery, and the posterior third, fourth, and fifth intercostal arteries, which are branches of the

Figure 15.2 The structures of the breast. (From Shah P, ed. Breast. In: Standing S, ed. *Gray's Anatomy*. London: Churchill Livingstone; 2005:969.)

thoracic aorta. The inferior and central portion of the breast is the least vascular area.

The lymphatics of the breast converge in the subareolar plexus of Sappey. Approximately 75% of the lymphatics, particularly from the outer quadrants, drain to the 30 to 60 ipsilateral

Figure 15.3 Histologic photograph of a mammary lobule. Note the ductal tissue surrounded by fibrous tissue. Terminal ductules (TD) surround the central ductule (ID). EF, extralobular fibrocollagenous tissue. (From Stevens A, Lowe J. *Human Histology*. 3rd ed. Philadelphia: Mosby; 2005:390.)

axillary regional nodes. The axillary nodes are classified by three anatomic levels defined by their relationship to the pectoralis minor muscle. Level I nodes are located lateral to the lateral border of the pectoralis minor muscle. Level II nodes are located posterior to the pectoralis minor muscle. Level III nodes include the infraclavicular nodes medial to the pectoralis minor muscle. The remaining lymphatics drain to the internal mammary or parasternal nodes, which have direct drainage to the mediastinum, the medial quadrants of the opposite breast, or the inferior phrenic nodes. The latter is important as it provides a route for metastatic disease to the liver, ovaries, and peritoneum (Fig. 15.4). Lymphatic fluid usually flows toward the most adjacent group of nodes, forming the foundation for utilizing sentinel node mapping to evaluate for nodal spread in breast cancer. In most instances, breast cancer spreads in an orderly fashion within the axillary lymph node basin based on the anatomic relationship between the primary tumor and its associated regional (sentinel) nodes. However, lymphatic metastases from one specific area of the breast may be found in any or all of the groups of regional nodes.

Breast ductal epithelium is extremely sensitive to cyclic hormonal changes. Parenchymal proliferation of the ducts is seen during the follicular phase, and there is dilation of the ductal

Figure 15.4 Lymph vessels of the breast and axillary lymph nodes. (From Shah P, ed. *Breast*. In: Standring S, ed. *Gray's Anatomy*. London: Churchill Livingstone; 2005:971.)

system and differentiation of the alveolar cells into secretory cells during the luteal phase. Alveolar elements respond to both estrogen and progesterone. The stroma and myoepithelial cells also respond to estrogen and progesterone. Women often experience cyclic breast fullness and tenderness likely related to the 25 to 30 mL average fluctuation in volume of the premenstrual breasts. Additionally, premenstrual breast symptoms are produced by an increase in blood flow, leading to vascular engorgement, and water retention. A parallel enlargement of the ductal lumen and an increase in ductal and acinar cellular secretory activity also occur. Menstruation brings a regression of cellular activity in the alveoli and the ducts become smaller. These changes are clinically reflected by the cyclic changes noted on breast examination.

The breast undergoes normal maturational changes throughout a woman's lifetime. In addition to the pubertal and pregnancy-induced changes in the lactiferous duct lobule, the fibrous and adipose components evolve as well. The normal maturation involves a gradual increase in fibrous tissue around the lobules. With time the glandular elements are completely replaced by fibrous tissue. Women in their 20s and 30s have a gradual increase in nodularity as the lobular tissue increases with repetitive cyclic hormonal stimulation. After pregnancy and lactation, breasts may decrease in size and shape, compared with the prepregnancy state. Thus breast examination often yields different findings in the 20-year-old, the 40-year-old, as well as during and after menopause. These changes underscore the value of breast self-awareness, as each woman personally knows the changes in her body at different times in her cycle and life (Fig. 15.5).

CONGENITAL DEVELOPMENTAL BREAST ABNORMALITIES

NIPPLE

Accessory nipples can occur along the breast or milk lines that run from the axilla to the groin. Polythelia (supernumerary or accessory nipples) occurs in 1% (European descent) to 6% (Asian descent) of women. They typically present in the inframammary region (90%), may be unilateral or bilateral, and occur in equal frequency in men and women. The condition is both sporadic and familial. Sporadic cases may be associated with urologic anomalies and cardiovascular problems (hypertension and conductive or rhythm disturbances). Development may be partial or complete. When present, they have the same risk for disease as normal nipples. Treatment is generally reserved to manage irritation or to improve cosmesis.

Congenital nipple inversion occurs in 2% of women, typically in those with a family history of the same condition. The etiology is related to shortening and tethering of breast ducts and to the development of fibrous bands during intrauterine life. Nipple inversion may increase mechanical problems with breast-feeding. Surgical correction often leads to loss of sensation and inability to breast-feed.

Athelia, complete unilateral or bilateral absence of nipple and areola, can be familial (autosomal dominant) and is seen in association with amastia (absent nipple, areola, and breast tissue) or other rare syndromes (e.g., Poland syndrome). Associated ectodermal abnormalities (such as absence of the pectoral muscles) should be excluded. Treatment includes nipple

Figure 15.5 **A**, Micrograph showing normal breast tissue from a 23-year-old woman. At the center is a breast lobule in which the system of terminal ducts and ductules is embedded in loose intralobular fibrocollagenous stroma (F). There is a narrow surrounding zone of dense extralobular fibrocollagenous support tissue (DF), outside of which is the soft adipose tissue (A) that forms the bulk of the breast. **B**, Micrograph showing normal breast tissue from a 43-year-old woman. As women age, the amount of fibrocollagenous tissue (F) in the breast increases, replacing some of the adipose tissue. The mammary lobules become enclosed in dense collagen. (From Stevens A, Lowe J. *Human Histology*. 3rd ed. Philadelphia: Mosby; 2005:393.)

and areola reconstruction commonly using tissue flaps and tattooing.

BREAST TISSUE

Amastia, complete absence of both breast tissue and the nipple-areola complex, occurs with regression or failure to develop the mammary ridge. It is often associated with other ectodermal defects, including cleft palate.

Polymastia, accessory breast tissue or supernumerary breasts, occurs in approximately 1% to 2% of the general population with a female preponderance. Accessory breast tissue most commonly presents in the axilla, and multiple site occurrence is not uncommon (~33%). Initial diagnosis is common at puberty or during pregnancy when the accessory breast tissue development parallels that of normal breast tissue. Supernumerary breast tissue, be it rudimentary or fully developed, is customarily

Table 15.1 ANDI Classification of Benign Breast Disorders

	Normal	Disorder	Disease
Early Reproductive Years (age 15-25)	Lobular development Stromal development Nipple eversion	Fibroadenoma Adolescent hypertrophy Nipple inversion	Giant fibroadenoma Gigantomastia Subareolar abscess
Later Reproductive Years (age 25-40)	Cyclical changes of menstruation Epithelial hyperplasia of pregnancy	Cyclical mastalgia Nodularity Bloody nipple discharge	Incapacitating mastalgia
Involution (age 35-55)	Lobular involution Duct involution Dilation Sclerosis Epithelial turnover	Macrocysts Sclerosing lesions Duct ectasia Nipple retraction Epithelial hyperplasia	Periductal mastitis Epithelial hyperplasia with atypia

asymptomatic; however, it can cause discomfort and may be considered cosmetically unacceptable. Importantly, supernumerary breast tissue is subject to normal changes and the entire disease spectrum seen in the normal breast. Conservative management is encouraged, as surgery can be associated with unattractive scars, restriction of movement, pain, and other complications. Liposuction may be useful to decrease the fatty element of accessory breasts.

Asymmetric breast development, common in adolescence and maturity, represents a benign, normal variation unless an associated palpable abnormality is present. In the extreme, a breast can be hypoplastic or absent (aplasia), and this can occur in isolation or in association with a defect in (one or both) pectoral muscles. Significant asymmetry can be deeply disturbing and affect a teenager's self-image. Full breast development usually occurs by 18 to 21 years of age and if deemed necessary, consideration of any corrective surgery, such as augmentation or reduction, should be timed appropriately.

Breast hypertrophy may be asymmetric and is separated into pubertal (virginal hypertrophy), gestational (gravid macromastia), or adult types. Medical treatment is typically not successful and reduction mammoplasty is not indicated until a significant volume of breast tissue requires removal to relieve associated symptoms such as headache, neck or back pain, upper extremity paresthesias, brassiere strap grooving, or intertrigo. Surgical outcome can be maximized when the procedure is planned after allowing for a stable breast size for 6 to 12 months.

Tubular breasts or tuberous breasts, unilateral or bilateral, are a congenital abnormality of the breasts that occurs in both sexes. During puberty breast development is stymied and the breasts fail to develop normally and fully. The transverse breast diameter is narrowed and the base constricted related to glandular hypoplasia with a deficiency in the circumferential skin envelope of the breast base. The breast appears to herniate into an oversized and protuberant areola. The exact cause of this condition is as yet unclear; however, a genetic link in a disorder of collagen deposition is suspected. Corrective procedures can be divided into operations that involve augmentation, mastopexy, combined augmentation/mastopexy, and tissue expansion followed by augmentation (Winocour, 2013).

BENIGN BREAST DISORDERS

The majority (~90%) of breast complaints and abnormalities are associated with benign breast disorders (BBDs), a

heterogeneous group of lesions or abnormalities that may present with a wide range of symptoms. They may be incidental or detected clinically or radiographically. The spectrum of BBD includes developmental abnormalities, inflammatory lesions, epithelial and stromal proliferations, and neoplasms. Benign breast diseases are often misdiagnosed and misunderstood because of their variety in presentation and anxiety about the possibility of malignancy. In fact, women with a new breast problem or complaint commonly assume the worst. Understanding the etiology and management of BBD is essential to proper clinical management and to psychologically allay patient and family fears. Unfortunately, when compared with malignancy, clinical expertise in diagnosis and management of BBD is deficient.

Numerous terminologies have been used to describe BBD. Most emphasize clinical signs, symptoms, or histologic findings. BBDs can be classified as follows:

1. Aberrations of normal development and involution (ANDI)
2. Pathologic classification
3. Clinical classification
4. Classification based on the risk for malignancy

The ANDI classification incorporates symptoms, signs, histology, physiology, pathogenesis, and degree of the breast abnormality, classified in relation to the normal processes of reproductive life and involution through a spectrum of breast conditions that range from "normal" to "disorder" to "disease" (Hughes, 1991). Thus ANDI classification suggests that BBDs are a result of minor aberrations in the normal development process, hormonal response, and involution of the breast (Table 15.1).

Additionally, BBDs can be subdivided pathologically by their potential future cancer risk:

- Nonproliferative disorders: no increased risk
- Proliferative disorders without atypia: mild to moderate increase in risk
- Atypical hyperplasia: substantial increase in risk (relative risk 5×)

Finally, a clinical classification is frequently used in which abnormalities can be subgrouped as follows:

- Physiologic swelling and tenderness
- Nodularity
- Breast pain (not usually associated with malignancy)

- Palpable breast lumps
- Nipple discharge including galactorrhea
- Breast infection and inflammation—typically associated with lactation

Most common benign breast disorders involve pain, discharge, or a mass. Infection or mastitis is less common. These symptoms and subsequent physical findings often result in denial, anxiety, and fear as patients worry that the symptoms represent cancer. The increase in size, density, and nodularity during the second half of the menstrual cycle is often associated with increased sensitivity or breast pain. Importantly, breast pain associated with cancer is generally a late symptom and is a lone presenting symptom in less than 6% of women. Nipple discharge is also a less frequent sign of cancer. The correlation of a mass with malignancy is dependent on the patient's age. The incidence of BBD begins to rise during the second decade of life and peaks in the fourth and fifth decades, as opposed to malignant diseases, whose incidence continues to increase after menopause.

Many breast symptoms stem from fibrocystic changes, previously termed *fibrocystic disease*, which are a common and natural maturation of breast tissue over time. The functional unit of the breast (the lobule), the alterations associated with the interaction among hormones, and the epithelial and stromal components of the lobule are responsible for many cases of BBDs. Initial or immature lobules, primarily developing in the early reproductive years (15 to 25 years of age), are typically replaced during pregnancy and subsequently by mature lobules. Lobular changes manifest most commonly during the menstrual cycle. Late cycle peak mitosis, followed by apoptosis, provides a milieu for stromal or ductal tissues to transform from a normal to abnormal state. Over time, these deviations produce marked differences in the structure and appearance of the breast tissue, which are histologically described as *fibrosis* or *adenosis*, frequently observed in women with no clinical complaint or finding.

Involutional breast changes, clinically apparent prior to 35 years of age, affect stromal and epithelial components of the lobules. Early stromal involution can result in the formation of microcysts from the remaining epithelial acini. Microcyst formation is common and is frequently present in healthy breasts. Ductule obstruction facilitates progression of microcysts to macrocysts. Loose, hormonally receptive connective tissue in the stroma is replaced by denser connective tissue, and epithelial involution results in gradual disappearance of the ductal elements. Epithelial involution is dependent on the continuing presence of surrounding specialized stroma. Thus cyclical and involutional changes are concurrently present for >30 years, and the involution changes will be extensive, sparing few ductal and lobular structures by menopause.

FIBROADENOMAS

Fibroadenomas, composed of fibrous and epithelial elements, are the most common benign breast neoplasms (15% to 20%) and are often noticed accidentally while bathing. They occur most frequently in adolescents and women in their 20s (15 to 25 years of age) and are related to an aberration in normal lobular development. They demonstrate hormonal dependence, lactate during pregnancy, and involute to be replaced by hyaline connective tissue during perimenopause. Clinically they usually

present as solitary slow growing, painless, freely mobile, firm, solid breast masses. The average size is 2.5 cm, and they usually remain fairly constant in size. Giant fibroadenoma, >5 cm, are rare. Hyperplastic lobules histologically resembling fibroadenomas are present in virtually all breasts. All the cellular elements of fibroadenomas are normal on conventional and electron microscopy, and the epithelium and myoepithelium maintain a normal relationship.

On clinical examination it may be difficult to distinguish a fibroadenoma from a cyst. In fact, diagnosis based solely on CBE is correct 66% of the time. Importantly, complex cysts and any cysts with solid areas should be biopsied or excised. Ultrasound is the initial, noninvasive study to differentiate a solid versus a cystic mass, as mammography is rarely indicated in a woman younger than 35 with fibroadenomas. Core needle biopsy is indicated if, and when, the cause of a palpable mass cannot be established. Surgical evaluation is appropriate for any mass (at any age) that exhibits a rapid size increase. Fibroadenomas can be followed clinically. Surgical excision of fibroadenomas should be considered if they are symptomatic or to relieve anxiety related to the palpable mass. They have a “rubbery” consistency, are usually well circumscribed, and easily delineated from surrounding breast tissue in approximately 95% of cases (Fig. 15.6). Nonoperative management can be considered for small, asymptomatic fibroadenomas, discovered in women younger than 35 if clinical exam, imaging evaluation (either mammogram or ultrasound), and biopsy (usually core needle) are 100% concordant. Approximately 35% of fibroadenomas will disappear, and approximately 10% become smaller when followed for many years. Conservative management requires continued surveillance at 6-month intervals for at least 2 years. Despite the option of conservative management, many women prefer to have the fibroadenoma excised. Excision should be performed through a cosmetically placed inframammary, axillary, or circumareolar incision. The long-term risk of invasive breast cancer in women with fibroadenomas is approximately twice that for women without fibroadenomas, as fibroadenomas are a proliferative disorder. Women with fibroadenomas should be made aware of this risk and encouraged to maintain annual mammographic screening. The postoperative risk of recurrent fibroadenoma is ~20%. Studies support the successful use of ultrasound-guided high-intensity focused ultrasound or cryoablation as an alternative treatment to surgery (Kovatcheva, 2015).

Phyllodes tumors, previously termed *Cystosarcoma phyllodes*, represent the opposite end of the spectrum of fibroepithelial tumors. Phyllodes tumors are rare, representing only 2.5% of fibroepithelial tumors and less than 1% of breast malignancies. The typical age of onset is 15 to 20 years later than fibroadenomas (fourth and fifth decades of life). They are almost exclusively seen in females and may be benign, borderline, or malignant. Differentiating benign from malignant phyllodes can be difficult and involves assessment of the size, histologic stroma/epithelium ratio, border of the lesion, stromal cellularity, number of stromal mitoses, and presence or absence of necrosis. All three generally present as a breast mass, often grow rapidly, and are typically larger at diagnosis than a fibroadenoma or ductal carcinoma. Histologically, stromal elements dominate and will invade the ducts in a leafy projection, hence the name *phyllodes*, or “leaf” (Fig. 15.7). Even the most experienced pathologists may have difficulty distinguishing between fibroadenoma, benign phyllodes tumors, and malignant

Figure 15.6 **A**, Fibroadenoma with characteristic tan, well-circumscribed nodule. **B**, Histologic section of fibroadenoma with epithelial cells surrounded by loose mesenchymal fibrous tissue. (From Voet RL. *Color Atlas of Obstetric and Gynecologic Pathology*. St Louis: Mosby-Wolfe; 1997:204.)

cystosarcoma phyllodes. Phyllodes tumor's mammographic appearance as a rounded density with smooth borders is similar to that of fibroadenomas. Mammography and ultrasonography are therefore unreliable in differentiating between fibroadenomas, benign phyllodes tumors, and malignant phyllodes tumors.

Phyllodes tumors can be locally aggressive and require wide local excision with 1-cm margins. Unlike fibroadenomas, phyllodes tumors should not be shelled out, as it will result in an unacceptably high recurrence rate. Unfortunately, the pathologic appearance of a phyllodes tumor does not always predict the neoplasm's clinical behavior; however, risk of local recurrence of the tumor is associated with microscopic margin involvement. Malignant tumors metastasize hematogenously, and the risk of metastases is 25%; however, local recurrence is common (>20%), even with benign and borderline tumors.

FIBROCYSTIC CHANGE

Fibrocystic change, previously termed *fibrocystic disease*, is the most common of all benign breast conditions. Clinicians use

the nonspecific term *fibrocystic change* to describe the clinical, mammographic, and histologic findings associated with multiple irregularities in contour and texture typically associated with cyclical breast pain. Fibrocystic change presents as a spectrum of changes throughout a woman's reproductive age with significant patient variation. Fibrocystic change has an extensive list of synonyms and terminology that includes more than 35 different names and terms. The 10th revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) terms this as diffuse cystic mastopathy.

The true frequency of fibrocystic change is unknown; however, autopsy evidence of histologic fibrocystic change is noted in 53% of normal breasts. Clinical evidence of fibrocystic change is evident in nearly one in two premenopausal women during breast examination; however, depending on the definition, some authors have noted that as many as 90% of women demonstrate some aspect of fibrocystic change. Although no consistent abnormality of circulating hormone levels has been proved, fibrocystic changes represent an exaggeration of normal physiologic response of breast tissue to the cyclic levels of ovarian hormones. These changes, unusual in adolescence, are most common in women of reproductive age (20 to 50 years) and unusual after menopause unless associated with exogenous hormone replacement.

Cyclic bilateral breast pain is the classic symptom of fibrocystic breast change. Clinical signs include increased breast engorgement and density, excessive breast nodularity, fluctuation in the size of cystic areas, increased tenderness, and infrequently spontaneous nipple discharge. Signs and symptoms are typically more prevalent during the premenstrual state.

Associated mastalgia is bilateral, often difficult to localize, and most frequent in the upper, outer breast quadrants. Pain may radiate to the shoulders and upper arms. Severe localized pain occurs when a simple cyst rapidly expands. The pathophysiology that produces these symptoms and signs includes cyst formation, epithelial and fibrous proliferation, and varying degrees of fluid retention. The differential diagnosis of breast pain includes referred pain from a dorsal radiculitis or inflammation of the costochondral junction (Tietze syndrome). The latter two conditions have symptoms that are not cyclic and unrelated to the menstrual cycle.

Figure 15.8 Breast biopsy from a 38-year-old woman demonstrating the characteristic gross appearance of fibrocystic changes. Note the multiple cysts interspersed between the dense fibrous connective tissue. (Courtesy of Fidel A. Valea, MD.)

The physical findings of excessive nodularity due to fibrocystic changes have been described as similar to palpating the surface of multiple peas. There may be multiple areas of seemingly ill-defined thickening or areas of palpable lumpiness that seem more two-dimensional than the three-dimensional mass usually associated with a carcinoma (Fig. 15.8). Larger cysts may be ballotable, analogous to a water-filled balloon.

There are three general clinical stages of fibrocystic change, with each stage having characteristic histologic findings. Clinically these stages are variable and overlap, but they are described to assist in the understanding of the natural history. The first stage, mastoplasia (mastoplasia), is associated with intense stromal proliferation and occurs in the early reproductive years (20s). Breast pain is noted primarily in the upper, outer breast quadrants with most tenderness in the axillary tail.

The second clinical stage, adenosis, is characterized by marked proliferation and hyperplasia of ducts, ductules, and alveolar cells and typically occurs in women in their 30s. Premenstrual breast pain and tenderness is less severe. Multiple small breast nodules varying from 2 to 10 mm in diameter are present.

The cystic phase is the last stage and typically occurs another decade later in women in their 40s. Typically there is no breast pain unless a cyst increases rapidly in size with associated sudden pain, point tenderness, and a lump. Cysts are tender to palpation and vary from microscopic to 5 cm in diameter. Although breast cysts may occur at any age, they are generally simple and may be managed with aspiration alone. Complex cysts have internal septations, debris, or solid components and may require core needle

Figure 15.9 Fibrocystic changes from histologic section. Note: Fibrosis (F), adenomatous changes with increased ductal tissue (A), and cysts (C). (From Stevens A, Lowe J. *Human Histology*. 3rd ed. Philadelphia: Mosby; 2005:392.)

biopsy if stability cannot be documented. The fluid aspirated from a large cyst is typically straw colored, dark brown, or green, depending on the chronicity of the cyst.

Women with a clinical diagnosis of fibrocystic change have a wide variety of histopathologic findings. The histology of fibrocystic change is characterized by proliferation and hyperplasia of the lobular, ductal, and acinar epithelium (Fig. 15.9). Usually, the proliferation of fibrous tissue occurs and accompanies epithelial hyperplasia. Many histologic variants of fibrocystic change have been described, including cysts (from microscopic to large, blue, domed cysts), adenosis (florid and sclerosing), fibrosis (periductal and stromal), duct ectasia, apocrine metaplasia, intraductal epithelial hyperplasia, and papillomatosis. Ductal epithelial hyperplasia with atypia and apocrine metaplasia with atypia are the most prominent histologic findings directly associated with the subsequent development of breast carcinoma. If either of these two conditions is discovered on breast biopsy, the chance of future breast carcinoma is increased fivefold.

Clinical management of fibrocystic change is age dependent and includes appropriate use of breast imaging. First and foremost, malignancy should be excluded, particularly in the presence of a mass or with a concerning or uncertain examination. Thereafter, successful symptom control may involve a number of medical options. Initial therapy for fibrocystic change involves mechanical support utilizing a firm support or sports bra. Dietary changes reducing methylxanthines or caffeine exposure have been helpful in relieving symptoms for some women. Although confirmatory medical studies evaluating the benefit of these dietary changes are lacking, there seems to be little harm to trying this inexpensive option for 3 to 6 months. The only dietary substance that seems, at this time, to correlate with fibrocystic symptoms is dietary fat, particularly saturated fat. Studies have

demonstrated a dose-related effect between increased saturated fat and fibrocystic breast symptoms. Incorporating a low-fat, nutrient-dense diet makes sense, and limiting intake of saturated fat intake should be considered as a simple therapeutic tool for the management of women with symptomatic, refractory fibrocystic changes. Additionally, some advocate limiting or eliminating alcohol consumption to lessen estrogen levels. Diuretics are sometimes prescribed during the premenstrual phase and may lessen symptoms of breast discomfort/engorgement.

Oral contraceptives or supplemental progestins administered during the secretory phase of the cycle have also been used to treat fibrocystic changes. Oral contraceptives are reported to decrease the incidence of fibrocystic changes by 30% (Schindler, 2013). Unfortunately, 40% of women will have recurrent symptoms after discontinuation.

Danazol, dosed at 100, 200, and 400 mg daily for 4 to 6 months, suppresses gonadotropins and effectively relieves symptoms and decreases breast nodularity in ~90% of patients. Unfortunately, virilizing side effects such as hirsutism, acne, and voice changes frequently limit its use. Danazol therapy for 6 months or more should be tapered to eliminate side effects. The beneficial effects of danazol persist for several months after discontinuation.

Oral tamoxifen, 20 mg daily, is superior to placebo in randomized, double-blind trials, and pain relief is reported to be sustained in 72% of women for >1 year after discontinuation. Tamoxifen administration restricted to the luteal phase of the menstrual cycle abolishes pain in 85% of women; however, adverse side effects are frequent (21%). Following treatment, 25% of women suffer recurrent pain within 1 year. Tamoxifen 10 mg daily can be prescribed during the luteal phase of the menstrual cycle and results in similar improvements in symptoms, but with a marked reduction in adverse effects.

The selective estrogen receptor modulator (SERM) Ormeloxifene (30 mg twice weekly), a weak estrogen receptor (ER) agonist and a strong ER antagonist, demonstrated significant efficacy in the management of breast pain and fibrocystic nodularity. On rare occasions, gonadotropin-releasing hormone (GnRH) agonists may benefit women with severe fibrocystic change.

MASTALGIA (BREAST PAIN)

Over two thirds of women will experience breast pain at some time during their reproductive years, most commonly in the perimenopausal years. Approximately 90% of conditions that cause breast pain are benign. Breast pain is typically divided into cyclic pain, related to the menstrual cycle, and noncyclic pain. Cyclic pain is diffuse and bilateral and most commonly associated with fibrocystic changes. Noncyclic breast pain is commonly localized and related to a cyst. Noncyclic breast pain should be evaluated, particularly in older women, as there is a small association with malignancy. Mammography and additional imaging can be valuable. The differential diagnosis includes a cyst, chest-wall pain, radicular pain, costochondritis, mastitis, pregnancy-related pain, prolactinomas, and medication exposure (Box 15.1). Laboratory evaluation should include an HCG and prolactin in premenopausal women. Breast cysts occur in as many as 7% of women during their lifetime and may be therapeutically aspirated if they are simple. A negative postaspiration breast examination is reassuring. Recurring

simple cysts can be followed with ultrasound, typically withholding repeat aspiration for symptomatic cysts. For a more complex cyst, a more detailed workup is usually necessary. Complex cysts should have a tissue diagnosis with core needle biopsy if they are symptomatic or show progressive changes on serial sonography. Pain as a presenting symptom of malignancy is uncommon and is extremely rare in the absence of mass or skin changes. Breast pain treatment is directed at the cause; however, nonsteroidal anti-inflammatories are often useful when pain is idiopathic.

MASTITIS AND INFLAMMATORY DISEASE

Breast infection is often subdivided into lactational, non-lactational, and postsurgical. Although decreasing in overall incidence, mastitis, infection of the ductal systems or smaller sebaceous glands, is most commonly related to *Staphylococcus aureus*. Empiric treatment with an agent that covers gram-positive organisms is appropriate. If there is poor response to the initial course of antibiotics, then cultures for methicillin-resistant *Staphylococcus aureus* (MRSA) should be performed and an agent such as a doxycycline or sulfamethoxazole/trimethoprim is indicated. These two agents are contraindicated if a woman is pregnant or lactating.

Lactational mastitis commonly occurs in the first pregnancy during the first 6 weeks of breast-feeding. Curiously, mastitis in pregnancy usually responds to first-line antibiotics such as a cephalosporin, even in the presence of MRSA; however, infection may progress to a breast abscess in 5% to 11% of patients. Continued breast-feeding or manual pumping of the affected breast is recommended to decrease engorgement.

Nonpuerperal mastitis is often associated with breast cysts and cyst rupture. Ultrasonography assists in excluding an abscess. Obviously, one should always consider and exclude the presence of malignant breast disease, particularly inflammatory cancer. Additional testing for diabetes and HIV may be indicated, particularly if yeast is the offending organism. Syphilis, tuberculosis, atypical bacterial, and fungal infections

Box 15.1 Medications Associated with Mastalgia

- Antihypertensives
- Atenolol and other beta-blockers
- Hydrochlorothiazide
- Methyldopa
- Minoxidil
- Spironolactone
- Antidepressants and antipsychotic agents
- Amitriptyline and other tricyclic antidepressants
- Chlorpromazine/promethazine
- Fluoxetine
- Haloperidol
- Hormonal agents
- Estrogens
- Progestins
- Androgens
- Ginseng
- Clomiphene citrate
- Digoxin
- Chlorpropamide

may rarely cause nonpuerperal mastitis. In patients with recurrent mastitis, consider choosing an antibiotic to cover MRSA, such as clindamycin, trimethoprim-sulfamethoxazole, doxycycline, or vancomycin. Nipple piercing, particularly in smokers, is associated with mastitis and a 20-fold increase in subareolar abscess formation. As with any infection, the clinician should strongly consider removal of the foreign body. The American College of Obstetricians and Gynecologists recommends counseling women who are planning to get piercings to have a prepiercing hepatitis-B vaccine and tetanus vaccinations.

Idiopathic granulomatous mastitis (IGM), also called *idiopathic granulomatous lobular mastitis (IGLM)*, is a rare cause of breast inflammation, which may affect any age group. This disease may present with a mass, abscess, inflammation, or granuloma formation. The granulomas are often found within the lobules and on biopsy are noted to be sterile. Mammography may be equivocal or may be suspicious for malignancy. Steroid treatment has been reported to be effective in small series with equivocal results. The disease is usually self-limited, resolving within months. Skin scarring and residual small abscesses may remain, frequently necessitating surgical treatment. Chronic inflammatory diseases, such as lupus, sarcoid, and Wegner granulomatosis, are rare causes of noninfectious mastitis, and evaluation for these diseases should be performed if antibiotics are not effective. Importantly, any breast inflammation not responsive to adequate antibiotic treatment warrants a tissue diagnosis. Core needle biopsy is frequently performed when there is a lack of response to antibiotics. The diagnosis is frequently made when the biopsy demonstrates sterile granulomas after excluding other causes of granulomatous mastitis such as tuberculosis.

NIPPLE DISCHARGE

Nipple discharge is responsible for 7% of physician visits involving breast complaints. The majority have a benign etiology; however, 55% present with a coexisting mass of which 19% are malignant. An underlying malignancy is more likely when the discharge is spontaneous (vs. induced with nipple pressure), arises from a single duct, is blood stained, and is unilateral and persistent (occurring more than twice weekly). Age is important, as an underlying malignancy is present in 3% of women under 40, 10% of women between 40 and 60, and 32% of women over 60 when nipple discharge is the *only* presenting symptom.

Intraductal papilloma and fibrocystic changes are the two most common causes of spontaneous nonmilky discharge. Galactorrhea is likely when breast discharge is bilateral, copious, pale milky in color, and occurs from multiple ducts. Importantly, numerous medications and conditions can affect the hypothalamic-pituitary axis and lead to prolactin secretion and galactorrhea. As many as 65% of premenopausal women may have a normal benign physiologic discharge with gentle squeezing of the nipple. Evaluation includes physical examination, mammography, and sonography. History may not differentiate spontaneous discharge from elicited discharge as a woman may continually attempt to express the discharge, which causes more fluid to leak.

Evaluation and diagnosis includes clinically separating the discharge into those that are spontaneous and those that only

are expressed by pinching or squeezing the nipple. Nipple discharges range in color from milky to green, brown, purple, and bloody. Hemocult testing for detection of blood in the discharge is neither sensitive nor specific. Malignancy should be excluded in any woman with a bloody discharge or any discharge associated with a mass or if the discharge originates from only one or two adjacent ducts.

Assessment of *pathologic* nipple discharge involves a careful breast examination to identify the presence or absence of a breast mass. Firm areola pressure can assist in identifying the site of any dilated duct (pressure over a dilated duct will produce the discharge); this finding helps to define where an incision should be made for any subsequent surgery. The nipple is squeezed with firm, gentle digital pressure and if fluid is expressed, the site and character of the discharge are recorded. Although bloodstained breast discharge is more likely to be associated with malignancy, fewer than 20% of patients who have a bloodstained discharge, or who have a discharge containing moderate or large amounts of blood, will have an underlying malignancy. Importantly, the absence of blood in nipple discharge does not exclude an underlying malignancy. Nipple discharge cytology can be helpful but has a poor sensitivity (<50%).

Management of a suspicious discharge begins with a physical examination and mammography, ultrasound, or magnetic resonance imaging (MRI). Any mass associated with discharge requires appropriate biopsy. A number of techniques have been evaluated to determine etiology and avoid unnecessary extirpative surgery. Ductoscopy (using a microendoscope passed into the offending duct) allows direct visualization. Ductal lavage involves duct canalization, and collection of fluid for cytologic evaluation. This technique increases cell yield by 100 times that of simple discharge cytology but can be uncomfortable for the patient. Ductography (imaging of the ductal system by injecting contrast into the symptomatic duct), also called a *galactogram*, has 60% sensitivity for detecting malignancy. This study can identify intraductal filling defects or cutoff lesions, which have a high positive predictive value for the presence of either a papilloma or a carcinoma. The procedure can be technically challenging and cause significant patient discomfort. Surgical excision of the duct and its associated lobular unit is both diagnostic and therapeutic. With the patient anesthetized, a 4-0 lacrimal probe is passed through the duct. A periareolar flap is then created, and the retroareolar duct with the probe can be identified and excised individually.

INTRADUCTAL PAPILLOMA

Intraductal papillomas are broad-based or pedunculated polypoid epithelial lesions that may obstruct and distend the involved duct, most commonly diagnosed in perimenopausal women. Classically, their clinical presentation includes an intermittent but spontaneous discharge from one nipple involving one or two ducts. The associated discharge can be watery, serous, or bloody, and of variable volume. Approximately 75% of intraductal papillomas are located beneath the areola, are small and soft, and are often difficult to palpate, typically measuring 1 to 3 mm in diameter. During examination of the breast it is important to circumferentially put radial pressure on different areas of the areola. This technique helps to identify whether the discharge emanates from a single duct or multiple openings. When the

discharge comes from a single duct, the differential diagnosis includes both intraductal papilloma and carcinoma.

Treatment of intraductal papilloma involves excisional biopsy of the involved duct and a small amount of surrounding tissue. Although these tumors tend to regress in postmenopausal women, excision should be considered to rule out malignancy. Careful surveillance at 3- to 4-month intervals is necessary if the papilloma is not surgically excised. Women with a solitary papilloma have a twofold increase in subsequent development of breast carcinoma.

FAT NECROSIS

Fat necrosis, a benign nonsuppurative inflammatory process of adipose tissue, is a condition with a wide variety of presentations on mammography, ultrasound, and MRI. The incidence of fat necrosis of the breast is estimated to be 0.6% in the breast, representing 2.75% of all breast lesions. Fat necrosis is found to be 0.8% of breast tumors and 1% in breast reduction mammoplasty cases. The average age of patients is 50 years. Fat necrosis is most commonly the result of trauma to the breast, although it can be associated with radiotherapy, anticoagulation (warfarin), or breast procedures including breast aspiration or biopsy, lumpectomy, reduction mammoplasty, implant removal, breast reconstruction, and infection. Other rare causes for fat necrosis include polyarteritis nodosa, Weber-Christian disease, and granulomatous angiopanniculitis.

Patients commonly present with a firm, tender, indurated, ill-defined mass that may have coexisting ecchymosis, erythema, inflammation, pain, skin retraction or thickening, nipple retraction, and occasionally lymphadenopathy. As many as 70% present as an occult lesion without a history of trauma. The area of fat necrosis may liquefy and become cystic forming an oil cyst with a characteristic calcified rim. Mammography may demonstrate coarse calcifications, focal asymmetries, or microcalcifications. Treatment of fat necrosis is excisional biopsy. There is no relationship between fat necrosis and subsequent breast carcinoma.

BREAST CARCINOMA

Globally, breast carcinoma is the most common malignancy of women, and in the United States it is the second most common cause of all cancer deaths in women. Approximately 12.3% of women (one in eight women) will develop carcinoma of the breast at some point during their lifetime. In 2014, approximately 234,190 women in the United States were diagnosed with invasive breast cancer, with 40,730 women dying from the disease (Siegel, 2015). The importance of early detection and diagnosis of breast carcinoma cannot be overemphasized. An increase in public awareness combined with improvements in mammography and newer imaging techniques have facilitated earlier detection of breast carcinoma. Earlier detection, combined with improvements with therapy, has resulted in improved survival rates. With the advent of chemoprevention in the high-risk woman, there is an opportunity to alter the natural course of the disease.

Breast carcinoma generally presents in one of two ways, either with clinical symptoms or found on screening evaluation. In the United States, most breast cancer is diagnosed as a

result of an abnormal screening test. Screening includes breast self-examination, examination by a health provider (referred to as *clinical breast examination*), and imaging. The ideal time to initiate screening, along with determination of intervals, is individualized for each woman based on her risk factors. A thorough understanding of the epidemiology of breast cancer is warranted when calculating the risk of developing breast cancer. There are several models that help assess a patient's risk. If no risk factors are noted, she is said to be at average or normal risk, corresponding to the 12% (or one in eight) risk for a woman of developing breast malignancy during her lifetime. Because a woman's risk may change as her family history evolves and new findings occur on imaging, risk assessment should be ongoing.

EPIDEMIOLOGY AND RISKS FOR BREAST CANCER

Breast cancer continues to be the most commonly diagnosed cancer in women worldwide. It is caused by a progressive accumulation of mutations in the cell's DNA. Epidemiologic studies help identify factors that through either exposure or inheritance place a woman at risk for a greater chance of cellular change. Approximately 50% of newly diagnosed breast cancers are attributable to known risk, whereas 10% are associated with simply a positive family history. The degree of risk is important to know in order to advise women and establish plans for screening or interventions.

Most epidemiologic literature when reporting breast cancer risks describes the risk from any given factor as a relative risk. Relative risk is the risk compared with subjects in an exposed group to subjects in a comparison or nonexposed group. In contrast, clinical and genetic studies usually report results as a woman's lifetime risk: the risk of developing or dying from a disease over the course of one's lifetime. The distinction can be confusing for patients and families. For example, the *BRCA* mutation causes a 10 times increase in relative risk and up to an 85% lifetime risk. Clinicians must be aware of the difference when reviewing the literature and subsequently when counseling patients and their families.

The risk factors for breast cancer may be divided into several categories (Table 15.2): demographic, estrogen exposure, lifestyle, personal breast characteristics, familial and inherited genetic mutations, and radiation exposure. Risk is generally grouped as minor and major. Minor risk factors increase a woman's lifetime risk from 12% to approximately 15%. Importantly, epidemiologic studies have also noted factors that decrease a woman's risk (Table 15.3).

DEMOGRAPHIC ASSOCIATIONS

Age continues to remain the strongest risk factor for developing breast cancer. The risk of breast carcinoma increases directly with the patient's age (Box 15.2). Data from the Surveillance, Epidemiology, and End Results (SEER) database report the probability of a woman developing breast cancer from birth to age 39 as 0.49% (1 in 203 women) compared with 6.58% (1 in 15 women) at age 70 or older (Siegel, 2012).

Table 15.2 Risk Factors for Breast Cancer

Risk Factor	Qualification
Demographic—minor (less than $5 \times RR$)	
Age	Rare under age 30, common in sixth and eighth decades
Geographic	Common in Western countries
Estrogen exposures—minor	
Age at menarche	Younger than 12 years old
Age at first birth	Older than 30 years old
Late menopause	
Hormone replacement therapy	
Lifestyle—minor	
Alcohol use	Dose related (two or more drinks daily)
Sedentary lifestyle	
Obesity	
Postmenopausal weight gain	
Low vitamin D	
Abnormal day/night work patterns (airline attendants and variable shifts)	
Breast characteristics—minor	
Benign breast disease	Very low increased risk
Hyperplasia without atypia on biopsy	
Breast characteristics—major (increasing a woman's risk $>5 \times RR$)	Major factors usually push a woman into the high-risk category
Dense breasts	Density proportional to increase in risk Increased fibroglandular elements
Hyperplasia with atypia	
Previous breast cancer	
Familial factors—minor	
Multiple relatives, not first-degree, with breast cancer	
One first-degree relative with breast cancer	First degree—mother or sister
Family history—major	
Two or more first-degree relatives	Increased risk if the cancers are premenopausal
Inherited breast cancer syndrome such as <i>BRCA</i>	Very high risk
Radiation—minor	
Exposure to chest CT	
Radiation—major	
Mantle radiation for treatment of malignancy	Very high risk, which increases with age

CT, Computed tomography; RR, relative risk.

The incidence of breast cancer varies based on geographic region. The highest rates are found in North America, Australia/New Zealand, and Western and Northern Europe. Women in Eastern Europe, South Africa, Japan, and the Caribbean form a middle group in terms of incidence. The lowest incidences are found in Asia and sub-Saharan Africa.

In the United States, white women have the highest rate of breast cancer; however, black women have a higher breast cancer mortality. Data from 2005 to 2009 report the rate of newly diagnosed breast cancer was 122 per 100,000 white women and

Table 15.3 Factors Associated with a Decreased Risk for Breast Cancer

Demographic	Qualification
Born and living outside Western countries	
Estrogen exposures	
Late menarche	After age 14
Oophorectomy	Prior to age 35 without supplemental estrogen
Lactation	Proportional to total cumulative months breast-feeding
Age of first birth	Prior to age 20
Parity	5 or greater
Induced abortion	Trend ($5 < P < .1$)
Lifestyle	
Postmenopausal body mass	Minimal postmenopausal weight gain
Physical activity	
Dietary	
Vitamin D	Low levels associated with risk
Intake of vitamin D	Associated with decreased risk
Olive oil and omega 3 fatty acids	
Low-fat diet	Results suggestive but not yet conclusive
Medications	
Aspirin	Associated with decreased incidence, recurrence, and mortality

Box 15.2 A Woman's Risk of Having Developed Breast Cancer

Age	Risk
25	1 in 19,608
30	1 in 2525
35	1 in 622
40	1 in 217
45	1 in 93
50	1 in 50
55	1 in 33
60	1 in 24
65	1 in 17
70	1 in 14
75	1 in 11
80	1 in 10
85	1 in 9
Ever	1 in 8

Data from National Cancer Institute. Painter K. Factoring in cost of mammograms. *USA Today*. December 5, 1996, p 11D.

117 per 100,000 black women. Black women more commonly presented with regional or advanced disease (45% vs. 35%) and had a 41% higher breast cancer specific mortality rate (32 vs. 22 deaths per 100,000 women) ([Centers for Disease Control and Prevention \[CDC\], 2012](#)). This difference may be due to several factors that include both socioeconomic aspects as well the histologic variety of tumors.

ESTROGEN-RELATED EXPOSURE RISKS

Breast cancer risk is increased with high endogenous estrogen levels in both premenopausal and postmenopausal women. This

effect is especially noted in hormone receptor–positive breast cancer. Various studies have shown that both prolonged exposure to and higher concentrations of estrogen are associated with a higher risk of breast cancer. Breast cancer is rare in the prepubertal female. Women who have breast cancer and undergo oophorectomy have a lower recurrence rate. Interestingly, the rate of recurrence in oophorectomized women is decreased, even in women with hormone-receptor-negative cancers.

Reproductive factors must also be considered in determining the risk of developing breast cancer. Nulliparous compared with parous women are at an increased risk of breast cancer, but the protective effect of pregnancy is not noted until 10 years following delivery. It is unclear whether an association exists between either multiparity or nulliparity and breast cancer. The age at which a woman delivers her first child is an important risk factor. Age at first pregnancy was analyzed in the Nurses' Health Study. When compared with nulliparous women at or near menopause, women who delivered their first child at age 20, 25, or 35 years had a cumulative incidence of breast cancer (up to age 70) of 20% lower, 10% lower, and 5% higher, respectively (Colditz, 2000). Early age at menarche is associated with a higher risk of breast cancer. Women with menarche at or after age 15 years of age compared with menarche before the age of 13 years were less likely to develop estrogen receptor–positive breast cancer. Additionally, a 16% decreased risk of estrogen receptor/negative breast cancer was noted in women with menarche at or after age 15 years.

Breast-feeding decreases the risk of breast cancer. A pooled analysis of data from 47 studies involving 50,302 women with breast cancer and 96,973 women without the disease found a direct correlation between the length of time of lactation and decreasing risk for breast malignancy (Collaborative Group on Hormonal Factors in Breast Cancer, 2002). Women who breast-fed longer were more protected against breast cancer. The relative risk of breast cancer decreased by 4.3% per 12 months of breast-feeding. This decrease did not vary significantly by parity, ethnicity, age of menarche and menopause, and geographic factors. Newcomb and colleagues reported that after adjusting for parity, age at first delivery, and other confounding factors, lactation was associated with a slight reduction in the risk of breast cancer among premenopausal women compared with those who had never lactated (relative risk [RR] 0.78, confidence interval [CI] 0.6 to 0.91) (Newcomb, 1994). Overall, breast-feeding decreases the risk of breast cancer in a dose-response relationship.

Hormone replacement, specifically the use of combined estrogen and progesterone, is an established risk factor for breast cancer. Data from the Women's Health Initiative (WHI) showed that compared with the placebo group, combined hormone replacement increases the risk of breast cancer by 24%. Estrogen-only use in women with a history of a hysterectomy did not increase the risk of breast cancer (Chlebowski, 2003). The decision to use hormone replacement therapy in patients with and without other risk factors should be individualized and the risks and benefits discussed so that the woman may make an informed decision. Unlike hormonal replacement, oral contraceptives and other forms of estrogen-related contraception do not increase the risk of breast cancer. Multiple studies have noted that the oral contraceptives used since the 1980s do not pose an increased risk compared with the extremely high levels of estrogen used in oral

contraceptives in the 1960s and 1970s. There is no association between abortion and breast cancer incidence.

LIFESTYLE AND DIETARY RISK FACTORS

The relationship between dietary habits and the risk of breast cancer is not clear. A direct association between dietary fat and the risk of breast cancer has not been clearly established. Various studies have failed to show a significant association between the highest and the lowest category of consumed dietary fat and an increased risk of breast cancer. In the WHI study of postmenopausal women, the dietary arm of the study evaluated 48,835 healthy postmenopausal women who tried to reduce fat intake (Prentice, 2006). There was a minimal effect on decreasing malignancy in the breast, (RR, 0.91; CI, 0.83-1.01) after a mean follow-up of 8.1 years. Although no direct association between dietary fat intake and breast cancer risk has been established, there may be a modest effect when comparing extremes of fat intake. In the AARP Diet and Health Study, women in the highest quintile of fat intake had rates of invasive breast cancer 11% to 22% higher than those of women in the lowest quintile (Thiébaud, 2007). Although obesity is associated with a general increase in morbidity and mortality, the risk of breast cancer related to body mass index (BMI) is linked to the menopausal status of women. Obese women are at a higher risk for developing breast cancer during their postmenopausal years, with increased amounts of peripheral conversion of androstenedione to estrone. In premenopausal women, an increased BMI is associated with a lower risk of breast cancer.

Studies also have found a significant association with decreased levels of vitamin D and decreased calcium and increased risks of breast cancer and increased morbidity once breast cancer is diagnosed. Increase in plasma 25-hydroxyvitamin D (25[OH]D) levels between 27 and 35 ng/mL, were associated with a decrease in breast cancer risk in postmenopausal women (Bauer, 2013). No association between 25(OH)D levels and breast cancer risk is noted in premenopausal women. Antioxidant supplementation (vitamin A, E, or C, or beta carotene) has not been shown to be protective for breast cancer. Data regarding the effect of non-steroidal anti-inflammatory drugs (NSAIDs) on breast cancer risk is varied. Several small studies and a nested study from the WHI noted aspirin to decrease risk for breast cancer, breast cancer recurrence, and breast cancer mortality; however, data from the Nurses' Health Study showed no association between use of aspirin, NSAIDs, or acetaminophen and the incidence of breast cancer (Zhang, 2012).

Alcohol consumption has been associated with increased risk for multiple cancers including breast cancer. Older studies reported a 40% to 50% increase in the relative risk of developing breast cancer related to alcohol consumption. The alcohol effect was primarily in estrogen receptor–positive tumors. Breast cancer risk is higher in women consuming both low and high levels of alcohol compared with no consumption. Longnecker showed that the risk of breast cancer was strongly related to the amount of alcohol consumed and that even light drinking was associated with a 10% increase in relative risk (Longnecker, 1994). A 2013 meta-analysis of 110 epidemiologic studies reported a 5% (RR 1.05%) increase in female breast cancer with light alcohol intake (Bagnardi, 2013).

Phytoestrogens are naturally occurring plant substances with a chemical structure similar to 17-beta estradiol. They consist mainly of isoflavones (found in high concentrations in soybeans and other legumes) and lignans (found in a variety of fruits, vegetables, and cereal products). There is low-quality evidence that soy-rich diets in Western women prevent breast cancer. A 2008 meta-analysis of eight studies evaluated the impact of soy food intake and breast cancer risk (Wu, 2008). A higher intake of isoflavones (≥ 20 mg per day) was associated with a 29% reduction in breast cancer risk in Asian women but no association with soy intake was noted among Western women. Of note, the highest level of soy intake in Western women was only about 0.8 mg daily, which may not have been an adequate amount to detect an effect.

Various miscellaneous environmental exposures have been studied for possible associations with the development of breast cancer. Megdal and associates found in a 2005 meta-analysis of 13 studies that altered day/night exposure, shift work, and increased light exposures to show an increased risk of breast cancer, RR 1.48 (CI: 1.36-1.61). Suppression of nocturnal melatonin production by the pineal gland secondary to nocturnal light exposure may contribute to the increased risk of developing breast cancer. Magnetic radiation, power lines, computer terminals, and electric blanket exposure do not increase the risk of breast cancer. Breast implants have not been shown to increase the risk for breast cancer.

BREAST HISTORY AND BREAST CHARACTERISTICS

Women with a personal history of breast cancer or ductal carcinoma in situ are at an increased risk of developing invasive breast cancer in the contralateral breast. Analysis of SEER data showed the incidence of invasive contralateral breast cancer in women with a history of primary breast cancer was 4% during a 7.5-year follow-up period (Nichols, 2011). The risk of a contralateral breast cancer depends on the age at the time of the index breast cancer diagnosis in conjunction with the hormone receptor status of the primary tumor. The presence of ductal carcinoma in situ did not modify the rate of contralateral breast cancer.

Boyd and coworkers reported that women with dense breasts, as defined by more fibrous tissue, have a relative risk of 4.7 (CI: 2-6.2) for breast cancer (Fig. 15.10) (Boyd, 2007). This finding has been verified in other studies, and the increased risk is not due to a more difficult or later diagnosis but to the biologic characteristics

Figure 15.10 Risks of breast cancer with increasing breast density. (Modified from Santen RJ, Mansel R. Benign breast disorders. *N Engl J Med*. 2005;353[3]:275-285.)

of the breast itself. Women with dense breasts noted on mammograms (dense tissue involving at least 75% of the breast) have a risk of breast cancer four to five times greater compared with women with less dense tissue. Both usual and atypical hyperplasia increases the risk of breast cancer. There is a mild increase in risk when biopsies have shown hyperplasia; however, hyperplasia with atypia increases the risk by four to six orders of magnitude. The cumulative incidence of breast cancer among women with atypical hyperplasia approaches 30% at 25 years of follow-up.

INHERITED AND FAMILIAL RISKS

Most cases of breast cancer are sporadic in nature and not an inherited cancer. About 5% to 10% of all breast cancers are caused by an inherited gene mutation. There are at least four specific breast cancer syndromes, each associated with a specific mutation. Each of these syndromes is autosomal dominant and involves mutations in the proteins that repair DNA. The most common are the mutations in the breast cancer susceptibility gene 1 (*BRCA1*) and breast cancer susceptibility gene 2 (*BRCA2*). Less common are Li-Fraumeni syndrome, associated with the *p53* gene, and Cowden syndrome, associated with the *PTEN* gene (Table 15.4).

Women with genetic syndromes tend to develop breast cancer at earlier ages and tend to have more aggressive tumors with a higher prevalence of bilateral disease. Hereditary breast and ovarian cancer (HBOC) syndrome is the most common cause of hereditary breast and ovarian cancers. This syndrome is associated with *BRCA1* and *BRCA2* mutations and is responsible for approximately 5% of breast cancer cases in the United States. Though the incidence of *BRCA* mutation is 1:250 in the United States, due to the founder effect the prevalence of *BRCA1* and 2 mutations is variable among ethnic groups and geographic area. It is highest among Ashkenazi Jews, in which approximately 2% of the population carries a deleterious *BRCA1* or 2.

The *BRCA* genes code for very large tumor suppressor proteins. Germ line mutations in *BRCA* genes result in mutation carriers losing one of their wild-type alleles. These mutation carriers have only one functional allele of these genes in their cells. Tumors in carriers tend to demonstrate loss of the other wild-type allele through other somatic mutations or loss of heterozygosity. This genomic instability of women with *BRCA* mutations

Table 15.4 Major Inherited Gene Mutation Syndromes Associated with Breast Cancer

Syndrome	Gene	Incidence	Lifetime Breast Cancer Risk	Associated Cancer Risks
<i>BRCA 1</i>	<i>BRCA 1</i>	1/500 to 1/1000	85%	Ovary and pancreas
<i>BRCA 2</i>	<i>BRCA 2</i>	Unclear	85%	Ovary and pancreas
Cowden	<i>PTEN</i>	1/100,000 to 1/200,000	50%	Thyroid and endometrium
Li-Fraumeni	<i>TP53</i>	1/20,000	90%	Sarcoma, brain, and leukemia

Other syndromes, including Peutz-Jeghers syndrome, ataxia telangiectasia, *CHEK2* gene mutation, and Fanconi syndrome, have much smaller lifetime risks with poorer penetrance.

causes them to be more susceptible to further mutations of DNA, which subsequently leads to malignant transformation of breast and ovarian epithelial cells.

BRCA1 has 1863 amino acids, with several different functions, and was mapped at 17q21. In combination with several other genes including *BARD1*, *BRCA2*, *CHK1*, and *RAD51*, *BRAC* is involved in repair of double-strand DNA breaks and control of cell cycle checkpoints. Women with a *BRCA1* mutation have a risk of breast cancer of approximately 55% to 70% to age 70 and an average lifetime risk of ovarian cancer approaching 40%. The *BRCA2* gene was mapped to chromosome 13q12 and the DNA sequence determined by Schutte and coworkers in 1995. Women with a *BRCA2* gene mutation have a 45% to 70% risk of breast cancer to age 70 and a 15% to 20% lifetime risk of ovarian cancer. The risk of a contralateral breast cancer in women with a deleterious *BRCA1* or *BRCA2* mutation has been estimated to range from 10% to 65%. The contralateral breast cancer risk also depends upon age of first breast cancer presentation with the risk being higher when the age diagnosis is less than 40 compared with older than 50 years of age. *BRCA2* mutations are also associated with male breast cancers, conferring a 5% to 10% risk for a man who has inherited the mutation. Because male breast cancer is so rare, any male with breast cancer should be tested for a *BRCA* mutation.

Data also suggest a potential role of *BRCA1* and *BRCA2* mutations in sporadic breast and ovarian cancers, in particular triple-negative (i.e., breast cancers that lack expression of the estrogen receptor, progesterone receptor, and human epidermal growth factor receptor 2 [HER2]) breast cancers, some of which exhibit hypermethylation of *BRCA1*, *BRCA2*, or other downstream genes, leading to abnormal gene expression. The genomic instability of *BRCA1*- and *BRCA2*-deficient cells in hereditary and triple-negative breast cancer provides an opportunity for therapeutic development, especially drugs that target DNA repair pathways. This includes platinum-type drugs that generate double-stranded DNA breaks or poly (adenosine diphosphate-ribose) polymerase (PARP) inhibitors, which are involved in the repair of DNA single-strand breaks.

Women with a family history of breast cancer have an increased risk of developing breast cancer. Approximately 15% of breast cancers are related to familial risk. Women in such families have a combination of low penetrance polygenic inheritance contributing to their personal risk. The risk for breast cancer is significantly affected by the number of female first-degree relatives with and without cancer. The risk increases for a woman the more relatives she has with breast cancer. Additionally, the age at diagnosis of the affected first-degree relative is another factor that influences the risk for breast cancer. The risk is threefold higher if the first-degree relative was diagnosed before age 30. Models that will predict a woman's breast cancer risk are discussed later.

RADIATION EXPOSURE

Exposure to therapeutic ionizing radiation is a recognized risk factor for the development of breast cancer. The risk of developing breast carcinoma is consistent with a linear dose-response relationship. This was first recognized in Japanese women who survived the atomic bombs, with exposed teenagers developing breast carcinoma in high incidence in their 30s. Other historical

examples of ionizing radiation-induced breast cancer include women with a history of radiation treatments for postpartum mastitis, irradiation of the thymus in infancy, or multiple fluoroscopic examinations during treatment for tuberculosis. Currently, women at highest risk from radiation exposure are those who were treated with radiation for childhood malignancies, in particular Hodgkin lymphoma. Those with prepubertal exposure represent the most vulnerable age group; however, increased risk is evident in women exposed as late as 45 years of age. It is important to differentiate therapeutic ionizing radiation from radiation exposure from diagnostic imaging. One 64-slice chest computed tomography (CT) adds to a woman's lifetime risk of breast cancer by less than 1%.

RISK ASSESSMENT AND PREVENTION

Stratification of a woman's risk of developing breast cancer is paramount. This should be an ongoing and dynamic process, as her risk increases with age and with changes in both personal and family history. The chance of developing a malignancy can be calculated based on her risk profile. This profile will influence the recommendations for both her screening as well as for preventive measures such as chemoprevention.

The risk factors that influence a woman's chances of developing a malignancy are multifactorial. With the exception of certain genetic mutations, a single risk factor is not sufficient by itself to stratify a woman into a risk group. Consequently, individualized counseling is the most effective approach to evaluating risk. Risk factors can be stratified into (1) major factors that increase relative risk greater than two times normal and (2) minor factors (see Table 15.2). A women's personal risk of developing breast cancer is divided into three levels: average, moderate, and high. Additionally, within the latter group a very high-risk group is identified for purposes of prophylactic options (Table 15.5). Women of average risk have a personal risk of about 12% of developing breast cancer, the risk of the general population. In the moderate risk group, women have personal risks from 12% to 15% of developing breast malignancy during their lifetime and have one or more minor risk factors. Women

Table 15.5 Risk Levels for the Development of Breast Cancer

Level	Lifetime Risk for Breast Cancer	Recommendations for Screening
Average	12%	Yearly exams and mammograms beginning at age 40
Moderate	12% to 15%	Yearly exams and mammography beginning at age 40
High	15% to 20%	Yearly exams and mammography beginning at age 40; offer chemoprevention
Very high risk	>20%	Exams every 6 months; mammography alternating with MRI should be started on an individualized basis depending on the risk factor (e.g., for women with mantle radiation, imaging should begin at age 30 or 8 years after radiation is finished); offer chemoprevention

in the moderate risk category do not need any changes from those of the general population in screening recommendations. Women at high risk include those who have greater than a 15% personal risk of developing breast cancer, usually from a major risk factor. In the very high-risk category, women have a personal risk over 25% and include women with a *BRCA* mutation or those who have had mantle radiation. They are often referred to breast specialists for ongoing evaluation.

Several models have been empirically developed to estimate a woman's risk of breast cancer. The most widely available and accepted tool is the Breast Cancer Risk Assessment Tool (BCRAT) developed by Dr. Mitchell Gail and is commonly known as the *Gail model*. The original model was based on data acquired from the Breast Cancer Detection and Demonstration Project to calculate the risk of a woman developing breast cancer over the next 5 years till the age of 90. The model was developed in white women, taking into account age, race, age of menarche, number of births, number of first-degree relatives with breast cancer, and number of breast biopsies that have shown atypia. This model has been updated to estimate the risk for African-American women using data from the Contraceptive and Reproductive Experiences Study and for Asian-American and Pacific Islander women using data from the Asian American Breast Cancer Study (Gail, 2007; Matsuno, 2011). The BCRAT was designed for women who have never had a diagnosis of breast cancer, ductal carcinoma in situ (DCIS), or lobular carcinoma in situ (LCIS) and who do not have a strong family history suggesting an inherited gene mutation. It is not applicable to women with more than two first-degree relatives with breast cancer and does not consider more distant relatives, the age at which relatives developed breast cancer, or a family history of ovarian cancer. It is not useful for women with a strong family history of breast cancer on the paternal side. Most important, it does not estimate the risk of carrying a deleterious *BRCA1* or *BRCA2* gene.

The Claus model, developed by Elizabeth Claus in 1994, uses data from the Cancer and Steroid Hormone Study. This model uses first- and second-degree relatives, both maternal and paternal, to calculate risk but does not use risk factors beyond family history and also is not as robust in nonwhites. The Claus model provides the lifetime risks for a woman over any given decade of her life.

Computerized risk prediction models have been developed to not only assess the risk of breast cancer but also the risk of carrying a deleterious *BRCA1* or *BRCA2* genes and include the BRCAPRO model (incorporates six predictive models for inherited or familial breast cancer), the International Breast Cancer Intervention Study or Tyrer-Cuzick model (incorporates both genetic and nongenetic risk factors to determine the risk of developing breast cancer and estimates of *BRCA1/2* mutation probabilities), and the BOADICEA model (developed to determine breast and ovarian cancer susceptibility because of genetic mutations).

An important role of the clinician in evaluating a woman's breast cancer risk is to determine which women should be evaluated for the inherited cancer syndromes (Box 15.3). There are several risk factors that raise suspicion for an inherited mutation. If a woman has a 5% to 10% probability of having a *BRCA* mutation, then she should be referred to a genetic counselor for a comprehensive assessment and workup of the family history.

Reasons for referral to a genetic counselor for hereditary cancer risk evaluation include patients with a female breast cancer diagnosed at a young age (<50 years), a triple-negative receptor tumor, two or more synchronous primary breast cancers, male breast cancer, or invasive ovarian/fallopian tube/primary peritoneal cancer. Additional criteria include women with first-degree (sister, mother, or daughter) relatives with a history of breast cancer, a confirmed mutation in another family member, and women of Ashkenazi Jewish heritage, especially those with a family history of ovarian or breast cancer. Pre- and postgenetic counseling is essential and includes discussing the issues and implications of the results, legal and insurance aspects, noninformative results, and choices for chemoprevention or surgical prophylaxis. Women with negative or noninformative *BRCA* results may still need high-risk screening, as their risks may be greater than that of the general population.

The benefits of screening have been emphasized by major health societies and professional organizations (Table 15.6). The U.S. Preventive Services Task Force (USPSTF) recommendations updated the screening guidelines for breast cancer in 2015. The task force's recommendations were designed for women age 40 and older who do not show any signs or symptoms of breast cancer, who have no personal history of breast cancer, and who do not have a known genetic mutation or a history of chest radiation at a young age. The updated recommendations are as follows: (1) routine screening of average-risk women should begin at age 50, (2) routine screening should end at age 74, (3) women should get screening mammograms every 2 years, and (4) recommend against teaching breast self-examination. These recommendations were based on evidence that shows the value of mammography increases with age, with women ages 50 to 74 benefiting the most. In this age group screening is most beneficial and has the least amount of harm when performed every 2 years.

The American College of Obstetricians and Gynecologists (ACOG) recommends annual mammography screening for healthy women beginning at age 40. ACOG recommendations include screening mammography every 1 to 2 years for women aged 40 to 49 years and screening mammography every year for women aged 50 years or older (ACOG, 2011).

The American Cancer Society (ACS) screening guidelines for women with an average risk of breast cancer were revised in 2015. The updated recommendations are as follows: (1) regular screening mammography starting at age 45 years, (2) annual screening

Box 15.3 Indications for Referral for Genetic Counseling for *BRCA* Gene Testing

- Personal history of both breast and ovarian cancer
- Personal history of ovarian cancer or premenopausal breast cancer and Ashkenazi Jewish ancestry
- First-degree male relative with breast cancer
- Personal history of premenopausal breast cancer, particularly if it is triple negative
- Personal history of breast cancer and two first-degree relatives with breast cancer, any ages
- Personal history of high grade serous ovarian cancer (also primary peritoneal or fallopian tube cancers)

Modified from American College of Obstetricians and Gynecologists, et al. ACOG Practice Bulletin No. 103: hereditary breast and ovarian cancer syndrome. *Obstet Gynecol.* 2009;113:957-966.

Table 15.6 Professional Society Recommendations for Screening Mammography

Organization	Age to Initiate Mammography	Age to Conclude Mammography	Interval between Screenings
American Academy of Family Physicians	Routinely at ≥ 50 y Screening before age 50 should be individualized	Screening recommended to age 74 y Evidence insufficient for age ≥ 75 y	Not stated for age 40-49 y 2 y for age 50-74 y
American Cancer Society	Routinely at ≥ 45 y Offered for age 40-44 y	While in good health and is expected to live 10 more years or longer None stated	1 y for age 45-54 y 2 y for age ≥ 55 y 1 y for all ages

Modified from Nattinger AB. In the clinic. Breast cancer screening and prevention. *Ann Intern Med.* 2010;152(7):ITC41, 2010.

*All values are risk ratio (95% CI). Four trials compared tamoxifen with placebo, two trials compared raloxifene with placebo, and one trial compared raloxifene with tamoxifen.

should be offered to women aged 45 to 54 years, (3) women 55 years and older undergo biennial screening or have the opportunity to continue screening annually, (4) women between the ages of 40 and 44 years should have the opportunity to begin annual screening, and (5) screening mammography should be continued as long as a woman's overall health is good and she has a life expectancy of 10 years or longer (Oeffinger, 2015).

No data exist regarding the ideal age at which to begin clinical breast examinations (CBEs). In the asymptomatic, low-risk patient it is unclear at what age to begin CBEs. The occurrence of breast cancer is rare before age 20 years and uncommon before age 30 years. ACOG and the National Comprehensive Cancer Network recommend that CBE be performed annually in women aged 40 years and older and every 1 to 3 years in women aged 20 to 39 years. Per the USPSTF guidelines, insufficient evidence exists to assess the additional benefits and harms of CBE beyond screening mammography in women 40 years or older. The ACS does not recommend CBE for breast cancer screening among average-risk women at any age.

CHEMOPROPHYLAXIS AND CHEMOTHERAPEUTIC RISK REDUCTION

Breast cancer risk reduction should be considered throughout a woman's life. For women who are high risk, endocrine therapy should be discussed to reduce the risk of invasive or in situ breast cancers. The American Society of Clinical Oncology (ASCO) and the USPSTF both provide recommendations regarding the use of endocrine therapy. Selection criteria in identifying women who would benefit from endocrine therapy include age >60 years, age over 35 years with a history of lobular carcinoma in situ, ductal carcinoma in situ or atypical proliferative lesion of the breast (atypical ductal or lobular hyperplasia), women 35 to 59 years with a Gail model risk of breast cancer $\geq 1.66\%$ over 5 years, and women with known *BRCA1* or *BRCA2* mutations who do not undergo prophylactic mastectomy.

Tamoxifen and raloxifene, both selective estrogen receptor modulators, are proved options that can decrease the risk of breast cancer in high-risk women (Table 15.7). Tamoxifen

blocks the effects of endogenous estrogens in both the normal breast and the one with breast cancer. In the National Surgical Adjuvant Breast and Bowel Project (NSABP) B-14 trial, tamoxifen users had a significant decrease in the incidence of contralateral breast cancers compared with placebo. As a result, the Breast Cancer Prevention Trial (BCPT) was designed to assess whether tamoxifen would decrease the incidence of breast cancer in a high-risk population as determined by the Gail model for breast cancer risk assessment (Fisher, 1998). The trial enrolled 13,388 women in a double-blinded, randomized, placebo-controlled trial to evaluate the effects of tamoxifen on risk reduction. The trial was closed prematurely because of a large discordance between the two groups. Tamoxifen significantly reduced the incidence of breast cancer in this population of patients by 49% compared with controls ($P < .00001$). It did not reduce the incidence of estrogen receptor-negative cancers. A 2013 meta-analysis by the USPSTF analyzed data from four trials comparing tamoxifen to placebo (Nelson, 2013). The results showed a reduction in the risk of invasive breast cancer (RR 0.70, 95% CI: 0.59-0.82), primarily noted in estrogen receptor-positive breast cancer. A significant reduction in the incidence of nonvertebral fractures (RR 0.66, 95% CI: 0.45-0.98) was also seen (RR 0.66, 95% CI: 0.45-0.98). Additionally, the long-term follow-up results from the International Breast Cancer Intervention Study I (IBIS-1) showed a long-term reduction in the risk of hormone receptor-positive breast cancer (Cuzick, 2015). In this study of more than 7000 women, tamoxifen compared with placebo reduced the risk of invasive breast cancer between years 0 and 10 (hazard ratio [HR] 0.72, 95% CI: 0.59-0.88) and after 10 years (HR 0.69, 95% CI: 0.53-0.91). This risk reduction was observed in hormone receptor-positive breast cancer (HR 0.66, 95% CI: 0.54-0.81). Although treatment with tamoxifen compared with placebo is associated with an increased incidence in thromboembolic events and an increased incidence of endometrial cancer, the overall incidence of adverse events is small.

Raloxifene was approved by the Food and Drug Administration (FDA) for breast cancer risk reduction following the results of the Study of Tamoxifen and Raloxifene (STAR) trial (Vogel, 2006). A reduced incidence of thromboembolic events and endometrial cancer was noted in the raloxifene group compared with tamoxifen. In an 81-month median follow-up analysis, long-term raloxifene retained 76% of the effectiveness of tamoxifen in preventing invasive disease and grew closer over time to tamoxifen in preventing noninvasive disease. Less toxicity in regard to the development of endometrial cancer, uterine hyperplasia, and thromboembolic events was observed in the raloxifene group.

Aromatase inhibitors (AIs) are a reasonable alternative to SERMs for postmenopausal women. In the International Breast Cancer Intervention Study (IBIS-II), postmenopausal women at high risk of breast cancer were randomized to treatment with anastrozole or placebo for 5 years (Cuzick, 2014). After a median follow-up of 5 years, a 50% reduction in the number of invasive breast cancer was noted with anastrozole compared with the placebo group (HR 0.47, 95% CI: 0.32-0.68) along with a similar decrease in the incidence of ductal carcinoma in situ (DCIS). However, musculoskeletal side effects, vaginal dryness, and vasomotor symptoms were significantly greater in the anastrozole group.

Women with *BRCA1* mutations have significantly less benefit from tamoxifen. This is because almost all *BRCA1*-associated tumors are hormone receptor negative, unlike *BRCA2* carriers who should be offered chemoprevention. Though these medications are effective, many women do not want to take them because of the side effects related to premature or perimenopausal symptoms. These women should be offered additional medications to control the side effects.

Surgical prophylaxis is another option for the woman who wants to reduce risk. In a retrospective cohort of 639 patients, Hartmann was able to demonstrate a 90% breast cancer risk reduction for the patient with a high risk of breast cancer after prophylactic bilateral mastectomy. In a follow-up study, Hartmann was able to demonstrate a similar risk reduction in a population of women with *BRCA* gene mutations (Hartmann, 2001). Although prophylactic bilateral mastectomy provides the greatest risk reduction, it is usually reserved for the very high-risk patient because of the associated physiologic and complicated psychological consequences. Although most women who have undergone prophylactic bilateral mastectomy do not regret having undergone the procedure, approximately 5% to 20% report dissatisfaction.

DETECTION AND DIAGNOSIS

In the United States and countries with established screening programs, most breast cancers are diagnosed as a result of an abnormal mammogram. However, a significant number are also noted during patient or clinician breast examination, and up to 15% of women are diagnosed with breast cancer not detected on mammography. Breast cancer is usually asymptomatic prior to the development of locally advanced disease. Approximately 10% of women with early breast carcinoma experience breast pain that is associated; however, focal mastalgia is usually associated with a benign condition. The classic sign of a breast carcinoma is a solitary, solid, immovable, dominant breast mass with irregular borders. About 75% of breast cancers present as a palpable breast mass. Axillary adenopathy is a potential sign of more advanced locoregional disease. Nipple discharge is an even less common symptom of breast cancer. Findings suggestive of inflammatory breast cancer include erythema, skin thickening, or skin edema causing the appearance of an orange peel (peau d'orange). With increased screening, many cancers and in situ lesions are found prior to any symptoms.

Screening utilizes tests in asymptomatic women at periodic intervals to discover breast malignancies. There is more scientific evidence regarding screening for breast cancer than for any other cancer. The kinetics of growth in breast carcinoma is the basis for the recommendations for screening and detection. The average breast mass doubles in volume every 100 days, and the diameter doubles every 300 days. A breast carcinoma grows for 6 to 8 years before reaching a diameter of 1 cm, after which it doubles in less than another year. The mean diameter of a breast mass discovered by women who perform BSE at monthly intervals is 2 cm.

The three screening modalities are breast self-examination, clinical breast examination, and imaging with mammography. BSE has the major advantages of no cost to the patient and convenience. However, studies have failed to show a beneficial

effect of regular BSE in rates of breast cancer diagnosis, mortality, or tumor stage or size. BSE is associated with higher rates of breast biopsy for benign disease. Clinical breast examination (CBE) and mammography are complementary procedures and therefore the effectiveness of CBE in screening by itself is difficult to assess. As part of the screening process, the sensitivity of CBE was estimated to be 54% and specificity 94% (Barton, 1999). Various imaging modalities are available for identifying lesions that are suspicious for breast cancer. Mammography continues to be the primary choice in screening for breast cancer. It is important to note that a negative mammogram does not rule out breast carcinoma. Ultrasound is used as an adjunct to mammography for diagnostic follow-up of an abnormality seen on screening mammography. Additional imaging techniques include MRI and tomosynthesis. Current data do not support the use of MRI in screening women at average risk for breast cancer. Its use is limited to screening in high-risk patients. Newer tests, such as tomography, are under evaluation.

In summary, present protocols for screening of breast carcinoma are not ideal and continue to evolve. Nevertheless, screening tests result in a reduction in the mortality rate from breast cancer of approximately 25% to 30%.

SELF-EXAMINATION OF THE BREASTS

Few randomized trials regarding breast self-examination exist. A 2003 Cochrane systematic review included two large population studies from China and Russia. Twice as many biopsies with benign results were performed in the screening group compared with the control group (RR, 1.89; 95% CI: 1.79-2.00) (Gemignani, 2011). Several other studies did not show an advantage of breast self-examination in the rates of breast cancer diagnosis, breast cancer death, or tumor stage or size. Although this procedure has long been advocated, breast self-examination in itself does not decrease breast cancer mortality. However, research has shown that routine breast self-examination does play a role in detecting breast cancer compared with finding a breast lump by chance or simply knowing what is normal for each woman. For this reason, some societies continue to recommend self-breast examination. ACOG recommends breast self-awareness, which for some patients includes performing a BSE and reporting changes to their physician. The ACS recommends educating women about the benefits and limitations of BSE and to report any changes. BSE is an option for women starting in their 20s. The USPSTF, however, recommends against teaching breast self-examination.

Women who choose to perform a BSE should do so when their breasts are least likely to be tender or swollen. In premenopausal women, a few days immediately after a menstrual period are the best time to detect changes in normal lumps or texture of the breasts. Postmenopausal women or women who have had a hysterectomy should be instructed to perform BSE on the same calendar days each month. Breast changes that women should be aware of include development of a lump or mass, swelling of the breast, nipple abnormalities or discharge, and skin irritation or dimpling. The examination is best done in both supine and upright positions using the finger pads of the three middle fingers. Three different levels of pressure (light, medium, and firm) are used to examine the breast. Women should be consistent in their technique used. One of the easier techniques to follow is to

palpate the breasts in a clockwise fashion beginning at the nipple and gradually circumscribing larger circles; however, some advocated the vertical pattern (up and down pattern) as the most effective pattern for examining the entire breast without missing any breast tissue.

CLINICAL BREAST EXAMINATION

Several studies have investigated the use of physical exam in addition to mammography; however, for ethical reasons no randomized trial comparing physical exam without mammography has been conducted. In meta-analysis investigating the effectiveness of CBE, Barton and colleagues included all controlled trials and case-control studies in which CBE was at least part of the screening process (Barton, 1999). CBE alone detected between 3% and 45% of breast cancers that were missed during mammography screening. The authors estimated CBE sensitivity at 54% and specificity at 94%. Factors associated with greater accuracy included longer duration of exam and a higher number of specific techniques used during the exam.

Considerable variability exists among physicians ability to detect breast lumps. Fletcher and coworkers tested the physical examination techniques of 80 different physicians using simulated breasts (Fletcher, 1985). Detection rates ranged from 17% to 83%. The ability to detect the mass was directly related to the size of the mass; 87% of 1-cm, 33% of 0.5-cm, and 14% of 0.3-cm masses were discovered. Physicians with higher discovery rates spent more time performing the examination.

Differing guidelines exist in the medical literature regarding the use of CBE in breast cancer screening protocols. However, it must be noted that no group recommends clinical breast examination alone. The ACS does not recommend clinical breast examination for breast cancer screening at any age among average-risk women. ACOG recommends clinical breast examination for everyone every 3 years from age 20 to 39, and annually thereafter. The USPSTF recommendations state that current evidence is insufficient to assess the additional benefits and harms of CBE beyond screening mammography in women 40 years or older.

Several palpation techniques exist for the clinical breast examination, and limited comparative data on the efficacy of these techniques are available. A complete breast examination involves inspecting and palpating the breasts with the patient in the sitting as well as the supine position. Initially in the sitting position with the patient arms at her sides, the clinician observes the contour, symmetry, and vascular pattern of the breasts and the skin for irritation, retraction, or edema. The patient is next asked to raise her arms over her head and any tethering of breast tissue to the chest wall should be noted. Examination of the axilla and supraclavicular nodes is best performed with the patient sitting upright. The breast examination is then performed in the supine position with both the woman's arms at her side and raised above her head. The examination includes palpation of all quadrants of the breast, axilla, supraclavicular areas, and adjacent chest wall. Palpation should use the pads of the first three fingers placed together, exerting firm but gentle pressure. It is important to examine both nipples for retraction or skin irritation. The areola should be compressed to identify any discharge. The normal

(From Degrell I. *Atlas of Diseases of the Mammary Gland*. Basel, Switzerland: S Karger; 1976:20.)

breast has a small depression directly below the nipple. The skin of the breast is again carefully inspected for unusual vascular patterns, edema, erythema, or retraction (Fig. 15.11).

MAMMOGRAPHY

The goal of screening mammography is the detection of cancer before it is clinically palpable and less likely to have progressed to the regional nodes or distant metastases. Mammography may identify cancer up to 4 years before it comes clinically evident. The 5-year survival rate for women whose breast cancer is believed to be localized to the breast with negative axillary nodes is approximately 99% versus 84% with regionalized disease (when axillary nodes are involved). In contrast to screening mammography, diagnostic mammography is performed when women have complaints such as breast pain, a palpable lump (or mass), nipple discharge, abnormality on a screening study, or to follow women who have been treated for breast cancer.

Screening mammography is the primary imaging technique for breast cancer detection and the only breast imaging method found to reduce breast cancer related mortality. Mammography uses x-ray photons and can identify fine calcifications or small asymmetric densities associated with breast neoplasms months to years before the carcinoma enlarges to a size that may be

palpated on physical examination. Nine randomized controlled trials using mammography with or without a clinical breast examination have been conducted. Systematic reviews of the trials differentiating mammogram screening with no screening indicate a protective effect among women ages 40 to 69. A 2012 meta-analysis of randomized trials showed a 20% relative risk reduction for breast cancer mortality in women who underwent screening compared with controls ([Independent UK Panel on Breast Cancer Screening, 2012](#)). However, critics suggest that breast cancer screening now may be less effective as the majority of these trials were initiated before 1990 and do not reflect modern therapy or modern imaging.

In the detection of breast cancer, the sensitivity of mammography ranges from 80% to 90% and decreases in women with dense breasts. Density is not a function of the size or firmness of the breast but refers to the ratio of glandular tissue to fatty elements. It is also a significant risk factor for the development of breast cancer. In cases where a woman is noted by plain-film mammography to have dense breasts, she should be referred for digital mammography preferably with tomosynthesis, or if she has dense breasts and she is in a known high-risk group, greater than 20% risk of the development of breast cancer, she should be offered an MRI.

Mammographic views can be generalized into two groups: standard views and supplementary views. The mediolateral

Figure 15.12 A, Right breast, MLO view. B, Right breast, CC view. (Courtesy of Laura Isley, MD.)

oblique (MLO) view and the craniocaudal (CC) view (Fig. 15.12) are the two standard projections performed on routine screening. The MLO view is the most important projection as it depicts the greatest amount of breast tissue and is the only view that includes all of the upper outer quadrant and axillary tail. The amount of visible pectoral muscle in the MLO view determines the amount of breast tissue included in the image. This is an important factor in reducing the number of false negatives and increasing the sensitivity of mammography. Additionally, it is important to visualize the upper outer quadrant in the MLO view as most breast pathology develops in this area. An optimal CC view depicts the external lateral portion of the breast, the retromammary fat tissue (Chassaignac's bag), the pectoral muscle on the posterior edge, and the nipple.

Abnormalities noted on mammography include calcifications, masses, asymmetry, and architectural distortion. The most specific mammographic feature of malignancy is a focal mass with spiculated margins (Fig. 15.13). The positive predictive value of a mass with a spiculated margin is 81% and with irregular shape it is 73%. Clustered microcalcifications (Fig. 15.14) are noted in approximately 60% of cancers detected mammographically. Microcalcifications range from 0.1 to 1 mm in diameter, and the presence of five or more calcifications within a volume of 1 cm³ is termed a *cluster*. Subsequent breast biopsies will find 25% of clusters associated with cancer and 75% with benign disease. Clustered microcalcifications can be associated with intraductal calcifications in areas of necrotic tumor or calcifications within mucin-secreting tumors. Linear branching microcalcifications have a higher predictive value for malignancy than do granular microcalcifications, particularly for high grade DCIS. Breast cancers, including DCIS, are more often diagnosed with the granular type of calcifications.

Mammographic findings are summarized employing the American College of Radiology Breast Imaging Reporting and Data

Figure 15.13 Spiculated breast mass. (Courtesy of Laura Isley, MD.)

System (BI-RADS) (Fig. 15.15). This reporting system was devised to standardize mammographic terminology, reduce confusing interpretations, and facilitate the monitoring of outcomes. There are six assessment categories, each associated with a specific risk of cancer. Category 0 is an incomplete assessment and therefore requires additional evaluation, which may include further imaging. Categories 1 and 2 are nonmalignant. Category 3 represents a lesion that is felt to be benign but requires interval follow-up imaging to confirm

Figure 15.14 Breast microcalcifications. (Courtesy of Laura Isley, MD.)

BI-RAD class	Description	Probability of malignancy (%)	Follow-up
0	Needs additional evaluation	1	Diagnostic mammogram, ultrasound
1	Normal mammogram	0	Yearly screening
2	Benign lesion	0	Yearly screening
3	Probably benign lesion	<2	Short-interval follow-up
4	Suspicious for malignancy	20	Biopsy
5	Highly suspicious malignancy	90	Biopsy

BI-RAD, Breast Imaging Reporting and Data Systems.

Figure 15.15 BI-RAD classification of mammographic lesions. (From Pazdur R, Coia LR, Hoskins WJ, Wagman LD, eds. *Cancer Management: A Multidisciplinary Approach*. 4th ed. Melville, NY: Cligott Publishing Group; 2006:143.)

stability. Categories 4 and 5 are lesions felt to be suspicious enough to warrant biopsy. Category 6 represents malignancy that has been proved. The BI-RADS final assessment is provided to standardize the reporting of mammographic findings and provide recommendations for further management.

DIGITAL MAMMOGRAPHY

Digital mammography is the technique by which the radiographic image is obtained with digital detectors and recorded electronically in a digital format. The image is further processed and displayed as a gray-scale image that can be displayed in multiple formats. Digital mammography has several advantages compared with conventional film screen mammography.

Figure 15.16 Breast MRI showing mass. (Courtesy of Laura Isley, MD.)

Image acquisition, display, and storage are much faster. Image manipulation through adjustments in contrast, brightness, and magnification of selected regions enables radiologists to obtain superior views. This technology makes it possible to subtract various layers of computerized imagery in order to examine suspicious areas and improve the ability to detect and diagnose breast carcinoma. Greater contrast resolution allows better screening of women with dense breasts and breast implants. With the ability to manipulate and postprocess the images, subtle abnormalities are increasingly detected. Images can be stored easily for future reference and can be sent electronically to be read at multiple viewing stations, thereby allowing double reading when necessary. The main disadvantages of digital mammography include the cost of the equipment and the reduced spatial resolution compared with film.

Digital mammography has been compared with film screen mammography in various studies with little difference reported in cancer detection rates. In the Digital Mammographic Imaging Screening Trial (DMIST), 49,528 asymptomatic women underwent both film and digital mammography (Pisano, 2008). Although there was no significant difference in overall diagnostic accuracy, digital mammography was more accurate for premenopausal and perimenopausal women. Furthermore, it was superior for women with dense breasts. Approximately 25,000 women aged 45 to 69 years were randomized to either digital or film screen mammography in the Oslo II Study (Skaane, 2007). The breast cancer detection rate at 2 years was significantly higher in the full field digital mammography group compared with film screen mammography (0.59% and 0.38%, respectively). In the United States, the majority of imaging centers utilize digital mammography. It may provide a small screening advantage in women younger than 50 years old. However, it must be noted that film mammography is an acceptable screening method for all women.

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) is another imaging modality utilized to detect breast cancer. MRI does not use ionizing radiation. Malignant tumors with increased tumor angiogenesis are differentiated from benign tumors based on the rapid uptake and release of contrast (Fig. 15.16). Lesions are classified as mass

or nonmass. The reported sensitivity of MRI ranges from 71% to 100%. The lower specificity, less than 65%, is secondary to the overlap in the enhancement pattern of benign and malignant lesions. Although the specificity of MRI is lower than that for mammography, the sensitivity is higher and it is especially useful in women with dense fibroglandular breasts and implants.

Current screening recommendations are that women with a 20% or higher lifetime risk of breast cancer should be scheduled for annual MRI screening. In women of average risk, breast MRI has poor specificity. Additional potential uses or indications for MRI are to improve imaging of structures close to the chest wall, to improve imaging of women with breast implants, to detect occult primary tumors, and to evaluate for silicone implant integrity. MRI is useful in the documentation of response to neoadjuvant chemotherapy and diagnosis of recurrence and for screening of high-risk patients. MRI may be useful in the identification of multifocal, multicentric, or contralateral disease.

Several limitations of breast MRI exist. MRI cannot identify microcalcifications, and there is loss of image quality with respiratory movements. Breast MRI with gadolinium is not performed during pregnancy. MRI is contraindicated in patients with a history of gadolinium allergy, diminished renal function, cardiac pacemakers, defibrillators or other implanted devices whose operation may be disturbed by the MRI magnet.

ULTRASOUND

Ultrasound has an established role in conjunction with mammography for evaluating abnormalities and is frequently used in the diagnostic follow-up of an abnormal screening mammogram. It should not be used by itself as a screening tool in average risk women. No randomized trials exist comparing combination ultrasound and mammography versus mammography alone for screening in average-risk women. However, women with dense breasts may benefit from the addition of ultrasound to screening mammography. Ultrasound screening increased the detection of otherwise occult cancers by 37% in a study involving 3626 women age 42 to 67, with dense breasts and no visible abnormalities on mammography. In women with dense breasts as their only risk factor, the American College of Radiology recognizes that ultrasound as an addition to screening mammography may be useful for incremental cancer detection.

Ultrasonography of the breast is a highly operator- and reader-dependent test with a great deal of variation among different centers. Ultrasound utilizes sound waves to image tissues and is particularly effective in differentiating cystic from solid masses. The accuracy rate of ultrasound to diagnose a cystic mass is 96% to 100%, which exceeds the combined accuracy of mammography and physical examination. It can be used in examining the axilla and determining lymph node status.

Ultrasound is frequently used to guide needle aspiration, or direct core needle biopsy. It has also been used to localize tumors intraoperatively without a guide wire with excellent success rates (Fig. 15.17). In pregnant women or women younger than 30 years old with focal breast symptoms or findings, ultrasound is the first line of imaging. Although MRI is superior at detecting silicone implant ruptures, ultrasound is usually more readily available and can be used in cases where MRI is contraindicated. In summary, ultrasound should not be used as a sole imaging technique for breast disease. Because of its lack of sensitivity and

Figure 15.17 Intraoperative ultrasound-guided wire bracketing of a nonpalpable breast lesion for excision. (Photo courtesy of David T. Rock, MD.)

specificity for early breast carcinoma, it should not be used in an attempt to detect subclinical disease in the general population at this time.

COMPUTED TOMOGRAPHY

CT is not routinely used for breast cancer screening or diagnosis. Due to higher radiation doses and longer study times, CT has limited value when compared with mammography. The thickness of cross-sectional slices with CT misses the majority of areas of microcalcification. It is useful for contrast-enhancing lesions, for lesions close to the chest wall, and for studying the most medial and lateral aspects of the breast. It is sometimes used for preoperative wire location of a mass that is difficult to localize by mammography. However, the increased expense and radiation exposure virtually eliminate CT scans from screening programs.

TOMOSYNTHESIS

Breast tomosynthesis, commonly referred to as *three-dimensional (3D) mammography*, is a modification of digital mammography. The 3D image is created by taking multiple low-dose images per view along an arc over the breast. The compressed breast remains stationary while the x-ray tube rotates approximately 1 degree for each image in a 15- to 50-degree arc. The 11 to 49 acquired images are projected as cross-sectional “slices” of the breast, with each slice typically 1-mm thick. Thin slice reconstruction with tomosynthesis allows true lesions to be distinguished from spurious lesions caused by overlapping structures identified on routine mammography. Breast tomosynthesis has been approved in the United States for breast cancer screening,

when used in combination with mammography. Friedewald and colleagues compared screening by digital mammography with digital mammography plus tomosynthesis (Friedewald, 2014). In this large retrospective study with data collected from 13 sites, the addition of tomosynthesis to digital mammography resulted in an overall decrease in recall rate of -16 per 1000 screens (95% CI, -18 to -14; $P < .001$) and more invasive cancers detected (4.2 cancers vs. 5.4 cancers per 1000 studies, $P < .001$). The detection rate for ductal carcinoma in situ was similar in both groups.

Disadvantages of tomosynthesis include increased radiation exposure and reading time. The radiation exposure is approximately double the usual radiation dose associated with mammography and can be even greater in patients with dense or thick breasts. Facilities with newer techniques that have a lower radiation dose are expensive and not widely available.

BREAST TISSUE SAMPLING

The evaluation of a breast mass includes a clinical examination, imaging, and tissue sampling. This triple test has been advocated as a reliable alternative to excisional biopsy. If the physical exam, imaging findings, and cytologic evaluation of the mass all confirm the same benign process, the mass can be followed. However, if any of these assessments indicate cancer, a biopsy should be performed. The false-negative rate of triple test diagnosis approaches that of surgical biopsy, and the false-positive rate is comparable with that for frozen section.

Common indications for tissue biopsy include bloody discharge from the nipple, a persistent three-dimensional mass, or suspicious mammography. Additionally, nipple retraction or elevation and skin changes, such as erythema, induration, or edema, are also indications for breast biopsy. Imaging should precede biopsy, as the inflammation and bleeding that can occur secondary to the biopsy may significantly impair needed visualization of the breast with imaging. The choice of initial biopsy methods is dependent on the lesion characteristics, including whether it is palpable, and location. The least invasive technique that is likely to produce a diagnostic specimen should be used.

FINE-NEEDLE ASPIRATION

Fine-needle aspiration (FNA) is the least invasive first-line sampling technique followed by core needle biopsy. FNA is a simple, office-based procedure. It is appropriate for new, well-circumscribed, usually tender masses that are thought to be simple (not complex) cysts. It is also valuable in the evaluation of ipsilateral axillary lymph nodes. If the lesion is not palpable, ultrasound guidance may be used to localize the lesion.

The skin over the breast is the most sensitive area, but the breast tissue itself has few pain fibers. Some providers choose to inject a small amount of local anesthetic (1 mL of 1% lidocaine). Care must be taken to avoid the development of a hematoma, which may obscure the mass and decrease the accuracy of the FNA. A small (18- to 21-gauge) needle is used when performing an FNA. The breast mass is secured with one hand, and the other hand introduces the needle attached to a 10- or 20-mL syringe into the mass. If the mass is found to be a cyst, the procedure can be converted into a cyst aspiration. The color of the fluid

obtained via aspiration varies from clear to grossly bloody. Samples should be sent to a cytopathologist for evaluation. However, if the aspirated fluid is clear, it is not necessary to submit it for cytologic evaluation, and the patient is to be reevaluated in 1 to 2 months. If the cyst recurs, imaging should be performed to confirm their benign nature and reaspiration performed under ultrasound guidance. Less than 20% of cysts recur after a single aspiration, and fewer than 10% recur after two aspirations. A biopsy should be performed on cysts that recur within 2 weeks or that necessitate more than one repeat aspiration. In cases of a solid mass, a fixed specimen is obtained and submitted for cytopathologic evaluation. Several passes are made through the mass with continuous suction from the syringe. Moving the needle within a single tract will give a satisfactory cellular yield in the majority of cases.

Complications of needle aspiration are rare and include hematoma formation and infection. The theoretic risk of spreading cancer along the needle track has not been substantiated. Finally, it is difficult to determine the difference between carcinoma in situ and invasive cancer from the cytologic specimen obtained from FNA.

CORE NEEDLE BIOPSY AND EXCISIONAL BIOPSY

Core needle biopsy retrieves more tissue than FNA, permitting the differentiation between invasive versus in situ cancer. A more definitive histologic assessment including tumor grade angiolymphatic invasion and hormone receptor status can be made. In addition, core needle biopsy usually provides adequate tissue for genomic analysis or cancer profiling. Vacuum-assisted directional biopsy can be used to acquire a greater volume of tissue. Excisional biopsy should be reserved for certain situations when a diagnosis is not established using the diagnostic triad.

Core needle biopsy is usually performed using a larger needle (9 to 14 gauge) than FNA. Following administration of local anesthetic, a small skin incision is made and the core biopsy needle is inserted. Three to five cores of solid tissue are collected for pathologic evaluation. A biopsy clip must be placed at the time of the biopsy for future localization of the lesion. Core needle biopsy may be performed with ultrasound, mammographic, or MRI guidance. Mammographic or stereotactic guidance is primarily used for biopsy of calcifications. The breast is imaged at 30-degree angles with 2D mammography, and the lesion is localized using computer-assisted positioning and targeting devices.

Nonpalpable breast lesions discovered by breast imaging techniques, including screening mammography, require preoperative localization by the radiologist. Under mammographic, ultrasound or MRI guidance, a wire is placed percutaneously so that the tip of the wire is fixed in the lesion. Image-guided techniques play a vital role in preoperative staging of breast cancer patients and in the planning of definitive surgery.

CLASSIFICATION

Carcinomas make up the majority of breast malignancies and originate in the epithelium of the collecting ducts (ductal) or the terminal lobular ducts (lobular). Sarcomas are rare, constituting less than 1% of primary breast cancers, and arise

Table 15.8 Simplified Classification of Breast Carcinoma Based on Histology

Type of Carcinoma	Percentage of All Cases Diagnosed
Ductal carcinoma	
In situ	5
Infiltrating	70
Infiltrating with uniform histologic appearance	10
Medullary, colloid, comedo, tubular, papillary	
Lobular carcinoma	
In situ	3
Infiltrating	9
Inflammatory carcinoma	2
Paget disease	1

from stromal or connective tissue. Tumor grade is based on tubule formation, nuclear pleomorphism, and mitotic counts using the Nottingham score to determine low, intermediate, or high grade. Higher grade is associated with a poorer long-term prognosis.

Initially, breast carcinoma may be divided into invasive and in situ lesions (Table 15.8). Invasive ductal carcinoma accounts for the majority, approximately 80%, of invasive carcinomas. Invasive lobular carcinomas constitute approximately 10% to 15% of cases. Other subtypes include mucinous, tubular, medullary, micropapillary, and papillary. Both in situ and invasive carcinomas are often found in the same quadrant of the breast. Additionally, multifocal carcinomas are not uncommon, and bilateral breast carcinomas occur in 1% to 2% of newly diagnosed cases.

DUCTAL CARCINOMA IN SITU

Ductal carcinoma in situ (DCIS) is a noninvasive lesion in which the cellular abnormalities are limited by the basement membrane of the breast ducts. The risk of DCIS increases with age and accounts for approximately 20% of newly diagnosed breast cancers. It is most commonly discovered in perimenopausal and postmenopausal women. Mammography has significantly increased the detection of this lesion. DCIS, evidenced by clustered microcalcifications, is not usually detectable by palpation. Diagnosis is confirmed with a core needle biopsy, usually using stereotactic guidance.

The histologic diagnosis of ductal carcinoma in situ includes a heterogeneous group of tumors with varying malignant potential. Classification is based on architectural pattern (comedo, micropapillary, cribriform, or solid), tumor grade (high, intermediate, or low), and evidence of necrosis. Identification of microinvasion, a minute focus of stromal invasion, is crucial as treatment recommendations may change.

The goal of treatment is to prevent the development of invasive cancer. Treatment approaches include surgery, radiation therapy, and adjuvant endocrine therapy. Mastectomy is curative for over 98% of DCIS patients. Breast-conserving surgery (lumpectomy, partial mastectomy) followed by radiation therapy has shown equivalent survival when compared with mastectomy. Chemoprevention with either a SERM or

aromatase inhibitor is recommended for women with estrogen receptor–positive DCIS who have undergone breast conservation therapy to reduce the risk of developing additional invasive or noninvasive breast cancers.

LOBULAR CARCINOMA IN SITU

Lobular carcinoma in situ (LCIS) is a noninvasive lesion arising from the lobules and terminal ducts of the breast. Historically, LCIS is found with an invasive carcinoma in approximately 5% of malignant breast specimens. Although it does not have the same malignant potential as DCIS, women with LCIS are at an increased risk of developing breast cancer. Eighty to ninety percent of cases occur in premenopausal women.

LCIS has a greater tendency to be bilateral and multifocal. The latent period for development of malignancy is longer than with DCIS. Approximately one fifth of women diagnosed with LCIS develop invasive breast carcinoma over a 20- to 25-year follow-up period. National Comprehensive Cancer Network guidelines recommend reexcision in cases where LCIS is diagnosed by core needle biopsy to rule out an invasive component. LCIS is not managed as a precursor lesion. In cases in which LCIS is diagnosed on an excisional biopsy, obtaining histologically negative margins is not mandatory as LCIS is frequently multicentric. Breast cancer chemoprevention with a SERM or an aromatase inhibitor may be indicated for women diagnosed with LCIS.

INFILTRATING OR INVASIVE DUCTAL CARCINOMA

Infiltrating or invasive ductal carcinoma is the most common breast malignancy, comprising approximately 70% to 80% of breast malignancies. Histologically, nonuniform malignant epithelial cells of varying sizes and shapes infiltrate the surrounding tissue (Fig. 15.18). Cytologic features range from bland to highly malignant, and tumors are graded based on architectural and cytologic characteristics. Typically, infiltrating ductal carcinomas are firm and gray-white. The degree of fibrous response due to the invading malignant cells is responsible for the firm palpable mass, radiologic density, and texture during biopsy.

INFILTRATING LOBULAR CARCINOMA

Infiltrating lobular carcinomas constitute approximately 10% to 15% of invasive lesions and are the second most common type of invasive breast cancer. These lesions are characterized by the uniformity of the small, round neoplastic cells that infiltrate the stroma and adipose tissue in a single-file fashion (Fig. 15.19). This neoplasia tends to have a multicentric origin in the same breast and tends to involve both breasts more often than infiltrating ductal carcinoma. Infiltrating lobular carcinomas are more frequently ER positive. Unlike infiltrating ductal carcinomas, the excised breast tissue frequently has a normal consistency and no mass lesion is grossly evident. Histologic subdivisions of infiltrating lobular carcinoma include small cell, round cell, and signet cell carcinomas.

INFLAMMATORY BREAST CANCER

Inflammatory breast cancer is rare and accounts for approximately 1% to 5% of breast cancers. This type is recognized clinically as a rapidly growing malignant carcinoma with highly angiogenic and angioinvasive characteristics. Due to its aggressive features, most inflammatory breast cancers are diagnosed as either stage III or IV. Most are invasive ductal carcinomas. Infiltration of malignant cells into the dermal lymphatics of the skin produces a clinical picture that appears like a skin infection (Fig. 15.20). The breast is firm, warm, and enlarged with thickened, erythematous, peau

Figure 15.20 Inflammatory breast carcinoma—cellulitic appearing plaque. (From Marks J, Miller J. *Lookingbill and Marks' Principles of Dermatology*. 4th ed. Philadelphia: Saunders; 2006.)

Figure 15.21 Paget disease of the breast. Note the erythematous plaques around the nipple. (From Callen JP. Dermatologic signs of systemic disease. In: Bologna JL, Jorizzo JL, Rapini RP, eds. *Dermatology*. Edinburgh: Mosby; 2003:714.)

d'orange skin changes. Histologically, dermal lymphatic invasion by malignant cells is noted.

PAGET DISEASE

Paget disease of the breast is rare, constituting 1% to 3% of new breast carcinomas (Fig. 15.21). This lesion has an innocent appearance and looks like eczema or dermatitis of the

nipple. The clinical picture of a scaly, raw, or ulcerated lesion of the nipple and areola is a result of an infiltrating ductal carcinoma that invades the epidermis. In approximately 85% of the patients, an underlying breast cancer is present with Paget disease of the breast. Punch biopsy or a full thickness wedge of the nipple is used for diagnosis. Intraepithelial adenocarcinoma cells (Paget cells) are noted on histology, presenting either singly or in small groups within the epidermis of the nipple.

GENOMIC PROFILING

Historically, the treatment of breast cancer was based on tumor histology, axillary node status, tumor size, receptor patterns, and grade of differentiation. In addition to simplified histologic classification, a classification based on gene expression or profiling, including the presence of hormone receptors, has evolved. Identification of tumor receptor status is critical as endocrine therapy is utilized both for adjuvant therapy and in the management of advanced disease. The genomic analysis of tumors has led to the molecular subtyping of breast cancers. In the early 2000s, Perou and coworkers classified breast tumors into four different molecular subtypes: luminal, basal, HER2, and normal (Perou, 2000). Subsequently, the luminal group was further differentiated into luminal-A and luminal-B subgroups. Basal-like tumors include triple-negative tumors, tumors that are estrogen, progesterone, and HER2 negative by immunohistochemistry. A more aggressive subtype of triple-negative tumors, claudin-low tumors, has also been described. These divisions are detailed in Table 15.9.

The lactiferous ducts have two layers: the inner layer closest to the lumen and the outer layer next to the basement membrane with more myoepithelial elements. Cancers that appear to have expression of genes similar to luminal cells are usually hormonally estrogen sensitive. Luminal-A tumors make up approximately 40% of all breast cancers. These tumors are generally of the best prognosis, low grade, estrogen and progesterone receptor positive, and HER2 (Neu) negative. These are more commonly found in older women.

Luminal-B tumors account for approximately 20% of all breast cancers and have a more aggressive behavior compared

with the luminal-A subtype. These tumors have overexpression of HER2 (Neu) and have a higher expression of the proliferation-related genes. Often they are estrogen and progesterone as well as p53 gene mutation positive (these are acquired p53 mutations as opposed to inherited mutations).

The third subtype, HER2 enriched, constitutes 10% to 15% of breast cancers. It is characterized by a high expression of both HER2 and proliferation gene clusters. These tumors are usually estrogen and progesterone negative, high grade, have a high rate of p53 mutations, and have a poor prognosis.

The basal subtype makes up 15% to 20% of breast cancers. It is similar to basal-type duct cells in terms of expression of more myoepithelial gene profiling. These triple-negative tumors are usually high grade and exhibit a low expression of the luminal and HER2 gene clusters. BRCA1 tumors are up to 95% basal type.

A fifth type of breast cancer, claudin-low tumors, constitutes approximately 10% of breast cancers. Claudin-low tumors are also triple-receptor negative (estrogen, progesterone, and HER2 [Neu]). They have a high proliferation capability and are more aggressive than other subtypes.

MANAGEMENT

A multidisciplinary team approach is necessary in the treatment of breast cancer. Local disease is treated with surgery, radiation therapy, or both. Systemic treatment includes chemotherapy, endocrine therapy, biologic therapy, or a combination of these regimens. Determination of local or systemic treatment is based on several prognostic and predictive factors including tumor histology, tumor hormone receptor status (estrogen/progesterone), tumor HER2 status, multigene testing, axillary lymph node status, evaluation of metastatic disease, patient age, comorbidities, and menopausal status.

The primary algorithm of treatment is primarily determined by the tumor stage. The tumor-node-metastasis TNM system is a widely recognized staging system based on both clinical and pathologic criteria (Table 15.10). The goal of treatment for stage 0, pure noninvasive carcinomas (LCIS, DCIS), is preventing the development of invasive disease or diagnosing the development of an invasive component when still confined to the breast. In cases of invasive disease, treatment is based on the stage-appropriate guideline for invasive carcinoma. The major objectives of treating breast carcinoma are control of local disease, treatment or prevention of distant metastasis, and improved quality of life for women treated for the disease. With multiple therapeutic options in both local and systemic therapy for breast carcinoma, women have an active role in deciding their own treatment regimen. There are several methods for controlling local disease. Breast conservation with lumpectomy or quadrantectomy is a frequent choice for the control of local disease. Sentinel node biopsy has become standard practice in the treatment of early stage breast cancer. Chemotherapy is used not only for patients with proved metastatic disease but also for women at high risk for developing distant or recurrent disease. Emphasis on conservative surgery plus radiation therapy to control multifocal cancer in the same breast and on reconstructive surgery after mastectomy has improved the quality of life for women with breast carcinoma.

Table 15.9 Classification of Breast Carcinoma Based on Gene Profiling and Hormone Receptor

Expression Type	Grade	Characteristic Behavior	Hormone Receptor Status*
Luminal A	Usually low grade	Good prognosis	E and P +
Luminal B	All grades	Mixed prognosis	E and P +, Her 2 (Neu) +
Her 2 (Neu)	Higher grades	Poor prognosis	E and P -, Her 2 (Neu) +
Basal	Usually grade 3	Poor prognosis	Triple negative
Normal breast†	Usually low grade	Good prognosis	Triple negative

*E, Estrogen receptor; P, progesterone receptor.
†Normal breast does not express gene profiling of basal elements, myoepithelial gene expression.

Table 15.10 TNM Staging of Breast Cancer

Primary Tumor (T)			
TX	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
Tis*	Carcinoma in situ; intraductal carcinoma, lobular carcinoma in situ, or Paget disease of the nipple with no tumor		
T1	Tumor is ≤2 cm in greatest dimension		
T1a	Tumor is ≤0.5 cm in greatest dimension		
T1b	Tumor is >0.5 cm but not more than 1 cm in greatest dimension		
T1c	Tumor is more than 1 cm but not more than 2 cm in greatest dimension		
T2	Tumor is >2 cm but not more than 5 cm in greatest dimension		
T3	Tumor is >5 cm in greatest dimension		
T4	Tumor of any size with direct extension to chest wall or skin		
T4a	Extension to chest wall		
T4b	Edema (including peau d'orange) or ulceration of the skin of the breast or satellite skin nodules confined to the same breast		
T4c	Both T4a and T4b above		
T4d	Inflammatory carcinoma		
Regional Lymph Node Involvement (N) (Clinical)			
NX	Regional lymph nodes cannot be assessed (e.g., previously removed)		
N0	No regional lymph node metastasis		
N1	Metastasis to movable ipsilateral axillary lymph node(s)		
N2	Metastasis to ipsilateral axillary lymph node(s) fixed to one another or the other structures		
N3	Metastasis to ipsilateral mammary lymph node(s)		
Distant Metastasis (M)			
MX	Presence of distant metastasis cannot be assessed		
M0	No distant metastasis		
M1	Distant metastasis (includes metastasis to ipsilateral supraclavicular lymph node[s])		
Stage Grouping			
Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage IIa	T0	N1	M0
	T1	N1*	M0
	T2	N0	M0
Stage IIb	T2	N1	M0
	T3	N0	M0
Stage IIIa	T0	N2	M0
	T1	N2	M0
	T2	N2	M0
	T3	N1, N2	M0
Stage IIIb	T4	Any N	M0
	Any T	N3	M0
Stage IV	Any T	Any N	M1

From Eberlein TJ. Current management of carcinoma of the breast. *Ann Surg.* 1994;220(2):121-136.

Paget disease associated with a tumor is classified according to the size of the tumor. Chest wall includes ribs, intercostal muscles, and serratus anterior muscle but not pectoral muscle.

*The prognosis of patients with pN1a is similar to that of patients with pN0.

Surgical Therapy

The decision concerning appropriate therapy and extent of the surgical operation to treat breast carcinoma should be made by the patient in consultation with the surgeon, radiation oncologist, and medical oncologist who will treat her. The size of the tumor, the initial extent of disease, the virulence of the neoplasm, and the presence of estrogen, progesterone, or HER2 receptors are key medical factors in the decision. The initial size of the breast carcinoma is the single best predictor of the likelihood of positive axillary nodes. The presence and number of axillary node metastasis are the best predictors of survival. Traditionally, the evaluation for localized invasive disease includes bilateral diagnostic mammography, possible subsequent ultrasonography, tumor hormone receptor status, HER2 receptor status, and pathology review. MRI for the evaluation and determination of the extent of disease has been controversial. Supporters cite high sensitivity in evaluating the extent of disease, especially for invasive cancer and in dense breasts as well as the identification of second cancers. Arguments against MRI use include a high percentage of false-positive findings resulting in additional diagnostic workup or more extensive surgery than necessary.

Locoregional treatment of clinical stage I, IIA, IIB, or T3N1MO (a subset of stage IIIA) invasive breast cancer includes lumpectomy (or total mastectomy ± reconstruction) with surgical axillary staging. Intensive discussions concerning breast reconstruction or external prostheses are important to help the patient contemplate the effects of surgery on body image. Morris and coworkers have studied the psychological and social adjustments to mastectomy in 160 women, who were followed at intervals of 3, 12, and 24 months after surgery (Morris, 1977). One in four women was still having problems with depression and associated marital and sexual problems 2 years after the initial therapy. Until the 1980s, radical mastectomy was the standard operation for carcinoma of the breast. Radical mastectomy was designed to control local disease by an extensive en bloc removal of the breast and underlying pectoralis major and pectoralis minor muscles and complete axillary dissection. It is a cosmetically disfiguring operation, leaving a major deformity of the chest wall. With an increased understanding that cancer of the breast is often a systemic disease and prognosis is similar with conservative surgery, the therapeutic emphasis has changed to less radical surgery and increased use of radiotherapy and chemotherapy (Table 15.11). Often patients are not cured even with extensive local therapy. Thus protocols were established for more conservative approaches to treat local disease. The modified radical mastectomy removes

Table 15.11 Ten-Year Disease-Free Survival Rates of Women with Breast Cancer

	Conservation Surgery and Radiation	Radical or Modified Radical Mastectomy Alone
Minimal breast cancer	92%	95%
Stage I	78%	80%
Stage II	73%	65%

From Montague ED. Conservation surgery and radiation therapy in the treatment of operable breast cancer. *Cancer.* 1984;53(3 Suppl):700-704.

the breast and only the fascia over the pectoralis major muscle. The pectoralis minor muscle may be removed to facilitate the axillary dissection. Simple mastectomy includes removal of the breast without underlying muscle tissue. A nipple-areolar sparing mastectomy can be considered in select patients undergoing a therapeutic mastectomy followed by immediate reconstruction. Candidates include women with small to moderate breast size with minimal ptosis and tumors smaller than 2 cm with a tumor-to-nipple areolar complex distance larger than 2 cm. Contraindications to this procedure include inflammatory breast cancer, clinical involvement of the nipple areolar complex, nipple retraction, Paget disease, or bloody nipple discharge. For patients having a mastectomy for prophylactic indications, a skin-sparing or nipple-sparing mastectomy is an option with good cosmetic results.

Breast-conserving therapy (lumpectomy, axillary sentinel lymph node biopsy followed by whole breast irradiation) has been shown to be equivalent to mastectomy and axillary lymph node dissection in the primary treatment of women with stages I and II breast cancer. Resection of a wider area of the breast than lumpectomy is referred to as a quadrantectomy. In cases of positive margins, surgical reexcision is recommended. Mastectomy may be necessary in cases of positive margins after further surgical reexcision. Contraindications to lumpectomy include the need for radiation therapy during pregnancy, extensive disease not amenable to resection by a local excision with a single incision resulting in satisfactory cosmetic outcome, and diffuse suspicious or malignant appearing microcalcifications. Relative contraindications include tumor size greater than 5 cm, history of previous radiation therapy to the breast or chest wall, and active connective tissue disease such as scleroderma and lupus that is adversely affected by radiation therapy.

Surgical axillary staging is recommended for stages I, IIA, IIB, and IIIA breast cancer. Sentinel lymph node mapping and resection is recommended in the surgical staging of the clinically negative axilla for stages I, IIA, IIB, and IIIA breast cancer. Sentinel node biopsy has decreased the need for complete axillary lymphadenectomy. Compared with standard axillary lymphadenectomy, sentinel lymph node (SLN) biopsy results in less arm/shoulder pain, lymphedema, and sensory loss. By injecting with radioactive colloid tracers and dyes, the surgeon can identify the first set of regional lymph nodes that receive lymphatic drainage from the tumor. These are termed *sentinel lymph nodes*. Subsequently, these nodes can be removed and the axillary dissection can be deleted if they are negative. In a large multi-institutional trial, Krag and colleagues were able to identify the sentinel nodes in 93% of the cases. The accuracy of sentinel node mapping in this series for predicting the status of axillary nodes was 97%. The positive predictive value was 100%, and the negative predictive value was 96% (Krag, 1998). In the American College of Surgeons Oncology Group (ACOSOG) Z0011 study, women 18 years or age or older with T1/T2 tumors, fewer than three positive SLNs, and who were undergoing breast-conserving surgery followed by whole breast radiation were randomized to SLN resection alone versus axillary lymph node (ALN) dissection. No difference was noted in local recurrence, disease-free survival, or overall survival. Locoregional recurrences at a follow-up of 6.3 years occurred in 4.1% of the ALN group and 2.8% of the SLN group (P

= .11). Median overall survival was 92% in both groups. No further axillary surgery is recommended in patients with a T1 or T2 tumor with less than three positive SLNs who did not receive neoadjuvant therapy and were treated with lumpectomy and whole breast radiation (Giuliano, 2010). Level I or II axillary dissection is recommended in patients with either clinically positive nodes at the time of diagnosis confirmed by FNA or core biopsy or in cases where sentinel nodes are not identified.

Breast reconstruction must be considered for any woman undergoing mastectomy for breast cancer. Although reconstruction is an optional procedure that does not influence the probability of disease recurrence or death, it is associated with an improvement in the patient's quality of life. Consultation with a reconstructive plastic surgeon should be offered. Various factors influence the type of reconstruction including patient preference, smoking history, body habitus, comorbidities, and radiation therapy plans. Obesity and smoking increase the risk of wound healing complications and flap failure.

Postmastectomy reconstruction with implants can be performed by either immediate placement of a permanent subpectoral implant or by placement of a subpectoral tissue expander implant. The pectoral muscle is stretched with gradual expansion of the expander implant by the addition of saline. Implants may contain silicone gel, saline, or a combination of both. Reconstruction techniques with autologous tissue include abdominal flaps: a transverse rectus abdominis (TRAM) flap and the deep inferior epigastric perforator (DIEP) flap, a gluteus maximus myocutaneous flap, and a latissimus dorsi flap reconstruction. There is also another option that is only offered in a few centers that does not use skin or muscle from the abdominal wall or buttocks but instead uses skin, fat, and muscle from the upper inner thigh called the *transverse upper gracilis (TUG) flap* (ACS, 2015) (Fig. 15.22). In patients undergoing postmastectomy radiation, placement of a tissue expander at the initial procedure followed by implant placement after completion of radiation therapy is preferred. If autologous tissue is used, reconstruction should be delayed until at least 6 months following completion of radiation therapy.

Radiation Therapy

The majority of women treated with breast-conserving surgery are candidates for breast radiation therapy. After breast-conserving surgery, external beam whole breast irradiation is usually administered. In the 2011 meta-analysis by the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) of 10,801 women in 17 trials, whole breast irradiation resulted in a significant reduction in the 10-year risk of any first recurrence compared with breast-conserving surgery alone (19.3 vs. 35%, RR 0.52, 95% CI: 0.48-0.56). Additionally, a significant reduction in the 15-year risk of breast cancer death (21.4% vs. 25.2%, RR 0.82, 95% CI: 0.75-0.90) was noted in the whole breast irradiation group (EBCTCG 2011a). Radiation therapy boost to the tumor bed is offered to women at higher risk of recurrence (positive lymph nodes, lymphovascular invasion, young age, or high-grade disease after lumpectomy). In women 70 years or older with node negative, stage 1 ER-positive breast cancer, postoperative radiation therapy may be omitted if they receive postoperative endocrine therapy, as the risk of an in breast recurrence is low.

Figure 15.22 **A**, Pedicle TRAM flap incisions through which the flap of muscle, fat, and skin are tunneled under the skin to fill the defect in the breast. **B**, Incisions used for the DIEP flap. **C**, Latissimus dorsi flap. **D**, Gluteal-free flap. **E**, Transverse upper gracilis (TUG) flap. (Modified from American Cancer Society. Breast reconstruction after mastectomy, 2015.)

Women with positive axillary lymph nodes after mastectomy and axillary lymphadenectomy are also candidates for breast radiation therapy. Randomized trials have shown both a disease-free and overall survival advantage of chest wall and regional node irradiation in these women. National Comprehensive Cancer Network (NCCN) guidelines recommend irradiation after mastectomy in women with four or more positive axillary lymph nodes and strong consideration of radiation in women with one to three positive axillary lymph nodes (NCCN, 2016). Chest wall irradiation is also recommended in women with negative

nodes but with primary tumor greater than 5 cm or positive surgical margins.

Medical Therapy

Along with earlier detection, advancements in systemic adjuvant therapy have resulted in a decrease in the breast cancer mortality rate. Clinicopathologic factors including stage, tumor grade, and vascular space invasion are used to calculate the risk of disease recurrence. The two major factors in predicting the likelihood of systemic disease in breast carcinoma are the diameter of

the primary tumor and the number of positive axillary nodes. Women whose initial tumor is less than 1 cm in diameter and who have negative axillary nodes have excellent chances for disease-free survival. The 10-year relapse rate is less than 10%.

Hormonal Therapy

The presence and concentration of receptors should be obtained at the initial diagnostic biopsy or surgery. Women with hormone receptor-positive breast cancer are candidates for endocrine therapy. Receptor status may change after radiotherapy or chemotherapy. Estrogen receptors are of two types, ER-alpha and ER-beta. Most laboratories test only for the ER-alpha receptors, and its biology is better understood. ER-beta receptors' role in malignancy is still under investigation. As tumors mutate and metastasize, the expression of estrogen receptors decreases. Hormonal therapies become less effective in controlling disease. Progesterone receptor positivity is a sign of better differentiation and a greater response to hormonal therapy. Progesterone receptors are often lost as tumors metastasize, as well. In general, luminal type A receptor-positive tumors are usually better differentiated and exhibit a less aggressive clinical behavior, including a lower risk of recurrence and lower capacity to proliferate. When estrogen receptors are positive, approximately 60% of breast cancers will respond to hormonal therapy; an 80% response rate is noted when both estrogen and progesterone receptors are present. If estrogen receptors are negative, less than 10% of tumors respond to hormonal manipulation.

Hormonal therapy is usually accomplished by drugs that change endocrine function by blocking receptor sites or blocking synthesis of hormones. Hormonal therapy is effective in producing a response in advanced metastatic carcinoma for approximately 1 year. Metastatic disease in soft tissue and bone is the most sensitive to hormonal manipulation. Tamoxifen, a selective estrogen receptor modulator, is a frequently prescribed hormonal agent for breast carcinoma. The 2011 EBCTCG meta-analysis compared tamoxifen treatment for 5 years with no endocrine treatment (EBCTCG, 2011b). Analysis showed a significant reduction in the risk of breast cancer recurrence at 15 years (RR 0.61, 95% CI: 0.57-0.65) and a significant reduction in the risk of breast cancer mortality at 15 years (RR 0.70, 95% CI: 0.64-0.75). Treatment with tamoxifen was associated with an increased risk of thromboembolic disease, strokes, intrauterine polyps, as well as endometrial hyperplasia and carcinoma. The overall incidence of uterine cancer was low and confined to women over 55 years. Most tamoxifen-related endometrial cancers were stage I, grade 1, and were successfully treated with surgery alone.

Tamoxifen has the greatest effect in postmenopausal women. As one would expect, tamoxifen is of greater benefit in women with tumors that have estrogen receptors than in tumors that are negative for estrogen receptors. There is no significant improvement in survival rates in patients with estrogen receptor-negative tumors. However, even in receptor-negative patients, 5 years of tamoxifen use will decrease the risk of a second primary or contralateral breast cancer by as much as 45%. Trials of tamoxifen in the adjuvant treatment setting for breast cancer showed that 10 years of tamoxifen improved outcomes when compared with 5 years. In the worldwide Adjuvant Tamoxifen: Longer Against Shorter (ATLAS) trial, approximately 13,000 women were randomized to continue tamoxifen to 10 years or stop at 5 years (Davies, 2013). Among women with ER-positive disease, continuation of

tamoxifen reduced the risk of breast cancer recurrence, reduced breast cancer mortality, and reduced overall mortality. The reductions in adverse breast cancer outcomes appeared to be less extreme before than after year 10 with halve breast cancer mortality during the second decade after diagnosis. Extended tamoxifen use demonstrated no effect on breast cancer outcome in the cohort of women with ER-negative disease, and an intermediate effect among women with unknown ER status. Based on these results and those of other major trials, the American Society of Clinical Oncology updated the practice guidelines on the optimal duration of treatment of adjuvant endocrine therapy, particularly adjuvant tamoxifen (Burststein, 2014). Pre- or perimenopausal women who have received 5 years of adjuvant tamoxifen should be offered tamoxifen for a duration of 10 years. Postmenopausal women who have received 5 years of adjuvant tamoxifen should be offered the choice of continuing tamoxifen or changing to an aromatase inhibitor for 10 years total adjuvant endocrine therapy.

Aromatase inhibitors (AIs) (anastrozole, letrozole, and exemestane) block the peripheral conversion of adrenal androgens to estrone. They are ineffective in women with intact ovarian function, including those who experienced chemotherapy-induced amenorrhea, as AIs may cause an inadvertent rise in gonadotropins from the ovary, limiting their effectiveness. Cessation of ovarian function can be definitively attained by oophorectomy or pelvic radiation. Ovarian suppression can also be accomplished with pharmacologic interventions that inhibit ovarian production of estrogen, such as the gonadotropin-releasing hormone (GnRH) agonists. In premenopausal women with ER-positive breast cancer, combined results of the Suppression of Ovarian Function Trial (SOFT) and Tamoxifen and Exemestane Trial (TEXT) show that ovarian suppression plus an AI compared with ovarian suppression plus tamoxifen in premenopausal women with ER-positive breast cancer will result in better disease-free survival but not overall survival (Pagani, 2014). When compared with tamoxifen, AIs have been shown to improve outcomes for postmenopausal women with hormone receptor-positive breast cancer. In a meta-analysis of approximately 32,000 postmenopausal women with ER-positive breast cancer, AIs when compared with tamoxifen were noted to reduce recurrence rates by approximately 30%, have a higher risk of osteoporosis/fractures, and have a lower risk of endometrial cancer (EBCTCG, 2015).

HER2-Directed Therapy

The determination of HER2 tumor status is recommended for newly diagnosed invasive breast cancers as well as for recurrences of breast cancer. The *HER2/neu* gene is an epithelial growth factor determinant (human epidermal receptor), and amplification or overexpression HER2 oncogene is found in 18% to 20% of women with breast cancer. When overexpressed on tumor cells, the *HER2/neu* gene is a poor prognostic sign and a marker for aggressive disease. Breast tumors are classified as HER2 positive if the tumor has either an immunohistochemical (IHC) stain of 3+ (defined as uniform membrane staining for HER2 in 10% or more of tumor cells), a HER2/chromosome enumeration probe 17 (CEP17) fluorescent in situ hybridization (FISH) amplification ratio ≥ 2 or a HER2/CEP17 ratio < 2 with an average HER2 copy number > 6 signals/cell.

HER2-targeted therapy is recommended in patients with *HER2/neu*-positive tumors. Trastuzumab is a humanized monoclonal antibody, which is directed against the

extracellular domain of the *HER2/neu* receptor. Several trials have shown significant improvement in outcome and were stopped early because of the improved outcomes compared with placebo. The drug affects multiple steps in the cell cycle and importantly sensitizes cells to other chemotherapy agents. It also increases antibody-dependent, cell-mediated cytotoxicity. Trastuzumab given for 1 year in conjunction with chemotherapy in patients with HER2-positive tumors improved disease-free and overall survival (Moja, 2012). Treatment with trastuzumab is associated with a higher risk of cardiotoxicity including congestive heart failure and a decrease in left ventricular ejection fraction. Caution must be used when patients are also receiving anthracycline-based chemotherapy, and patients should undergo routine cardiac monitoring. Pertuzumab, a monoclonal antibody that binds to HER2 and prevents dimerization of HER2 with other HER receptors, may be used in conjunction with chemotherapy and trastuzumab regimens to overcome trastuzumab resistance due to HER2:HER3 heterodimer formation. The addition of pertuzumab does not appear to increase toxicity.

Chemotherapy

Chemotherapy is utilized in the treatment of breast cancer in both the adjuvant and neoadjuvant settings. Chemotherapy is recommended for the treatment of most triple-negative breast cancers, HER2-positive breast cancers, and high-risk luminal tumors. The benefit of chemotherapy is more pronounced in ER-negative tumors.

The decision to use adjuvant chemotherapy is based on several variables including the surrogate intrinsic phenotype determined by ER/PR, HER2, and Ki-67 assessment with the selective help of first-generation genomic testing. The two most commonly used molecular prognostic profiles are the Oncotype DX test and the MammaPrint assay. The Oncotype DX Breast Cancer Assay measures the expression of 16 cancer genes and 5 reference genes to produce a recurrence score (RS) from 0 to 100. It is utilized to estimate both the risk of recurrence of early-stage breast cancer and the benefit from adjuvant chemotherapy. Currently, this assay is indicated in women with node negative or 1 to 3 positive nodes and ER-positive breast cancer. The MammaPrint test analyzes 70 genes (Amsterdam 70 gene prognostic profile) and calculates either a high-risk or low-risk recurrence score for early stage breast cancer. This clinically validated prognostic profile can be used in breast cancers that are either hormone-receptor-positive or negative, node negative or one to three positive nodes, and in patients with HER2-positive disease.

Combination therapy of cytotoxic drugs is vastly superior to single-agent regimens. Anthracycline-containing combinations are more effective than regimens that do not contain anthracyclines. Paclitaxel therapy has excellent activity in breast cancer. The addition of four to five cycles of paclitaxel to four to six cycles of the Adriamycin and cyclophosphamide regimen improved disease-free and overall survival rates in patients with node-positive breast cancer. Overall, chemotherapy regimens based on anthracyclines and taxanes reduce breast cancer mortality by about one third.

In the neoadjuvant setting, chemotherapy has the potential to change unresectable tumors to resectable ones and decrease the extent of surgery necessary to achieve adequate resection.

Neoadjuvant chemotherapy may be considered for patients who desire breast-conserving surgery but initially are not candidates due to tumor size. Neoadjuvant therapy is commonly used in patients with inflammatory breast cancer and may confer a survival benefit in this population of patients. The chemotherapy regimens used in the neoadjuvant setting are the same as those used in the adjuvant setting. Endocrine and HER2 targeted therapy may also be used in the preoperative setting. HER2-positive breast cancer and triple-negative breast cancer are the most chemosensitive and are excellent subtypes for neoadjuvant chemotherapy. These patients have the highest pathologic complete response rate. In HER2-positive breast cancer, neoadjuvant therapy should include trastuzumab and pertuzumab with a taxane.

BREAST CANCER DURING PREGNANCY

Breast cancer is not frequently diagnosed during pregnancy. Less than 5% of breast cancers diagnosed before the age of 50 are during pregnancy or in the postpartum period. However, most breast cancers diagnosed during pregnancy are poorly differentiated, ER/PR negative, ALN positive, and have a large primary tumor size. Diagnosis of cancer during pregnancy is frequently delayed by 2 months or longer. Similar to non-pregnant women, in pregnant or postpartum women a breast mass is usually the presenting sign. A mass that persists for more than 2 weeks should be evaluated. Mammography is not contraindicated in pregnancy, although abdominal shielding is recommended. Breast ultrasonography can also be used to better define a mass and guide biopsy. A clinically suspicious mass should be biopsied either by FNA or core needle biopsy. Staging studies should be tailored in an effort to minimize fetal exposure to radiation.

Treatment options during pregnancy are not very different from the nonpregnant state and include mastectomy, breast-conserving therapy, and systemic therapy, but not radiation therapy. Although radical mastectomy is the most common surgery, breast-conserving therapy is an option if radiation therapy can be delayed to the postpartum period. According to the NCCN guidelines, SLN biopsy may be safely performed during pregnancy with a radiolabeled sulfur colloid. The use of blue dye is contraindicated in pregnancy. Systemic chemotherapy should be avoided in the first trimester and not be given after week 35 of pregnancy or within 3 weeks of delivery to avoid transient neonatal myelosuppression and other complications. The risk of fetal malformation during the second and third trimester is approximately 1.3%. Most data regarding chemotherapy in pregnancy are with anthracycline and alkylating chemotherapy. Fewer data exist regarding taxanes. NCCN guidelines recommend weekly administration of paclitaxel after the first trimester if indicated. Trastuzumab is not recommended for use during pregnancy and should be delayed to the postpartum period. Endocrine therapy is also contraindicated during pregnancy.

Various studies have shown no significant difference in outcomes between women diagnosed with breast cancer during pregnancy and nonpregnant women. In a meta-analysis of 30 studies including 37,100 controls and 3628 cases of pregnancy associated breast cancer, a higher risk of death was noted in

women diagnosed in the postpartum period (HR 184, 95% CI: 1.28-2.65) rather than during pregnancy (HR 1.29, 95% CI: 0.72-2.24) (Azim, 2012). Termination of pregnancy does not appear to improve survival.

SURVEILLANCE

There are approximately 14.5 million cancer survivors in the United States as of 2014. The number of cancer survivors has increased in part due to aging and growth of the population as well as advancements in early detection and treatment. Breast cancer accounts for 41% of female cancer survivors, and close surveillance after treatment is paramount. Although most breast cancer recurrences occur in the first 5 years following treatment, recurrence may be diagnosed decades after treatment. Ongoing age-appropriate screening and preventive care for other conditions not related to breast cancer should continue as recommended for the general populations.

The NCCN guidelines are not stratified according to stage at time of diagnosis or treatment. Interval history and physical examination are recommended every 4 to 6 months for 5 years and annually thereafter, with mammography every 12 months. Women on tamoxifen are recommended to have an annual gynecologic examination every 12 months if the uterus is present. Regular bone mineral density determination is recommended for women on an aromatase inhibitor. Adherence to adjuvant endocrine therapy and maintaining an ideal body weight are also recommended. Other routine laboratory tests and imaging are not recommended for routine surveillance. The use of estrogen, progesterone, or SERMs in the treatment of osteoporosis or

osteopenia is discouraged, although it may be considered in select cases. In general, bisphosphonates are preferred for bone mineral density health. Similar to the NCCN guidelines, ASCO recommendations for the follow-up and management of breast cancer include regular history, physical examination, and mammography. The ASCO guidelines recommend history and physical examination every 3 to 6 months for the first 3 years, every 6 to 12 months for years 4 and 5, and annually thereafter. Additional testing is recommended only if symptoms arise. For women who have undergone breast-conserving surgery, a posttreatment mammogram should be obtained 12 months after the initial mammogram and at least 6 months after completion of radiation therapy. Thereafter, annual mammography is recommended. Women should have regular gynecologic follow-up, and those who received tamoxifen should report any vaginal bleeding as they are at an increased risk of developing endometrial cancer.

Treatment of breast cancer with chemotherapy or hormonal therapy may cause menopausal symptoms. Women often report that sexual activity is less enjoyable and more painful. Women who have undergone mastectomy report problems with body image and interest in sex. Depression is associated with sexual dysfunction in breast cancer survivors. Physicians must regularly inquire about sexual functioning, and women with complaints of dyspareunia or other sexual disorders should be offered a referral to a sexual health expert. Women who report dyspareunia or difficulty reaching orgasm may benefit from vaginal dilators, vaginal lubricants and moisturizers, or counseling. The risks and benefits of local or vaginal estrogen therapy should be discussed and individualized based on patient symptoms and tumor characteristics. The use of vaginal estrogens in this setting is to improve the patient's quality of life and should not be underestimated.

KEY POINTS

- The breast consists of approximately 20% glandular tissue and 80% fat and connective tissue; increasing proportions of fibroglandular to fatty tissues are the mark of denser breasts. Breast density is associated with increased risks of malignancy.
- Lymph drainage of the breast usually flows toward the most adjacent group of nodes. This concept represents the basis for sentinel node mapping in breast cancer. In most instances, breast cancer spreads in an orderly fashion within the axillary lymph node basin based on the anatomic relationship between the primary tumor and its associated regional (sentinel) nodes.
- The breast undergoes normal maturational changes throughout a woman's lifetime. The normal maturation involves a gradual increase in fibrous tissue around the lobules; with time the glandular elements are completely replaced by fibrous tissue.
- The incidence of benign breast disorders begins to rise during the second decade of life and peaks in the fourth and fifth decades. In malignant diseases, the incidence continues to increase after menopause.
- Fibroadenomas are the most common benign breast neoplasm and are most frequently present in adolescents and women in their 20s.
- Approximately 35% of fibroadenomas will disappear, and 10% will become smaller after many years.
- Over two thirds of women will experience breast pain at some time during their reproductive years, most commonly in the perimenopausal years. Approximately 90% of conditions that cause breast pain are benign.
- Cyclic bilateral breast pain is the classic symptom of fibrocystic breast change. The signs of fibrocystic changes include increased engorgement and density of the breasts, excessive nodularity, rapid change and fluctuation in the size of cystic areas, increased tenderness, and occasionally spontaneous nipple discharge.
- The majority of nipple discharge complaints have a benign etiology; however, 55% present with a coexisting mass of which 19% are malignant. An underlying malignancy is more likely when the discharge is spontaneous (vs. induced with nipple pressure), arises from a single duct, is blood stained, and is unilateral and persistent (occurring more than twice weekly).
- Intraductal papilloma and fibrocystic changes are the two most common causes of spontaneous nonmilky nipple discharge.
- Lactational mastitis commonly occurs in the first pregnancy during the first 6 weeks of breast-feeding. Continued breast-feeding or manual pumping of the affected breast is recommended to decrease engorgement.

KEY POINTS—cont'd

- One out of eight women (12.5%) in the United States will develop carcinoma of the breast over the course of her lifetime.
- Approximately 50% of newly diagnosed breast cancers are attributable to known risk, whereas 10% are associated with a positive family history.
- Approximately 5% to 10% of breast cancers have a familial or genetic link. Genetic predisposition to develop breast carcinoma has been recognized in some families. In these families, breast cancer tends to occur at a younger age, and there is a higher prevalence of bilateral disease.
- Mutations in the *BRCA* family of genes have been identified that confer a lifetime risk of breast cancer that approaches 85%. *BRCA1* and *BRCA2* genes are involved in the majority of inheritable cases of breast cancer. These genes function as tumor suppressor genes, and several mutations have been described on each of these genes.
- Once a woman has developed carcinoma of one breast, her risk is approximately 1% per year of developing cancer in the other breast.
- Both tamoxifen and raloxifene significantly decrease the relative risk of developing breast carcinoma. AIs are a reasonable alternative to SERMs for postmenopausal women.
- Screening mammography is the primary imaging technique for breast cancer detection. The sensitivity of mammography ranges from 80% to 90% and decreases in women with dense breasts.
- The incidence of carcinoma in biopsies corresponds directly with the patient's age. Approximately 20% of breast biopsies in women age 50 are positive, and this figure increases to 33% in women age 70 or older.
- Breast cancer is usually asymptomatic before the development of advanced disease. Breast pain is experienced by only 10% of women with early breast carcinoma. The classic sign of a breast carcinoma is a solitary, solid, three-dimensional, dominant breast mass. The borders of the mass are usually indistinct.
- Microscopic metastatic disease occurs early via both hematogenous and lymphatic routes. For example, 30% to 40% of women without gross adenopathy in the axilla will have positive nodes discovered during histologic examination. With the additional assessment tools of immunohistochemical staining for the presence of cytokeratin and serial sectioning of axillary nodes, 10% to 30% of patients considered to have negative nodes by standard histologic analysis are found to be node positive.
- The initial size of the breast carcinoma is the single best predictor of the likelihood of positive axillary nodes. The presence and number of axillary node metastasis are the best predictors of survival.
- Carcinomas make up the majority of breast malignancies and originate in the epithelium of the collecting ducts (ductal) or the terminal lobular ducts (lobular). Invasive ductal carcinoma is the most common, constituting approximately 70% to 80% of malignancies.
- A multidisciplinary team approach is necessary in the treatment of breast cancer. Determination of local or systemic treatment is based on several prognostic and predictive factors including tumor histology, tumor hormone receptor status (estrogen/progesterone), tumor HER2 status, multigene testing, axillary lymph node status, evaluation of metastatic disease, patient age, comorbidities, and menopausal status.
- The primary therapy for the majority of women with stages I and II breast cancer is conservative surgery, which preserves the breast, followed by radiation therapy.
- Gynecologists should actively address the psychosexual problems that breast cancer causes in women, early in the evaluation of the disease and for several years.

Spontaneous Abortion and Recurrent Pregnancy Loss Etiology, Diagnosis, Treatment

Sanaz Keyhan, Lisa Muasher, Suheil J. Muasher

Pregnancy loss is a devastating event for patients and their caregivers. It often poses a medical puzzle and can be accompanied by strong emotions. Unfortunately, it is common, affecting about 15% of clinically recognized pregnancies and up to 50%, or more, of all conceptions (Kutteh, 2007). *Spontaneous abortion (SAB)*, *miscarriage*, and *pregnancy loss* are used throughout the literature to describe the involuntary loss of a pregnancy before 20 weeks of gestation, as dated by the last menstrual period, or the loss of a fetus weighing 500 g or less. Because the term *abortion* may carry negative connotations, especially among patients, *miscarriage* is frequently substituted. Miscarriage within the first 12^{6/7} weeks of gestation is termed *early pregnancy loss* and denotes a nonviable intrauterine pregnancy in which the gestational sac itself is empty or contains a fetus with no cardiac activity (ACOG, 2015). After 20 weeks of gestation, pregnancy loss is called *preterm birth* or *stillbirth*, as the point of fetal viability continues to fluctuate (Kutteh, 2007).

Recurrent pregnancy loss has traditionally been defined as three or more consecutive, clinically recognized losses (Rai, 2006). More recent definitions have recommended including two or more clinically recognized losses (ASRM, 2012). The term *habitual abortion* has now been almost completely replaced by *recurrent pregnancy loss*. In addition, recurrent loss may be further stratified into primary, secondary, and tertiary. These terms denote whether the patient has ever had a viable infant or if her losses have been interspersed with deliveries of viable infants. Multiple studies have shown the risk of miscarriage approaches 45% with three previous consecutive losses. A thorough evaluation will reveal a cause of recurrent loss in over half of couples who seek treatment. The prognosis is good for these patients, with over 80% of women younger than 30 years and 60% to 70% of women ages 31 to 40 achieving a successful pregnancy within 5 years of their first visit to a physician (Lund, 2012).

This chapter discusses the epidemiology of pregnancy loss and reviews the etiology, diagnosis, and management of loss. For the purposes of this chapter, the terms *recurrent pregnancy loss* and *recurrent miscarriage* will be used interchangeably, although some groups have argued that these two adverse pregnancy outcomes have different definitions. Loss at less than 10 weeks is

usually due to a chromosomal abnormality, as opposed to loss at 18 to 20 weeks' gestation, which is more often due to structural problems of the uterus or cervix (Stephenson, 2002). Some women may have more than one cause for miscarriage. Similarly, not all women with a known abnormality will suffer a loss. Because miscarriage should be viewed as a syndrome, as well as a continuum, recurrent pregnancy loss is discussed throughout the chapter.

EPIDEMIOLOGY

Miscarriage is more common in women younger than 18 years and older than 35 years and rises both with increasing parity and number of prior losses (Fig. 16.1). Loss rates of 9% to 17% for women ages 20 to 34, 20% for women ages 35 to 40, and 40% for women over age 40 have been observed in longitudinal studies. The loss rate is believed to approach 80% in women age 45 and older (ASRM, 2012). Likewise, women with two prior losses, and no live births, have been shown to experience a loss rate of 25%, which increases to 45% with three losses (Table 16.1). The spontaneous abortion risk also increases with older paternal age, reaching 19.5% for men between ages 40 to 44 (Kleinhaus, 2006). Evaluation of the medical literature should take into account that the majority of patients will eventually have a successful pregnancy even without intervention. Remembering that 90% of pregnancy losses are not recurrent, watchful waiting may prove the best, albeit emotionally hardest, thing to do.

Nearly 80% of all clinical abortions occur in the first trimester, and the incidence declines with advancing gestational age. The loss rate remains stable through 12 weeks and decreases in the following weeks (Fig. 16.2). When a gestational sac is visualized by ultrasound, the loss rate is 11.5% but falls to 6% to 8% if embryonic cardiac activity is observed at 6 weeks and falls to 2% to 3% if cardiac activity is persistent at 8 to 12 weeks. Compared with their younger counterparts, however, women older than age 34 experience a loss rate twice as high, even after visualization of a fetal heartbeat (Achiron, 1991). Studies show

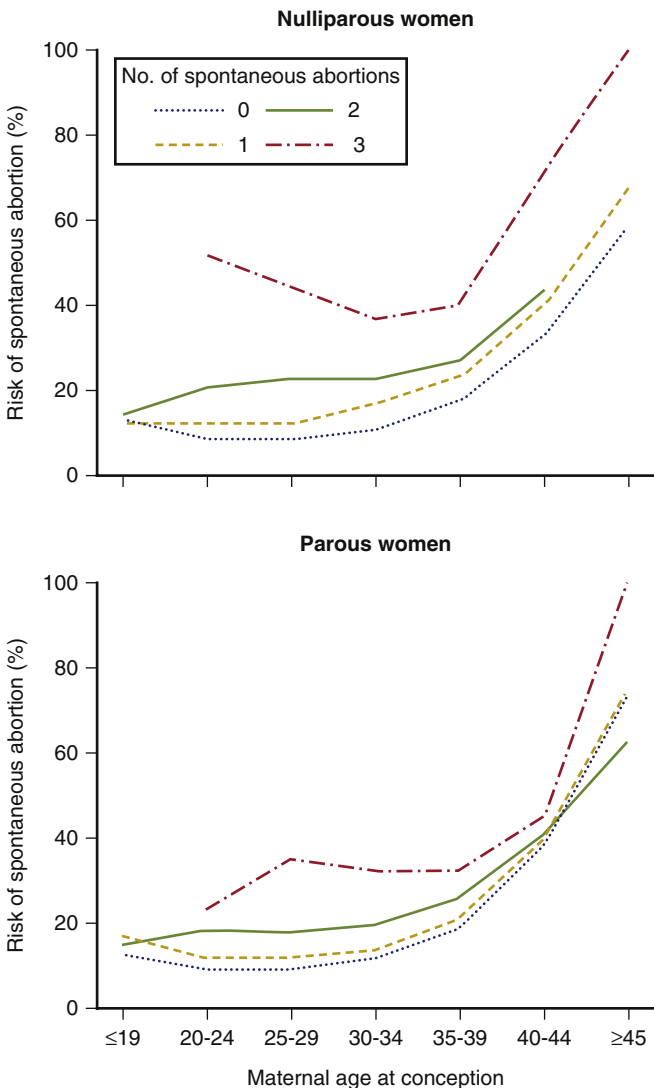

Figure 16.1 Risk of spontaneous abortion in nulliparous and parous women according to maternal age at conception and number of spontaneous abortions in preceding 10 years. (From Nybo Andersen AM, Wohlfahrt J, Christens P, et al. Maternal age and fetal loss: population based register linkage study. *BMJ*. 2000;320[7251]:1708-1712.)

that the majority of losses before 10 weeks are attributable to chromosomal abnormalities. Women with bleeding in the first trimester and confirmed presence of fetal cardiac activity have a 15% risk of suffering a miscarriage (Hasan, 2009).

ETIOLOGY

Causes of pregnancy loss can be described as either maternal or fetal. Maternal factors include medical conditions, structural issues involving the uterus and cervix, and environmental exposures. Fetal reasons for loss include chromosomal abnormalities and derangement of organ development, which may or may not have a chromosomal component.

CHROMOSOMAL

Chromosomal origins of pregnancy loss include embryonic errors as a result of known parental abnormalities and de novo embryonic errors in the setting of parents with normal karyotypes. Several terms are used interchangeably in the literature, often leading to flawed interpretation because the definitions vary subtly. *Congenital* means present at birth but does not infer whether a condition is inherited. *Inherited* means passed on from the parents. In other words, one or both parents have a genetic change that can be passed to their offspring. *Genetic* denotes changes in the genes or chromosomes that can be sporadic, a new mutation, or inherited. *Chromosomal* problems are all genetic, but few are inherited. Inherited chromosomal abnormalities are those resulting from familial translocations. Additional sources of chromosomal anomalies include microdeletions and microduplications. These changes are in between single gene defects and full chromosomal abnormalities and represent small portions of the DNA involving only a few genes. They may be inherited or sporadic.

Studies confirm that 50% to 60% of miscarriages are due to chromosomal anomalies and up to 85% of pregnancies shown to be nonviable by ultrasound will demonstrate aneuploidy on pathologic review following surgical evacuation. Most of the abnormal karyotypes are numeric irregularities resulting from errors during gametogenesis (chromosomal nondisjunction during meiosis), fertilization (triploidy as a result of digyny or diandry), or the first division of the fertilized ovum (tetraploidy or mosaicism). About 56% of these abnormalities are trisomic, 20% are polyploid, 18% will be chromosome X monosomies, and 4% will represent unbalanced translocations (Jacobs, 1987).

Fetal aneuploidy is the most common cause of miscarriage, with autosomal trisomies accounting for the majority of losses. Aneuploidy is usually caused by errors in the first meiotic division of the oocyte, although some trisomies are due to errors in paternal meiotic division. Trisomy 16 is the most frequently observed abnormality in abortuses, followed by trisomy 22. The most common single chromosome abnormality is monosomy 45,X; however, nearly 1 in 300 of these gestations will survive to viability (Hassold, 2007) (Table 16.2). It is important to remember that the rate of chromosomally abnormal abortuses seen in couples with recurrent pregnancy loss does not differ from their maternal and gestational age cohorts in the population at large. In women younger than age 36, recurrent loss is usually due to causes other than chromosomal abnormalities (Stephenson, 2002).

Figure 16.2 Spontaneous abortion by week of pregnancy. (From Harlap S, Shiono PH, Ramcharan S. A life table of spontaneous abortions and the effects of age, parity, and other variables. In: Porter IH, Hook EB, eds. *Human Embryonic and Fetal Death*. New York: Academic Press; 1980.)

Although more than 98% of miscarriages due to aneuploidy occur spontaneously, some are caused by translocations in one or both parents (ASRM, 2012). In 3% to 6% of recurrent pregnancy loss, one parent, usually the woman, will carry a chromosomal abnormality (Hassold, 2007). About 50% of these will be balanced translocations, 25% are Robertsonian translocations, and another 12% are female sex chromosome mosaicism. The remainder are either inversions or other types of sporadic abnormality. Translocations are more likely to interfere with spermatogenesis than oogenesis, thus culminating in more females than males with chromosomal abnormalities attempting to conceive (Goldstein, 1994). A loss rate of 80% would be predicted if a translocation is diagnosed in one parent, but this is not actually observed as the percentage of viable, unaffected infants born depends on the type of translocation (Philipp, 2003). Large studies have shown spontaneous live birth rates of up to 71% in carriers of a structural rearrangement (Stephenson, 2006).

Loss of a chromosomally normal conceptus usually occurs at a later gestational age than one involving an embryo with chromosomal abnormalities. Although the peak incidence of euploid abortion occurs around 12 to 13 weeks' gestation, it is helpful to remember that the time of diagnosis or expulsion of products of conception does not necessarily coincide with embryonic or fetal death. Accurate timing of embryonic or fetal death is important when evaluating patients for a cause of pregnancy loss (Goldstein, 1994).

There are multiple causes for loss of chromosomally abnormal conceptions. About 2% of live-born infants will have a single gene mutation or polygenic abnormality, making these gene irregularities more common than chromosomal abnormalities, which affect 0.5% of live births. These defects may induce loss by interfering with fetal metabolism or embryonic structural differentiation (Philipp, 2003). Another theory postulates a gene

that blocks normal meiotic division, as evidenced by studies of recurrent loss among women with an abnormal inactivation of one of their X chromosomes.

UTERINE ANOMALIES

Uterine abnormalities, either congenital or acquired, may not provide the optimal environment for nourishment and survival of the embryo and thus may cause the loss of a genetically normal embryo. Congenital uterine abnormalities can be divided into those brought about by abnormal uterine fusion, those produced by maternal diethylstilbestrol (DES) ingestion, and those caused by abnormal cervical function. The last condition, the incompetent cervix, can also be acquired after mechanical cervical dilation. Uterine polyps or submucous myomas may be considered acquired.

ANOMALIES OF UTERINE DEVELOPMENT

Congenital abnormalities of the female reproductive tract are discussed in detail in Chapter 11. The discussion in this section is limited to their importance in women with spontaneous and recurrent miscarriages.

Uterine anomalies can be observed in 4.3% (range, 2.7% to 16.7%) of the general population and in 12.6% (range, 1.8% to 37.6%) of patients with recurrent pregnancy loss. The prevalence of uterine malformations in women with recurrent pregnancy loss has varied widely due to the differences in diagnostic criteria and the imaging techniques used. The septate uterus is the most common uterine anomaly in the general population as well as in women with recurrent pregnancy loss. Women with uterine anomalies have higher rates of first- and second-trimester miscarriages compared to women with a normal uterus. Uterine

*Consisting of 118 cases of 46,XX and two cases of balanced translocations.

†Consisting of 105 cases of 46,XY.

septa tend to be associated with the poorest reproductive outcome. A review by Grimbizis and colleagues found a high rate of miscarriage in women with septate ($n = 499$, 44.3% loss), unicornuate ($n = 260$, 36.5% loss), bicornuate ($n = 627$, 36% loss), didelphys ($n = 152$, 32.3% loss), and arcuate ($n = 241$, 25.7% loss) uteri (Grimbizis, 2001).

Several imaging modalities may be used to evaluate the uterus, including hysterosalpingogram, transvaginal ultrasonography, and sonohysterography. Magnetic resonance imaging (MRI) and three-dimensional transvaginal ultrasonography may help to better characterize the anomaly.

Hysteroscopic septoplasty is the treatment of choice for women with a septate uterus and a history of pregnancy loss, with laparotomy reserved for exceptional and complicated anomalies.

March and Israel initially reported that it was possible to incise the septum, even those thicker than 1 cm, of all of the 82 women with recurrent abortion studied, using the hysteroscope. After this treatment, the abortion rate declined from 95% to 13% (March, 1987). A large review of studies found that correction of uterine septa improved reproductive performance with live birth

rate of 83.2% in 366 pregnancies. The benefits of hysteroscopic septoplasty have not yet been assessed by a randomized trial. A transfundal metroplasty technique originally described by Strassmann may be the appropriate surgical procedure for unification in women with a bicornuate uterus who have a history of recurrent pregnancy loss or previable birth. When necessary, cervical cerclage may also be used. Cervical cerclage may improve pregnancy outcomes in women with bicornuate uteri and in women with a unicornuate uterus or uterus didelphys who have a history of late-trimester pregnancy loss. Bider and coworkers reported that when cervical cerclage was used to treat women with a bicornuate uterus and recurrent pregnancy loss, the incidence of viable pregnancies markedly increased. In one series of 41 women with bicornuate uteri and recurrent abortion, 85% had a successful pregnancy outcome after cervical cerclage and the other 18 women had a term delivery following hysteroscopy (Bider, 1992). Sonographic measurements of cervical length help distinguish which patients may benefit from cerclage.

UTERINE ANOMALIES AFTER DIETHYLSTILBESTROL

DES was prescribed to women throughout the 1950s and early to mid-1960s. Because it was withdrawn from the U.S. market in 1971, it is not a current cause of miscarriage, except in women at the end of their childbearing years. Diethylstilbestrol can lead to uterine malformations, including hypoplastic cavity, T-shaped uterus, constriction bands, a wide lower segment, and irregular borders. Studies have shown that nearly 70% of women who were exposed to DES in utero had uterine abnormalities detected on hysterosalpingography, most commonly hypoplastic T-shaped cavity (31%). Comparative studies have shown that women exposed to DES during their fetal life have a significantly greater incidence of spontaneous abortion than do controls. One study noted that the endometrial cavity of women exposed to DES in utero had a significantly smaller surface area than normal, which could perhaps contribute to the increased spontaneous abortion rate in women who had been exposed to DES in utero. No therapy, including cerclage, has been shown to significantly lower the abortion rate in women exposed to DES who have abnormalities of the uterine cavity and recurrent abortion unless they also have cervical incompetence. Because the length of gestation tends to increase with subsequent pregnancies among women who had fetal DES exposure, most of these women ultimately had a viable pregnancy.

CERVICAL INCOMPETENCE (CERVICAL INSUFFICIENCY)

Cervical incompetence is characterized by an asymptomatic dilation of the internal cervical os, leading to dilation of the cervical canal during the second trimester of pregnancy. The consequent lack of support of the fetal membranes leads to their prolapse and rupture, which is usually followed by expulsion of the fetus and placenta. The incidence of this problem was previously estimated to vary from 1 in 57 to 1 in 1730 pregnancies. The huge range of incidence speaks to the difficulty in diagnosis. It is believed that most cases occur as a result of surgical trauma to the cervix from conization, loop electrosurgical excision procedures, mechanical dilation of the cervix during pregnancy termination, or obstetric lacerations. Cervical incompetence has also been associated with

the presence of uterine anomalies, congenital defects in the cervical tissue, and fetal DES exposure. Cervical incompetence rarely causes recurrent miscarriage, as it is treated after the first occurrence of loss. There is no absolute test for the definitive diagnosis of cervical incompetence. The diagnosis is usually made by obtaining a history of second-trimester pregnancy loss without contractions or labor and in the absence of other clear etiology (e.g., bleeding, infection, ruptured membranes). Many times the patient will have mild contractions shortly before expelling the pregnancy or before an examination that finds the cervical dilatation to be advanced. Commonly, the cervix is noted to be unexpectedly dilated at the time of a mid-trimester ultrasound. Ultrasound diagnosis of cervical shortening has been shown to be a marker of preterm birth rather than cervical insufficiency. Nevertheless, cerclage may be beneficial in women with a short cervix.

History-indicated cerclages are typically placed at approximately 13 to 14 weeks. Multiple studies have shown that women at risk of cervical insufficiency can be monitored with serial transvaginal ultrasound examinations from 16 weeks to the end of 24 weeks' gestation. Ultrasound monitoring may avoid the placement of a history-indicated cerclage in more than one half of patients (Fig. 16.3). Although women with a singleton pregnancy who have a history of a prior spontaneous preterm birth at less than 34 weeks' gestation and a cervical length less than 25 mm before 24 weeks' gestation do not meet the diagnostic criteria for cervical insufficiency, studies have suggested that cerclage placement may be effective in this setting. Normal cervical length is approximately 3.5 cm or greater (Fig. 16.4, A and B). Women who are found to have cervical dilation either from digital or speculum exam at less than 24 weeks of gestation are candidates for examination-indicated cerclage, known as *emergency or rescue cerclage*. The benefit of a rescue cerclage in these women has only been demonstrated from one small randomized trial and retrospective studies.

Cerclage placement consists of a concentric nonabsorbable suture as close to the level of the internal os as possible. If strict criteria are used to diagnose cervical incompetence, fetal survival rates after cerclage have been reported to increase from 20% to 80%. However, if the criteria for diagnosis are less certain, in several randomized clinical trials, there is only a slight increase in the incidence of term deliveries after cerclage is performed. It is recommended that the suture be placed electively between 12 to 14 weeks' gestation after major embryogenesis has been completed and the incidence of spontaneous abortion caused by genetic abnormalities has markedly lessened. An ultrasound examination should be performed before the cerclage is placed to document that a normal gestation is present. Occasionally, if there is a markedly shortened cervix or placement of a cerclage has failed to maintain the pregnancy, a transabdominal cerclage may be performed. If the suture is placed externally, it is usually removed at 36 to 37 weeks' gestation, and vaginal delivery is permitted to occur. If the suture is buried as in the Shirodkar procedure, then elective cesarean delivery at or beyond 39 weeks of gestation may be considered.

ACQUIRED UTERINE DEFECTS

Leiomyomas

Leiomyomas are common benign uterine tumors that are present in about one third of women of reproductive age. Uterine

Figure 16.3 Transvaginal ultrasound of a normal-appearing cervix. Large arrow to small area denotes canal from external os to internal os, respectively. H, Fetal head. (From Fong KW, Farine D. Cervical incompetence and preterm labor. In: Rumack CM, Wilson SR, Charboneau JW, eds. *Diagnostic Ultrasound*. 2nd ed. St. Louis: Mosby; 1998.)

leiomyomas may be associated with repetitive miscarriage, but there is a lack of substantial evidence and the majority of studies linking leiomyomas and spontaneous miscarriage have involved women undergoing in vitro fertilization (IVF). Leiomyomas that distort the uterine cavity, including submucosal or intramural with an intracavitary component, may result in decreased pregnancy and implantation rates as well increased risk of miscarriage. A systematic review of 11 controlled studies found the spontaneous miscarriage rate to be higher in women with submucosal and intramural fibroids (in descending order) undergoing IVF compared with women with no fibroids (Klatsky, 2008). Although a causal relationship is difficult to establish, studies have shown a significant reduction in miscarriage rates following an abdominal myomectomy. In a major review published in 1981, Buttram and Reiter reported that when abdominal myomectomy was performed in a total of 1941 women, the rate of spontaneous abortion was reduced from 41% to 19% (Buttram, 1981). A more recent, smaller study by Marchionni and colleagues showed that miscarriage rates decreased from 69% to 25% postmyomectomy (Marchionni, 2004). These data indicate that fibroids are associated with miscarriage, particularly those that distort the uterine cavity, and that a myomectomy may confer reproductive benefits. The role of intramural fibroids remains controversial. Subserosal fibroids, with greater than 50% of their mass outside the myometrium are unlikely to cause adverse pregnancy outcomes. Recurrent miscarriage is a more acceptable indication for myomectomy than a single loss. Uterine polyps are a rare cause of miscarriage based on observational studies and are found and treated hysteroscopically. The presentation is similar to that of submucous myomas. Intermenstrual spotting in this setting is an indication for hysteroscopy.

Intrauterine Adhesions (Asherman Syndrome)

Asherman syndrome is characterized by adhesions in the uterine cavity that can cause partial or complete obliteration of the endometrium, leading to menstrual abnormalities and amenorrhea, as well as pregnancy loss. Miscarriage is thought to be the result of insufficient endometrium to support adequate fetal growth when

IUA, Intrauterine adhesion; IUD, intrauterine device.

intrauterine adhesions (IUAs) are present. In the majority cases, adhesions result from uterine curettage for pregnancy complications such as missed or incomplete abortion as well as postpartum complications such as postpartum hemorrhage or retained placental remnants (Table 16.3). Women who undergo curettage after a pregnancy loss at a later gestational age are at higher risk compared with early pregnancy. The number of intrauterine surgical procedures seems to also increase the risk of IUA formation. In a meta-analysis of 10 prospective studies, the risk of IUA development was 2.1-fold higher for two or more curettage procedures compared with one curettage procedure (Hooker, 2014). Adhesions can also form in a nongravid uterus as a result of procedures that cause endometrial injury such as a myomectomy or curettage. In a study by Taskin and coworkers, hysteroscopic resection of multiple submucosal leiomyomas was shown to have the highest risk of IUA compared to other hysteroscopic procedures (Taskin, 2000).

The diagnosis of IUA is usually made by the finding of filling defects seen at the time of hysterosalpingogram (HSG) or by sonohysterography (Fig. 16.5). On HSG, the defects are typically irregular, with sharp contours and homogeneous opacity that persist in a series of films (Fig. 16.6). The diagnosis is best confirmed and treated by hysteroscopy.

The recommended treatment for IUA is hysteroscopic lysis of the adhesions. After adhesion lysis, a mechanical barrier such as balloon catheter or intrauterine device (IUD) is usually placed in the cavity. The balloon catheter is typically removed after 10 days and prophylactic antibiotics with doxycycline can be given while the balloon catheter is in place. High-dose estrogen is often administered postoperatively to promote reepithelialization and reduce risk of recurrent adhesions. A common regimen involves 2.5 to 5 mg of conjugated equine estrogen or 4 mg of estradiol

Figure 16.5 Sonohysterography of intrauterine adhesions (arrows). (From Goldberg JM, Falcone T. *Atlas of Endoscopic Techniques in Gynecology*. London: WB Saunders; 2000:27.)

Figure 16.6 Endometrial adhesions. The patient was a 23-year-old gravida 5, para 0, spontaneous abortus 4, ectopic 1, with previous left linear salpingostomy, being evaluated for recurrent abortion. Irregular, linear filling defect represents adhesions between anterior and posterior walls of the endometrial cavity, extending from the internal os to a level near the fundus. (From Richmond JA. Hysterosalpingography. In: Mishell DR Jr, Davajan V, eds. *Infertility, Contraception, and Reproductive Endocrinology*. 3rd ed. Oradell, NJ: Medical Economics Books; 1991.)

valerate for 1 month, adding medroxyprogesterone acetate 10 mg per day for the last week. To minimize the chances of developing IUA, curettage of the pregnant or recently pregnant uterus should be gentle and superficial and not extend deep into the muscle.

ENDOCRINE CAUSES

PROGESTERONE DEFICIENCY

Maintenance of the endometrium for the first 7 weeks of gestation depends on progesterone produced by the corpus luteum. After this time the corpus luteum regresses, and progesterone

synthesized by the trophoblast maintains the decidual tissue. Luteal progesterone synthesis depends on human chorionic gonadotropin (HCG) produced by the trophoblast. When progesterone secretion from the corpus luteum is lower than normal or the endometrium has an inadequate response to normal circulating levels of progesterone, endometrial development may be inadequate to support the implanted blastocyst and may lead to spontaneous abortion.

The diagnosis of luteal insufficiency had historically been made by performing a histologic examination of the endometrium and finding a discrepancy of 3 days or more between the expected and actual endometrial dating pattern in at least two menstrual cycles. Investigators using this method of diagnosis have reported luteal deficiency to occur in as many as one third of women with recurrent pregnancy loss, whereas others have reported it to be an uncommon cause of miscarriage. This discrepancy may have occurred because the precision of endometrial dating by histologic examination varies among different observers, and different criteria are used for determining the day of ovulation. In fact, studies have found that diagnosing by endometrial biopsy is of limited accuracy and value because of significant inter- and intraobserver variability. Similarly, measurement of progesterone levels in the luteal phase is not considered a reliable diagnostic test due to the pulsatile release of luteinizing hormone. Moreover, there is no standard progesterone value that defines normal luteal function, as the corpus luteum function varies from cycle to cycle in normal fertile women.

Currently, most investigators believe that luteal insufficiency is rarely, if ever, the cause of recurrent spontaneous abortion. Goldstein and coworkers performed a meta-analysis of randomized control trials of the use of progestational agents given to women in early pregnancy who had a history of two or more miscarriages without a specific diagnosis of luteal deficiency. There was no significant reduction in the rate of pregnancy loss with the use of progestational agents (Goldstein, 1989). The Cochrane Collaboration Data Review evaluating 15 trials in 2013 found insufficient evidence to support the use of progesterone to prevent miscarriage, but the researchers did find a statistically significant reduced risk of pregnancy loss in women who had had three or more consecutive miscarriages (Haas, 2013). Progesterone is available as either vaginal suppositories or intramuscular progesterone beginning 3 days after ovulation and continuing throughout the first trimester.

There is no benefit to be derived by initiating progesterone therapy or administering exogenous HCG if the woman develops symptoms of threatened abortion. Low progesterone levels at this gestational age are a result, not the cause, of the abortion. When patients inquire about the use of progesterone as a rescue measure, they can be assured that if progesterone deficiency is the cause of a pregnancy loss, the pregnancy is expelled early in gestation, usually before the sixth week.

THYROID DISEASE

Untreated overt hypothyroidism as well as subclinical hypothyroidism are also associated with miscarriage. The 2012 American Society for Reproductive Medicine (ASRM) guidelines for the treatment of recurrent pregnancy loss states that although thyroid-stimulating hormone (TSH) values of 4 to 5 mIU/L

were once considered normal, the new consensus is that TSH levels above 2.5 mIU/L are outside the normal range. In fact, the Endocrine Society recommends that patients with recurrent pregnancy loss be treated to keep a TSH level of between 1 and 2.5 mIU/L. Studies regarding treating euthyroid patients with positive thyroid antibodies have been conflicting. A large prospective study of 984 euthyroid pregnant women with positive antithyroid antibodies had a significantly decreased risk of pregnancy loss if treated with levothyroxine (Negro, 2006). However, both ASRM and the Endocrine Society do not recommend routine screening for antithyroid antibodies in women with recurrent pregnancy loss.

HYPERPROLACTINEMIA

Hyperprolactinemia has been associated with a greater risk of miscarriage. Elevated levels of prolactin can alter the hypothalamic-pituitary-ovarian axis, resulting in impaired folliculogenesis and oocyte maturation or a short luteal phase. A randomized trial found that normalization of prolactin levels with bromocriptine before pregnancy in women with a history of two or more pregnancy losses improved pregnancy outcomes. Treatment led to a live birth rate of 85.7% in the treated group compared with 52.4% in the untreated group (Hirahara, 1998).

DIABETES MELLITUS, INSULIN RESISTANCE, AND POLYCYSTIC OVARY SYNDROME

Uncontrolled and poorly controlled diabetes mellitus is an accepted cause of miscarriage. The increased miscarriage rate is due in part to structural anomalies in the fetus. Among women with diabetes and good control of blood glucose, diabetes is an unlikely cause of miscarriage. However, diabetes without good metabolic control is associated with an increased risk of early pregnancy loss, with a direct correlation between the level of hemoglobin A1C and the rate of abortion.

Studies regarding the relationships among polycystic ovary syndrome (PCOS), elevated luteinizing hormone (LH) levels, and spontaneous abortion have been conflicting. Clifford and colleagues conducted a randomized controlled trial, which indicated that LH suppression with a GnRH analogue is not beneficial for improving live birth rates in PCOS women with recurrent abortion (Clifford, 1996). More recent evidence has supported the association among PCOS, insulin resistance, and spontaneous abortion. Insulin resistance is common in women with recurrent miscarriage and has been associated with increased risk of pregnancy loss. Proposed mechanisms include not only the inherent metabolic problems associated with higher glucose levels and decreased insulin activity such as increased inflammatory mediators but also increased levels of plasminogen activator inhibitor 1. This protein functions as a strong procoagulant and thrombophilic agent, which may result in thrombotic induction of placental insufficiency. Observational studies suggest that metformin reduces miscarriage risk in women with PCOS. In addition, metformin has been shown to be effective in insulin-resistant PCOS women with recurrent miscarriages. However, a Cochrane review in 2012 concluded that metformin treatment has no effect on the risk of miscarriage in the entire PCOS population (Tang, 2012). Currently, treatment with metformin

for prevention of miscarriage is not routinely recommended for patients with PCOS.

IMMUNOLOGIC FACTORS

ALLOIMMUNE DISORDERS

The physiologic mechanism by which the partially foreign fetal tissue is protected from the mother's immunologic system is poorly understood. It is thought that in normal pregnancy, the maternal immune system recognizes the paternally derived antigens on embryonic tissues and produces several alloantibodies that protect the trophoblast from cytotoxic maternal immune response. Since the 1960s, investigators have postulated that miscarriage, and recurrent miscarriage in particular, may be associated with abnormalities in this maternal alloimmune response. Numerous studies have found differences in the immune mechanisms of couples with recurrent loss. However, to date, immunologic treatments have not been shown to be effective.

It has been suggested that if there is sharing of major histocompatibility locus antigens (HLA) between the male and the female in the couple with recurrent abortion, then maternal recognition of paternally derived fetal antigens is less likely to occur. Therefore the production of essential natural blocking antibodies would be hampered and abortion would be more likely to occur. Numerous studies have investigated the degree of HLA sharing at several loci in groups of couples with recurrent abortion in whom no cause for the problem could be detected. In their own study of women with three successive spontaneous abortions, Bellingard and colleagues found that there is no higher level of HLA sharing in couples with recurrent abortion than in a control group of parous women without spontaneous abortion. They also did not find a particular HLA specificity that was associated with recurrent abortion (Bellingard, 1995).

The formation of antipaternal lymphocytic antibodies is another mechanism that has been suggested as a cause of recurrent pregnancy loss. However, these antibodies have been recognized in normal pregnancies and in fact are more prevalent in fertile couples than in those with recurrent pregnancy loss. The presence of these antibodies is more likely a function of the number and duration of pregnancies and has no effect on subsequent pregnancy outcome. Others have proposed that there is a maternal failure to recognize and respond to fetal antigens by producing blocking factors, which then leaves the embryo at risk for a cell-mediated immune rejection. However, studies have shown that blocking antibodies are frequently detectable in women with recurrent pregnancy loss and are, in fact, not always present in women with normal pregnancies.

Several other aspects of the immune system have been investigated as potential causes of recurrent loss. One line of research involves the presence of natural killer cells in the early pregnancy decidua compared with the peripheral maternal circulation. Normally, there are few B lymphocytes and neutrophils but a large proportion of natural killer cells in the decidua, which are thought to contribute to control of trophoblast invasion. These proportions of uterine versus peripheral natural killer cells have been found to be different in patients with unexplained recurrent loss than in controls. However, a systematic review of 12 studies concluded that neither peripheral natural killer cell nor the peripheral killer cell number or activity predict recurrent

miscarriage. Therefore the value of testing women with recurrent pregnancy loss for the levels of natural killer cells in the peripheral blood or in the uterus is questionable. The researchers recognized that there was significant heterogeneity between studies in terms of inclusion criteria, methodology of natural killer cells analysis, and outcome measurements (Tang, 2011).

Natural killer cells in the uterine decidua play a role in the cytokine response at the maternal-fetal interface. The cytokine response relevant to pregnancy is characterized as either T-helper1 (Th1) type or T-helper2 (Th2) type. Th1 responses are considered cytotoxic and associated with the release of interleukin 2, interferon, and tumor necrosis factor α , whereas Th2 responses exert a beneficial effect by inhibiting strong cellular responses and are associated with the release of interleukins 4, 6, and 10. Most women with normal pregnancies exhibit a predominant Th2 immune response. Studies have shown, however, that women with recurrent pregnancy loss have a greater Th1 response, which may be harmful to an implanting embryo. These findings support the theory that cytokine dysregulation of the immune mechanisms operating at the maternal-fetal interface may contribute to recurrent miscarriage. However, it remains unclear whether the Th1 response is the cause of pregnancy loss. The mechanism by which these factors act is not well known.

Immunotherapies developed for women with unexplained recurrent miscarriages have not been shown to be effective. A Cochrane review of 20 randomized trials concluded that immunotherapies including paternal cell immunization, third-party donor leukocytes, trophoblast membranes, and intravenous immunoglobulin do not improve the live birth rate compared with placebo treatment (Wong, 2014).

Abnormal immune responses may eventually prove for some patients to be a cause of recurrent loss, but which patients and which therapies are as of now unknown. Therefore testing for Th1 and Th2 profiles, parental HLA profiles, natural killer cells, and antiparental cytotoxic antibodies is not clinically justified.

AUTOIMMUNE DISORDERS

Antiphospholipid syndrome (APS) is an autoimmune disorder that is associated with recurrent pregnancy loss. This disorder is characterized by the production of moderate to high levels of antiphospholipid antibodies (aPLs) as well as certain clinical features (Box 16.1). Approximately 5% to 20% of all recurrent pregnancy loss patients will test positive for aPLs, and it has been shown in a large meta-analysis that the incidence of APS is between 15% and 20% in women with recurrent pregnancy loss.

The authors of the international consensus statement recommend certain clinical criteria that should prompt testing for aPLs (Miyakis, 2006). These clinical criteria include thromboembolic events (arterial or venous) and pregnancy loss. Most pregnancy losses in women with recurrent pregnancy loss occur before 10 weeks' gestation; however, a greater proportion of losses related to aPLs occur in the fetal period greater than 10 weeks' gestation. One of the obstetric indications for aPLs testing therefore includes a single unexplained loss of a morphologically normal fetus at or beyond 10 weeks' gestation. If a pregnancy loss is diagnosed after 10 weeks' gestation but an ultrasound demonstrates that the pregnancy stopped developing before 10 weeks, testing for aPLs is not warranted. Another indication for testing is three

Box 16.1 International Consensus Definition for the Diagnosis of Antiphospholipid Syndrome

Diagnosis requires one of the following clinical criteria and one of the laboratory criteria:

Clinical Criteria

1. Vascular thrombosis
2. Pregnancy morbidity
 - (a) One or more unexplained deaths of a morphologically normal fetus at or beyond the 10th week of gestation, or
 - (b) One or more premature births of a morphologically normal neonate before the 34th week of gestation because of eclampsia, severe preeclampsia, or features consistent with placental insufficiency, or
 - (c) Three or more unexplained consecutive spontaneous losses before the 10th week of pregnancy

Laboratory Criteria

1. Lupus anticoagulant present on two or more occasions at least 12 weeks apart
2. Anticardiolipin antibody of IgG or IgM isotype in medium to high titer (i.e., greater than 40 GPL or MPL, or greater than the 99th percentile) on two or more occasions, at least 12 weeks apart
3. Anti- β 2-glycoprotein 1 antibody of IgG or IgM isotype in 99th percentile titer on two or more occasions, at least 12 weeks apart

Data from Committee on Practice Bulletins—Obstetrics, American College of Obstetricians and Gynecologists. Practice Bulletin No. 132: antiphospholipid syndrome. *Obstet Gynecol.* 2012;120(6):1514-1521.

IgG, Immunoglobulin G; *IgM*, immunoglobulin M; *GPL*, IgG phospholipid units; *MPL*, IgM phospholipid units.

or more unexplained consecutive losses before the 10th week of gestation excluding maternal anatomic or hormonal abnormalities and paternal and maternal chromosomal causes. Preterm severe preeclampsia and early onset placental insufficiency (intrauterine growth restriction) have been associated with APS and are therefore another indication to test for aPLs. However, there is insufficient evidence to demonstrate that screening and treatment of women with these pregnancy morbidities improves subsequent pregnancy outcomes.

The antibodies that are most commonly tested include lupus anticoagulant (LAC), anticardiolipin antibody (ACA), and anti- β 2-glycoprotein 1. LAC is paradoxically named because it was first described in women with lupus, and in vitro, due to its binding with phospholipids, it will inhibit coagulation and increase the clotting time. In vivo, LAC is a strong procoagulant. To test for LAC, pathologists use specifically prepared assays, such as the kaolin clotting time or the dilute Russell viper venom test. If blood does not clot, normal serum is added to assess if the result of the clotting is due to a deficiency of clotting factors. If the blood still fails to clot with normal serum being added, then LAC is suspected. Up to 2% of normal women will have low levels of the LAC. Of note, the Venereal Disease Research Laboratory (VDRL) test for syphilis uses a phospholipid assay, and therefore the presence of LAC may induce a false-positive VDRL. Anticardiolipin antibodies are usually measured using enzyme-linked immunosorbent assays (ELISA). Both immunoglobulin G and M isotypes should be measured and must be in the 99th percentile to be considered positive. Between 3% and 5% of the population will have

low levels of immunoglobulin for ACA that is of unknown significance. Similarly, anti- β 2-glycoprotein 1 is detected using ELISA and a high titer is considered sufficient to establish the diagnosis of APS. Assays for antiphospholipids other than LAC, ACA, and anti- β 2-glycoprotein 1 have not been standardized and routine screening is not warranted.

Phospholipids are ubiquitous molecules that occur throughout the body and are found in almost all vasculature, particularly the placental vasculature. These antibodies react with proteins on the endothelium and induce platelet activation and thrombosis. The reaction induced by the antibody antigen complexes will induce both arterial and venous thrombosis. However, the primary mechanism by which these antibodies mediate pregnancy loss is not through thrombosis in the placental circulation, but by inducing deleterious effects on the developing trophoblast. These effects include inhibition of villous cytotrophoblast differentiation and extravillous cytotrophoblast invasion into the decidua, induction of syncytiotrophoblast apoptosis, and activation of maternal inflammatory pathways at the maternal-fetal interface (ACOG, 2012).

The treatment of antiphospholipid syndrome is both 81 mg of aspirin daily and prophylactic unfractionated heparin (usually 5000 to 10,000 units by subcutaneous injection twice a day) initiated with a positive pregnancy test. This therapy has shown to increase the live birth rate and decrease pregnancy loss. A Cochrane review in 2005 found that the combination of low-dose aspirin and unfractionated heparin reduced the pregnancy loss rate by 54% compared with aspirin alone in the treatment of APS in women with recurrent pregnancy loss (Empson, 2005). Although low-molecular-weight heparin (LMWH) has a number of advantages over unfractionated heparin, it has not shown comparable efficacy in reducing pregnancy loss in patients with APS. Similarly, other therapies including prednisone and intravenous immunoglobulin have not been proven to show any benefit and their use is not recommended. Multiple large randomized trials have evaluated the use of heparin or aspirin in women with unexplained recurrent pregnancy loss not meeting the diagnosis of APS and have not shown a benefit. Heparin and aspirin should therefore be used in women who have met the strict criteria for the diagnosis of APS.

Celiac Disease

Celiac disease (sprue) is a systemic autoimmune disease caused by an allergy to gluten and is associated with miscarriage. Though its most pronounced symptoms are related to intestinal malabsorption, most patients will have minimal gastrointestinal manifestations. A strong association has been documented with adverse pregnancy outcomes, including recurrent miscarriage, intrauterine growth restriction, stillbirth, and the antibodies of celiac disease. Antigliadin antibodies appear to be toxic to trophoblasts, and suppression of the antibodies through dietary control has decreased the incidence of miscarriage. In the setting of an evaluation for miscarriage, any woman with a personal or family history of celiac disease or gluten intolerance should be tested for antigliadin and antiendomysial antibodies. The prevalence of celiac disease in first-degree relatives of patients with sprue is 10%. A study by Tursi and coworkers of women with recurrent miscarriage and celiac disease noted a decreased miscarriage rate when women were placed on gluten-free diets (Tursi, 2008).

INHERITED THROMBOPHILIAS

An essential and vital component of a successful gestation is the healthy growth and development of the placental vasculature. The uteroplacental interface receives nearly 20% of maternal cardiac output. A self-protective physiologic adaptation is the increased thrombogenic characteristics of this interface to prevent hemorrhage during implantation, placentation, and the third stage of labor. If the mother has an inherent thrombotic tendency such as a thrombophilia, this thrombogenic microenvironment in the placenta can intensify, leading to multiple small infarctions at the uteroplacental interface. The potential for thrombosis of the microvasculature of the placenta has been used to explain the association between thrombophilia and recurrent pregnancy loss as well as adverse pregnancy outcomes such as preeclampsia, fetal growth restriction, and placenta abruptio. Although there is a strong association between inherited thrombophilias and venous thromboembolism, there is still controversy whether the same is true for thrombophilias and adverse pregnancy outcomes including recurrent pregnancy loss (ACOG, 2013).

The incidence of thrombophilias, both acquired and inherited, is fairly large (>10% of the Caucasian population); thus it is difficult to equate the presence of a thrombophilia as a definitive cause of a specific adverse pregnancy event. As discussed earlier, miscarriages are frequently multifactorial, particularly recurrent loss. Thrombophilias have been associated with both early and late pregnancy loss (Box 16.2). However, the association appears to be stronger for second-trimester and later losses than for early miscarriages. In a case control trial of 3496 primarily Caucasian women with unexplained pregnancy loss and matched controls, an association was seen between factor V Leiden and prothrombin gene mutation and pregnancy loss after 10 weeks. There was no association found less than 10 weeks of gestation (Lissalde-Lavigne, 2005). This finding is logical given that placental development has not taken place very early in pregnancy. Consequently, thrombosis of placental vasculature in women with thrombophilias is less likely to explain early pregnancy loss, again highlighting that thrombophilia cannot be the only pathophysiologic mechanism playing a part. There may be individual predilections and comorbidities in addition to the thrombophilias that lead to recurrent pregnancy loss in certain women. As of yet, most of these cofactors have not been identified.

Box 16.2 Thrombophilias Associated with Miscarriage

Antiphospholipid antibodies—anticardiolipin, lupus anticoagulant, and anti-beta-2 glycoprotein
 Antithrombin III deficiency
 Elevated factor VIII levels
 Factor V Leiden mutation
 MTHFR mutations*
 Plasminogen activator inhibitor-1 deficiency
 Protein C deficiency
 Protein S deficiency
 Prothrombin G20210A mutation
 Thrombocytosis (thrombocythemia—platelet counts >750,000)

*Methylenetetrahydrofolate reductase mutations. (Mild hyperhomocysteinemia is technically not a thrombophilia, though it may be associated with thrombosis. Many laboratories include testing for the mutations in thrombophilia panels.)

Although retrospective studies and meta-analyses of the thrombophilias indicate that there is an association between thrombophilias and miscarriage, prospective studies have shown no association. The Eunice Kennedy Shriver National Institute of Child Health and Human Development's Maternal-Fetal Medicine Units Network prospectively studied 134 pregnant women who were heterozygous for factor V Leiden and found no increase in the incidence of fetal loss (Dizon-Townson, 2005). A secondary analysis was conducted for maternal carriers of the prothrombin G20210A mutation and again no increased risk was noted (Silver, 2010).

The essential point to be made with couples is that it is almost impossible to know that a thrombophilia caused their miscarriage. Causation and association are not the same. Furthermore, there is insufficient evidence that antepartum prophylaxis with unfractionated heparin or LMWH prevents recurrence of miscarriage in these patients.

Factor V Leiden is the most common inherited thrombophilia in whites. The prevalence of this mutation in European populations is approximately 5%; however, it is rare in Asians and Africans. The Leiden mutation is a substitution of glutamine for arginine at position 506 on the factor V protein. This mutation in factor V leads to a defect in binding with the activated protein C (APC) complex. Consequently, factor Va is resistant to degradation by APC, which results in less down-regulation of thrombin. Women who are heterozygous for factor V Leiden account for approximately 40% of cases of venous thromboembolism (VTE) during pregnancy. Patients who are homozygous for factor V Leiden account for only 2% of VTE cases during pregnancy but have 80 times higher lifetime risk of thrombosis. The second most common thrombophilia is the G20210A mutation in prothrombin. The prothrombin mutation is a point mutation that is found in approximately 3% of the European population. It causes an excess concentration of prothrombin in the circulation and accounts for 17% of thromboembolism cases in pregnancy. Less common thrombophilias include deficiencies in protein C, protein S deficiency, and antithrombin III deficiency. All three of these proteins contribute to the thrombolytic pathway, and the homozygous states are not compatible with life. Protein C and antithrombin-3 levels may be assessed in pregnancy. However, protein S is an acute-phase reactant, decreasing with pregnancy, trauma, or surgery. Levels are significantly decreased by estrogen in general, and thus they should be measured at least 6 to 8 weeks after a pregnancy. Elevated factor VIII, greater than 180% of normal, and plasminogen activator inhibitor deficiency (PAI-1) have also been described as causes of thrombophilia, but they appear to have little independent risk of venous thromboembolism. Mild hyperhomocysteinemia is sometimes considered a thrombophilia. Homocysteine is an essential amino acid, which in excess may lead to damage to the vascular endothelium. One enzyme system that metabolizes homocysteine is methylenetetrahydrofolate reductase (MTHFR). Mutations in this enzyme are the most common cause of hyperhomocysteinemia and occur in 10% to 15% of the white and Asian populations. Hyperhomocysteinemia was thought to be a risk factor of VTE, but data suggest that it is a weak risk factor. There is insufficient evidence to screen for MTHFR polymorphisms or to measure fasting homocysteine levels as part of the evaluation of thrombophilias as a cause for venous thromboembolism.

Screening for inherited thrombophilias, specifically factor V Leiden and prothrombin gene mutations as well as protein C, protein S, and antithrombin deficiencies, may be considered when a patient has a personal history of a VTE in the setting of a non-recurrent risk factor or has a first-degree relative with a history of a high-risk thrombophilia. Treatment of the inherited thrombophilias involves subcutaneous heparin. Either unfractionated heparin or LMWH regimens may be used. Testing for inherited thrombophilias in women with recurrent pregnancy loss or placental abruption is not recommended given insufficient evidence of an association and of treatment benefit with heparin.

INFECTIONS

Numerous infectious agents such as *Ureaplasma urealyticum*, *Mycoplasma hominis*, *Chlamydia trachomatis*, *Listeria monocytogenes*, *Toxoplasma gondii*, rubella, cytomegalovirus, and herpes virus have all been identified in cultures from women who have had spontaneous pregnancy losses. There are fewer data regarding the relationship between these infectious agents and recurrent loss.

Although *Listeria monocytogenes* produces abortion in several animal species as well as humans in the second trimester, there is no convincing evidence that it is an abortifacient in women in the first trimester or in recurrent miscarriages. *Chlamydia trachomatis* is a common sexually transmitted pathogen, but there is no evidence that it causes miscarriage in asymptomatic women. Primary infections have been associated with pregnancy loss but not recurrent loss.

Several authors have suggested that T strain mycoplasma, both *Ureaplasma urealyticum* and *Mycoplasma hominis*, can cause miscarriage. Data indicating that *U. urealyticum* is a cause of miscarriage are stronger than for *M. hominis*. Penta and colleagues found that *U. urealyticum* and *M. hominis* were the most common bacterial species found in cultures from women who have had spontaneous pregnancy losses (Penta, 2003). Stray-Pedersen and Stray-Pedersen reported that eradication of *U. urealyticum* in the endometrium by tetracycline treatment for 10 days resulted in a significantly lower subsequent miscarriage rate (19%) (Stray-Pedersen, 1984). However, there are no randomized placebo-controlled clinical trials to prove that these organisms cause miscarriage and that treatment is effective.

The parasite *Toxoplasma gondii* may infect the embryo and lead to miscarriage. However, it is difficult to document the presence of this organism before a miscarriage occurs because there is a lack of correlation between serologic immunoassays for this organism and its detection in the endometrium by immunofluorescence.

The data for bacterial vaginosis as a cause of early miscarriage due to endometritis have been inconsistent; however, overgrowth of these bacteria has been repeatedly reported as a risk factor for late miscarriage and preterm birth.

Many viral agents may cause miscarriage if acquired as primary infections. Viral infections have been associated with both first- and second-trimester loss in cohort and case-control studies using histology and polymerase chain reaction (PCR). Parvovirus B-19 may be embryotoxic in the first trimester but is not a cause of recurrent loss. Similarly, infection from varicella, cytomegalovirus, and rubella may cause miscarriage but are not

a cause of recurrent loss. Primary infection with herpes simplex virus in the genital tract has been reported to cause miscarriage. Kapranos and coworkers were able to detect HSV by sensitive and accurate nested PCR in 41 of 95 cases (43.2%) of early pregnancy loss and in 6 of 36 cases (16.7%) of elective pregnancy termination (Kapranos, 2009). There does not appear to be an association between HSV-2 infection in pregnancy and fetal death after 16 weeks.

Given the lack of prospective studies linking any infectious agent to recurrent pregnancy loss, routinely screening for these organisms or using antibiotics empirically is not indicated.

ENVIRONMENTAL FACTORS

SMOKING

There are numerous studies evaluating smoking and miscarriage, and they all suggest an increased risk of miscarriage in a dose-dependent manner. In a large retrospective study of 47,146 women, an increased risk of pregnancy loss was seen in women who smoked as few as 10 cigarettes per day (Armstrong, 1992). A meta-analysis of 112 articles confirmed that any active smoking during pregnancy increased the risk of miscarriage and the risk of miscarriage was increased with the amount smoked (1% increase in relative risk per cigarette smoked per day) (Pineles, 2014). Cigarette smoke contains several toxic agents such as nicotine, carbon monoxide, and mutagens, which may be harmful to the developing embryo. Nicotine also has a vasoconstrictive effect that can reduce the blood flow to the placenta. Interestingly, most women who smoke do not miscarry, supporting the multifactorial nature of miscarriage. Paternal smoking also increases the risk of miscarriage. When both parents smoke, some studies have found a four times increased rate of miscarriage compared with nonsmoking controls.

ALCOHOL

Kline and associates also reported that drinking alcohol, acting independently from smoking, was a risk factor for miscarriage (Table 16.4). Women who drank alcohol at least 2 days a week had an approximate twofold greater risk of having a miscarriage than women who did not drink during pregnancy (Kline, 1980). More recent studies have confirmed these findings. After

studying 24,679 singleton pregnancies, Kesmodel and colleagues found more than a threefold increased risk of first-trimester spontaneous abortion for women who drank on average more than five drinks per week (Kesmodel, 2002).

COFFEE AND CAFFEINE

Some epidemiologic data have suggested that moderate to heavy caffeine ingestion may be an independent risk factor for miscarriage. Studies suggest a threshold effect with more than 300 mg/day of caffeine (equivalent to three cups of coffee) is associated with a modest increase in risk for spontaneous miscarriage. A prospective study has shown that preconceptional caffeine consumption, however, is not associated with spontaneous miscarriage. Although it is not clear whether the relationship between caffeine and miscarriage is causal, women who become pregnant are recommended to limit their caffeine intake (Cnattingius, 2000).

IRRADIATION AND MAGNETIC FIELDS

Animal studies have shown that ionizing radiation can produce congenital malformations, growth retardation, and embryonic and fetal death. These effects are dose related, and there is a threshold dose below which an adverse effect does not occur. Although there is evidence in the human that high-energy radiation exposure is associated with teratogenic effects and intrauterine growth restriction, there is no conclusive evidence that similar exposure increases the risk of spontaneous abortion. Because these studies will never be done, it is presumed that a threshold effect extends from teratogenicity to miscarriage.

Extrapolation from animal data indicates that the embryo is most sensitive to the lethal effect of irradiation during the day of implantation and a few days later (Table 16.5). The sensitivity decreases during the period of early embryogenesis, after which the minimum lethal dose (MLD) remains constant to term gestation. Animal and human data have shown that there is no increased risk of abortion with irradiation exposures of less than 5 rads. Diagnostic procedures, which are several-fold less than 5 rads, are therefore unlikely to cause a miscarriage even if they are administered during the time of implantation.

Exposure to magnetic fields induced by electric currents has not been associated with a significantly higher rate of miscarriage.

Table 16.4 Frequency (%) of Alcohol Consumption among Women Experiencing Spontaneous Abortions (Cases) and Women Delivering at 28 Weeks' Gestation or Later (Controls)

PERCENTAGE DISTRIBUTION				
Frequency of Alcohol Consumption during Pregnancy	Cases	Controls	Adjusted Odds Ratio	95% Confidence Interval
Never	42.6	43.7	1.00	0.59-0.99
Twice a month and less	28.9	38.0	0.77	0.71-1.52
Less than twice a month	10.4	1.04	1.30-2.95	
2-6 days a week	6.5	1.96		
Daily	4.5	1.4	3.00	1.39-6.49
Total	648			645

From Kline J, Stein Z, Susser M, et al. Environmental influences on early reproductive loss in a current New York City study. In: Porter IH, Hook EB, eds. *Human Embryonic and Fetal Death*. New York: Academic Press; 1980.

Video display terminals, electric blankets, and power lines are not harmful to a pregnancy.

ENVIRONMENTAL TOXINS

The information that exists concerning the effect of environmental toxins on human pregnancy and miscarriage is based on case reports and small case-control studies. Recommendations have been developed from data based on effects that cause fetal anomalies. These recommendations are to avoid contact.

Some, but not all, studies have shown an increased risk of pregnancy loss among women occupationally exposed to anesthetic gases, but most of these studies are retrospective questionnaires. A well-done case-control study indicated that the incidence of miscarriage in women exposed to anesthetic gases was not significantly increased. A more recent meta-analysis found that nurses exposed to anesthetic gases may be at an increased risk of spontaneous abortion; however, the strength of association was weaker in the well-designed studies. The current practice is to adequately scavenge gases in hospitals and physician's and dental offices. Similarly, women exposed to chemotherapeutic agents, such as nurses and pharmacy technicians, may have an increased risk of miscarriage (Connor, 2014).

High-quality evidence regarding a possible association between other environmental toxins and miscarriage is even less available. Heavy metals, lead, cadmium, mercury, and arsenic are embryotoxic. Of these, lead is the most common exposure and most well documented as a cause of miscarriage. If elevated lead levels are found in a patient, then chelation treatment is indicated prior to pregnancy and can be used in pregnancy as well. Organic solvents, particularly those used in the computer industry, and organic pesticides are worrisome and may induce miscarriage.

OBESITY

Obesity, defined as body mass index (BMI) greater than or equal to 30 kg/m², has been shown to increase the risk of miscarriage. Obesity has not only been shown to increase the risk of first-trimester miscarriage but has also been shown to increase recurrence risk in patients with recurrent pregnancy loss. An observational cohort study of 372 women with recurrent early pregnancy loss found that obese women have an increased frequency of euploid miscarriages, which is a known risk factor for subsequent miscarriages (Boots, 2014). The pathophysiology

of the association between obesity and miscarriage is unclear. A proposed mechanism includes leptin resistance and its detrimental effect on endometrial receptivity.

EXERCISE, STRESS, AND DEPRESSION

Severe stress is a well-documented cause of pregnancy loss in the animal model, and anecdotally stress has been associated with pregnancy loss in humans. Older literature, from 75 to 150 years ago, proposed that emotional stress led to adverse pregnancy outcomes. Severe stress may lead to a higher incidence of late pregnancy outcomes by affecting uteroplacental function in some cases but has not been associated with early pregnancy loss. Women who receive counseling for depression associated with recurrent loss seem to have a higher successful pregnancy rate. The interaction among stress, depression, and pregnancy outcome is complex. Currently, the relationship with pregnancy loss is equivocal at best. Many studies have repeatedly shown that employment, work, and exercise are not associated with miscarriage.

Although the Danish National Birth Cohort study, which included 92,671 pregnancies, found that moderate to intense exercise including "high-impact" exercise in the first trimester may increase pregnancy loss, the study's design was problematic and affected by recall bias (Madsen, 2007).

DIAGNOSIS

Miscarriage is ultimately diagnosed through confirmation of a nonviable gestation. Originally, the types of abortion were described by the appearance of the patient upon presentation to the physician. They include (1) *threatened abortion*—vaginal bleeding in the setting of a viable intrauterine pregnancy and closed cervical os, (2) *missed abortion*—a nonviable intrauterine gestation less than 20 weeks with a closed cervical os, (3) *incomplete abortion*—an intrauterine gestation at less than 20 weeks with an open cervical os and partial passage of products of conception, (4) *inevitable abortion*—an open cervical os with no passage of products of conception in the setting of either a viable or nonviable intrauterine pregnancy, and (5) *complete spontaneous abortion*—passage of all products of conception in the setting of an intrauterine pregnancy. These definitions have been rendered somewhat less helpful with the widespread use of transvaginal ultrasound in the diagnosis of early pregnancy.

The level of B-hCG in a normally developing pregnancy should rise in a predictable fashion. A minimal increase of 24% in 24 hours and 53% in 48 hours was observed for viable pregnancies in a large longitudinal study. Levels may peak around 100,000 IU at 10 weeks with the steepest rate of increase observed in the first 6 weeks, followed by a slower rise and eventual fall after the peak. A "discriminatory zone" of B-hCG level has been used to predict when an intrauterine gestational sac should be visible on imaging. A B-hCG of 1500 IU has traditionally been accepted as the level at which transvaginal ultrasound should reveal an intrauterine gestational sac in a viable pregnancy. However, discussion in the literature has called this data point into question (Barnhart, 2012).

The first sonographic finding of a pregnancy is the gestational sac (Table 16.6). This is a sonographic term, not a true anatomic

Table 16.5 Estimation of Abortigenic Hazards of X-Irradiation to Human Embryo from Animal Experiments

Stage of Human Gestation (Days)	Lethal Dose/50 (Rads)	MLD (Rads)
1	70-100	10
14	140	25
18	150	25
28	220	50
50	260	50
Late fetus to term	300-400	50

MLD, Minimum lethal dose.

delineation (Goldstein, 1994). The sac is an echolucent area in the uterus surrounded by echodense-reactive endometrium (decidualized endometrium; Fig. 16.7). Intrauterine lucencies may be first visualized as early as 3 weeks after the last menstrual period, 1 week after conception, and may represent purely fluid in the secretory phase. In the interior of the sac is the developing fluid-filled chorionic sac. With visualization of the chorionic sac with secondary echoes, a true gestational sac may be defined. If the fluid is endometrial secretions, it is considered a pseudogestational sac. The first fetal structure that may be visualized on ultrasound is the yolk sac. A distorted or large yolk sac, greater than 7 mm, has been associated with pregnancy loss.

The embryonic disc is notable as a thickening on the yolk sac as early as a few days after the yolk sac appears. An embryonic disc should be visualized by approximately 5 to 6 weeks' gestational age. If the mean gestational sac diameter is more than 25 mm and no embryo is visible, an anembryonic gestation is present. The earliest cardiac activity was noted to have occurred 5 weeks after the last menstrual period in a 28-day cycle. Initially,

Table 16.6 Ultrasound Findings in Early Pregnancy

Ultrasound Findings	Gestational Age from LMP (days)	Approximate HCG (IU)	Approximate Risk of Miscarriage*
Gestational sac	23-29	1500	<12%
Yolk sac	32-45	5000	<9%†
Embryonic disc	35-45		<8%
Fetal cardiac activity	>42 with CRL × 5 mm	13,000-15,000	<8%
Embryo 2 cm with heart rate	56		<2%

*If no vaginal bleeding.
†If the gestational sac is 10 mm.
CRL, Crown-rump length; HCG, human chorionic gonadotropin; LMP, last menstrual period.

Figure 16.7 Endovaginal ultrasound 6 days after a gestational sac, with mildly increased decidual reaction surrounding the echolucent sac. UT, Uterus. (From Lyons EA, Levi CS, Dashefsky SM. The first trimester. In: Rumack CM, Wilson SR, Charboneau JW [eds]: *Diagnostic Ultrasound*. 2nd ed. St. Louis: Mosby; 1998.)

the fetal heart rate should be in the 80 to 110 beats per minute (beats/min) range and will then often increase into the 180 to 220 bpm range for the first few months of pregnancy, but by 12 weeks it should return to 110 to 160 bpm.

Diagnosis of pregnancy loss should be made by thorough medical history and physical examination combined with ultrasound and B-hCG values. Care should be taken in basing the diagnosis on a single B-hCG level or ultrasound, as a point-in-time measurement is often unreliable. Trending of values and examination findings are usually required for accuracy. Early studies of transvaginal ultrasound for determination of fetal viability used a crown-rump length (CRL) of 5 mm without cardiac activity or an empty intrauterine gestational sac with a mean sac diameter (MSD) of 16 mm to diagnose a miscarriage. However, more recent data have prompted the Society of Radiologists in Ultrasound Multispecialty Panel on Early First Trimester Diagnosis of Miscarriage and Exclusion of a Viable Intrauterine Pregnancy to recommend more conservative guidelines. These new criteria require a CRL of 7 mm or more with no heartbeat or an MSD of 25 mm or more with no embryo to diagnose an early pregnancy loss. The aim of these new criteria is to facilitate achievement of 100% specificity with a 0 false-positive rate in the diagnosis of a nonviable pregnancy. Included in these guidelines are findings suggestive, but not diagnostic, of pregnancy loss (Doubilet, 2013).

THREATENED ABORTION

Bleeding may occur in 30% to 40% of pregnancies during the first 20 weeks, and about 50% of these will ultimately end in miscarriage (Hasan, 2009). Women who do not suffer a loss are slightly more apt to deliver preterm or encounter fetal anomalies. Ultrasound is the most useful diagnostic tool in patients with bleeding, and a subchorionic hematoma, seen as a lucency behind the brighter placental disk, will be observed in 20% of these women. About two thirds of women with bleeding will have a live fetus on ultrasound examination, and nearly 85% of these women will go on to deliver a live-born infant.

MISSED ABORTION

The advent of early, widespread use of transvaginal ultrasound has largely made the term *missed abortion* irrelevant. Rarely will a patient have delayed diagnosis of either a fetal demise or anembryonic gestation. Retention of a dead fetus in the uterus beyond 5 weeks following the demise can be associated with consumptive coagulability and hypofibrinogenemia. The condition is usually self-limited and resolves in a few weeks without intervention. The incidence is higher with both the length of gestation and duration of fetal death, occurring uncommonly before 16 to 18 weeks.

SEPTIC ABORTION

Infection may occur in 1% to 2% of all miscarriages, with an increased incidence following induced abortions using non-sterile equipment. A high suspicion of septic abortion should accompany symptoms of bleeding or spotting and clinical signs of infection during the first 20 weeks of pregnancy. Septic abortions may be threatened, inevitable, missed, or incomplete.

Infection can spread from the endometrium through the myometrium and eventually affect the parametrium and peritoneum. Elevated temperature, leukocytosis, lower abdominal pain, cervical motion tenderness, and a purulent vaginal discharge are all signs of septic abortion. The cause is most frequently polymicrobial, with *E. coli* and other aerobic gram-negative rods involved. Group B B-hemolytic streptococci, anaerobic streptococci, *Bacteroides*, and *Clostridium perfringens* may also be implicated. Shock can occur from the release of endotoxins.

TREATMENT

THREATENED ABORTION

There is no evidence to support limitation of physical activity or any medical intervention to improve the prognosis of a threatened abortion. Avoidance of excessive physical activity/exercise and coitus may serve as comfort measures. Likewise, administration of natural progesterone, synthetic progestins, or hCG should be avoided, as this may increase the probability of a missed abortion by falsely elevating monitoring levels of progesterone or B-hCG. If the patient is Rh negative, Rh immune globulin should be administered.

DIAGNOSED ABORTION

Once a nonviable pregnancy has been diagnosed, a thorough discussion with the patient and her partner or support person should ensue. Her feelings surrounding the pregnancy, as well as cultural preferences and past experience, may influence her decision regarding intervention.

Provided there is no evidence of infection, expectant management, medical therapy, or surgical evacuation of the uterus are all viable alternatives. Multiple studies confirm that no option is superior. Whereas uterine perforation may occur with surgical intervention, heavy bleeding is more common with expectant management (ACOG, 2015).

About 50% to 70% of women will opt for expectant management. Up to 95% will successfully expel an incomplete abortion without intervention (Sotiriadis, 2005). Within 2 weeks, 25% to 85% of women with a missed abortion will spontaneously resolve the pregnancy, 37% doing so within 7 days (Luise, 2002). As there is no agreed-upon value, ultrasound should not be used to measure endometrial thickness for confirmation of completion of a miscarriage but rather solely to document the absence, thus presumed passage, of a previously seen gestational sac. Should expectant management be undertaken, the patient should have a short interval follow-up within 1 to 2 weeks.

Medical management most often employs misoprostol, a prostaglandin E1 analogue, as a means to expedite expulsion of products of conception. The majority of women, 80% to 90%, will completely expel a first-trimester loss after one or two doses. Older gestations are more apt to fail medical management. Misoprostol is administered either orally or vaginally, with the vaginal route preferred to maintain steady serum levels and to avoid gastrointestinal side effects. Candidates for medical management include women without evidence of infection, hemorrhage, anemia or a bleeding disorder. Results of a large randomized controlled trial showed success rates of 71% after a single dose and 84% after a second dose of 800 micrograms misoprostol

per vagina (Zhang, 2005). Based on robust evidence, 800 micrograms of vaginal misoprostol is recommended with a repeat dose as needed in patients undergoing medical management of an early pregnancy loss. The addition of mifepristone (a progesterone receptor antagonist) to misoprostol has not been shown to be more effective than misoprostol alone (ACOG, 2015). A Cochrane review in 2013 concluded that misoprostol does not lead to higher rates of complete expulsion of products of conception than expectant management over a 7- to 10-day interval in patients with incomplete pregnancy loss (Neilson, 2013). Therefore misoprostol may not be more effective than expectant management in these women.

Surgical evacuation of the uterus should be considered in patients with hemorrhage, sepsis, or who are hemodynamically unstable. Surgical treatment may also be preferable to women who desire an immediate end point. Suction curettage has been shown superior to sharp curettage, which adds little once complete suction evacuation of the uterus has been performed. One advantage of suction evacuation is the ability to perform the procedure in an outpatient office setting using local anesthesia.

SEPTIC ABORTION

Septic abortion carries a fatality rate of 0.4 to 0.6 per 100,000 spontaneous abortions. Women presenting with septic abortion should receive a complete blood count, urinalysis, blood chemistry, and electrolyte panel. Cervicouterine cultures should be taken, and a Gram stain may provide rapid analysis. Blood cultures, chest x-ray, and panels for coagulation and disseminated intravascular coagulation (DIC) should be obtained in women who are acutely ill. Evacuation of the uterus should occur within 2 hours of the initiation of broad-spectrum, intravenous antibiotics. Hysterectomy may be warranted for patients with severe sepsis or those whose uterus cannot be evacuated through the cervix.

FOLLOW-UP CARE

An essential aspect of the care of women with spontaneous miscarriage is the follow-up visit. At this time, the patient should be asked open-ended questions about her experience and thoughts. Multiple studies have noted patient's anger and difficulty with the health care system during the time of a miscarriage. Dealing with those frustrations will improve interactions in the future and may also decrease the risk of depression after the loss. Grieving and depression are significant issues after miscarriage. Open-ended questions are the best way to assess a patient's mood and status. Many women experience guilt after miscarriage, believing that the loss was something that they caused by some action that they performed. In fact, one study found that 80% of women had some guilt associated with a particular act or habit that is perceived as causing the miscarriage. These issues should be addressed. Some women develop physical symptomatology with grieving that may mimic symptoms of depression, such as fatigue, anorexia, sleeplessness, and sometimes somatic symptoms such as headache and back pain.

As many as 30% of women will suffer from depression after miscarriage. If symptoms of depression are apparent, then

counseling and therapy with antidepressants should be pursued. A patient should be advised that if such symptoms develop, she and her family should return. Studies have also shown that couples experiencing miscarriage are at an increased risk for breaking up compared to couples with live births.

Five percent to 20% of women may develop transient symptoms of thyroid disease after a pregnancy loss. These women have a risk of thyroid disease over the next 5 years. The symptoms should be treated with thyroid replacement for low thyroid and antithyroid medications for hyperthyroid symptoms. Treatment is usually continued for 6 to 9 months, at which point the patient is reevaluated. A free thyroxine level should be obtained.

Also, at the follow-up visit an assessment is given as to potential causes of miscarriage and possible explanations. Any testing can be ordered after two or more miscarriages. The workup that is initiated for a cause of recurrent pregnancy loss is discussed next.

Future pregnancy planning is also discussed at this visit. There is no compelling evidence showing that delaying conception after an early pregnancy loss will decrease subsequent miscarriage risk. If another pregnancy is not desired, hormonal-based contraception may be initiated immediately after completion of early pregnancy loss, if appropriate.

RECURRENT MISCARRIAGE

Historically, recurrent miscarriage has been defined as three or more consecutive spontaneous losses. ASRM defines recurrent pregnancy loss as two or more failed clinical pregnancies, documented by ultrasonography or histopathologic examination. These criteria should be used to determine whether an evaluation for recurrent pregnancy loss is appropriate. For epidemiologic studies, however, ASRM recommends that three or more losses should be used. There are no consistent or generally accepted terms and definitions of pregnancy loss prior to viability at this time. The heterogeneity in the definition of recurrent pregnancy loss makes it difficult to compare scientific data from different research groups.

The calculated probability that a woman will have two consecutive spontaneous abortions is fewer than 5%, whereas only 1% of women will experience three or more. Approximately 50% of the time, a risk factor for the recurrent losses can be determined. Often this is a factor associated with miscarriages. The remaining couples are said to have “unexplained” recurrent miscarriage.

As discussed earlier, miscarriage risk does increase with the number of previous pregnancy losses (see [Table 16.1](#)) as well as with age. Some studies have shown that past obstetrical history of a successful pregnancy does lower the risk for another spontaneous miscarriage, whereas others have not. The frequency of chromosomally normal miscarriages is higher in women under the age of 35 with recurrent miscarriage than in those with a single spontaneous abortion. In fact, the likelihood of a normal embryonic karyotype also increases with the number of previous miscarriages and after a previous abortion with a normal karyotype. After stratifying for maternal age, the distribution of chromosomal abnormalities seen in couples with recurrent miscarriage is not different than the normal populations ([Stephenson, 2002](#)). Women with recurrent miscarriages also

have a tendency to abort later in gestation, indicating that maternal or environmental factors are a more likely cause of repeated pregnancy loss.

It is recommended that diagnostic evaluation be initiated after a woman has had two failed clinical pregnancies, as one early miscarriage is relatively common. Not uncommonly a history may elicit a particular line of investigation that should be initiated even after one loss. If a pregnancy loss occurs in the second trimester, the cause is more likely to recur. Thus a diagnostic evaluation should be considered after a woman has had only one second-trimester loss.

The evaluation for women with recurrent miscarriage starts with a history and physical examination with pertinent questions regarding cervical incompetence, abnormal exposures, gastrointestinal diseases, previous gynecologic surgery, any pathologic tests that were performed on previous miscarriages, family history of miscarriages or birth defects, family history of unusual thrombosis, and open-ended questions that explore the patient's ideas about causation. Laboratory evaluation should be pointed toward clues from the history. Any history suggestive of thyroid disease may prompt studies for a TSH and antithyroid antibodies. Other studies should include prolactin, hemoglobin A1C, and antiphospholipid antibodies. An evaluation of the uterine cavity is an important part of the workup and may include a hysterosalpingogram, saline sonohysterogram, three-dimensional ultrasound, hysteroscopy, or MRI. Sonohysterography is a sensitive, specific, and accurate screening method for assessing abnormalities in the uterine cavity of women with recurrent miscarriage. A karyotype of the husband and wife should also be performed to determine if any balanced structural chromosomal abnormalities exist. More controversial screening includes the following: PCOS and insulin resistance, luteal phase progesterone, sperm DNA, alloimmune disorders such as HLA typing, and infectious agents with endocervical cultures.

If any of these tests reveals an abnormality, it may be corrected with appropriate surgical or medical therapy. If a chromosomal abnormality is found, genetic counseling is indicated. When one of the partners carries a structural genetic abnormality, several options are available to detect genetic abnormality in the offspring including IVF with preimplantation genetic diagnosis (PGD), chorionic villus sampling, or amniocentesis. IVF/PGD allows for the diagnosis of specific translocations and transfer of only unaffected embryos. Two systematic reviews have evaluated the success rates with IVF/PGS compared with natural conception and observation. These reviews reported that the live birth rates with IVF/PGD were approximately 31% to 35% per cycle and cumulative live birth rates were 55% to 74% for natural conception ([ASRM, 2012](#)). Scriven and associates performed a large intent-to-treat study evaluating 59 couples with reciprocal translocations who were undergoing PGD using the fluorescence in situ hybridization (FISH) technique. These authors found that couples would need to undergo up to three IVF cycles to achieve a 50% chance of successful live birth ([Scriven, 2013](#)). The techniques for PGS/PGD have improved since these studies were published, and therefore the live birth rates with this technology may be higher now. Given the current published evidence, however, routine preimplantation genetic testing is not recommended for couples with recurrent pregnancy loss and a structural genetic abnormality.

Approximately half of women with recurrent miscarriage will not have an identifiable factor to explain their losses. Many clinicians will offer progesterone supplementation in early pregnancy to women with unexplained recurrent miscarriages. Administration of exogenous progesterone is not recommended in women with sporadic miscarriages but may be of some benefit in women with three or more consecutive miscarriages. Regardless of any treatment, however, the majority of these women will have a successful pregnancy next time with no intervention. In fact, approximately 75% of these women will ultimately achieve a successful pregnancy. Many studies have also demonstrated that these women benefit from extensive counseling and emotional support throughout early gestation. Stray-Pedersen and Stray-Pedersen reported that when a group of women with a history of unexplained recurrent abortion were given extensive antenatal counseling and psychological support, the live birth rate was 86% (Stray-Pedersen, 1984). Clifford and associates reported that women with unexplained recurrent miscarriage given supportive care early in pregnancy had a 74% viable birth rate without other therapy. When only routine antenatal care was given to a similar group of women, the live birth rate in these three reports was between 33% and 51%, significantly less (Clifford, 1997). Thus tender loving care (TLC) defined as psychological support with routine medical and ultrasonographic examinations during early pregnancy appears to be very beneficial for improving the prognosis of couples with recurrent abortion whose cause remains undetermined.

If a woman does abort, she should be offered cytogenetic evaluation of the conceptus. Although some view karyotyping as unnecessary and expensive, other experts have reasoned that women who abort aneuploid fetuses should be spared unnecessary and costly evaluation given that the event was likely random and the greater likelihood of success with a subsequent pregnancy. However, there are drawbacks to this approach. A normal 46,XX karyotype can actually be maternal cell contamination of the tissue specimen, particularly when care is not taken to isolate only chorionic villi for cell culture. Additionally, a full evaluation of causes of recurrent pregnancy loss may be overlooked if cytogenetic assessment reveals an aneuploid abortus (ASRM, 2012).

Some authors have proposed preimplantation genetic screening (PGS) for patients with unexplained recurrent pregnancy

loss to test for numerical (aneuploidy) abnormalities in order to reduce the risk of miscarriage in these patients. Investigators have argued that the percentage of aneuploidy losses in women with unexplained pregnancy loss may be underestimated given that conventional karyotyping using tissue culture is not definitive and studies on products of conception are not often performed in very early losses. Data derived from several studies have also shown a high rate of aneuploidy in patients with recurrent pregnancy loss, particularly in those over the age of 35. Garrisi and associates published a controlled clinical trial comparing the rate of miscarriage after IVF/PGS in patients with idiopathic pregnancy loss to their own expected loss rate. For patients 35 years or older, the expected loss rate was 34%, but the observed loss rate was 13.6% after IVF/PGS. These authors concluded that PGS improves pregnancy outcome in women with idiopathic recurrent pregnancy loss, particularly those older than 35 years and with two or more previous losses (Garrisi, 2009). Other studies have shown a decrease in miscarriage rate but no clear benefit of PGS in terms of live birth rate compared to natural conception in this patient population. The medical risks and financial burden of IVF/PGS must also be justified before recommending routine use of this intervention. As the technology improves, wider application of IVF with PGS is likely.

However, the possibility of having an explanation is a tool in dealing with the grief of repetitive losses. Couples with unexplained recurrent miscarriage are at even greater risk of anxiety than couples with one loss. It is that anxiety that often pushes them toward “any possible cure.” The clinician is all too commonly requested to “try anything.” Thus some couples are offered treatment without evidence of a diagnosis or that the treatment provides a higher chance of live birth beyond no intervention. Large studies and a *Cochrane Review* have shown that heparin, heparin and aspirin, intravenous immunoglobulin, and aspirin alone are not, and do not, increase the likelihood of a viable pregnancy. Moreover, further compelling studies are needed for interventions such as IVF with PGS. The “give it everything we’ve got” approach is not helpful and is potentially dangerous. The skill and art of the practitioner must be used to teach and guide families through this difficult time period with gentleness and good medicine based on the best evidence available.

KEY POINTS

- About 15% to 20% of all human pregnancies end in a clinically recognized miscarriage, with 80% occurring in the first trimester; the incidence decreases with increasing gestational age.
- If embryonic cardiac activity is seen sonographically at 6 weeks’ gestation, then the subsequent abortion rate is about 6% to 8%. If the embryo is viable at 8 weeks, then the subsequent abortion rate is 2% to 3%.
- For a woman with a reproductive history of three pregnancy losses with no live births, her chance of having a miscarriage in a subsequent pregnancy is about 45%; if she has had at least one live birth and three spontaneous abortions, the chance that her next pregnancy will result in a miscarriage is only about 30%.
- The major cause of early pregnancy loss is chromosomal. About 56% of these abnormalities are trisomic, 20% are polyploid, 18% will be chromosome X monosomies, and 4% will represent unbalanced translocations.
- Uterine anomalies can be observed in approximately 12.6% of women with recurrent pregnancy loss. Women with uterine septa have the highest risk of miscarriage.
- Women at risk of cervical insufficiency should be monitored with serial ultrasound examinations from 16 weeks to the end of 24 weeks. If strict criteria are used to diagnose cervical incompetence, fetal survival rates after cerclage have been reported to increase from 20% to 80%.

Continued

KEY POINTS—cont'd

- Untreated overt hypothyroidism and subclinical hypothyroidism as well as hyperprolactinemia and uncontrolled diabetes are all potential causes of miscarriage
- The incidence of antiphospholipid syndrome is between 15% and 20% in women with recurrent pregnancy loss. The treatment is both 81 mg of aspirin daily and prophylactic heparin initiated with a positive pregnancy test.
- The prevalence of major chromosomal abnormalities present in either partner of a couple with two or more pregnancy losses is about 3%, five to six times higher than in the general population. Abnormalities occur in the female parent about twice as frequently as in the male, with balanced reciprocal translocations occurring in half of these individuals.
- Studies that have followed women who had medical, surgical, and expectant management of miscarriage have noted no difference in subsequent pregnancy rates.
- Trending B-hCG levels and serial ultrasound examinations should be used to confirm a failed pregnancy. Care should be taken to avoid a single data point to diagnose an early pregnancy loss.
- Approximately 50% of women with recurrent pregnancy loss will not have an identifiable factor to explain their loss. The majority of these women will ultimately achieve a successful pregnancy without any intervention.

Ectopic Pregnancy Etiology, Pathology, Diagnosis, Management, Fertility Prognosis

Rosanne M. Kho, Roger A. Lobo

Ectopic pregnancy occurs when the fertilized ovum/developing blastocyst implants at a site outside of the endometrial cavity. It was probably first described in 963 AD by Albucasis, an Arab writer. In 1876, before the initiation of surgical therapy, the mortality rate from ectopic pregnancy was estimated to be 60%. The first successful operative treatment of ectopic pregnancy was performed in 1883 by Lawson Tait in England. In 1887, he reported that he had performed salpingectomy on four women with ectopic pregnancy and that they all survived.

EPIDEMIOLOGY

The incidence of ectopic pregnancy has been estimated to be between 1% to 2% of all pregnancies. Although the incidence of ectopic pregnancy increased sixfold between 1970 and 1992, it has remained stable since then. In the United States in 1989, the annual ectopic pregnancy rate per 10,000 women aged 15 to 44 was 15.5, similar to that in Finland, but higher than the rate in France. The last and most recent national data reported by the Centers for Disease Control showed that the overall incidence of ectopic pregnancy had plateaued to approximately 20/1000 pregnancies in the early 1990s. The current incidence of ectopic pregnancy is difficult to estimate from available hospitalization and insurance records because the number of ectopic pregnancy cases requiring inpatient hospital treatment has decreased. The incidence varies among different countries, with rates as high as 1 in 28 and 1 in 40 pregnancies reported in Jamaica and Vietnam, respectively. The risk of ectopic pregnancy associated with assisted reproductive technology is increased compared with the general population with rates from 0.8% to 8.6%. Data from the National ART Surveillance System from 2001-2011 showed that the rate of ectopic pregnancy declined from 2% to 1.6% out of 553,577 pregnancies in the United States (Perkins, 2015).

There has been an increasing trend toward treating ectopic pregnancy conservatively (without resorting to salpingectomy) and on an ambulatory basis without overnight hospitalization. With earlier detection of ectopic pregnancy, a steadily increasing percentage of women with this problem are now being treated before tubal rupture occurs by outpatient laparoscopic

procedures or by medical treatment with methotrexate. An analysis of both hospital discharge data and an ambulatory medical care survey revealed that the estimated number of hospitalizations for ectopic pregnancy in the United States declined from nearly 90,000 in 1989 to about 45,000 in 1994. However, in 1992 about half of all women with ectopic pregnancy in the United States were treated as outpatients, and the estimated number of total ectopic pregnancies in this year was 108,000, for a rate of 19.7 per 1000 reported pregnancies. Thus, in the United States in 1992, about 2 of every 100 women who were known to conceive had an ectopic gestation. The increased incidence of ectopic pregnancy is thought to be due to two factors: (1) the increased incidence of salpingitis, caused by increased infection with *Chlamydia trachomatis* or other sexually transmitted pathogens, and (2) improved diagnostic techniques, which enables the diagnosis of unruptured ectopic pregnancy with more precision and earlier in gestation, before asymptomatic resolution of the pregnancy occurs.

There is an increase in the rate of ectopic pregnancy with increasing age. However, because of the lower pregnancy rate in older women, overall only about 11% of ectopic pregnancies in the United States occur in women aged 35 to 44, whereas more than half, 58%, occur in women aged 25 to 34 years. Most ectopic pregnancies occur in multigravid women. Only 10% to 15% of ectopic pregnancies occur in nulligravid women, whereas more than half occur in women who have been pregnant three or more times. In the United States, the rates of ectopic pregnancy are similar in each section of the country, but the rates are higher for nonwhite than white women. About 3% of all reported pregnancies in nonwhite women aged 35 to 44 in the United States were ectopic.

MORTALITY

Even with the increased use of surgery and blood transfusions and earlier diagnosis, ectopic pregnancy remains a major cause of maternal death in the United States today. From the last Centers for Disease Control and Prevention (CDC) report, 6% of pregnancy-related mortality during the period

of 1991-1999 was due to ectopic pregnancies. In the United States, 876 deaths were attributed to ectopic pregnancy between 1980 and 2007. Ectopic pregnancy is the most common cause of maternal death in the first half of pregnancy. The ectopic pregnancy to mortality ratio has declined by 57% from the period 1980-1984 to 2003-2007, from 1.15 to 0.5 (Creanga, 2011). The mortality ratio was 6.8 times higher for African Americans than whites and 3.5 times higher for women older than 35 years compared with women younger than 25 years. Of the 76 deaths among women hospitalized with ectopic pregnancy between 1998 and 2007, 70% of the ectopic pregnancies were located in the fallopian tubes. Unmarried women of all races have a 1.7 times greater chance of dying of ectopic pregnancy than married women. Overall the risk of death from ectopic pregnancy is about 10 times greater than the risk of childbirth and more than 50 times greater than the risk of legal abortion.

The major cause of mortality from ectopic pregnancy is blood loss. Most cases of mortality (70%) result from gestations in the tube, and the other 30% were interstitial cornual or abdominal gestations. Because the overall incidence of ectopic pregnancy occurring in these latter locations is slightly less than 4%, interstitial and abdominal ectopic pregnancies have about a five times greater risk of being fatal. About three fourths of the women with fatal ectopic pregnancies initially developed symptoms and died in the first 12 weeks of gestation. Of the remaining one fourth who developed symptoms and died after the first trimester, 70% had interstitial or abdominal pregnancies. Patient delay in consulting a physician after development of symptoms accounted for one third of the deaths, whereas treatment delay resulting from misdiagnosis contributed to the half of the deaths.

ETIOLOGY

FACTORS CONTRIBUTING TO THE RISK

The major factor contributing to the risk of ectopic pregnancy is **salpingitis**. Its morphologic sequelae account for about half of the initial episodes of ectopic pregnancy. However, in about 40% of cases the cause cannot be determined and is presumed to be a physiologic disorder resulting from the delay of passage of the embryo into the uterine cavity. Ovulation from the contralateral ovary has been implicated as a cause of the delay of blastocyst transport, and it has been suggested that contralateral ovulation occurs in about one third of tubal pregnancies, although this has not been confirmed.

Another possibility in the etiology of ectopic pregnancy is a hormonal imbalance; an elevated circulating level of either estrogen or progesterone can alter normal tubal contractility. An increased rate of ectopic pregnancies has been reported in women who conceive with physiologically and pharmacologically elevated levels of progestogens. The latter condition can be produced locally with a progestogen-releasing intrauterine device (IUD), as well as systemically with progestin-only oral contraceptives. Iatrogenic, physiologically increased levels of estrogen and progesterone occur after ovulation induction and assisted reproduction techniques (ART) with either clomiphene citrate or human menopausal gonadotropins, and an increased rate of ectopic pregnancies has been reported in women conceiving after each of these treatment modalities.

Another possible cause is an abnormality of embryonic development. Although aneuploidy has been found to be prevalent in ectopic pregnancies, it may not be higher than the normal rate of aneuploidy and is unlikely to be a cause of ectopic pregnancies. Inherited genetic abnormalities are most probably not a cause of ectopic pregnancy either. Also, there is no increased incidence of ectopics among first-degree relatives.

Several epidemiologic studies indicate that cigarette smoking is associated with about a twofold increased risk of ectopic pregnancy, even when the data were controlled for the presence of other risk factors. The risk of ectopic pregnancy was directly related to the number of cigarettes smoked per day, with a fourfold increased risk noted among women who smoked 30 or more cigarettes per day. Known risk factors for ectopic pregnancy, presented as odds ratios and attributable risk, are depicted in Table 17.1 (Bouyer, 2003).

The major causes of ectopic pregnancy will be discussed in more detail next.

TUBAL PATHOLOGY LEADING TO ECTOPIC RISK

Disruption of normal tubal anatomy from infection, surgery, congenital anomalies, or inflammatory disease such as endometriosis is a major cause of ectopic pregnancy. The agglutination of the plicae (folds) of the endosalpinx produced by salpingitis can allow passage of sperm but prevent the normal transport of the larger morula. The morula can be trapped in blind pockets formed by adhesions of the endosalpinx. In their 20-year longitudinal study, Weström and colleagues found that nearly half (45.3%) of the women with ectopic pregnancy had a clinical history or histologic findings of a prior episode of acute salpingitis (Weström, 1981). This is in agreement with the 40% incidence

Table 17.1 Odds Ratios for Ectopic Pregnancy (Compared with Women with Recent Successful Pregnancies) and the Attributable Risks Associated with Different Risk Factors

	Odds Ratio	Attributable Risk*
Probable salpingitis	2	
Confirmed salpingitis	3.5	
History of tubal surgery	3.5	0.18†

†Risk attributable to history of genital infection and tubal surgery together is 0.33.

of prior salpingitis found on histology by several groups of investigators in women with ectopic pregnancy (Fig. 17.1).

Weström and colleagues prospectively followed 900 women aged 15 to 34 years who had laparoscopically confirmed acute salpingitis and found that the subsequent ectopic pregnancy rate was 68.8 per 1000 conceptions, yielding a sixfold increase in the risk of ectopic pregnancy. The risk of ectopic after acute salpingitis increased both with the number of episodes of infection and with the increasing age of the women at the time of infection. The odds ratios for ectopic pregnancy after two and after three or more episodes of chlamydial infection were 2.1 and 4.5, respectively. Data also suggest that a history of chlamydial infection results in the production of PROKR2 protein that results in a microenvironment that predisposes to tubal implantation (Shaw, 2011).

Endometriosis

Inflammation of the fallopian tubes due to conditions such as endometriosis is a risk factor for ectopic pregnancy. Compared with women without endometriosis, women with endometriosis had two times the risk for ectopic pregnancy (relative risk 1.9, 95% confidence interval 1.8 to 2.1) (Hjort Hansen, 2014).

Salpingitis Isthmica Nodosa

Salpingitis isthmica nodosa (SIN) is defined as the microscopic presence of tubal epithelium within the myosalpinx or beneath the tubal serosa (Fig. 17.2). In two histopathologic studies of tubes removed from women with ectopic pregnancy, it was found that about half contained lesions of SIN compared with 5% in a control group. With serial sectioning, it has been determined that SIN is actually a diverticulum or intrauterine extension of the tubal lumen. Associated histologic evidence of chronic salpingitis was seen in only 6% of the tubes, suggesting that SIN was not necessarily the result of infection. It has been found that the **tubal pregnancy** usually implanted in a portion of the tube distal to the SIN, indicating that mechanical entrapment of the morula is not the mechanism whereby SIN causes tubal gestation. It may be that it is SIN itself or associated tubal anomalies that may be responsible for dysfunction of the tubal transport mechanism without anatomic obstruction.

Figure 17.1 Histology of ectopic pregnancy. Note the trophoblastic tissue (arrows) in the fallopian tube lumen. (Modified from www.imagingpathways.health.wa.gov.au.)

It is likely that adhesions between the tubal serosa and bowel or peritoneum may interfere with normal tubal motility and cause ectopic pregnancy because, as reported, 17% to 27% of women with ectopic pregnancy have had previous abdominal surgical procedures not involving the oviduct. On the other hand, neither endometriosis nor congenital anomalies of the tube have been associated with an increased incidence of ectopic pregnancy.

Tubal Surgery

An operative procedure on the tube itself is a cause of ectopic pregnancy whether the tube is morphologically normal, as occurs with sterilization procedures, or abnormal, as occurs with post salpingitis reconstructive surgery. The incidence of ectopic pregnancy occurring after salpingoplasty or **salpingostomy** procedures to treat distal tubal disease ranges from 15% to 25%, probably because the damage to the endosalpinx remains. The rate of ectopic pregnancy after reversal of sterilization procedures is lower, about 4%, because the tubes have not been damaged by infection.

Women who have had a prior ectopic pregnancy, even if treated medically or by unilateral salpingectomy, are at increased risk for having a subsequent ectopic pregnancy. Of women who conceive after having one ectopic pregnancy, about 25% of subsequent pregnancies are ectopic. The rates of recurrent ectopic pregnancy after single dose methotrexate, salpingectomy and linear salpingostomy are 8%, 9.8%, and 15.4%, respectively, among women who conceive (Yao, 1997). In two large series of women with ectopic pregnancy, 7% had a history of a prior ectopic pregnancy.

Diethylstilbestrol Exposure

Although it is less frequently encountered today, the incidence of ectopic gestation is significantly greater (four to five times) in women who have been exposed to diethylstilbestrol (DES) in utero and has been reported at the rate of 4% to 5%. This is likely due to abnormal tubal morphology and impaired function of the fimbriae. In women exposed to DES whose hysterosalpingograms demonstrated abnormalities in the uterine cavity, the ectopic pregnancy rate was as high as 13%.

CONTRACEPTION FAILURE

For several decades, sterilization has been the most popular method of contraception used by couples in the United States.

Figure 17.2 Laparoscopic view of salpingitis isthmica nodosa in the isthmus tube and cornual regions of the uterus. Note the normal distal tube. (From www.danmartinmd.com.)

Since the development of laparoscopic surgery, female tubal sterilization is performed about twice as frequently as vasectomy. In an analysis of the long-term risk of pregnancy after tubal sterilization reported by Peterson and coworkers, it was found that within 10 years after the procedure, the cumulative life table probability of pregnancy was 1.85%. The 10-year failure rate after bipolar coagulation of the oviducts was 2.48%, which rose to 5.43% if the sterilization procedure was performed when the woman was younger than 28 years of age. These investigators reported that for all 143 pregnancies occurring after tubal sterilization, 43, or 32.9%, were ectopic pregnancies (Peterson, 1997).

Several investigators have reported that if pregnancy occurred after tubal sterilization by laparoscopic fulguration, the ectopic pregnancy rate was as high as 50%. It has been hypothesized that with the extensive tissue destruction caused by electrocoagulation, an uteroperitoneal fistula develops that allows sperm to pass into the distal segment of the oviduct and fertilize the egg (Fig. 17.3) (Corson, 1986). Such fistulas can be demonstrated radiographically in about 11% of women after laparoscopic electrocoagulation. Peterson and colleagues reported that within 10 years after the sterilization procedure, twice as many women sterilized by bipolar coagulation had ectopic pregnancies than those sterilized with metal clips or silicone bands. The overall ectopic pregnancy rate after bipolar coagulation sterilization was 1.7%.

Because about one third of pregnancies that occur after all tubal sterilizations are ectopic, women should be counseled that if they do not experience the expected menses at any time following tubal sterilization before menopause, a test to detect human chorionic gonadotropin (HCG) should be performed rapidly, and if they are pregnant, a diagnostic evaluation to exclude the presence of ectopic pregnancy is necessary. In women who have an ectopic pregnancy after sterilization with the use of electro-surgery, because the site of the fistula usually cannot be determined clinically, salpingectomies should be carried out.

Although women who become pregnant while using diaphragms or combination oral contraceptives do not have an increased chance of having an ectopic pregnancy and reliable contraception decreases the risk of all pregnancies, including ectopics, women who become pregnant while using a Copper

T380 IUD or progestin-only oral contraceptives have about a 5% chance of having an ectopic pregnancy. The incidence of ectopic pregnancy in women who become pregnant with the progestogen-releasing IUDs is even higher, about 23%. The progestogen-releasing IUD inhibits tubal contractions and has a higher failure rate than the copper IUD. Women who use this method of contraception have about twice the risk of ectopic pregnancy (7.5 per 1000 woman-years) than women who use no method of contraception (3.5 per 1000 woman-years). Women using IUDs who elect to have their pregnancies terminated should have a histologic examination of the tissue removed from the uterine cavity to be certain the pregnancy was intrauterine.

HORMONAL ALTERATIONS

As occurs with exogenous progesterone administration, if increased levels of exogenous or endogenous estrogens are present shortly after the time of ovulation, the incidence of ectopic pregnancy is increased. Several investigators have reported that the ectopic pregnancy rate is about 1.5% for conceptions that occur after ovulation has been induced with clomiphene citrate. The ectopic rate in pregnancies occurring after ovulation with human menopausal gonadotropins (HMG) has been reported to range between 3% and 4%. Fernandez and colleagues, in a case-control study, found the risk of ectopic pregnancy was increased about fourfold among ovulatory women treated with controlled ovarian hyperstimulation—clomiphene citrate, HMG, or a combination of both—for unexplained infertility (Fernandez, 1991). These reports indicate that increased levels of estrogen, as well as of progesterone, interfere with tubal motility and increase the chance of ectopic pregnancy. Ectopics occur in about 1% of pregnancies that develop after in vitro fertilization and embryo transfer. The reason for this increased incidence is likely due to one or more of several factors: increased sex steroid hormone levels, the presence of proximal tubal disease (although the ratio is similar in women with normal tubes), and flushing an embryo directly into the tube.

In vitro fertilization has been associated with an increased risk of ectopic pregnancy. Data from the National ART Surveillance system identified that 1.7% out of more than 550,000 pregnancies were ectopic between the period of 2001 and 2011. The ectopic pregnancy rate was also noted to be associated with multiple embryo transfer. The rate of ectopic pregnancy was 1.6% when one embryo was transferred compared with 1.7%, 2.2%, and 2.5% when two, three, or four or more embryos were transferred, respectively (Perkins, 2015).

PREVIOUS ABORTION

Although some studies have suggested that a prior induced abortion increases the risk of ectopic pregnancy, there is probably no major association of increased risk.

SITES OF ECTOPIC PREGNANCY

Most ectopic pregnancies occur in the tube. In Breen's and more recent series, (Breen, 1970; Bouyer, 2002), 97.7% of the ectopic pregnancies were tubal, 1.4% were abdominal, and less than 1% were ovarian or cervical (Fig. 17.4). The majority of tubal

Figure 17.3 Mechanism of ectopic pregnancy after sterilization. (From Corson SL, Batzer FR. Ectopic pregnancy: a review of the etiologic factors. *J Reprod Med*. 1986;31:78.)

Figure 17.4 Anatomic site of ectopic pregnancy. (From Breen JL. A 21 year survey of 654 ectopic pregnancies. *Am J Obstet Gynecol.* 1970;106:1004.)

pregnancies, 70% to 81%, were located in the ampullary portion of the tube, being about equally divided between the distal and middle third of the tube. About 12% of tubal gestations occur in the isthmus and 5% to 11% in the fimbrial region. Although Breen considered pregnancies located in the cornual area of the uterus to be uterine in origin, they are in fact pregnancies implanted in the interstitial portion of the tube. About 2% of all ectopic pregnancies are interstitial and are frequently associated with severe morbidity, because they become symptomatic later in the gestation, are difficult to diagnose, and frequently produce massive hemorrhage when they rupture (Fig. 17.5) (Bolaji, 2010). A true **cornual pregnancy** is one located in the rudimentary horn of a bicornuate uterus, and this occurrence is quite rare. In a review of 240 true cornual pregnancies reported by O'Leary and O'Leary, about 90% of them ruptured with massive hemorrhage (O'Leary, 1963).

About 1 in 200 ectopic pregnancies are true ovarian pregnancies that fulfill the four criteria originally described by Spiegelburg:

1. The tube and fimbria must be intact and separate from the ovary.
2. The gestational sac must occupy the normal position of the ovary.
3. The sac must be connected to the uterus by the ovarian ligament.
4. Ovarian tissue should be demonstrable in the walls of the sac.

Many women with ovarian pregnancies are believed to have a ruptured corpus luteum cyst, and the correct diagnosis was made during the surgical procedure only 28% of the time. The hemorrhagic mass (ovarian ectopic) should be located adjacent to the corpus luteum, never within it. **Ovarian pregnancy** is also associated with profuse hemorrhage, with 81% of reported to have a **hemoperitoneum** greater than 500 mL. Nevertheless, most can be successfully treated by ovarian resection and not oophorectomy.

Figure 17.5 Right interstitial pregnancy at laparoscopy. (Modified from Bolaji I, Gupta S. Medical management of interstitial pregnancy with high beta selective human chorionic gonadotropin. *Ultrasound.* 2010;18[2]:60-67.)

Most abdominal pregnancies occur secondary to **tubal abortion** with secondary implantation in the peritoneal cavity (Fig. 17.6). On rare occasions a primary **abdominal pregnancy** may occur. For the latter diagnosis to be made, the following three criteria originally set forth by Studdiford must be present: (1) the tubes and ovaries must be normal, with no evidence of recent or past injury; (2) there must be no evidence of a uteroplacental fistula; and (3) the pregnancy must be related only to the peritoneal surface and early enough in gestation to eliminate the possibility of secondary implantation after primary tubal nidation (Studdiford, 1942). An unusual type of primary abdominal pregnancy may implant in the spleen or liver and produce massive intraperitoneal hemorrhage.

The prognosis for fetal survival in abdominal pregnancy is poor, found to be 11%, and is difficult to diagnose. Once the diagnosis is established, a laparotomy with removal of the fetus should be performed immediately to prevent a possible fatal hemorrhage. An adjunctive option is to administer methotrexate. On occasion, when the placenta is tightly adherent to bowel and

Figure 17.6 MRI of abdominal pregnancy showing placental infarction. Note the distance of the pregnancy from the uterus. (From www.Hmer.ch/selected.)

blood vessels, it should be left in the abdominal cavity. In such instances, the placental tissue usually resorbs. However, there may be symptoms of abdominal pain and intermittent fever for many months as well as possible partial bowel obstruction and abscess formation. Thus, it is highly desirable, if it is surgically feasible, to remove the placenta entirely. Partial removal also may result in massive hemorrhage, so the surgical approach and decision making are challenging and critical.

The four pathologic criteria for the diagnosis of **cervical pregnancy** as reported by Rubin and colleagues are (1) cervical glands must be present opposite the placental attachment, (2) the attachment of the placenta to the cervix must be intimate, (3) the placenta must be below the entrance of the uterine vessels or below the peritoneal reflection of the anteroposterior surface of the uterus, and (4) fetal elements must not be present in the corpus uteri (Fig. 17.7).

The usual characteristic clinical findings of cervical pregnancy are uterine bleeding after amenorrhea without cramping pain, a softened cervix that is disproportionately enlarged, complete confinement and firm attachment of the products of conception to the endocervix, and a closed internal os.

Most cervical pregnancies are associated with previous cervical or uterine surgery such as curettage or cesarean delivery. The differential diagnosis is difficult and includes incomplete abortion, placenta previa, carcinoma of the cervix, and a degenerating leiomyoma. Although cervical ectopics previously have been associated with a high mortality because of massive hemorrhage, currently, with better methods of diagnosis and treatment, death is rare. In the past, more than half of the women with cervical pregnancy required a hysterectomy for treatment, and this was nearly always necessary if the pregnancy had advanced beyond 18 weeks. There have been several case reports in which a cervical pregnancy was successfully treated by systemic methotrexate. Other case reports have shown that after angiographic uterine artery embolization evacuation of the pregnancy can be easily

Figure 17.7 Cervical pregnancy as viewed by 2D ultrasound (*left panel*). Note the normal endometrium to the left of the gestational sac and the larger fetal pole. The right panel shows the same cervical ectopic on 3D ultrasound. Note the ballooned-out cervix and narrowed uterine isthmus/lower segment above it.

performed transcervically with minimal blood loss. Transvaginal ultrasound-guided injections of potassium chloride directly into the gestational sac have successfully terminated the pregnancies, as has the local injection of methotrexate, with or without uterine artery embolization.

Another uncommon form of ectopic gestation is combined intrauterine and extrauterine (heterotopic) pregnancy (94% tubal and 6% ovarian). **Heterotopic pregnancy** is traditionally considered a rare occurrence with an incidence between 1 in 16,000 or 1 in 30,000 pregnancies. With the increase of use of ovulation-inducing agents and assisted reproduction techniques (ART), the overall incidence of heterotopic pregnancy has risen to approximately 1 in 3900 pregnancies. In a series of all registered ART pregnancies in the United States from 1999 to 2002, the incidence of heterotopic pregnancy was 1.5 per 1000 ART pregnancies.¹⁶ The incidence has been reported to be higher when tubal damage was present or four or more embryos were transferred.

A **chronic ectopic pregnancy** occurs when the intraperitoneal hemorrhage associated with tubal abortion or rupture is relatively minor and ceases spontaneously, but the ectopic gestation neither resolves completely nor implants and continues to develop as an abdominal pregnancy. The trophoblast continues to secrete HCG in small amounts, with the circulating levels less than 1000 mIU/mL in 50% of cases and less than 100 mIU/mL in 20% of cases. In one series, about 6% of all surgically treated ectopic pregnancies in one institution were classified as chronic. The most common (72%) gross pathologic finding was dense adhesions produced by the inflammatory response to the trophoblast. These adhesions attach omentum and bowel to the site of the ectopic pregnancy. In one third of the cases, a collection of clotted blood or old hematoma was present. It has been reported that because of the extensive disease, it was necessary to perform a hysterectomy in 25% of cases and an oophorectomy in 60% of women with a chronic ovarian ectopic pregnancy.

Cesarean scar ectopic pregnancy is a rare but potentially serious complication of early pregnancy. In this type of ectopic pregnancy, the gestational sac is located in the previous cesarean scar and is surrounded by myometrium and connective tissue. It occurs in about 1 in 2000 pregnancies and 6% of ectopic pregnancies among women with previous cesarean deliveries (Rotas, 2006). In a large series of 268 cesarean scar ectopic pregnancies, Sadeghi and colleagues reported four cases of uterine rupture including one case of fetomaternal death at 38 weeks of gestation (Sadeghi, 2010). The incidence does not appear to correlate with the number of cesarean deliveries. It is believed that the mechanism for implantation is due to the migration of the embryo through a small defect in the previous incision site or a microscopic fistula within the scar. Adenomyosis, in vitro fertilization, previous dilation and curettage, and manual removal of the placenta are also reported as risk factors.

HISTOPATHOLOGY

When the morula implants in the tube, it does not grow mainly in the tubal lumen as has been assumed for many years. A review of the pathology of tubal gestation found that after implanting on the mucosa of the endosalpinx, the trophoblast invaded the lamina propria and then the muscularis of the tube and grew mainly between the lumen of the tube and its peritoneal

covering. Growth occurred both parallel to the long axis of the tube and circumferentially around it. As the trophoblast invaded vessels, retroperitoneal tubal hemorrhage occurred that is mainly extraluminal but may extrude from the fimbriated end and create a hemoperitoneum before tubal rupture (Fig. 17.8) (Budowick, 1980).

The stretching of the peritoneum covered by this hemorrhage results in episodic pain before the final perforation into the peritoneal cavity. Rupture occurs when the serosa is maximally stretched, producing necrosis secondary to an inadequate blood supply.

Hemoperitoneum is nearly always found in advanced **ruptured ectopic pregnancy** other than that which is cervical in origin. Usually there is a combination of clotted and unclotted blood in the peritoneal cavity. The unclotted blood does not clot on removal from the peritoneal cavity because it originates from lysis of blood that has previously coagulated, similar to what occurs during menstrual bleeding. The hematocrit value of this nonclotting blood is nearly always greater than 15%, such a finding being reported in 98% of specimens obtained by **culdocentesis** in a series of ectopic pregnancies. Historically, at the time of laparotomy for a ruptured ectopic pregnancy, about half of the women have less than 500 mL of hemoperitoneum, one fourth between 500 and 1000 mL, and one fifth more than 1000 mL.

When the tube is removed and examined histologically, inflammatory cells are nearly always seen. These include plasma cells, lymphocytes, and histiocytes. The presence of chorionic villi, which are frequently degenerated or hyalinized, as well as nucleated red cells established the diagnosis of ectopic pregnancy. Decidual reaction in the tube is uncommon.

Because of limited space or inadequate nourishment, the trophoblastic tissue of most ectopic pregnancies does not grow as rapidly as that of pregnancies within the uterine cavity. As a result, HCG production does not increase as rapidly as in a normal pregnancy, and although steroid production of the corpus luteum is initiated, elevated progesterone levels cannot be maintained. Thus initially the endometrium becomes decidualized because of continued progesterone production by the corpus luteum. Sometimes the secretory cells of the endometrial glands become hypertrophied with hyperchromatism, pleomorphism,

Figure 17.8 Artist's rendition of dissected ampullary ectopic pregnancy showing space between tube and peritoneum, revealed when blood clots and placenta were removed. Toward fimbriated end, no dissection was performed and external appearance is that of a dilated tube. (From Budowick M, Johnson TRB, Genadry R, et al. The histopathology of the developing tubal ectopic pregnancy. *Fertil Steril*. 1980;34:169. Courtesy of The American Fertility Society.)

Figure 17.9 Histology of In text, Arias-Stella reaction. Note the enlarged secretory endometrial cells, which are hypertrophied, hyperchromatic, and pleomorphic. (From www.jpathology.com.)

Figure 17.10 Decidual cast. (From www.ispub.com.)

and increased mitotic activity, as originally described by Arias-Stella (Fig. 17.9). The **Arias-Stella reaction** can be confused with neoplasia, but it is not unique for ectopic pregnancy, because it can occur with an IUP as well as after ovarian stimulation with clomiphene citrate. In a histologic study of the endometrium in 84 women with ectopic pregnancies, 40% of cases had secretory endometrium, with the remainder being about equally divided among the findings of proliferative endometrium, decidual reaction, and an Arias-Stella reaction. When progesterone levels fall as a result of insufficient HCG, endometrial integrity is no longer maintained and it breaks down, producing uterine bleeding. Sometimes nearly all the decidua is passed through the cervix in an intact way, producing a **decidual cast** that may be clinically confused with a spontaneous abortion (Fig. 17.10).

SYMPTOMS

Among women with risk factors for ectopic pregnancy, with the use of early hormonal testing and vaginal sonography, it is now frequently possible to establish the diagnosis of ectopic pregnancy before symptoms develop. However, symptoms often develop when intraperitoneal bleeding occurs from extrusion of blood through the fimbriated end of the tube in cases of tubal pregnancies or from disruption of overlying tubal, ovarian, or myometrial tissue from rupture of the gestational sac.

The most common symptoms of ectopic pregnancy are abdominal pain, absence of menses, and irregular vaginal bleeding (Table 17.2). Abdominal pain is nearly a universal symptom of intraperitoneal bleeding, but its characteristics are similar with different causes of bleeding. Before rupture occurs, the pain may be characterized as only a vague soreness or be colicky in nature. Its location may be generalized, unilateral, or bilateral. Shoulder pain occurs in about one fourth of women with ruptured ectopic pregnancy as a result of diaphragmatic irritation from the hemoperitoneum. During rupture of the tube, the pain usually becomes intense. Syncope occurs in about one third of women

Table 17.2 Contraindications to Medical Management of Ectopic Pregnancy with Systemic Methotrexate

Contraindication	ACOG	ASRM
Absolute contraindications	Breast-feeding; laboratory evidence of immunodeficiency; preexisting blood dyscrasias (bone marrow hypoplasia, leukopenia, thrombocytopenia, or clinically significant anemia); known sensitivity to methotrexate; active pulmonary disease; peptic ulcer disease; hepatic, renal, or hematologic dysfunction; alcoholism; alcoholic or other chronic liver disease	Breast-feeding; evidence of immunodeficiency; moderate-to-severe anemia, leukopenia, or thrombocytopenia; sensitivity to methotrexate; active pulmonary or peptic ulcer disease; clinically important hepatic or renal dysfunction; intrauterine pregnancy
Relative contraindications	Ectopic mass >3.5 cm; embryonic cardiac motion	Ectopic mass >4 cm detected by transvaginal ultrasonography; embryonic cardiac activity detected by transvaginal ultrasonography; patient declines blood transfusion; patient is not able to participate in follow-up; high initial HCG level (>5000 mIU/mL)
Choice of regimen based on HCG level	Multidose regimen of methotrexate may be appropriate if presenting HCG value >5000 mIU/mL	Single-dose regimen of methotrexate better in patients with a low initial HCG level

Data from American Society for Reproductive Medicine. The Practice Committee: medical treatment of ectopic pregnancy. *Fertil Steril*. 2008;90:S206. ACOG, American College of Obstetricians and Gynecologists; ASRM, American Society for Reproductive Medicine.

with tubal rupture. Other symptoms that occur following tubal rupture include dizziness and an urge to defecate.

The majority of women with ectopic pregnancy fail to have menses at the expected time but have one or more episodes of irregular vaginal bleeding when the decidual endometrial tissue is sloughed. The interval of amenorrhea is usually 6 weeks or more. The bleeding is usually characterized as spotting but may simulate menstrual bleeding. It is rarely as heavy as that which occurs in spontaneous abortion. About 5% to 10% of women with an advanced ectopic pregnancy will note passage of a decidual cast, as noted previously (see Fig. 17.10).

SIGNS

The most common presenting sign in a woman with symptomatic ectopic pregnancy is abdominal tenderness, which, together with adnexal tenderness elicited at the time of the bimanual pelvic examination, is present in nearly all women with an advanced or ruptured ectopic pregnancy. It is possible to palpate an adnexal mass in half of the women, and about one third have some degree of uterine enlargement that is nearly always smaller than a normal 8-week intrauterine gestation except when an interstitial gestation is present. Tachycardia and hypotension can occur after rupture if blood loss is profuse, but temperature elevation is an uncommon finding, present in only about 5% to 10% of women with tubal rupture, and is rarely greater than 38° C.

DIFFERENTIAL DIAGNOSIS OF SYMPTOMATIC ECTOPIC PREGNANCY

The diagnosis is usually obvious for women with the classic symptoms of ruptured ectopic pregnancy: a history of irregular bleeding followed by sudden onset of pain and syncope accompanied by signs of peritoneal irritation. However, before rupture the symptoms and signs are nonspecific and may also occur with other gynecologic disorders. Entities frequently confused with ectopic pregnancy include salpingitis, threatened or incomplete abortion, ruptured corpus luteum, appendicitis, dysfunctional uterine bleeding, adnexal torsion, degenerative uterine leiomyoma, and endometriosis.

In the past, studies have found that women with an ectopic pregnancy were seen multiple times before a correct diagnosis was made. Because of the possibility of a fatal outcome from undiagnosed ruptured ectopic pregnancy, it is essential that the diagnosis of ectopic pregnancy be considered in any woman of childbearing age with abdominal pain and irregular uterine bleeding even if she has had a previous tubal sterilization procedure or is using an effective method of reversible contraception.

Ectopic pregnancy should be suspected in any woman who develops the symptoms listed earlier, particularly if she has previously had a pelvic operation, especially tubal surgery, either a tubal reconstructive procedure or a sterilization procedure. Other risk factors include one or more episodes of salpingitis, a previous ectopic gestation, current use of a progesterone-releasing IUD, use of a progestin-only oral contraceptive, use of pharmacologic methods of ovulation induction, or a history of infertility. In any woman with the symptoms of ectopic gestation, the diagnosis is facilitated by a quantitative assay for HCG and pelvic ultrasonography and can be established and treated by laparoscopy or laparotomy. Culdocentesis and measurement of serum progesterone

levels have also been used for diagnostic assistance. Prior to the development of pelvic vaginal ultrasound, the finding of nonclotting blood at the time of culdocentesis, especially if the hematocrit was above 15%, was of great assistance in establishing the diagnosis of ruptured ectopic pregnancy. With the use of high-resolution pelvic ultrasound, the presence of intraperitoneal fluid can be easily visualized and culdocentesis is no longer routinely done.

PROCEDURES USED FOR THE DIAGNOSTIC EVALUATION OF THE ASYMPTOMATIC OR MILDLY SYMPTOMATIC WOMAN WITH SUSPECTED ECTOPIC PREGNANCY

Human Chorionic Gonadotropin

About 85% of women with ectopic pregnancy have serum HCG levels lower than those seen in normal pregnancy at a similar gestational age. However, a single quantitative HCG assay cannot be used to diagnose ectopic pregnancy because the actual dates of ovulation and conception are often not known. Even if the date of ovulation is known, 2.5% of women with normal gestations will have HCG levels lower than the normal 95% confidence limits. Furthermore, low HCG levels are also found in women with various stages of spontaneous abortion, conditions that must be considered in the differential diagnosis. Intact HCG and free β -HCG levels were measured in a large group of women in early pregnancy who presented with symptoms of ectopic pregnancy. Although mean levels of intact HCG and free β -HCG were significantly lower in the group of women with ectopic pregnancy and those who aborted than in those with viable intrauterine pregnancies, the individual HCG levels among the three conditions overlapped too much to devise a cutoff level for diagnostic purposes (Fig. 17.11) (Ledger, 1994).

Figure 17.12, as constructed by Barnhart, shows the expected changes (increases) in HCG levels in women with an intrauterine pregnancy and in spontaneous abortion. Ninety-nine percent of normal intrauterine pregnancies have an increase of at least 53% in 2 days, which is less than the rise that was previously accepted (approximately 66%). This rate of increase should be similar in single or multiple gestations (Barnhart, 2009). Note in Table 17.3 (Barnhart, 2009) the expected decline in HCG levels in women who have an abnormal pregnancy destined for a spontaneous abortion. In women with an ectopic pregnancy, the rate of rise in HCG can mimic an intrauterine pregnancy 21% of the time and can mimic a spontaneous abortion 8% of the time. Note the overlap in this increase or decrease in HCG levels as depicted in Figure 17.12.

Today, the key to the diagnosis of ectopic pregnancy is transvaginal ultrasound (TVUS). The concept of a “discriminatory zone” has been advanced and is defined as the serum HCG level above which a gestational sac should be visualized by TVUS if an intrauterine pregnancy (IUP) is present. In most institutions, a serum HCG level of 1500 to 2000 mIU/mL is used. Setting the discriminatory zone at 2000 mIU/mL instead of 1500 mIU/mL may minimize the risk of intervening when an intrauterine pregnancy is viable but may increase the risk of delaying the diagnosis of an ectopic pregnancy. When an IUP is not seen on TVUS at the set discriminatory zone, an abnormal pregnancy is diagnosed, and an ectopic pregnancy needs to be ruled out. It has been suggested further that as reliable as using the discriminatory zone is, the length of gestational sac is at least as important when accurate dating is available (as occurs with luteinizing

Figure 17.11 The distribution of serum concentrations of progesterone, intact human chorionic gonadotropin (HCG), and free β -HCG in viable and ectopic pregnancies and spontaneous abortions. Means are indicated by horizontal bars (—). (From Ledger WL, Sweeting VM, Chatterjee S. Rapid diagnosis of early ectopic pregnancy in an emergency gynaecology service—are measurements of progesterone, intact and free beta human chorionic gonadotrophin helpful? *Hum Reprod.* 1994;9:157.)

hormone [LH] surge monitoring, etc.). Clearly by 5 1/2 weeks from LMP (in a woman with normal ovulatory cycle length) an intrauterine sac should be visible in a normal intrauterine pregnancy. Important ultrasound findings include visualization of a yolk sac at 5.5 weeks, a fetal pole by 6 weeks, and cardiac activity at 6.5 weeks. An abnormal pregnancy is likely if there is absence of a fetal pole with a gestational sac of 2 cm and if no cardiac activity is noted with a crown-rump length of >0.5 cm.

Thus serial measurements of HCG are of great assistance in the early diagnosis of unruptured ectopic pregnancy. However, a differentiation between ectopic pregnancies and impending spontaneous abortion cannot be made with this technique because the rate of increase of HCG in women with an ectopic pregnancy is often similar to that found in women with an impending intrauterine abortion. An algorithm for possible treatment will be presented here.

Figure 17.12 Change in the HCG level in intrauterine pregnancy, ectopic pregnancy, and spontaneous abortion. An increase or decrease in the serial human chorionic gonadotropin (HCG) level in a woman with an ectopic pregnancy is outside the range expected for that of a woman with a growing intrauterine pregnancy or a spontaneous abortion 71% of the time. However, the increase in the HCG level in a woman with an ectopic pregnancy can mimic that of a growing intrauterine pregnancy 21% of the time, and the decrease in the HCG level can mimic that of a spontaneous abortion 8% of the time. (Modified from Barnhart K. Ectopic pregnancy. *N Engl J Med.* 2009;361[4]:384.)

Progesterone

Serum progesterone values are lower in an ectopic pregnancy, with levels in normal intrauterine pregnancies at or above 10 ng/mL. An abnormal IUP will also have low values. However, a rising progesterone level is helpful in determining that there is a normal IUP (Fig. 17.13) (McCord, 1996). The clearance of progesterone from the circulation in a failed pregnancy or ectopic is also faster than that of HCG. Therefore progesterone levels have been used as a diagnostic aide for ectopic pregnancy. Nevertheless it is not commonly used today in practice.

Ultrasonography

Development of the transvaginal transducer probes with 7-MHz scanning frequency has enabled more precise imaging of the pelvic organs in early pregnancy than is possible with transabdominal ultrasonography. With these probes it is usually possible to identify an intrauterine gestational sac when the HCG level reaches 1500 mIU/mL and virtually always when the HCG level exceeds 2500 mIU/mL (First International Reference Preparation [1st IRP], now called the *Third International Standard*),

Table 17.3 Expected Change in Serum HCG Levels in First Week of Monitoring Women at Risk for Ectopic Pregnancy

Type of Pregnancy	CHANGE IN HCG (PERCENTAGE)	
	After 2 Days	After 7 Days
Growing Intrauterine Pregnancy		
In 50% of women	124	500
In 85% of women	63	256
In 99% of women	53	133
Spontaneous Abortion*		
Initial HCG, 50 mIU/mL	-12	-34
Initial HCG, 500 mIU/mL	-21	-60
Initial HCG, 2000 mIU/mL	-31	-79
Initial HCG, 5000 mIU/mL	-35	-84

From Sammel MD, Rinaudo PF, et al. Symptomatic patients with an early viable intrauterine pregnancy: HCG curves redefined. *Obstet Gynecol.* 2004;104:50-55. Data from Barnhart, *N Engl J Med.* 2009;361:4.
*This change occurred in 90% of women with spontaneous abortion. Data from Barnhart, 2009.

Figure 17.13 Predicted pregnancy outcome versus progesterone concentrations. The probability of ectopic pregnancy and spontaneous abortion decreases with rising progesterone levels, forming a negative-sloping sigmoid-shaped curve, a mirror image of the intrauterine pregnancy curve, with its slope decreasing sharply at approximately 5 ng/mL (15.9 nmol/L) and increasing sharply at approximately 17 ng/mL (54.1 nmol/L). (From McCord ML, Arheart KL, Muram D, et al. Single serum progesterone as a screen for ectopic pregnancy: exchanging specificity and sensitivity to obtain optimal test performance. *Fertil Steril.* 1996;66:513. Copyright 1996, The American Society for Reproductive Medicine.)

about 5 to 6 weeks after the last menses. Kadar and colleagues reported that in both singleton and multiple gestations a gestational sac should always be seen sonographically beyond 24 days after conception, 38 days' gestational age (Kadar, 1981). Because combined extrauterine and IUP is a rare event, the finding of an intrauterine gestational sac should nearly always exclude the presence of an ectopic pregnancy. When a gestational sac is not present and the HCG level is in the discriminatory zone, a pathologic pregnancy, either an ectopic or a nonviable intrauterine gestation, is most likely present and should be suspected. Usually an adnexal mass or a gestational saclike structure can be identified in the tube when an ectopic pregnancy is present that produces levels of HCG above 2500 mIU/mL.

Figure 17.14 Ultrasound showing a left tubal ectopic. Note the bagel appearance of gestational sac, which here has a fetal pole. (Modified from embryology.med.unsw.edu.au.)

Thus diagnostic criteria for the ultrasonographic diagnosis of ectopic pregnancy with the use of a vaginal probe include the detection of a complex or cystic adnexal mass (often called an echogenic “bagel” sign) or visualization of an embryo fetal pole in the adnexa (Fig. 17.14). This is in the absence of an intrauterine gestational sac when the gestational age is known to be more than 38 days, or the HCG level is above a certain threshold, usually between 1500 and 2500 mIU/mL.

About two thirds of women presenting with symptoms of ectopic pregnancy have HCG levels above 2500 mIU/mL, and when this occurs, the diagnosis of ectopic pregnancy can usually be made by ultrasound. For the other one third with lower HCG levels, unless a gestational sac is evident on ultrasonography, other diagnostic techniques, such as measurement of a serum progesterone level and serial HCG determination, should be performed. Repeat ultrasonographic examinations at 3- to 5-day intervals are often helpful in establishing a correct diagnosis.

Several investigators have shown that with the use of endovaginal color Doppler flow imaging, it is possible to establish the diagnosis of ectopic pregnancy with greater sensitivity and specificity than with ordinary endovaginal sonography. With endovaginal color flow imaging of the pelvic structures in the presence of an ectopic pregnancy, about a 20% difference in the degree of tubal blood flow between the adnexa has been found compared with less than an 8% difference with intrauterine gestations. Use of endovaginal color flow compared with routine transvaginal sonography increased the sensitivity of the diagnosis of ectopic pregnancy from 71% to 95%, with a specificity of 96% to 100% in various studies (Fig. 17.15).

Dilation and Curettage

When serum HCG levels are more than 1500 mIU/mL, the gestational age exceeds 38 days, or the serum progesterone level is less than 5 ng/mL and no intrauterine gestational sac is seen with vaginal ultrasonography, a curettage of the endometrial cavity (by D&C) with histologic examination of the tissue removed, by frozen section if desired, can be undertaken to determine if

Figure 17.15 Ectopic pregnancy showing enhanced blood flow using color Doppler. Examples of color “lighting up” ectopic pregnancies on ultrasound, panels **A–C**; which can be quantified, panel **D**.

any gestational tissue is present. This is a pragmatic approach reserved for those women who do not desire a pregnancy. Note that it has been shown that an endometrial biopsy (e.g., Pipelle) is inadequate in this scenario. Spandorfer and coworkers reported that frozen section was 93% accurate in identifying chorionic villi. If no chorionic villi are visualized in the removed tissue, serial HCGs can be followed. A presumptive diagnosis of ectopic pregnancy can be made with rising serum HCGs and treatment undertaken. An analysis by Ailawadi suggested that performing a dilatation and curettage (D&C) in this setting results in fewer complications and is at least as cost effective as the empiric use of methotrexate (Ailawadi, 2005). When chorionic villi are detected and an IUP is evacuated, the serum HCG should drop by at least 15% the day after curettage.

Diagnostic Evaluation of Women with Suspected Ectopic Pregnancy

Several authors have developed flow sheets to aid the clinician in establishing the diagnosis of an asymptomatic or mildly

symptomatic ectopic pregnancy. They involve the use of vaginal probe pelvic ultrasonography, measurements of serial quantitative HCG and single serum progesterone levels, and uterine curettage. One suggested algorithm is presented in Figure 17.16. Note that because of clinical variability, this is merely a guide to management. These diagnostic aids are of particular use when following an asymptomatic woman with risk factors for ectopic pregnancy, beginning shortly after conception. Performing a quantitative HCG assay twice weekly, calculating the rate of increase (measuring serum progesterone levels at 4, 5, and 6 weeks' gestational age), and performing serial ultrasonography beginning 3 weeks after ovulation will help to establish the diagnosis of ectopic pregnancy before tubal rupture. The combination of these two techniques is particularly applicable for stable women treated in institutions with adequate facilities for ultrasound and rapid serial quantitative β -HCG assays. If a woman with or without risk factors for ectopic pregnancy develops mild symptoms consistent with an ectopic gestation and is hemodynamically stable, vaginal sonography, measurement of serial

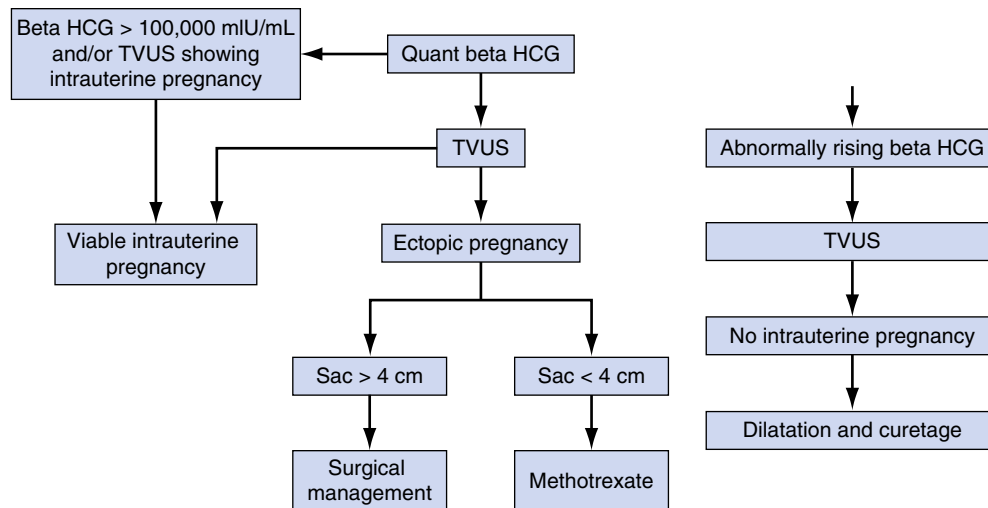

Figure 17.16 Possible algorithm for use of methotrexate versus surgery for ectopic pregnancy.

HCG levels, and possibly serum progesterone, as well as uterine curettage if indicated, will aid in establishing the diagnosis. The use of a quantitative serum HCG assay and transvaginal sonography enables the diagnosis of ectopic gestation in hemodynamically stable women to be made with a sensitivity of 97% to 100% and a specificity of 95% to 99% (Fig. 17.17) (Gracia, 2001).

Both suggested algorithms include the use of D&C. Although, as stated previously, this approach has been deemed to be cost effective, some women, particularly those who have been attempting pregnancy, are reluctant to have this treatment. In this setting it is reasonable to continue serial HCG and ultrasound monitoring. Unless HCG falls, it will be clear that with time, treatment of a nonviable pregnancy is needed. And this could be with either a D&C or the use of methotrexate.

In an in vitro fertilization setting, if HCG criteria suggest an abnormal pregnancy of unknown location, a suction cannula can be used in an outpatient setting to aid in the diagnosis. Using this approach to rule out an ectopic pregnancy resulted in avoiding the use of methotrexate in more than two thirds of patients (Brady, 2014).

If a woman develops symptoms of a ruptured ectopic pregnancy that are of sufficient hemodynamic severity to require emergency care, a sensitive qualitative pregnancy test and vaginal sonography are usually all the diagnostic aids necessary to establish the diagnosis. If vaginal sonography is not immediately available on an emergent basis, culdocentesis may be performed. If HCG is present and peritoneal fluid is seen sonographically, it is most likely that an ectopic pregnancy is present, and laparoscopy should be performed.

MANAGEMENT

SURGICAL THERAPY

Tubal Pregnancy

Laparoscopy is the procedure of choice for ruptured ectopic pregnancy as well as for cases when medical therapy (methotrexate) is contraindicated or refused. Laparoscopy is also useful at times when an accurate diagnosis cannot be made. Older studies have suggested that there is a false-positive and false-negative rate of approximately 2% with the use of laparoscopy for ectopic

pregnancies (i.e., either not being able to see the ectopic or confusing findings with hemorrhagic corpus luteal cysts, hematosalpinx, and other findings). See Video 17.1 showing laparoscopic salpingectomy for ectopic pregnancy.
